Polymeric solutions contain whole proteins isolated from casein, lactalbumin, whey, egg white, or a combination of these. Carbohydrates are usually glucose polymers in the form of starch and its hydrolysates. The fats are of vegetable origin, such as corn oil, safflower oil, sunflower oil, and others. Vitamins and essential trace elements are present in adequate quantities so that a daily intake of 1500 to 2000 kcal provides the necessary recommended daily allowances of these nutrients. The amounts of such minerals as sodium and potassium vary considerably among the various solutions, thus allowing a choice when intake of these minerals is restricted. Polymeric solutions are lactose free. The osmolality varies between 300 and 450 mosm/kg in solutions that contain 1 kcal/mL. In solutions that contain more than 1 kcal/mL, however, the osmolality is higher and may reach 650 mosm/kg. Some polymeric solutions contain fiber in the form of complex nondigestible carbohydrates. The amounts of fiber range between 6 and 14 g/1000 kcal. The caloric density is between 1 and 2 kcal/mL. The high-caloric formulas allow provision of large amounts of calories in a smaller volume and are particularly suitable for patients who require fluid restriction. Administration of these formulas requires close follow-up, however, because they can be associated with dehydration and electrolyte abnormalities. The ranges of the nutrient contents of

polymeric solutions are listed in [Table 100.1](#).

Monomeric Solutions

The main feature of monomeric solutions is that they require less digestion than do regular foods or polymeric solutions. The protein in these solutions is in the form of peptides and/or free amino acids and is derived from hydrolysis of casein, whey, and other proteins. Net absorption of dipeptides and tripeptides and the amino acids generated from their digestion is more rapid and efficient than absorption of equivalent amounts of free amino acids ([29](#)). In addition, di- and tripeptides create a lower osmotic load than the corresponding amounts of amino acids. Therefore, monomeric solutions containing partially digested protein have physiologic advantages over those containing only free amino acids.

The carbohydrates are in the form of partially hydrolyzed starch (maltodextrins and glucose oligosaccharides). Fat is frequently a mixture of MCTs and LCTs of plant origin. Most calories are present as carbohydrates (as much as 80%), whereas only 1 to 5% are in the form of fat. Protein contributes 12 to 20% of the total calories. The caloric density of monomeric formulas varies between 1 and 1.5 kcal/mL. The solutions contain sufficient minerals, trace elements, and vitamins; 2000 kcal may provide the daily requirements of these nutrients. Some of the micronutrients, however, may be inadequate for a patient with increased needs.

Monomeric formulas are lactose free and do not contain fiber. The partially digested macronutrients in monomeric solutions contribute to the higher osmolality than that of polymeric solutions. The osmolality of monomeric solutions ranges between 270 and 650 mosm/kg ([Table 100.1](#)).

Based on physiologic considerations, these solutions might be regarded as suitable for patients with impaired digestion, such as those with pancreatic insufficiency or short bowel syndrome (in which case time for digestion and absorption is insufficient because of the shortened bowel). Clinical trials to demonstrate such an advantage, however, have not been adequate.

When the osmolality of such solutions is above 300 mosm/kg, they tend to shift free water into the intestinal space and thus can induce rapid transit and diarrhea. Some polymeric solutions have a high osmolality; however, these are the more concentrated solutions that contain more than 1.5 kcal/mL. The osmolality of monomeric solutions is higher than that of polymeric solutions with the same caloric density.

Solutions for Specific Metabolic Needs

Solutions for specific metabolic needs are mostly complete nutritional solutions with specific nutrients either added or removed to meet special requirements. These can be divided into two categories:

1. Solutions designed for use in patients with inherited metabolic disorders ([Chapter](#)

- [61](#)). They are low in, or devoid of, specific nutrients (e.g., phenylalanine or other amino acids) that cannot be properly metabolized because of enzymatic defects or deficiencies.
2. Solutions designed for use in patients with specific medical conditions, such as liver failure, renal failure, or critical illness with multiple organ failure. Feeding solutions in this category are designed to lessen the metabolic burden on the failing organ or to correct metabolic abnormalities that result from the organ dysfunction.

Branched-Chain Amino Acid (BCAA) Solutions

BCAA solutions contain about 40 to 50% of the amino acids as leucine, isoleucine, and valine. Concentrations of the aromatic amino acids (AAA) tryptophan, tyrosine, and phenylalanine are low. Solutions high in BCAAs have been designed for use in two conditions: (a) hepatic failure and encephalopathy and (b) severe illness and stress with multiple organ failure, such as sepsis and major injury.

Patients with hepatic encephalopathy tend to have decreased levels of BCAAs and increased levels of AAAs in blood and cerebrospinal fluid. AAAs were postulated to act as false neurotransmitters in the central nervous system, contributing to hepatic encephalopathy ([30](#)). Thus, providing a nutritional solution containing high levels of BCAAs and low levels of AAAs was designed to reverse or improve the hepatic encephalopathy induced by the AAA false neurotransmitters. Randomized studies examining the use of solutions high in BCAAs in patients with hepatic encephalopathy, however, have not shown a clear benefit, and their role in these patients is controversial ([31](#), [32](#)) (for a detailed discussion see [Chapter 73](#)).

Major acute illnesses with severe metabolic stress, such as sepsis, severe trauma, major operations, and burns, are associated with accelerated muscle catabolism (see [Chapter 96](#) and [Chapter 98](#)). Because BCAAs are used extensively by muscles, providing solutions high in BCAA was proposed to be beneficial for muscle preservation in severely ill and catabolic patients. Some clinical trials have shown improved nitrogen balance with enteral or parenteral solutions high in BCAAs in critically ill patients ([33](#)); however, other studies have not shown such benefit or any clinically relevant benefit in decreasing morbidity or mortality ([34](#), [35](#)) (see [Chapter 98](#)). At present, no decisive information supports routine use of solutions high in BCAAs in patients who either are suffering from liver failure or are critically ill.

Essential Amino Acid Solutions

Essential amino acid (EAA) solutions are designed for feeding patients with renal failure ([Chapter 89](#)), many of whom have trauma and/or sepsis. Failing kidneys have a reduced capacity for clearance of various metabolites (urea, creatinine, uric acid) and minerals (potassium, phosphate, magnesium). Serum levels of some nonessential amino acids are elevated, and levels of essential amino acids, such as leucine, isoleucine, and valine, are decreased. The objectives of nutritional support in patients with renal failure are to provide optimal nutrition while minimizing the load of metabolites presented for handling by the compromised kidneys. The latter objective is particularly

important when an effort is being made to avoid dialysis in patients with compromised renal function. However, optimal nutrition should not be compromised because of a need for dialysis. Renal enteral feeding solutions contain EAAs, histidine, small amounts of fat, and electrolytes. They do not contain vitamins or trace elements, which must be supplemented as needed. The low content of electrolytes allows flexibility—electrolytes can be added on an individual basis as needed. Most of the clinical studies on the role of high-EAA feeding regimens have been performed with parenteral nutrition, and although some metabolic benefits have been noted, a clear clinical advantage has not been documented. The few studies in which enteral nutrition was examined suggest that administration of EAAs is associated with improved nitrogen balance and attenuation of the rise in BUN (for detailed discussion see [Chapter 89](#)).

High-Fat/Low-Carbohydrate Solutions for Pulmonary Insufficiency

In pulmonary insufficiency formulas, fat content is increased to 50 to 55% of the total calories, with a corresponding decrease in carbohydrate content. Calories provided from any source increase O₂ consumption and CO₂ production and thus present an added burden to the failing lungs. Carbohydrate calories require more O₂ consumption and produce more CO₂ than do fat calories. Hence, the notion that replacing carbohydrate calories by fat calories presents a lighter burden on the respiratory system. In most patients, the difference is not clinically significant; however, in those with borderline pulmonary function ([36](#), [37](#)) the difference may be important, especially when excess calories are given (see [Chapter 90](#)).

Immune-Modulating Solutions

Specific nutrients can influence the immune response ([Chapter 45](#)). The immune-enhancing role of zinc and the immune-inhibiting effect of certain fatty acids have long been known. Experimental studies suggest that substances that have not been considered essential nutrients for adults, such as derivatives of w-3 polyunsaturated fatty acids ([38](#)), ribonucleic acid (RNA) ([39](#)), and arginine ([40](#)), may also have beneficial effects on the immune response. These observations prompted formulation of enteral feeding solutions containing these nutrients in addition to the regular nutrients. A randomized study in surgical cancer patients found that compared with a standard enteral feeding solution, the immune-modulating solution administered postoperatively resulted in better immunologic and metabolic outcomes, with a decrease in infectious and wound complications and a decrease in postoperative hospitalization ([41](#)). However, a subsequent study in a large group of surgical cancer patients comparing the immune-modulating solution with routine intravenous fluids postoperatively did not demonstrate a benefit ([42](#)). In the critically ill patient, immune-modulating solution was observed to decrease major septic complications ([43](#)).

Modular Solutions

Modular solutions provide each of the macronutrients or micronutrients in suitable combinations or singly and can be used to prepare specialized formulas or to augment regular enteral or oral feeding. Protein modular products are usually available as

powder that has to be mixed with water prior to administration. Carbohydrates are available as glucose polymers; fat is supplied as triglycerides of long-chain polyunsaturated or medium-chain fatty acids. These nutrients can be added when extra calories or protein are needed. They are particularly useful when the patient cannot receive the required macronutrient by increasing the amount of enteral feeding formula because of limited tolerance to fluids or to other components present in the regular feeding solution. The use of these solutions to modify commercial solutions or to prepare a special solution is limited by the difficulty they present and the lack of specific indication for their use. For instance, fat emulsions require an emulsifier to keep them dispersed in solutions after they have been mixed with other enteral solutions. Glucose polymers added to solutions can increase the osmolality and induce diarrhea once they are digested to glucose. Protein powder is hard to mix and tends to clump, thereby creating mechanical difficulties when administered.

When requirements increase for certain micronutrient solutions, those available for oral intake and parenteral use can also be used for enteral feeding; thus, in patients needing additional potassium, an oral potassium solution can be added to regular enteral feeding to increase potassium intake. However, when adding nutrients to enteral feedings, caution must be exercised to prevent precipitation that will decrease absorption. For instance, phosphate added to enteral feedings may cause precipitation of calcium, which can clog small-diameter tubes and may not be absorbed in the intestines. Such problems can be avoided, preferably by administering additives separately from the enteral feeding solutions unless advance testing has been adequate.

Hydration Solutions

Hydration solutions have been designed mostly to provide fluid and minerals to children and adults with acute diarrhea to prevent dehydration. The solutions contain sodium and glucose. The osmolarity varies from 224 to 311 mmol/L (44). Glucose facilitates sodium absorption in the small bowel (see [Chapter 39](#)). Hydration solutions have been used successfully in underdeveloped countries during epidemics of infectious diarrhea to treat or to prevent dehydration (45). These solutions can be administered through tubes to patients with excessive fluid and mineral requirements, such as patients with certain types of short bowel syndrome.

INDICATIONS

Enteral feeding is indicated in patients who cannot ingest adequate amounts of food but have enough GI function to allow digestion and absorption of feeding solutions delivered into the GI tract through tubes. Choice of appropriate feeding solutions and method of administration based on sound pathophysiologic considerations of the GI tract are essential to maximize digestion and absorption of enteral feeding in the compromised GI tract. Specific indications for enteral feeding:

1. Severe dysphagia from obstruction or dysfunction of the oropharynx or esophagus
2. Coma or delirious state
3. Persistent anorexia
4. Nausea or vomiting; patients whose nausea and vomiting arise from a gastric

disorder (e.g., gastroparesis, gastritis, gastric outlet obstruction) can be safely fed enterally into the jejunum; in those whose symptoms result from intestinal obstruction, enteral feeding should be avoided

5. Partial obstruction of the stomach or small bowel
6. Fistulas of the distal small bowel or colon
7. Severe malabsorption secondary to decreased absorption capacity of the GI tract, such as a short bowel or inflammatory disease of the bowel; in these conditions, a pump-controlled slow drip of enteral feeding solution can maximize use of the limited absorption capacity, which may be overwhelmed by the large volume of food and fluids delivered to the intestines in oral feeding
8. Recurrent aspiration; in this condition, feeding solutions should be delivered through a jejunostomy; feeding into the stomach must be avoided
9. Diseases or disorders that require administration of specific solutions that cannot be taken orally for prolonged periods (see [Chapter 61](#))
10. Increased nutritional requirements that cannot be met by oral intake; this indication applies mostly to burn patients who have high nutritional requirements
11. Growth induction in children with Crohn's disease ([Chapter 69](#))

The clinical efficacy of enteral feeding in specific clinical conditions is reviewed in the various chapters dealing with these conditions.

Enteral feeding is contraindicated in patients with complete intestinal obstruction, paralytic ileus, severe pseudointestinal obstruction, severe diarrhea, or extreme malabsorption. In patients with a proximal intestinal fistula, enteral feeding can be attempted only if the tip of the feeding tube is distal to the fistula. In these conditions, however, enteral feeding may still aggravate the fistula by increasing the amount of fluid secreted into the GI tract (from stomach, pancreas, and bile). Enhanced secretion can occur even if the enteral feedings enter the GI tract distal to the duodenum.

A general indication for enteral feeding relates to maintaining the GI tract mucosa in a healthy state and preventing its atrophy, particularly in patients with trauma, postsurgical patients, or those for whom prolonged fasting is associated with a lengthy illness. Atrophy of the intestinal mucosa can occur rapidly after trauma and major illness ([45](#)). In an experimental setting, these disorders may lead to bacterial translocation from the gut ([45](#)). The presence of nutrients in the GI tract can serve as trophic factors both in the short bowel syndrome ([Chapter 68](#)) and in the presence of severe trauma. Thus, oral or enteral feeding early in the course of trauma or severe illness has been advocated not only to provide nutrition, but also to maintain a healthy GI mucosa and prevent bacterial translocation and sepsis ([45](#)). Whether such a benefit can be achieved in humans remains to be seen.

METHODS OF INFUSION

Enteral feedings can be administered by either bolus ([17](#)) or continuous drip ([18](#)). When possible, the bolus method is preferable because it takes less time, gives the patient more freedom, and is easier to use. It does not require pump control. The bolus of feeding solution can be given by administering as much as 500 mL over 10 to 15 minutes. The solution can be administered through a syringe with a slow push or by

gravity-driven drip from a bag.

Bolus feeding is suitable when the tip of the feeding tube is in the stomach. The bolus of feeding solution is delivered into the stomach, and outflow of the solution into the duodenum is regulated by the stomach and the pyloric sphincter. Thus, a bolus containing one-third of the daily volume can be delivered without causing dumping in a patient with a normal stomach. When the tip of the feeding tube is in the duodenum or jejunum, the feeding solution must be delivered in a continuous drip (preferably pump controlled) to avoid intestinal distention and dumping. Feeding into the small bowel usually can be tolerated at a rate as high as 150 mL/h, and some patients can tolerate higher rates.

When bolus feeding is used (e.g., in patients with dysphagia who are fed with gastrostomy tubes), daily intake of about 2000 mL can be given in 3 to 5 boluses administered every 3 to 5 hours (23). The bolus must be administered with the patient sitting or reclining 45° to prevent aspiration. When feeding into the stomach, isoosmolar and hyperosmolar solutions can be used because the pylorus prevents passage of a large volume of solution into the duodenum. When feeding into the small bowel, isoosmolar solutions usually are preferable to avoid passage of free water from the intestinal wall into the lumen.

COMPONENTS AND ABSORPTION

Protein

Protein is digested in the proximal intestinal tract and absorbed through the intestinal mucosa as dipeptides, tripeptides, or single amino acids (Chapter 2 and Chapter 39). With enteral feeding solutions containing intact protein, the process of digestion and absorption of protein does not differ from that of regular foods. An important issue regarding protein is whether incorporating it in enteral solutions as small peptides or amino acids presents any advantage, particularly in the compromised GI tract where digestion may be impaired or inadequate. In certain conditions there are theoretical physiologic advantages to predigested protein.

1. Pancreatic proteolytic enzymes are not required for hydrolysis of small oligopeptides; this hydrolysis occurs by mucosal peptide hydrolysis. Hence, small peptides would be absorbed in severe pancreatic insufficiency, whereas intact protein hydrolysis would be less efficient.
2. Patients with the short bowel syndrome may not have adequate time for proteolytic enzymes to break down whole protein. Dipeptides and tripeptides may be advantageous because they can be absorbed at once. However, predigested protein presents a higher osmotic load in the GI tract and thus may decrease tolerance to infusion.

In perfusion studies in persons with a normal GI tract, administration into the jejunum of lactalbumin as hydrolysates (dipeptides to pentapeptides) resulted in better absorption than administration of the corresponding large proteins or free amino acids (46).

Another study showed that ovalbumin hydrolysates that contained mostly di- and tripeptides were absorbed better than those containing mainly tetra- and pentapeptides (47). Other observations have not confirmed these results (48). Results of the British studies comparing absorption of free amino acids, small and larger peptides, and various intact proteins are complex (46, 47 and 48).

Various studies have addressed the question of whether administration of peptides or free amino acids as part of an enteral feeding solution rather than as a single nutrient (as in the above studies) offers an advantage. Undernourished patients with no malabsorption who were fed by a tube positioned in the proximal jejunum absorbed nitrogen as effectively from a solution with intact protein (Isocal) as from an isocaloric isonitrogenous solution containing protein hydrolysates (Criticare HN) (49). Better nitrogen retention was observed in subjects given Criticare HN than in those given a free amino acid formula (Vivonex) (50, 51). Jones et al. found only small differences between a solution containing free amino acids (Vivonex) and an intact protein diet (Clinifeed 400) infused by tube over 24 hours in a randomized fashion in 70 malnourished patients needing nutritional support after a period of inadequate intake (52). With similar nitrogen and caloric intakes, nutritional parameters were about the same, but the intact protein formula was associated with a better nitrogen balance. Other studies have shown that feeding a peptide-based formula (Reabilen) resulted in higher levels of serum transferrin and prealbumin than those attained by feeding a solution with intact protein (53, 54).

The same question about comparative value arises in patients with compromised absorptive and digestive capacity. A randomized crossover study in four malnourished patients with short bowel syndrome compared the nutritional and metabolic effects of isonitrogenous isocaloric enteral solutions containing a free amino acid mixture or hydrolyzed casein. Protein turnover was studied by leucine kinetics. There was no significant difference in the rates of protein flux, synthesis, breakdown, or oxidation during the period of administration of free amino acids compared with the period of casein hydrolysate (55). A crossover study in seven patients with the short bowel syndrome (less than 150 cm of residual jejunum ending in a stoma) examined absorption from a defined-formula diet with a protein isolate, a defined-formula diet with a protein hydrolysate (15 to 20% free amino acids, 80 to 85% 2- to 6-amino acid peptides), and three solid diets (56). The diets varied in fat, fiber, and carbohydrate. Although variations in absorption among patients were marked, almost all had similar percentages of caloric and nitrogen absorption when receiving the two defined-formula diets. Caloric and nitrogen absorption was generally better with the defined-formula diets than with the solid diets. The investigators concluded that a liquid diet consisting of peptides, oligosaccharides, and MCTs is not more beneficial than a polymeric diet in a patient with the short bowel syndrome. A randomized study comparing tolerance of polymeric solutions with that of elemental solutions in patients receiving enteral feeding following GI operations found no significant difference (57).

The various enteral feeding solutions differ not only in their sources and amounts of amino acids, but also in their content of carbohydrates, fats, and other nutrients. This point should be considered in evaluating results of comparative experiments, because these variables are essentially uncontrolled. Furthermore, in most comparison experiments that have been reported, the amino acid composition of the free amino acid

formulation differed from that of the protein hydrolysate or protein in the respective formulations (58).

The comparative value of enterally and parenterally fed amino acid mixtures regarding protein accretion was investigated in healthy dogs by use of a multilabeled leucine tracer. The study demonstrated that enteral administration of an amino acid mixture resulted in more-efficient protein anabolism in the gut and the splanchnic region. Overall whole-body leucine use was similar in the enterally and parenterally fed groups. The authors concluded that enteral feeding was superior to total parenteral nutrition (TPN) in this situation (59).

At present, no clear, consistent clinical data support the use of solutions containing protein in the form of hydrolysates or free amino acids. One reason for the lack of clear superiority of these forms of protein may be the great reserve and adaptive capacity of the absorptive mucosa of the small bowel (see Chapter 39). Even when a large percentage of the small bowel mucosa is injured or resected, the remaining parts may still process adequate amounts of nutrients. Although some patients with malabsorption might benefit from a peptide enteral feeding solution, this possibility must be clearly demonstrated in clinical trials. Because of the high cost of enteral solutions with free amino acids or peptides, their routine use cannot be supported at present.

Glutamine

Glutamine, a nonessential amino acid, is the most abundant free amino acid in the body (Chapter 2 and Chapter 35). It is synthesized mostly in muscle and used as the primary fuel in the small intestine. In recent years, glutamine has become increasingly recognized as important for maintenance of healthy intestinal mucosa, and it may protect the mucosa from injury induced by chemotherapy, radiation, and other injurious factors (60, 61). In addition, glutamine helps maintain acid-base equilibrium through generation of ammonia. Glutamine is unstable in aqueous solutions, spontaneously breaking down to ammonia and pyroglutamic acid; thus, including glutamine in nutritional solutions poses a manufacturing hurdle.

In rats with the short bowel syndrome, addition of glutamine (25% of total amino acids) to a defined-formula diet resulted in a trophic effect on the mucosa of the remaining small bowel, with increased villous height and greater hyperplasia (63). Glutamine in combination with growth hormone administration and a dietary regimen containing fiber was reported to enhance absorption in patients with short bowel syndrome (64).

In catabolic states, both release of glutamine from muscle and use of glutamine by the GI mucosa seem to increase (65, 66) (see Chapter 35). This increase may result in severe loss of muscle tissue. When catabolism is prolonged, glutamine synthesis and release from muscle decrease and may not cover the increased use by various tissues, especially the GI mucosa. Thus, glutamine deficiency may ensue. Glutamine consequently has been suggested to be essential for the intestinal mucosa and other organs of patients in catabolic states and thus may need to be added to nutritional regimens for patients with catabolic illnesses (67). Provision of adequate glutamine in nutritional regimens results in better immune response in the GI mucosa and in

maintenance of mucosal mass and its barrier function against bacteria (68). Such maintenance may provide protection against bacterial translocation and sepsis. However, such an advantage has not been demonstrated in humans. Before large amounts of glutamine are added to enteral feedings, its safety and efficacy must be studied. Some investigators are concerned that glutamine, a primary nutrient in some tumors, may act as a tumor stimulator (69). Therefore, any potentially adverse effects of glutamine must be carefully evaluated, particularly in cancer patients.

Proteins in enteral feeding solutions contain glutamine, but it is protein based. Determining the glutamine content is difficult because it requires hydrolyzing the protein with heat and acid, which also converts glutamine to glutamate. The data on the beneficial effect of glutamine on the small intestinal mucosa have been derived from studies in which free glutamine was administered. It is not clear that protein-bound glutamine has the same beneficial effects as the free form. Commercial enteral feeding solutions with intact protein contain glutamine in quantities of less than 14% of the total protein amino acids. However, solutions are available with added glutamine (Vivonex, Alitraq).

Carbohydrates

The various starches in commercial enteral feeding solutions are eventually hydrolyzed to glucose in the small intestine. Starches vary in their glucose units, from 400 to many thousands. Hydrolysis forms polymers with decreasing numbers of glucose units (see [Chapter 3](#)). The osmolality of a formula is influenced to a major extent by the sources and amounts of glucose, sucrose, and the shorter-chain glucose units and to a lesser extent by free amino acid and electrolyte concentrations.

The patient with normal GI function hydrolyzes starch and long-chain glucose polymers rapidly. Most of the glucose is absorbed in the proximal small bowel. In patients with marked pancreatic insufficiency, oligosaccharides may be useful because they are hydrolyzed to glucose by the intestinal brush-border enzyme α -dextrinase.

Initial rapid infusion of large volumes of high osmolality into the stomach or jejunum should be avoided in patients with vagotomy (which also occurs with esophagectomy), gastrectomy, and intestinal dysfunction, because this infusion can induce rapid transit, glucose malabsorption, abdominal discomfort, and diarrhea. Hyperosmolar nonketotic coma can occur with high-carbohydrate feedings; coma is most likely to develop in the diabetic patient who is infected and dehydrated. Excess carbohydrate calories in enteral feeding can result in hypercarbia in patients with respiratory insufficiency and in a rise in metabolic rate.

Lipids

The fat content of enteral feeding solutions varies from less than 2% to 45% of the total calories. The lipids, usually corn oil or soy oil, contain large amounts of polyunsaturated fatty acids; some contain lecithin (added as an emulsifier). Others have MCTs in small or large proportions. The rationale for adding MCTs is that they are easily hydrolyzed and absorbed in various states of malabsorption (70, 71); however, absorption of enteral

feeding solutions containing MCTs has not been proved superior to that of LCT-based solutions. Because MCTs are ketogenic, they should be avoided in patients with diabetes, ketosis, or acidosis (71). The relatively large amounts of polyunsaturated fat in most formulas provide more than enough essential fatty acids; the need is approximately 3 to 4.5% of total calories (see Chapter 4). An enteral feeding solution (Impact) has been introduced that contains part of the fat as fish oil. Fish oil has a high content of w-3 fatty acids and has been reported superior to vegetable oil in its effect on the immune response (38).

As for other nutrients, the efficiency of absorption of lipids depends on the rate of infusion, the concentration of the nutrient, and the digestive and absorptive capacities of the GI tract. (Lipid characteristics and other factors affecting digestion, absorption, and metabolism are reviewed in detail in Chapter 4). Patients with exocrine pancreatic insufficiency may absorb more than 50% of dietary fat despite the absence of measurable pancreatic lipase activity. This absorption appears to be related lingual and gastric lipases (72). Nevertheless, administration of pancreatic extracts is useful in patients with pancreatic insufficiency. Patients with the short bowel syndrome have been reported to absorb 54% of the fat from a diet containing 46% of the calories as fat (73). Fat did not adversely affect absorption of magnesium, calcium, and zinc. This finding dispels the notion that patients with the short bowel syndrome require a low-fat diet and has an important implication for the use of enteral feeding in such patients. A high-fat enteral feeding solution administered by continuous drip can provide a large number of calories and thus ensure absorption of adequate calories despite the malabsorption. A report compared the effectiveness of five different levels of fat (from 10 to 50% of nonprotein calories) in enteral feeding solutions given to guinea pigs with full-thickness burns over 30% of the total body surface (63). Fat content between 5 and 15% of nonprotein calories was deemed optimal for nutritional support.

Enteral feeding solutions are available with fat providing up to 55% of the calories. The value of such formulas in patients with impaired pulmonary function has been reviewed above in this chapter and in Chapter 90.

Vitamins and Trace Elements

Enteral feeding solutions were designed to provide the recommended dietary allowance (RDA) of vitamins and trace elements with an intake of 1500 to 2000 calories. Patients maintained on enteral feeding for periods exceeding 6 months had normal or high blood levels of the various vitamins (75).

The stability of vitamins in commercial enteral feeding solutions has been determined only to a limited extent. Short- and long-term studies demonstrated stability of vitamins A and E and riboflavin for as long as 3 months. Specific data regarding absorption of vitamins from enteral feeding solutions are lacking. However, the adequate or high levels of vitamins in the blood of patients who received long-term enteral feeding suggest that both stability and absorption are adequate and, consequently, that current enteral feeding solutions contain adequate vitamins (75).

Most enteral feeding formulas contain sufficient amounts of trace elements, including

iron, zinc, copper, and iodine, so that intake of 1500 to 2000 calories per day provides adequate amounts of these nutrients. However, deficiencies of zinc and other micronutrients can occur when the caloric intake from enteral feeding is low or when GI loss of zinc persistently exceeds intake, as can happen in patients with active Crohn's disease.

Fiber

Enteral feeding formulas initially were fiber free, except for those prepared by blenderizing natural foods. There has been increasing recognition that dietary fiber offers numerous physiologic and metabolic benefits ([Chapter 43](#)). Most Americans ingest 8 to 12 g of dietary fiber daily ([78](#)). The recommended amounts for healthy Americans are 10 to 13 g of fiber per 1000 calories ([77](#)).

Some enteral feeding solutions are now prepared with fiber. Blenderized enteral feeding solutions contain 1.9 to 3.3 g fiber per 250 mL ([79](#)). Some polymeric enteral solutions are manufactured with fiber from different sources, including soy polysaccharide fiber, oat fiber, and others. Soy polysaccharide is a tasteless and odorless material that is easily added to enteral feeding solutions because it can be suspended in liquid. Only about 6% of soy polysaccharide is water soluble. It can improve lipid metabolism and diabetic control in hyperlipidemic patients ([80](#)). The amounts of soy polysaccharide added to enteral feeding solutions vary between 2.5 and 5.9 g per 250 mL ([79](#)). Pectin and gum are poor candidates as fibers in enteral feeding solutions because they have high viscosity. Some enteral feeding solutions contain a combination of fibers including oat, pectin, gum arabic, and hydrolyzed gums, providing both soluble and insoluble fibers. Fiber derived from oats may have a cholesterol-lowering effect, whereas most insoluble fibers, such as cellulose and hemicellulose, act mostly as laxatives.

If a solution without fiber is used, fiber can be administered separately in other forms, such as natural bran or Metamucil. In spite of the physiologic considerations pointing to gastrointestinal and metabolic functions of dietary fiber, results of investigations on its role in enteral feeding have been inconsistent. The effects of different fibers in enteral feedings were studied in a randomized study in healthy subjects. Compared with a fiber-free polymeric enteral feeding solution, supplementation with 30 g of oat fiber, soy oligosaccharide fiber, or a soy polysaccharide had a negligible effects on bowel function ([81](#)). Other studies showed similar results with soy polysaccharides ([82](#), [83](#)).

A study of healthy young male subjects compared the effects of adding 0, 30, or 60 g/day of soy fiber to a feeding solution (Ensure). The results showed that dietary fiber increased daily fecal weights and frequency of bowel movements. All dosages of fiber resulted in decreased transit time in the GI tract ([84](#)).

The effects on bowel function of a fiber-containing enteral feeding solution (Enrich, 12.8 g fiber/1000 kcal) were compared in a crossover randomized study to the effects of a solution without fiber (Ensure)([85](#)). Mean daily fecal weight and frequency of bowel movements were similar during administration of the two solutions; however, patients fed Ensure required more laxatives and had more diarrhea. Constipation was similar in both groups. The authors reported that the fiber-containing solution was associated with

improved GI function. Because the patients fed Ensure received more laxatives, their worsened GI function (i.e., more diarrhea) could have been caused by the laxative use. Most of the patients in this study were comatose, and thus these results are of limited clinical application in other groups of patients.

A concern was raised that fiber in enteral feeding solutions would decrease absorption of minerals and vitamins (86). Addition of 120 g/day of soy polysaccharides to an elemental solution did reduce the overall absorption rate of magnesium, zinc, and phosphorus but did not affect potassium and calcium absorption. The balance for all five minerals was still positive, however (87). Others studied the effect of adding 20, 30, and 40 g of soy polysaccharides; 40 g of fiber caused negative balances for copper and iron, whereas zinc, calcium, and magnesium were in positive balance (88).

Administration of enteral feeding solutions containing soy polysaccharide apparently does not result in malabsorption and deficiency of major minerals and vitamins in the short term. The effects, however, in patients receiving long-term enteral feeding with fiber as the primary or sole diet are unclear. Appropriate monitoring for these nutrients is recommended.

COMPLICATIONS

Enteral feeding can be a safe and effective nutritional support method. Its safety depends on (a) choice of the appropriate formula and infusion method, (b) delivery of the formulas into the appropriate part of the GI tract, and (c) clinical and metabolic evaluation of the patient prior to and during enteral feeding.

The most severe potential complication of enteral feeding is aspiration. Numerous factors can predispose to aspiration, including misplacement of the tip of the feeding tube in the esophagus or upper stomach, impaired gastric emptying, decreased lower esophageal sphincter pressure, large feeding volume, patient's position during feeding, and various medications that decrease GI peristalsis. The risk of aspiration can be reduced by appropriately positioning the feeding tube, elevating the upper body to 30 to 45°, and avoiding enteral feeding when contraindicated. Placement of a gastrostomy tube per se does not affect the lower esophageal pressure. However, gastric distention caused by rapid delivery of an intragastric bolus of enteral feeding can relax the sphincter (89) and may predispose to reflux, heartburn, and aspiration. In the presence of impaired gastric emptying or in the absence of gag reflex, the feeding solution is best delivered into the jejunum. The incidence of aspiration depends on how vigorously it is sought and the type of patient. Severe aspiration was reported in 1% of patients receiving an average of 10 days of enteral feeding (90). In a prospective study, the incidence of aspiration was 2.4 per 1000 enteral feeding days. Little morbidity and no mortality resulted from aspiration (91). However, other studies reported aspiration rates between 17 and 32% in patients receiving gastric feeding (92, 93 and 94).

Bacterial contamination of enteral feeding formulas can occur easily because the solutions are an ideal growth medium for bacteria. Occasional case reports of sepsis associated with feeding contaminated enteral solutions have surfaced.

Nausea and vomiting have been reported to occur in as many as 20% of patients (95). Nonspecific symptoms of abdominal cramps, distention, and bloating can occur and are usually caused by too-rapid infusion or an underlying intestinal disorder.

Diarrhea has been reported in 5 to 30% of patients receiving enteral feeding (96). Defining diarrhea and determining its cause in patients receiving enteral feeding may be difficult, however, and the method of reporting may significantly alter the reported incidence of this complication (95). Tolerance to enteral feeding depends on several factors, including the functional capacity of the GI tract, the rate of infusion, the type of formula, and concomitant medications. The healthy GI tract can easily handle bolus feedings of as much as 500 mL given over 10 to 15 minutes. This feeding method has been used successfully in patients with dysphagia secondary to cancer of the head and neck (23).

Patients with GI diseases may require a slow rate of infusion. Those with a short bowel or with small bowel mucosal disease (e.g., radiation enteritis or Crohn's disease) may require a pump-controlled continuous feeding over 10 to 15 hours with a rate not exceeding 100 mL/hour. Isoosmolar solutions are better tolerated by patients prone to diarrhea because hyperosmolar solutions tend to draw fluids into the upper intestine, thereby increasing the load that must be absorbed distally. Solutions with an osmolality of approximately 300 mosm/kg do not require dilution to enhance tolerance and decrease diarrhea.

One of the most important factors in causing diarrhea during enteral feeding is concomitant use of medications, particularly antibiotics and magnesium-containing antacids. In some reports, as many as half of the patients on enteral feeding who were receiving antibiotics developed diarrhea; these two factors seem to work synergistically to induce diarrhea (97). Studies in healthy volunteers demonstrated that significant colonic secretion of water, sodium, and chloride occurs during enteral feeding (98). This may contribute to diarrhea, especially in patients with compromised intestinal function or when antibiotics are administered concomitantly. Infusion of short-chain fatty acids into the cecum prevented net fluid secretion into the colon. When these fatty acids are absorbed in the colon, they enhance water and electrolyte absorption (98).

Constipation occurs in as many as 15% of patients receiving long-term enteral feedings. As mentioned above, there is no clear evidence from clinical trials that fiber-containing enteral feeding solutions alleviate this problem.

Metabolic abnormalities can occur in patients receiving enteral feeding. Their frequency and severity depend mostly on the general medical condition of the patient. Thus, patients with renal failure are at risk for developing increased azotemia, hyperkalemia, hypermagnesemia, and hyperphosphatemia, and the diabetic patient is at risk for hyperglycemia. These potential complications are not inherent to enteral feeding and can be avoided by careful attention to the medical condition of the patient.

Dehydration is a potential complication in patients given high-osmolality enteral feeding solutions. When such solutions are administered, close observation is necessary to

prevent dehydration and metabolic complications.

ENTERAL FEEDING IN VARIOUS MEDICAL CONDITIONS

The role of enteral feeding in specific medical conditions is presented in the various chapters as follows: inherited metabolic diseases, [Chapter 61](#) and [Chapter 62](#); inflammatory bowel disease, [Chapter 69](#); pancreatic disorders, [Chapter 72](#); cancer, [Chapter 82](#); renal disorders, [Chapter 89](#); pulmonary disorders, [Chapter 90](#); the hypercatabolic state, [Chapter 96](#); infection, [Chapter 97](#); and surgery, [Chapter 98](#).

HOME ENTERAL NUTRITION (HEN)

HEN is used increasingly to provide nutrients and fluids outside the hospital. In 1992, an estimated 152,000 patients used HEN ([99](#)). The National Registry of Home TPN and HEN reported clinical data on 3931 patients ([99](#)). The two most common diagnoses of patients receiving HEN were cancer, which accounted for 42%, and swallowing disorders, 30%. The later group included mostly patients with strokes. The therapy was safe in the home. HEN complications requiring hospitalization occurred at an annual rate of 0.4 and 0.3% in the cancer and swallowing disorders groups, respectively. The 1-year survival was 30% for cancer patients and 55% for the neurologic disorders patients; 30% of the cancer patients and 15% of the neurologic patients were able to resume full oral nutrition. In patients with cancer of the head and neck whose tumors are successfully treated, HEN has been used for periods exceeding 7 years, providing good nutrition and rehabilitation with minimal impact on quality of life ([23](#), [100](#)). Regular medical follow-up is essential to ensure appropriate functioning of the feeding tube and optimization of the nutrition regimen.

[Chapter References](#)

The efforts to introduce fluid, salt, and food directly into the bloodstream began with Sir Christopher Wren in 1658 and the intervening history has been summarized ([1](#), [2](#) and [3](#)). The scientific groundwork resulting in successful parenteral nutrition was laid in the third to fifth decades of the 20th century. Such developments included (*a*) the ability to provide pyrogen-free fluids as a result of Seibert's work ([4](#)), (*b*) elucidation by many investigators of the chemical nature of essential nutrients and their eventual availability in safe intravenous forms, (*c*) increased understanding of fluid and electrolyte needs and the importance of acid-base balance, all of which were aided by advances in analytic instrumentation, and (*d*) recognition of the metabolic and nutritional changes and needs associated with disease ([5](#), [6](#)).

World War II stimulated further research into the metabolic changes induced by trauma and infection, led to wider recognition of the importance of nutrition in these and other clinical states ([7](#)), and furthered the use of parenteral nutrition (PN) in the seriously ill ([8](#), [9](#)). Peripheral (and occasionally central) parenteral feedings using 5 or 10% glucose, protein hydrolysates, intravenous fat (Lipomul), electrolytes, and multivitamins were used from 1955 to 1965 by various clinicians for limited periods ([3](#)). Serious side effects

led to withdrawal of intravenous Lipomul from the United States market in the early 1960s. This created a serious problem requiring that glucose be given either in large, relatively isotonic volumes for peripheral vein infusion or else in hyperosmolar form requiring infusion into a major vein. Although central catheters threaded into veins had been used as early as 1944 (3), they were uncommon. A safe and effective intravenous lipid preparation (Intralipid) had been developed by Schuberth and Wretling, tested by 1961 in Sweden (10), and approved for use in most European countries by 1963; it was not approved for use in Canada or in the United States until 1977. Intralipid availability in Europe in the early 1960s led to increased use of PN through peripheral veins.

Widespread interest and increased use of PN occurred after publication of reports by Dudrick et al. (11). Using percutaneous central catheters to deliver nutrient solutions with glucose as the source of nonprotein calories, these investigators demonstrated convincingly that PN as the sole source of nutrients resulted in good growth in malnourished infants and positive nitrogen balance and nutritional and clinical improvement in malnourished adults over periods of many weeks.

Development of PN has been marked by replacement of hydrolyzed casein or blood fibrin by free amino acid mixtures and by the advent of safe lipid formulations and the availability of improved formulations of parenteral vitamins and trace elements (3, 10, 12, 13). Sophisticated pumps with programmed metering controls have increased safety and simplified the care of these patients.

All parenteral solutions and emulsions are classified as drugs and must meet the standards of the United States Food and Drug Administration (FDA) for sterility, safety, and efficacy. Accordingly, these agents are appreciably more expensive than enteral products, with consequent limitations on development of new items or modifications of older ones. Nutrients of poor solubility or stability in aqueous solutions still present problems in formulations.

The major physiologic difference between parenteral and enteral products is the direct entry of parenteral solutions into the systemic circulation, bypassing the alimentary tract and the first circulatory pass through the liver by nutrients entering the portal vein. Other problems related to the parenteral route involve venous access, sterile and stable solutions, technique in administration, nutritional adequacy, and presence of an indwelling catheter in the vascular system.

NOMENCLATURE

Nutritional needs may be high (e.g., in the hypercatabolic patient) or relatively restricted (i.e., primarily water, electrolytes, and/or micronutrients). Various descriptive terms have been applied to the procedure used in supplying these requirements. The term *hyperalimentation* entered the clinical nutritional lexicon in various ways to indicate the need for large amounts of calories and certain other nutrients. Co Tui et al. used the term in 1944 and 1945 in describing large amounts of casein hydrolysate and carbohydrates given postoperatively by tube to patients who had undergone gastrectomy (14) and orally or by tube to patients with peptic ulcer (15). In 1965, the same term was used by others to describe supplementary intravenous lipid feeding

given to cancer patients. (16). The term was reintroduced by the University of Pennsylvania group (11) to describe techniques for supplying total nutritional support by the intravenous route. *Hyperalimentation* became widely used in the context of high caloric formulation and was often shortened to *hyperal*. Because it was applied also to tube feeding, *intravenous hyperalimentation* and *enteral hyperalimentation* appeared in the literature.

Both historically and etymologically, the term *hyperalimentation* has implied needing and providing amounts of nutrients that exceeded normal requirements (particularly for energy and amino acids). It is now clear that used in this way, the term has a potentially misleading connotation because provision of excess energy and certain nutrients is often undesirable. For this reason, the term is little used now. It was replaced by the designation *total parenteral nutrition* (TPN) and more recently by the general designation of *parenteral nutrition* (PN), with appropriate qualifiers such as total or supplementary, central or peripheral, to designate amount and route.

INDICATIONS

The primary objective of PN is maintaining or improving the nutritional and metabolic status of patients who, for a critical period of time, cannot be adequately nourished by oral or tube feeding (Table 101.1). The value and use of this treatment method in the management of patients with specific clinical problems are discussed in this book and elsewhere: the short bowel syndromes (Chapter 68), other types of bowel dysfunction (Chapter 70), pediatric disorders (Chapter 64), cancer (Chapter 82), obstetric problems (17), neurologic injuries (18), and other hypermetabolic states, surgery, sepsis, and AIDS (Chapter 96). Use of PN in the perioperative period has been evaluated and is discussed further in Chapter 98 and elsewhere (20, 21 and 22).

-
1. Malabsorptive syndromes (intestinal, renal tubular, or combined) with severe food, electrolyte and fluid losses not adequately managed by oral or enteral nutrition
 - a. Severe short bowel syndrome
 - b. Those induced by infection, inflammatory, and immunologic disorders, drugs, or radiation
 - c. High-output gastrointestinal fistulas unable to be bypassed by enteral intubation
 - d. Severe renal tubular defects with large fluid and ion losses
 2. Motility disorders
 - a. Persistent ileus (postoperative or disease related)
 - b. Severe intestinal pseudoobstruction
 - c. Severe persistent vomiting induced by medication, brain tumor, or other disease (e.g., hyperemesis gravidarum)
 3. Mechanical intestinal obstruction not immediately remediable by surgery
 4. Perioperative state with severe undernutrition
 5. Critically ill patients, especially those with hypermetabolism, when enteral nutrition is contraindicated or has failed
 6. Very low birth weight premature infants when enteral feeding is inappropriate
-

Table 101.1 Clinical States Likely to Benefit from Parenteral Nutrition

For those individuals who are well nourished or minimally malnourished before undergoing elective surgery and who are likely to be eating again in 5 to 7 days,

adequate postoperative nutritional support usually consists of hypocaloric glucose, electrolytes, and micronutrients. Preexisting serious undernutrition, however, increases the likelihood of postoperative complications, especially with major surgery ([Chapter 98](#)) ([20](#), [21](#) and [22](#)).

The decision to undertake PN requires weighing various factors and considering the patient's diagnosis and prognosis as discussed in appropriate chapters. It is not a defensible substitute for oral or tube feeding when adequate provision by either of these methods is feasible. Issues related to its use in the hopelessly ill are reviewed in [Chapter 102](#).

The conditions for PN listed in [Table 101.1](#) are widely accepted as noncontroversial indications. However, its use in a variety of other conditions listed in the chapters enumerated above is often controversial, because of the paucity of appropriate studies that give statistically valid data supporting or negating the value of PN. The many reasons for the lack of information to serve as acceptable clinical guidelines have been discussed often and recently ([Chapter 98](#), [23]). They include the variability of severity of disease, level of malnutrition in patients, complication rates, varying medication schedules, and other interventions, as well as differences in quality of management and protocol. The variable and changing healthcare system and payment practices have added to the pressures to justify use of PN. Answers will not be found easily or quickly. The purpose of this chapter is to help ensure that when PN is used, it will be done well, by considering the many aspects of this complex and potentially lifesaving procedure, including its potential for serious complications ([Chapter 98](#), [23]).

VENOUS ACCESS: PERIPHERAL AND CENTRAL

Infusion of nutrient solution directly into a peripheral vein has an advantage over central infusion in avoiding insertion and maintenance of a central catheter. Peripheral parenteral nutrition (PPN) with a short cannula reduces peripheral vein damage by substituting 10 or 20% isotonic lipid emulsions with their large caloric content for the hypertonic glucose solutions used in central PN. For example, a preparation composed of 1 L each of 6% amino acids, 10% lipid, and 18% dextrose provides 9 g of nitrogen and 1620 nonprotein calories, with an osmolality of 680 mosm/L ([24](#)). Infusion for 8 hours, cannula removal, and using the opposite arm the next day, minimized thrombophlebitis ([24](#)). Such PPN may be useful (although the restricted carbohydrate may present some problems) for the patient who needs nutritional support for 5 to 10 days and has ample patent peripheral vessels. Many patients requiring intravenous nutrition have had numerous prior peripheral infusions and venesections, with consequent vessel sclerosis. Critically ill patients whose condition is unstable must have reliable venous access at all times, and a central catheter is a necessity.

Providing sufficient energy by the central route without providing a large percentage as lipid necessitates infusing hypertonic glucose solutions. Consequently, the catheter tip must be in a vessel with high blood flow causing rapid dilution; this minimizes the occurrence of phlebitis and thrombosis. Numerous routes for such vascular access have been used ([Table 101.2](#)) ([25](#), [26](#), [27](#), [28](#), [29](#), [30](#), [31](#), [32](#), [33](#), [34](#), [35](#) and [36](#)). Popularized by Dudrick et al., the percutaneous subclavian vein approach in adults and the jugular

approach in infants were widely adopted (10, 11, 26). Arteriovenous fistulas of the internal type have been prepared, usually with a bovine graft, and external fistulas have been used; some of the early patients discharged home on PN had one or another of these fistulas. Other vascular approaches have been adopted when the usual vessels were not patent or were otherwise unavailable.

Route	Reference
Peripheral vein: percutaneous approach	24, 25
Jugular vein (internal or external): percutaneous approach	26
Jugular vein (internal or external): surgical approach ^a	27
Subclavian vein or tributary: percutaneous approach	26
Subclavian vein or tributary: surgical approach ^{a,b}	28
Portal vein	29

^aUsed in placement of tunneled catheter.

^bUsed in placement of tunneled or subcutaneous port.

Table 101.2 Vascular Access Routes for Parenteral Nutrition

Occasionally, peripherally inserted central catheters (PICC lines) are used for long-term PN. If these types of catheters are used for PN, the tip of the catheter *must* be positioned in a central vein such as the superior or inferior vena cava. Kearns et al. have reported a significantly higher incidence of thrombosis and infection and decreased catheter survival when the tip of a PICC resided in the axillosubclavian-innominate vein compared with use of the superior vena cava (25).

In an effort to reduce the incidence of infection, tunneled central catheters were introduced in 1973. These are usually placed surgically within the subclavian or jugular vein, with the tip in the superior vena cava. The extravascular portion of the catheter is tunneled under the skin for a variable distance before being taken through the skin. The catheter is often anchored at the skin exit with a Dacron cuff to eliminate the need for sutures in the skin. More recently, subcutaneously placed chambers of silicone or other elastomer, termed *ports*, have been developed; the chamber is connected by a catheter, usually placed into the subclavian vein with its tip in the superior vena cava (35). Nutrient solution is infused into the chamber via special needles inserted through the skin.

Insertion and use of an indwelling central venous catheter pose various risks to the patient, including pneumothorax, hemothorax, hematuria, aneurysms, venous or nerve injury, hypersensitivity-like reactions, and microbial contamination. Reported complication rates range from 0.3 to 12%, according to different definitions and physician expertise (38). Thrombogenicity varies with the catheter material; the earlier and stiffer polyvinyl and polyethylene catheters were associated with more thrombus

formation than silicone or polyurethane elastomers. Multilumen catheters have increased in use that provide additional access for infusing medications and blood and for blood sampling without interfering with PN administration. There are conflicting reports about the relative amount of catheter-related sepsis (39, 40). Placement site is related to infection rates; e.g., femoral and jugular sites tend to have higher rates than the subclavian site (40). Similarly, catheter tunneling (e.g., jugular) reduces percutaneous cannulation sepsis (41) and also reduces other problems such as dislodgement.

Complications tend to be less frequent when experienced surgical and other personnel (preferably members of a clinical nutritional team) exercise necessary precautions, including using aseptic technique in catheter insertion and maintenance, checking proper placement by x-ray study before use, and adequately caring for the insertion site. Recommendations for infection control in association with PN have been published (42, 43).

Ultrasound, recommended as a means of determining vein position and/or catheter placement, was evaluated by comparing ultrasound-guided location of the subclavian vein by marking the site before the attempt with standard insertion procedures. The two methods did not differ in catheterization failures or complication rates (9.7%). Complications increased with failed attempts: 28% with placement failure versus 7.2% with successful placement. The complication rate increased from 4.3% with one-pass failure to 24.0% with more than two passes. Realtime ultrasound guidance during actual placement and/or placement only by very experienced physicians would presumably reduce such complications (38).

In general, a diagnosis of bacteremia or fungemia with the possibility of catheter colonization should be seriously considered when the patient experiences sudden spiking fever and/or shaking chills. A sustained fever is more likely to be related to an abscess somewhere, often without catheter colonization. With onset of fever, sources of infection should be sought, and material taken from both the catheter and a peripheral vein for appropriate culture. Appropriate antibiotic treatment should be instituted as indicated.

When microbial colonization is suspected in a percutaneously placed catheter, a modified Seldinger technique may be useful. This involves rapid replacement of a central catheter over a flexible wire using appropriate sterile technique without another venipuncture (44, 45). The tip and/or subcutaneous portion of the removed catheter should be cultured in addition to other relevant cultures. The modified Seldinger technique greatly reduces the need for further venipunctures and possible complications and is particularly valuable for the patient considered a candidate for long-term PN, for whom continued vascular access is critical. Most catheters removed on suspicion of sepsis are found to be sterile. When an endoluminal brush is used to sample the catheter, the acridine orange leukocyte cytospin test may be useful for detecting infected catheters in situ (46).

Experience indicates that with good technique in both catheter placement and solution preparation and with proper maintenance, indwelling catheters of the percutaneous or

tunneled type may remain safely in place for months and years without infection or disruption (47, 48). Several comprehensive reports have been published regarding the catheter-related sepsis rate in patients who have long-term catheters for intravenous access. Buchman et al. reported on 527 patients receiving home PN (HPN) who were followed for a median time of 206 days (range, 7–6344 days) (49). Some 81% of the adults and 3% of the children were never infected. Thirty-six of these patients were infection free for more than 10 years. The catheter-related sepsis rate was 0.37/patient-year for all patients and 0.51/patient-year for children. Patients having catheters for more than 10 years had a catheter-related sepsis rate of 0.28/patient-year (49). Risk factors for sepsis were Crohn's disease, presence of jejunostomy, smoking, and central vein thrombosis (50).

Randomized large-scale hospital trials comparing standard central catheters with those either impregnated with chlorhexidine and silver sulfadiazine (50a) or with minocycline and rifampin (50b) found that the antiseptic or antibiotic-treated catheters significantly reduced the rates of catheter colonization and bloodstream infection with no apparent side effects.

The use of subcutaneously placed ports has been increasing, presumably on the assumption that the risk of infection is reduced during the 8 to 16 hours of infusion by having a fine needle as the only external vascular access. No controlled comparative data are available for comparison of this technique with other types of catheters. These devices are expensive and are not without infection and maintenance problems.

The designation “fibrin sheath” for the thin, white, adherent covering on chronically implanted catheters is incorrect. At this stage, the coating is vascularized fibrous connective tissue not likely to be dissolved by fibrinolytic agents such as urokinase, streptokinase, or tissue plasminogen activator (51).

DELIVERY SYSTEMS

Nutrient solutions for PN are usually delivered from bottles or plastic bags via electronic pumps without drop counters. Central PN solutions are generally delivered using peristaltic pumps of various types. These have become increasingly sophisticated, automated, and expensive. They ensure even flow rates, overcome the increased resistance of filters of small porosity (especially with continued use), minimize the likelihood of clotting at the catheter tip, and reduce the need for frequent nursing surveillance.

There has been a resurgence in the use of filters, especially after the two deaths reported from improper admixing of calcium and phosphorus into a total nutrient admixture (52). Many practitioners are now using 0.22- μ m filters for patients receiving 2-in-1 PN solutions (dextrose + amino acids), and 1.2- or 5- μ m filters for those receiving total nutrient admixtures (53).

The use of pliable plastic bags of various sizes eliminates the danger of breakage, simplifies transportation and storage, and reduces storage space requirements before and after filling, compared with use of glass or formed-plastic bottles. The usual water

solutions of nutrient formulations do not extract measurable amounts of phthalate plasticizer used in the manufacture of polyvinyl chloride (PVC) bags; however, albumin, lipids, and blood take up the plasticizer (54). The amount of plasticizer eluted from PVC administration sets by lipid emulsions is relatively small compared with that from the bags. Plasticizer-free ethylene vinyl acetate tubing and bags are available. Another elastomer contains the plasticizer trioctyl trimellitate, which is not extracted by lipid. These are useful with certain lipid formulas.

Dual-chambered plastic bags have been marketed (55) that allow admixture of macronutrients immediately before infusion of PN admixtures. These are very convenient for HPN, especially for patients who receive intravenous lipid on a regular basis. Dual-chambered bags are manufactured either empty or with the macronutrients in them (i.e., dextrose in one chamber and amino acids in the other chamber). When lipid is used, the dextrose, amino acids, and electrolytes are added to the bottom chamber of the empty bag and the desired intravenous lipid dose to the upper chamber. This increases stability, because the total nutrient admixture is not prepared until just before infusion.

Insulin adsorption varies appreciably, depending on the binding characteristics of the nutrients present, the type of plastic in the delivery system, the presence of filters, and the concentration of insulin added (56). When insulin is added to parenteral solutions for diabetic patients, the dosage must be closely monitored until properly adjusted (56, 57). An in vitro study simulating the clinical setting showed that 90% of regular insulin added to admixtures with and without lipid was available after infusion through tubing (58). This requires confirmation.

Because of adherence and loss of vitamins A and E (particularly the former) when solutions are infused very slowly to very low birth weight infants, a delivery system using minimal tubing and more rapid infusion has been recommended (59).

PARENTERAL COMPONENTS AND REQUIREMENTS

General Requirements

The weight of a relatively unstressed middle-aged patient with restricted activity, who has no fever or other hypermetabolic condition, should be maintained in an acceptable range by approximately 30 kcal (7.2 kJ) per kg of body weight per day. A ratio of grams of nitrogen to kilocalories (N:kcal) of approximately 1:130 to 150 (1:31–36 N/kJ) is an appropriate formula for such a patient (60). Malnourished nonhypercatabolic adults can be placed in positive nitrogen balance on a caloric intake of approximately 1.3 times resting energy expenditure (REE) or 29 kcal/kg while receiving PN supplying 1.13 g of amino acids/kg (180 mg N/kg) per day (61). When twice this amount of amino acids per kilogram was given, nitrogen retention was better; such patients appear to behave like growing children in this respect. More calories are required for weight gain, depending on the weight gain desired. Shaw et al. developed a graphic presentation of the effects of nitrogen and energy intakes on nitrogen and fat balance in depleted patients (61). The amount of additional protein needed is usually proportionally higher than that of energy; e.g., for adult patients acutely stressed by trauma, burns, or infection, the N:kcal

ratio is generally increased (1:100) ([Chapter 98](#)), with such patients receiving as much as 40 to 45 total kcal/kg or occasionally more. Care must be taken not to exceed caloric expenditure. The goals for infants and children are reviewed in [Chapter 64](#).

All essential and sufficient nonessential amino acids should be provided in amounts needed to sustain adequate protein synthesis and intermediary metabolism. Essential fatty acids should be supplied regularly. Macromineral, trace element, and vitamin intakes should meet individual requirements without excessive wastage or toxicity. No matter how adequate the formula is in other respects, a deficiency of any essential nutrient may lead to negative balance in nitrogen and other nutrients. A single deficiency of either potassium, sodium, phosphate, or nitrogen impaired or abolished retention of other elements ([63](#)), and zinc depletion also caused negative nitrogen balance ([64](#)).

Water

The fluid component must meet individual needs and avoid the twin dangers of over- and underhydration in patients who may have difficulty in excreting or retaining needed water. The close interrelationships of water, electrolytes, hormonal factors, and the kidney are considered in [Chapter 6](#). Proper management of fluid and electrolyte status is a most important aspect of nutritional support. In addition, clinical factors that could cause excessive retention or loss, consideration must be given to fluid intake with medications and “keep-vein-open” infusions, as well as changes in insensible water loss. As noted in [Table 101.3](#), formation of sodium-free water from the metabolism of nutrients may add a volume of approximately 18%. Daily weighing and meticulous recording of intakes and outputs are mandatory.

Sources	Amount
Muscle	1 g yields 0.85 mL 10.1 mL from protein + 0.75 mL cellular water
Mixed tissue	100 kcal yields 10 mL
Fat	1 g yields 1.0 mL
Protein	1 g yields 0.4 mL
Glucose	1 g yields 0.64 mL
Glucose - H ₂ O	1 g yields 0.60 mL
Mixed diet	100 kcal yields 20 mL
Example: high-glucose PN solution	
750 mL 10% amino acids	300 kcal yields 30 mL H ₂ O
1175 mL 50% glucose/water	2000 kcal yields 363 mL H ₂ O
143 mL 10% lipid	157 kcal yields 14 mL H ₂ O
Total: 2068 mL	2457 kcal yields 397 mL H ₂ O
Example: glucose-lipid PN solution	
750 mL 10% amino acids	300 kcal yields 30 mL H ₂ O
750 mL 50% glucose/water	1275 kcal yields 225 mL H ₂ O
800 mL 20% lipid	1000 kcal yields 100 mL H ₂ O
Total: 2000 mL	2575 kcal yields 355 mL H ₂ O

Table 101.3 Water Formed in the Metabolism of Tissue and Calorie Sources

Standard PN admixtures can be administered to the patient with increased fluid needs, especially when extrarenal losses are involved, with a supplemental intravenous solution to meet needs in the acute care setting. In the home setting, the extra intravenous solution can be added to the PN admixture in one plastic bag, in most

situations. For the patient who is fluid overloaded, the PN prescription should use the most concentrated macronutrients (D70W, amino acids 15%, and intravenous lipid 30%) to minimize intake.

Expansion of extracellular fluid (ECF) is common in hospitalized patients with malnutrition, and this increases body weight and decreases serum albumin levels. Starker et al. described different patterns of change in body weight and serum albumin in various clinical situations during the first week of PN (65). Severe malnutrition and inflammatory processes are associated with sodium and fluid retention in the early period of nutritional rehabilitation.

Carbohydrates

Glucose is the commonly used carbohydrate for caloric replacement in PN and is usually the major source of energy. Parenteral glucose is in the form of the monohydrate, with 1 g providing about 3.4 kcal. It is readily available in various concentrations in liquid form, is relatively inexpensive, and is rapidly metabolized by most patients. Using primarily glucose to meet large energy needs within a tolerable fluid volume requires an extremely hypertonic solution (Table 101.4).

Solution	Percentage (%)	mosm/kg H ₂ O ^a	kcal/L
Glucose ^b	5	278	170
Glucose	10	523	340
Glucose	20	1250	680
Glucose	30	1569	1020
Glucose	40	2092	1360
Glucose	50	2615	1700
Glucose	70	3660	2330
Lipid ^c	10	280	1100
Lipid	20	330	2000
Lipid	30	330	3000

^aPlasma, 290; 0.9% NaCl, 308 mosm/kg H₂O.

^bMonohydrate form.

^cIntravenous lipid contains glycerol adding approximately 100 kcal/L.

Table 101.4 Osmolalities and Energy Values of Intravenous Glucose and Lipid Preparations

Other carbohydrates given intravenously are metabolized wholly or in part. Fructose is converted to glucose in the liver and requires insulin for use of the formed glucose. Use of even small amounts of exogenous fructose is seriously impaired in hypoinsulinemic conditions (66). Fructose given in large quantities increases serum lactate, urate, and bilirubin and depresses hepatic adenosine triphosphate (ATP) and serum phosphate concentrations (67). It has a low renal threshold, with resultant urinary loss when given in high concentration. Sorbitol, a hexose hydroxyalcohol, is used in some countries other than the United States; it is converted to fructose. Xylitol is a pentose hydroxyalcohol that bypasses insulin-dependent glucose pathways (68); like sorbitol, it

is not available in the United States. Neither intravenous maltose (69) nor oligosaccharide (70) is hydrolyzed sufficiently to be useful as a source of carbohydrate energy in PN. A solution containing 3% glycerol, amino acids (3%), and electrolytes (Procalamine, McGaw) is available for use in PPN. The glycerol is a good energy source in traumatized patients when it is given with 10% lipid (71). Compared with glucose, glycerol required only about half the amount of insulin to maintain the glycemia of diabetics in the range of 150 to 200 mg/dL (72).

Glucose Metabolism and Hormonal Changes

Adaptation to increasing loads of parenteral glucose and other nutrients decreased as the duration of infusion was shortened in test subjects who were relatively stable adults being prepared for or already receiving HPN (73) (Fig. 101.1). Glucose and various hormone concentrations were measured in the course of 24-, 17-, and 12-h infusions of the same PN formulas and volumes and during the postinfusion period. Tapering the 24- and 17-hour infusions resulted in a fall of glucose to fasting levels in less than 30 minutes, together with a decline in insulin. No significant changes in glucagon, cortisol, or growth hormone were noted. With the 12-hour infusion, one of the five patients developed marked hyperglycemia, hyperinsulinemia, hyperglucagonemia, and increased growth hormone and cortisol levels; the elevated hormone levels persisted into and beyond the tapering period. Because such patients are not uncommon, tolerance to glucose must be checked before large amounts are infused in cyclic fashion. Other studies in adults found that abrupt termination of PN was rarely associated with significant hypoglycemia or its symptoms (74, 75). The literature on the effects of abrupt termination in young children is contradictory, but symptoms (when they occurred) were mild (reviewed in [76]), perhaps because the children remained in bed for a time following termination. Sudden increases or decreases in glucose infusion can be averted by the use of infusion pumps that can gradually increase infusion of the admixture and taper it automatically, without changing the pump settings.

Figure 101.1. Responses of glucose, insulin, glucagon, cortisol, and growth hormone to infusions of TPN solution in the same five adapted patients over 24 hours (*open circles*), 17 hours (*closed circles*), and 12 hours (*open triangles*) and over a 30-min period during which the infusions were tapered and stopped and over the first 60 min following cessation of infusion. Mean \pm SEM is depicted for all 5 patients at 24 and 17 hours and

for 4 patients at 12 hours. (Reprinted from Byrne WJ, Lippe BM, Strobel CT, et al. *Gastroenterology* 1981;80:947–56, with permission.)

Altered Substrate Metabolism in Hypercatabolic Patients

Glucose metabolism in patients with trauma, injury, burns, and sepsis or advanced cancer that induces weight loss differs markedly from that of normal individuals. This is discussed in some detail in [Chapter 82](#), [Chapter 96](#) and [Chapter 98](#) and elsewhere ([77](#), [78](#) and [79](#)), and some aspects that relate directly to PN use are summarized here.

The reasonably stable patient can oxidize infused glucose to CO₂ efficiently up to approximately 14 mg/kg/min, whereas the critically ill patient has only about half that capacity: 5 mg/kg/min in burn patients and 6 to 7 mg/kg/min in postoperative patients. Infusion above the limiting rate results in conversion of glucose to fat, with a rise in energy expenditure and a rise above 1.0 in the respiratory quotient (RQ). Conversion of excess glucose to fat is energy dependent; after oxidation of the resultant fat, the derived energy (as ATP sources) is 30% of that theoretically obtained by direct oxidation of the converted glucose ([80](#)). Other potentially detrimental effects of providing glucose in excess exist. Wolfe et al. have calculated that at an infusion rate of 9 mg/kg/min into the stressed patient, 206 g/day of triglyceride were synthesized in the liver. Only a small fraction of newly synthesized fat would have to remain in the liver for fatty liver to develop ([77](#)). Other undesirable effects of excess glucose relate to the risk of hyperglycemia and glycosuria, with resultant water and sodium losses and, particularly in the dehydrated and infected diabetic patient, the danger of hyperosmolar nonketotic coma.

The value of pharmacologic treatment to normalize the elevated rate of glucose production in severely hypermetabolic patients (e.g., burns) has been questioned. Lowering glucagon had no effect, and somatostatin infusion was not justified because of effort and cost, but exogenous insulin was beneficial in controlling hyperglycemia and increasing the anabolic response in muscle ([79](#)).

Elwyn et al. demonstrated that malnourished individuals had no increase in REE with increasing glucose intake in amounts below those needed for energy equilibrium; however, with excess glucose, REE increased by 1 kcal for each 5 kcal of intake in association with fat deposition and rise in RQ above 1.0 ([81](#)). In contrast, the injured and/or septic patient given a large amount of glucose with lipid-free PN exhibited major increases in both resting CO₂ production and O₂ consumption; however, the nonprotein RQ remained below 1.0 ([82](#)). This finding is compatible with other evidence indicating that some fat oxidation persists despite a glucose intake that normally abolishes fat oxidation ([77](#)).

Differences in energy expenditure were apparent when surgical patients receiving a high-glucose PN formula were compared with those receiving an isocaloric glucose-fat

formula with 69% of nonnitrogen calories as fat. When the high-glucose formula was given at an infusion rate that provided carbohydrate at 4 mg/kg/min, the energy increase was 11% of the mean daily energy intake and 21% of the mean REE; those receiving the glucose-fat formula had increases of 3 and 7%, respectively (83).

As would be expected from the absence of lipids and their phospholipids, PN solutions with glucose as the nonnitrogen energy source have been associated with low serum cholesterol and triglyceride levels (see below). A 26% increase occurred in the fractional catabolic rate of low-density lipoprotein (LDL) with an associated reduction of plasma cholesterol levels through changes in both LDL and high-density lipoprotein (HDL) (84).

The diabetic patient who has been on insulin prehospitalization and is to be placed on PN presents a special problem in glucose control. A tested procedure for estimating insulin requirement has been published (85).

Ventilatory Response to Glucose

When malnourished individuals were given glucose infusion in amounts exceeding the REE, with resultant lipogenesis, minute ventilation at rest increased by about 32%; it increased appreciably more in hypermetabolic patients who had an elevated resting ventilation before PN (86). In patients with decreased sensitivity to CO₂ or those with compromised lung function or who are already hyperventilating, the added ventilatory stimulus of high-glucose PN may aggravate preexisting pulmonary dysfunction. This is discussed in detail in Chapter 90.

Lipids

Composition

Lipid emulsions consist of tiny droplets (0.5 μm) with triglyceride as the core and cholesterol derived from egg yolk phosphatides surrounded by a solubilizing and stabilizing surface layer of the emulsifying phospholipids. Several intravenous lipid preparations are available as 10, 20, and 30% concentrations that serve as a source of calories and essential fatty acids (EFA) (Table 101.5).

	Spectrum 20				Spectrum Plus			
	Intralipid		Liposyn II		Intralipid		Liposyn II	
Total fat (%)	10	20	20	10	20	10	20

See also Chapter 19 for discussion of intravenous lipid emulsions.

Table 101.5 Comparison of Parenteral Lipid Emulsion Fat Sources

The cholesterol content per liter of Intralipid is appreciably higher than that of Liposyn II and III, presumably because of the phosphatide used. Per kilocalorie, the 20% emulsion has only half and the 30% only one-third, as much cholesterol as the 10% preparation. The rise in serum cholesterol concentration after a single infusion of lipid emulsion is transient and usually reverts to near preinfusion concentrations within 4 to 6 hours. As noted below, however, more-frequent use of lipid infusions is associated with elevated plasma phospholipid and free cholesterol levels.

Glycerin (glycerol) makes the emulsions isotonic and is also a carbohydrate source. The isotonicity and tolerance of the endothelium of small vessels for the intravenous lipid preparation permit peripheral infusion of a large number of calories. The 2000 kcal in 1 L of 20% lipid emulsion is the caloric equivalent of 1 L of 59% glucose solution, and the 3000 kcal in 1 L of 30% lipid is that of 1 L of 88% glucose solution. In the United States, the 30% intravenous lipid emulsion can only be used as part of a total nutrient admixture; in Europe, it can be directly infused into patients.

As noted in [Table 101.5](#), Intralipid and Liposyn III contain more linolenic acid (C18:3, n-3) than Liposyn II because of soy oil, whereas Liposyn II has more linoleic acid (C18:2, n-6) because of incorporation of safflower oil. The nutritional role of these EFAs and their metabolism and requirements are discussed in [Chapter 4](#) and elsewhere in this book. EFA deficiency is prevented by average daily provision of about 3.2% of total calories as highly unsaturated intravenous fat in adults ([87](#)). Requirements for infants and children are noted below in this discussion and reviewed in [Chapter 64](#). Newer lipid formulations under clinical study are reviewed below.

Metabolism

Although the particle sizes of lipid emulsions are within the range of those of chylomicrons, significant differences exist between the two types of particles ([88](#)). In emulsions, phospholipids (PLs) are in excess; some serve as surface emulsifiers of the triglycerides (TGs) and the rest is present as liposomes ([89](#)). The latter take up from the circulation free cholesterol, various lipoproteins (in particular apolipoprotein E (apoE) and albumin ([90](#)) to yield the abnormal lipoprotein X (LpX) ([91](#)).

On short-term ultracentrifugation in saline, two-thirds of the PLs separate from TGs in 10% Intralipid, whereas only one-third separated in the 20% emulsion. The former would contribute four times the amount of liposomal LpX of the 20% emulsion when expressed per gram of TG. The significance of this difference is illustrated by a study in which 1.75 g/kg/day of long-chain TGs was infused into postoperative patients as one of two 10% emulsions with PL:TG ratios of either 0.12 or 0.06. Over an infusion period of 5 days, plasma PL, free cholesterol and apoE levels increased progressively only when

the PL:TG ratio was 0.06. Free fatty acids (FFAs) and TGs remained constant with all formulations (92).

The LpX level is appreciably higher in the plasma of patients receiving 10% Intralipid than in those receiving 20% Intralipid, presumably because of the higher PL content per kilocalories infused in the 10% preparation. The half-life of LpX appears to be 2 to 4 days, with small amounts still present 7 days after termination of the lipid infusion (93). Excess PL induces alterations of plasma lipids even in a few days; use of lipid emulsions with a PL:TG weight ratio of 0.06 is preferable (i.e., 20% or 30%).

Tolerance

When the concentration of lipid increases to the level at which binding sites on lipoprotein lipase (LPL) are saturated, a maximum elimination capacity has been reached. In normal adults, this maximum rate is about 3.8 g of fat/kg/24 hours, which corresponds to about 35 kcal/kg/24 hours. It increases in starvation (approximately 50%) and even more in trauma (94).

Daily infusion of fat emulsion over a week or more is associated with increased tolerance, as indicated by decreased preinfusion serum TGs. Serum FFAs are cleared more rapidly with simultaneously administered carbohydrate. The clearance rate from plasma is not equivalent to the oxidative rate of lipid.

Effect of Lipid Infusion with PN

When lipid (supplying one-third of the calories) is infused for approximately 8 hours, together with a glucose-based PN formula given over 24 hours, fat oxidation is approximately 6 kcal/kg/min; it falls to about 3 kcal/kg/min after cessation of lipid. A PN formula with glucose and no lipid is associated with a fat oxidation rate of about 2 kcal/kg/min, decreasing to approximately 0 by the end of 24 hours (95).

Hypermetabolic patients with sepsis and/or trauma in the basal state have increased rates of lipolysis, as indicated by higher glycerol flux and fat oxidation than in normal individuals (e.g., 5.3 vs. 2.2 $\mu\text{mol/kg/min}$ and 2 versus 1 mg/kg/min, respectively) (78, 96). In patients with sepsis who were given PN with lipid, most of the fat oxidized was from endogenous fat stores rather than from infused cleared lipid (96).

Nonnitrogen Caloric Sources and Nitrogen Retention

Solid evidence exists for the nitrogen-sparing effect of carbohydrate (including glycerol), with and without amino acids (see Chapter 2 and Chapter 41). In the absence of amino acids, fat appears not to spare nitrogen beyond its glycerol content released on hydrolysis and its metabolism as a carbohydrate precursor. At low energy intakes, the effects of carbohydrate on nitrogen balance are much greater than those of fat. Increasing amounts of carbohydrate from 0 up to about 100 to 150 g intake (400 to 600 kcal) increase nitrogen balance by approximately 7.5 mg of N per added kcal (1.8 mg N/kJ). This effect is not shared by fat. Above this amount, however, the effect of added

carbohydrate on increased nitrogen balance is only about 1.5 mg N per added kcal; this effect is thought to be shared by fat (97).

Investigators have disagreed on the nitrogen-sparing effect of fat in the presence of amino acids in hypercatabolic subjects. Long et al. were unable to achieve nitrogen equilibrium or positive balance when fat was supplied as the nonnitrogen energy source in burn or trauma patients. Calories from carbohydrate were required in an amount equal to the resting metabolic rate to achieve maximum nitrogen retention (98). A review of nitrogen balance studies in patients with various inflammatory diseases, however, indicated that fat and carbohydrate were comparable in promoting nitrogen balance (99), presumably after the minimum of 100 g glucose had been met (97).

Total Nutrient Admixture

Use of lipid emulsions has increased as their cost has decreased and their clinical efficacy has been appreciated. They have been infused by piggybacking the tubing from the separate emulsion container into the tubing from the water-based PN solution. Admixtures of amino acids, dextrose, minerals, vitamins, and a fat emulsion are also used frequently; these are designated total nutrient admixture (TNA) or triple mix.

Stability and Safety Factor. The admixture system is potentially unstable. The relevant properties of the phosphatide emulsifiers and various factors influencing stability of the fat emulsions in the presence of various additives in the admixture have been reviewed (100, 101, 102 and 103). The cumulative effects on aggregation of various cations of different charge can be predicted from an equation defining the critical aggregation number (CAN) at and above which neutralization of anionic surface groups results in lipid particle aggregation.

Driscoll et al. found that iron dextran was the most disruptive component of TNAs (102). They studied the effects of many additives, including amino acids, lipids, dextrose, and mono-, di-, and trivalent ions. TNAs were assessed for stability by particle-size analysis, done by light obscuration and dynamic light-scattering methods. Based on these results, using more sophisticated analysis, addition of any iron dextran to a TNA is discouraged.

Microbial Growth. Less microbial growth over 24 hours occurs in TNAs than in fat emulsions per se (103). This finding led the Centers for Disease Control of the United States Public Health Service to recommend a 12-hour maximal infusion time for fat emulsions not in TNAs (104). The major advantages and disadvantages of the TNA system are listed in [Table 101.6](#).

Advantages

1. Decreased nursing personnel time and subsequent cost savings because of simplified administration
2. Increased compliance in home patients because of ease of administration
3. Decreased training time for home patients requiring daily lipid emulsion
4. Potential decrease in rate of extrinsic contamination because of fewer manipulations of i.v. delivery system by nursing personnel
5. Less likelihood of lipid toxicity by increased dilution and duration of lipid infusion; better tolerance by neonates
5. Decreased pharmacy preparation time

Disadvantages

1. Supports growth of a variety of microorganisms significantly better than conventional dextrose/amino acid solutions but less than fat emulsions per se
 2. Undesired effects (i.e., clogging) when base solution ratios and/or additives exceed the amounts tested under stipulated controlled conditions
 3. Inability of TNA systems to be filtered with a 0.22- μm bacterial-retention filter
 4. Inability to use total membrane sampling of TNA systems for a pharmacy quality assurance sterility testing program
 5. Unknown consequences of long-term administration of larger particle size (4-4 μm) in TNA system
-

Table 101.6 Advantages and Disadvantages of the Total Nutrient Admixture (TNA) System

Catheter Occlusion

Various investigators have reported blockage of catheters in patients receiving TNA for periods of 37 to 206 days, with deposition of a soft, creamy material on the internal catheter surface (105). Such material obtained after filtration (5- μm filter) of a specific TNA formulation stored for 7 days at 4°C in four different commercial EVA bags averaged 99.4% fat and less than 0.5% mineral salts (105). Of concern was finding plasticizer particles (means of 2,890 to 16,204 from different bags) with a size range of 1.4 to 43.8 μm that had been flushed out of the bags with saline before adding the TNA solution. As indicated above, filters are advised with such solutions (53). Sterile 70% ethanol has been used successfully by some investigators to unclog catheters that were occluded with fat from a TNA (106, 107). In fact, if urokinase is unsuccessful, ethanol should be used to attempt to clear the catheter, especially in patients who have been receiving TNAs.

Complications of Lipid Infusions

Because the ability to metabolize these emulsions is related directly to infant maturity, the risk of lipid accumulation in blood and its sequelae is greatest in the premature infant, the small-for-age gestational low-birth-weight (LBW) infant, and the nutritionally depleted older child (see Chapter 64).

Possible Altered Pulmonary Function. Lipid accumulation in the hepatic reticuloendothelial system (RES) with the likelihood of depressed immune responses and its competition with bilirubin and other substances for albumin binding have been described. Cases have been reported, primarily in young children, of bleeding dyscrasia in association with high plasma lipid levels and platelets engorged with lipid (108). Reports of altered pulmonary function during acute hyperlipidemia have varied; whereas decreased pulmonary diffusion capacity has been noted by some (109); other investigators have found no change in lung dynamics, but rather, decreased arterial

oxygenation (110). Still others have not found oxygen impairment in neonates with hyperlipidemia (94) or in healthy men (111). Patients with acute respiratory distress syndrome who received 500 mL of 20% intravenous fat emulsion over 8 hours (maximum rate suggested in package inserts) demonstrated a significant decrease in $\text{PaO}_2/\text{FiO}_2$ and mean pulmonary arterial pressure and a significant increase in pulmonary vascular resistance and pulmonary venous admixture (112). Intravenous lipid emulsions should be administered cautiously to patients with adult respiratory distress syndrome and at lower doses infused over longer periods of time than those noted above by Venus et al. (112). While recognizing the toxic potential of lipid infusions in infants, biochemical evidence of EFA deficiency occurred in more than half of premature infants at 7 days of age (113). A progressive program of lipid infusion for such infants has been described (113).

Fat Overload Syndrome. The fat overload syndrome, a rare complication of intravenous administration of fat, is characterized by sudden elevation of serum TGs in association with fever, hepatosplenomegaly, coagulopathy, and variable end-organ dysfunction. Fat sludging occurs within the microvasculature in spleen, liver, kidney, lungs, and brain. Plasma exchange benefited one patient who did not respond to conservative medical therapy (114).

Various fat emulsions given intravenously are known to elicit lipid particles and deposition of a ceroid pigment in the RES of the bone marrow, lymph nodes, and spleen, and the Kupffer cells and hepatocytes of the liver of adults, children, and laboratory animals (115, 116). To date, no deleterious effect of these histologic changes on hepatic function has been discovered.

Effects on Immunity. The increased uptake of long-chain lipids by the RES in patients with hepatosplenomegaly and decreased clearance of lipid have led to concern about possible depression of immune responses with such infusions and increased susceptibility to infection. Mice injected with streptococci demonstrated higher mortality rates and incidence of bacteremia and decreased neutrophil chemotaxis when Intralipid was given (115). In healthy and in burned guinea pigs, intravenous long-chain triglyceride (LCT) infusion at 75% or more of total nonprotein calories resulted in RES overload and an altered pattern of intravenously administered pseudomonas (117). In vitro studies of neutrophil chemotaxis have given variable results reflecting different dosages and conditions.

Using clearance of sulfur colloid technetium-99 as a marker of RES function, 3 days of administration of long-chain intravenous fat emulsion resulted in significant impairment in humans receiving PN at a dose of 0.13 g/kg/h for 10 hours daily. It took 3 days of lipid administration for this impairment to occur (118). A follow-up study demonstrated little change in the clearance of sulfur colloid technetium-99 when a lipid emulsion containing both LCTs and medium-chain TGs (MCTs) was used (119).

What has been observed with respect to infection rates in patients receiving PN? Various immune functions were studied in malnourished cancer patients maintained on either a glucose PN formula or one with both glucose and lipid; depressed cell-mediated immunity was noted before starting PN, and no alteration in these parameters was

observed with fat infusion (120). In a randomized trial, preoperative PN patients who received 50% of their caloric intake as lipid experienced more major complications and deaths than control subjects receiving lipid-free PN (121). A metaanalysis of randomized studies showed that cancer patients receiving chemotherapy and PN had a fourfold greater risk of significant infection than control subjects who did not receive PN (122). Meta-analysis of the same data by another group revealed that the infection rate for patients receiving PN who did not receive intravenous lipid did not differ from that of the control subjects, and those receiving lipid one to three times per week had a risk of infection ($P < .02$) 2.3 times that of controls, while those given lipid daily had 6.3 times the risk ($P < .01$) (123). Freeman et al. analyzed risk factors associated with bacteremia due to coagulase-negative staphylococci in neonatal intensive care units; this organism was the most common blood-culture isolate in this situation (124). Infants with this type of bacteremia were 5.8 times as likely as control subjects to have received intravenous lipid emulsion before the onset of bacteremia; because lipid infusions were common, 56.6% of all cases of nosocomial infections were attributed to lipid administration. Although such data are suggestive, whether intravenous lipid is immunosuppressive in humans and whether it leads to increased infection remain unresolved (125).

Newer Intravenous Lipids

Beyond providing the small basic needs for linoleic and linolenic acids, are there lipids suitable for intravenous use that are metabolically and nutritionally more efficacious than the present vegetable oil-derived LCTs? MCTs derived from coconut oil, mixed LCTs and MCTs, short-chain fatty acids, and w-3 fatty acids are all under current study as lipid fuels in PN (126).

Medium-Chain Triglycerides and MCT-LCT Mixtures. MCTs (see [Chapter 4](#)) have an established role given enterally by tube and orally in the management of malabsorptive disorders (see [Chapter 64](#) and [Chapter 65](#)). Experimental laboratory animal studies have indicated that MCT is cleared and oxidized more rapidly than LCT and is equivalent in providing energy and supporting protein synthesis. MCT (with octanoic acid as the main fatty acid) has been tested experimentally in laboratory animals as physical mixtures of MCT and LCT and as chemically structured TGs (127). The latter has fatty acids of various chain lengths (short, medium, or long) esterified on the same glycerol backbone; the amounts of the different fatty acids depend on the starting proportions of the types of fatty acids in their preparation.

Physical mixtures of MCT and LCT (as soybean oil) in equal amounts have been given intravenously to patients in Europe and elsewhere (89, 119, 127). Clinical investigations have been conducted in the United States with 75/25 physical mixtures of MCT and LCT (119). Long-term studies were conducted in Belgium in patients with inflammatory bowel disease with 20% LCT or a 20% MCT-LCT mixture (equal amounts), with glucose providing an equal proportion of energy; each emulsion was infused for 3 months, followed by the other in random order (89). None of the patients receiving an MCT-LCT mixture developed abnormal liver function tests; three of eight patients receiving LCT developed abnormal liver function tests that regressed to normal when LCT was replaced by an MCT-LCT mixture. MCFAs released in high amounts during MCT-LCT infusion were oxidized in greater proportions than LCFAs and produced more ketone

bodies. LCT infusion led to a significant increase in the LDL:HDL cholesteryl ester ratio, whereas MCT-LCT infusion did not; LCT infusion caused an imbalance in the fatty acid pattern of erythrocyte PLs, which was corrected by MCT-LCT infusion (89).

Ultrasonic comparison of liver size and gray-scale value (which relates to liver density and incorporation of fat and connective tissue) was done before and after patients were given PN with either 10% Intralipid or a 10% mixture of MCT and LCT in equal amounts; no changes were noted in either parameter with the MCT-LCT infusion, whereas both rose significantly with LCT (128). Although the rates and amounts of MCT infused in these and other studies appear to be safe (129), infusion of octanoate as the salt or as MCT in various laboratory species at higher doses can produce lactic acidosis and encephalopathy (130).

Structured TG (40:60, MCT:LCT by weight) emulsions have been shown to be well tolerated at 1 g/kg/day by postoperative patients in short-term studies (5–7 days), when compared with 20% Intralipid (131). One-day repeated crossover studies comparing this structured TG preparation with 20% Intralipid at 1.0 and 1.5 g/kg/day indicated similar tolerance in postoperative patients, and the former was associated with greater whole-body fat oxidation (132). It has been suggested that such structured TGs may be less toxic and less likely to promote acidosis (131).

One reason given for favoring MCT over LCT has been the belief that unlike LCFA transport, carnitine is not required for MCFA transport into the mitochondria (133). Measurements of the levels of the various plasma carnitine fractions in healthy subjects before and during infusion of glucose or amino acids, LCT, and 1:1 MCT-LCT revealed significant differences in the carnitine fractions between the LCT and MCT-LCT infusions; such data support the hypothesis that MCFA metabolism involves carnitine in some manner and suggest the need for more study of these interactions (133).

w-3 (n-3) Fatty Acids. Important physiologic differences among the prostanoids and leukotrienes, derived from linoleic and linolenic acids (see Chapter 4 and Chapter 45), have directed attention to the possible advantages of including n-3 fatty acids and/or dihomo-g-linolenic acid as TGs or PLs in intravenous fat emulsions to allow conversion to their eicosanoids (134). Eicosanoid synthesis must be carefully regulated to provide their various mediators in appropriate quantities in response to appropriate stimuli while avoiding harmful excesses of these potent compounds.

Mashima et al. developed and originally tested in rats a fish oil emulsion (FOE) containing purified fish oil (1.5%) that supplied EPA and DHA and soybean oil (8.5%) that supplied linoleic and linolenic acids. FOE was reportedly well tolerated by patients for up to 6 weeks and raised their low EPA and DHA serum levels to normal. The preparation was contained in a double shielded plastic bag with an oxygen absorbent between the layers to prevent oxidation (135).

Twenty postoperative trauma patients who received isonitrogenous and isocaloric PN were randomized to either soybean oil 1 g/kg/day or a combination of soybean oil 0.85 g/kg/day and fish oil 0.15 g/kg/day as part of the PN formula (135a). After 5 days of PN administration, patients receiving the FOE demonstrated a 2.5-fold increase in

eicosapentanoic acid, a 1.5-fold increase in leukotriene B(5), and a 7-fold increase in leukotriene C(5). In the group receiving the soybean oil fat emulsion, eicosapentanoic acid and leukotriene B(5) remained unchanged while leukotriene C(5) doubled (135a). Such data demonstrate the usefulness of modified lipids in elevating levels of desired eicosanoids and leukotrienes.

Short-Chain Fatty Acids. Supplementation of PN solutions with short-chain fatty acids (SCFAs) prevents PN-associated mucosal atrophy and facilitates morphologic adaptation to small bowel resection in rats (136). Rats with 80% small bowel resection had better ileal glucose absorption and higher expression of glucose transporter 2 messenger RNA, glucose transporter 1, and Na⁺,K⁺ ATPase RNA when receiving a glucose-lipid PN formulation with sodium acetate, propionate, and butyrate than with non-SCFA PN (137).

Lipids As Pharmacologic Vehicles. Some drugs are now marketed in intravenous fat emulsion. One example is propofol, originally marketed for induction of anesthesia, but used more often for sedation in the critical care setting. It is prepared by the manufacturer in 10% fat emulsion, and some patients who needed large doses of propofol have more than 1000 kcal/day from fat (137a). Also, several lipid formulations of amphotericin B have been marketed in the United States (138), including amphotericin B in liposomes, lipid complex, or colloidal dispersion. Preliminary data suggest that these lipid-based preparations are equivalent in efficacy to amphotericin B deoxycholate, with reduced toxicity, especially nephrotoxicity, mainly because of the lower renal concentrations observed with lipid-based amphotericin B preparations. The caloric contribution of lipid formulations of amphotericin B is negligible (138a).

Amino Acids

Intravenous amino acid solutions have evolved from the original hydrolysates of casein or blood fibrin to formulations of crystalline L-amino acids of different compositions and varying concentrations based in part on the amino acid composition of high-quality dietary proteins. This history has been reviewed (3, 12). Formulations of crystalline L-amino acids have been developed for specific clinical problems, with varying claims for superiority over more-general formulas for use in renal and hepatic failure, in trauma, and for growth of infants (see Chapter 51, Chapter 89, Chapter 94 and Chapter 98 for discussion of their value in such clinical situations). The compositions of some commercially available pediatric solutions are given in Chapter 64 and Appendix Table V-A-40-b. The reader is referred to the *Handbook of Injectable Drugs* for adult solution content (138a). Commercial formulations differ between and within manufacturers in amino acid composition and concentrations, depending on clinical purpose; in addition, they may have added electrolytes and/or glucose. Concentrated standard amino acids in a 15% solution are now available for patients who are fluid overloaded and require PN.

The eight amino acids essential for normal adults are present in all formulas, as are histidine and arginine, which are needed for young children. Glycine, alanine, and proline are present in moderately high concentration in the general adult formulations as sources of nonessential amino nitrogen. Some manufacturers add serine, tyrosine,

glutamic acid, and aspartic acid in variable amounts, and a few have taurine in small amounts. The ratio by weight of essential to total amino acids in the pediatric and standard adult solutions varies between 0.41 and 0.54; higher ratios are present in formulas designed for patients with renal or hepatic failure.

Amino acid infusion during surgery has been noted to increase body temperature, which otherwise falls customarily during anesthesia and surgery because of heat loss to the environment and a reduced threshold to initiate heat conservation ([139](#)). Hypothermia (core temperature $<35^{\circ}\text{C}$) can adversely affect coagulation, drug action, metabolism, and healing ([139a](#)). The thermic effect of amino acid infusion is high and may account for 30 to 40% of the energy infused. Although effective, use of amino acids for this purpose not only increases cost but also requires caution in patients unable to tolerate the extra fluid load and without the pulmonary and cardiac reserve needed for the resulting increased oxygen uptake and cardiac output. Use of intravenous fluids warmed to 38°C reduces hypothermia ([139a](#)).

Calculating the Energy Contribution of Amino Acids

Should the amino acids in PN be included in the total energy calculations of the formulation? This question is raised periodically, and a recent discussion states two opposing positions ([140](#)). The basic issue is whether the amino acids avoid oxidation by being incorporated in significant amounts of newly synthesized protein, being lost as such in urine or through the gut, or else being diverted into carbohydrate stores. In fact, the amounts of new protein laid down in successfully renourishing a child or an adult are a small proportion of the amino acid equivalent given (e.g., 3 to 4 g/protein/day or 60–90 g of protein-equivalent given to adults). Even though the energy cost of protein synthesis from amino acids is high, this is a small factor in terms of daily synthesis, even in growing, malnourished, and hypercatabolic individuals. Finally, accumulation of stored glucose (as glycogen) derived from gluconeogenesis from amino acids is limited, and the amino acids are mostly metabolized if hyperglycemia is minimized. It is our opinion that the energy contributed by the amino acids in the PN formulation should be included in the total calculation.

Achieving nitrogen equilibrium or positive nitrogen balance requires sufficient essential amino acids and sufficient nonessential amino nitrogen, adequate nonnitrogen energy, and other nutrients (such as potassium and phosphorus) essential for nitrogen use. Recent research on amino acids or their derivatives of interest in PN usage is summarized below.

Branched-Chain Amino Acids

Muscle uptake and metabolism of the essential amino acids isoleucine, leucine, and valine are reviewed in [Chapter 2](#), and their clinical applications are discussed in [Chapter 35](#), [Chapter 44](#), [Chapter 96](#) and [Chapter 98](#). The role of these branched-chain amino acids (BCAAs) as amino group donors in accelerated protein catabolism in muscle of hypermetabolic patients is noted in [Chapter 98](#). Do injured and/or septic patients need more BCAAs than are usually present in general PN formulations? Claims have been contradictory concerning beneficial effects (e.g., improved nitrogen balance with higher

BCAA levels than the 19 to 25% in standard United States amino acid formulations). An expert panel concluded: "In clinical studies, while some positive results in parameters of nitrogen metabolism have been noted using BCAA-enriched solutions in the most severely ill patients, little or no major effect on outcome has yet been demonstrated" (141). Additional negative effects have been published (142).

Taurine

Metabolism and formulation of taurine, which has a sulfuric acid group replacing the carboxyl group of what would otherwise be alanine, is discussed in [Chapter 34](#). Considered a nonessential amino acid for humans, taurine is of nutritional interest with respect to PN because its plasma, platelet, and urine levels are depressed in children and adults maintained on long-term PN. No other substantial evidence for deficiency has been forthcoming. In fact, the low levels in adult and pediatric patients receiving long-term PN did not appear to be correlated with any index of visual function (143). Because of limited ability of LBW infants to synthesize taurine, the low levels of its precursor cysteine in PN solutions, and the reduced capacity to reabsorb taurine, this amino acid is added to some pediatric formulas (see [Chapter 64](#)).

Glutamic Acid and Glutamine

The central role of glutamic acid and glutamine in metabolism is reviewed in [Chapter 2](#) and [Chapter 35](#). Although glutamic acid was present in the early parenteral protein hydrolysates, it was omitted from the later free amino acid formulations because it is synthesized in the body and glutamine synthetase catalyzes its reaction with ammonia to form glutamine. Interest in the clinical importance of glutamine has increased in recent years, partly because of its role as an energy and nitrogen source in rapidly dividing cells (e.g., intestine and stimulated lymphocytes) and because under conditions that include hypercatabolic disease states, glutamine levels can decrease markedly. These conditions are discussed briefly in their various aspects in [Chapter 35](#), [Chapter 96](#) and [Chapter 98](#).

The issues for PN concern proof of stability in solutions, safety, and evidence of efficacy of glutamine in improving nitrogen balance, muscle protein kinetics, and other metabolic parameters when added to standard formulas given to hypercatabolic patients. Concern about the stability of glutamine stored with PN components was alleviated; glutamine was stable for 22 days at 40°C when dissolved in sterile water and added to various TPN solutions at concentrations of 1 and 1.5% wt/vol with cold sterilization using two membrane filters (144). Infusing 20 to 57 g (136 to 390 mmol) of glutamine in PN solutions for more than 5 days did not significantly change serum ammonia and glutamate concentrations (145). (See also [Chapter 35](#)).

In an increasing number of clinical studies in stressed patients, L-glutamine has been given intravenously in PN solutions as such (146, 147), as the dipeptide L-alanyl-L-glutamine (148, 149 and 150), or as its α -keto precursors, α -ketoglutarate or ornithine α -ketoglutarate (148). In these studies, glutamine in its various forms was provided in daily amounts ranging from approximately 0.19 g (1.3 mmol)/kg body weight (148) to 0.57 g/kg (146). Given to postoperative patients in short 3- to 5-studies,

glutamine decreased the negative nitrogen balance noted in the control subjects, increased intramuscular free glutamine concentration (148, 150), and maintained skeletal muscle ribosome concentrations (150). After bone marrow transplantation, glutamine significantly decreased the negative nitrogen balance of the subjects during posttransplant days 7 to 11; over 3 weeks, glutamine infusion raised plasma glutamine without increasing plasma glutamate or changing the ammonia concentration gradient between the groups. Fewer patients given glutamine developed clinical infection and microbial colonization, and their hospital stay was shortened (146). Villus height was maintained and intestinal permeability was lower in patients receiving PN plus glycyl L-glutamine than in patients receiving PN alone (151). As noted above, glutamine in a protocol with growth hormone enhanced nutrient absorption. (The role of glutamine in intestinal translocation is discussed in [Chapter 35](#).)

Issues remain to be resolved concerning the reported beneficial effects of glutamine in hypercatabolic patients. How much glutamine is necessary and safe for optimum results? On the basis of their work and that of others, Fürst et al. suggest that in routine postoperative patients, about 13 g (89 mmol) of glutamine daily meets the intestinal mucosal need for cell replication plus increased muscle needs, whereas severely injured or stressed patients may need 27 to 40 g (187 to 237 mmol) per day (149).

How valid are the nitrogen balance data? Walser has pointed out that gains or losses of body free glutamine nitrogen should be included in overall nitrogen balance data, just as a net change in body urea nitrogen must be included in patients with renal disease (152). Furthermore, changes in free glutamine nitrogen pools do not represent modification of protein nitrogen. While this issue has raised some controversy (153, 154), Ziegler et al. acknowledge that about 25% of the improved nitrogen balance may represent a relative increase in the free glutamine pool within skeletal muscle; these investigators point out that direct measurement of intracellular glutamine concentrations in biopsy specimens is needed for confirmation (146). Further data are needed on the effect of glutamine on quantitative changes in net protein synthesis in muscle in hypercatabolic states.

Short-Chain Peptide Use

Adibi has summarized the advantages of using short-chain peptides in place of free amino acids in PN solutions: (a) increased usable nitrogen sources in more concentrated form (minimizing fluid volume), (b) decreased osmolality with its advantage for PPN, and (c) perhaps most important, the increased solubility as dipeptides of poorly soluble amino acids or the increased stability of unstable free forms (155). How well used are small peptides given intravenously? Adibi summarized his studies in baboons, in which a series of free amino acids and their dipeptides as the relevant nitrogen sources were infused as the only nitrogen sources, and his studies of glutamine in peptide form (155). In a 1-week crossover study and in 4-week studies comparing free amino acids and dipeptides, no significant differences were noted with respect to nitrogen balance, plasma and muscle amino acid concentrations, urinary losses, plasma concentration of insulin, glucose, and lipids, and other parameters (156).

Minerals

Sodium, potassium, calcium, magnesium, phosphate, and chloride are essential nutrients. Because a significant proportion of patients receiving or needing PN have malabsorption of the alimentary tract or impaired renal reabsorption or both, often associated with large fluid ionic losses, a continuing concern in the care of such patients is the adequacy of fluid and electrolyte balance. (These and related important issues are considered in some detail in [Chapter 6](#), [Chapter 7](#), [Chapter 8](#) and [Chapter 9](#) and elsewhere in this book.)

The basic daily needs of patients with reasonably normal cardiovascular, intestinal, renal, hormonal, and hydration status are 50 to 60 meq (mmol) of sodium, 40 meq (mmol) of chloride and bicarbonate (including those associated with amino acids as acetate), and 40 to 60 meq (mmol) of potassium. Excessive losses from the intestine or kidney and abnormal retention require appropriate changes, with suitable monitoring as needed.

Calcium, Phosphorus, and Magnesium

Calcium and phosphorus (as inorganic phosphate) are needed in relatively large amounts by infants; however, when both are present in relatively large concentrations, solubility in the PN solution becomes a problem. It has been recommended that glycerophosphate or glucose phosphate be given together with calcium gluconate ([157](#)) or calcium glycerophosphate ([158](#)) as more soluble forms of these nutrients. Reference curves have been developed to estimate calcium and phosphate compatibility in commonly used neonatal PN solutions ([159](#)). The electrolyte needs of infants and children per kilogram per day are given in [Chapter 64](#). Recommended pediatric concentrations of calcium, phosphorus, and magnesium per liter of PN solution are given in reference [160](#) and for children and adults in [Table 101.7](#) ([161](#)).

Mineral ^a	Pediatric ^b			
	Preterm infants (mg/L)	Term infants (mg/L)	Children <1 year (mg/L)	Adults (meq/day)
Ca	500-600	500-600	200-400	10-25
P	400-450	400-450	150-300	300-450 ^c
Mg	50-70	50-70	20-40	12-20 ^d

^aEquivalents: Ca, 100 mg = 2.5 mmol = 5 meq; P, 100 mg = 3.3 mmol; Mg, 12 mg = 0.5 mmol = 1 meq.

^bData from Greene HL, Hamidge M, Schaefer RL, et al. *Am J Clin Nutr* 1989;48:1324-1342 (rev. reprint issued Dec 1993).

^cTo avoid Ca-P precipitation, recommended intakes are given per liter and assume an average fluid intake of approximately 120-150 mL/kg/day with 25 g amino acids/L of a pediatric formulation. Dosages for preterm infants are to be given in a central vein infusion.

^dP and Mg needs vary from these ranges, depending on the extent of intestinal losses and renal retention or losses.

Table 101.7 Recommended Levels for Calcium, Phosphorus, and Magnesium in PN Formulations

Negative calcium balance related to hypercalciuria may occur in adults receiving PN, especially during the infusion period of cyclic PN; supplementation with either sodium or potassium acetate (replacing equimolar amounts of NaCl or KCl) resulted in major decreases in urinary calcium in patients receiving 24-hour and cyclic PN, primarily because of increased renal tubular reabsorption with reduced excretion to near-infusion levels (162). Reports are contradictory concerning whether urinary calcium excretion with 12-hour cyclic PN is greater than that with continuous 24-hour infusion (161). While this may not be a significant issue for the short-term patient, it may be important for those on prolonged PN because of skeletal calcium loss.

Hypophosphatemia has multiple causes; however, in PN patients it is often associated with sudden provision of glucose, the metabolism of which stimulates transfer of phosphate from plasma to cells (see Chapter 8). Hypophosphatemia was treated during provision of PN by using a graduated dosing scheme based on the serum phosphorus concentration in patients with normal renal function (163). For serum phosphorus concentrations below 1.5 mg/dL, 0.64 mmol/kg was given over 8 hours; doses of 0.32 mmol/kg over 4 to 6 hours and 0.16 mmol/kg over 4 hours were given for serum phosphorus concentrations of 1.6 to 2.2 mg/dL and 2.3 to 3.0 mg/dL, respectively (163).

The importance of magnesium and magnesium balance is being appreciated more, especially in the critical care setting where serum magnesium concentrations are being assessed with increased frequency and risk factors for magnesium depletion are now well recognized (see Chapter 9). Although the serum magnesium concentration does not always accurately reflect magnesium status, a low concentration usually indicates magnesium deficiency. Doses for management of moderate-to-severe deficiency in various clinical situations for various age groups are given in Chapter 9 and elsewhere (164, 165). Hypermagnesemia may occur with fluctuating or progressively deteriorating renal function or decreasing intestinal or renal magnesium loss; periodic monitoring of serum magnesium is necessary.

Fluid and electrolyte disorders are particularly prone to occur soon after discharge of patients on HPN, either because of inadequate testing in the hospital; fluctuating cardiac, renal, and intestinal functions; or variation in supplementary intake at home (166).

Trace Elements

Currently, acceptable direct evidence indicates that iron, iodide, zinc, copper, chromium (Cr^{3+}), and selenium are essential human nutrients. Manganese (Mn^{2+}) has been found essential for all experimental species studied, but clear evidence for manganese deficiency in man is lacking. A single well-documented case of molybdenum deficiency was noted in a patient receiving long-term PN. (The biochemical and physiologic roles of these trace elements and the effects of their depletion in humans and other species are reviewed in Chapter 10, Chapter 11, Chapter 12, Chapter 13, Chapter 14, Chapter

[15](#) and [Chapter 16](#).)

Several generalizations about essential trace elements are in order. The cationic trace elements (Fe, Zn, Cu, Cr³⁺, and Mn) in their salt forms are highly regulated and tend to be absorbed in small amounts from food by the normal intestine. When in excess in the body, all these elements may be toxic. Giving them intravenously risks excessive retention, because intestinal controls are bypassed. Iron, particularly, is poorly excreted in the urine after PN or blood infusion. Copper, manganese, and (to a much smaller extent) molybdate, are excreted through the bile into the intestinal tract; hence continued administration of the usual amounts of copper and manganese in the presence of excretory liver dysfunction imposes a risk (see below). In contrast, all the anionic forms of trace elements (iodide, selenite, or molybdate) are well absorbed and excreted in the urine; again, excess imposes a risk of toxicity. Many trace elements are present as contaminants in PN components and so contribute variably to the input. Finally, nonessential and potentially toxic trace elements, which may be contaminants, must be considered.

Iron. The intravenous requirement for the term infant is estimated to be about 100 µg/kg/day; the premature infant probably needs double that amount intravenously ([160](#)). Older children need 1 to 2 mg/day. Nonmenstruating females and men whose condition is stable need about 1 mg, and menstruating females double that amount. Iron loss through frequent venipuncture for various tests may be estimated on the basis of 1 mg of iron lost for every 1 mL of packed red cells removed (see [Chapter 10](#)).

Contamination of various PN additives with iron varies by item and by manufacturer; the amounts found in complete formulations with free amino acids vary from 0.025 to 1.4 mg/L ([167](#)). On average, the needs of children and adults who have no significant blood loss and are receiving their normal fluid and energy requirements are met by these contaminants. When evidence indicates iron depletion, iron may be given intravenously as dilute iron dextran solution in varying amounts, after ensuring that the patient has no hypersensitivity to a test dose; ferrous citrate may be used ([168](#)). As noted above, addition of iron dextran and other iron salts disrupts TNA stability ([100](#)).

Patients who receive chronic PN without iron and eat very little invariably become iron deficient over time. Iron should be added to the PN solution (preferably a dextrose/amino acid PN) to either prevent or treat iron deficiency in this situation. This can be accomplished by adding small daily doses of iron dextran to the PN solution (e.g., 1–2 mg/day) or by giving regular doses of therapeutic iron dextran via PN (e.g., 25–50 mg/day for 2–4 weeks). Patients who have a duodenum and proximal jejunum and eat a normal diet during chronic PN usually absorb enough iron to prevent deficiency; These patients may never need supplemental iron via PN. Regular measurement of serum iron, mean corpuscular volume, and serum ferritin helps in assessing iron stores. During acute stress such as infections, measuring serum iron and ferritin concentrations may not be helpful in the diagnosis of iron deficiency, because serum iron concentration decreases while serum ferritin concentration increases ([169](#)) (see [Chapter 10](#) and [Chapter 96](#)).

Iodide. Serum iodide often remains normal in infants ([170](#)) and adults ([171](#)) with no

added iodide in PN. Over 4 or more years of observation in adult patients receiving long-term PN at home without added iodide, the various parameters of thyroid function have remained within normal limits (171). This is explained by iodide contamination of various mineral additives, by efficient absorption in the upper gastrointestinal tract of iodides from any ingested diet, and by the use of iodide-containing topical antimicrobial solutions. For the occasional previously depleted adult patient with malabsorption who may have a low serum iodide level, 1 µg/kg appears adequate during the repletion period. The same amount has been recommended for infants, to avoid any risk of deficiency or toxicity (160).

Following the recommendation of an expert committee of the Nutrition Advisory Group of the American Medical Association (AMA) to the FDA in 1979 (172), commercial intravenous solutions of zinc, copper, manganese, and chromium became available, ending a period in which such solutions were available only to physicians and pharmacists who personally prepared them. We have modified the 1979 suggested intakes on the basis of newer information (Table 101.8). Some data relevant to PN are reviewed briefly below.

Trace element*	Infants (µg/kg/d)		Children† (µg/kg/d)	AMA (µg/kg/d)		
	Infants†	Term‡		Infants	Acute hypermetabolic	With intestinal losses

Table 101.8 Recommended Levels for Trace Elements

Zinc. Pediatric dosages of zinc have been more precisely defined by Greene et al. (160) (see Table 101.8). The original recommendations of the AMA committee (172) for stable and for hypermetabolic patients is deemed reasonable (167). As in adults, severe diarrhea secondary to infectious disease and the short bowel syndrome in children are associated with increased zinc losses and increased need (173). The guidelines in the appropriate footnote for zinc in Table 101.8 are helpful in estimating intestinal losses. Periodic checks of serum levels in such circumstances are essential. Zinc contamination of PN additives is variable, depending on the specific sources. As a result, total zinc in the formulation may be as high as 0.3 to 0.4 mg/L (174). Data on specific components have been published (172, 175).

Copper. The pediatric copper dose recommendations in Table 101.8 are the same as

the AMA recommendations (172). The work of Shike et al. showed that unlike zinc, increased stool volume is not associated with a major increase in copper excretion, and urinary losses tend to be low; thus, copper accumulates in the body when infused in amounts needed for maintenance or growth (176). On the basis of these and other findings, it is suggested that the range for copper be lowered to 0.3 to 0.5 mg/day for stable patients; hence the upper limit of the recommendation in Table 101.8 is at the lower limit of the AMA recommendation. Caution in copper administration in obstructive jaundice is emphasized because the major excretory route is through bile. The copper content of PN additives varies.

Manganese. The manganese content in PN components (177) and the blood levels found in PN patients given varying amounts of Mn^{2+} (178) suggested an appreciable reduction in the AMA recommendations. The current pediatric recommendations of 1 $\mu\text{g}/\text{kg}/\text{day}$ with a total of 50 $\mu\text{g}/\text{day}$ for older children in Table 101.8 are below the AMA recommendation of 2 to 10 $\mu\text{g}/\text{kg}/\text{day}$.

Manganese contamination of various PN additives produced in the United States may result in an adult receiving 8 to 22 $\mu\text{g}/\text{day}$ (177). HPN patients receiving 60 to 120 $\mu\text{g}/\text{day}$ (~1.5–3.0 $\mu\text{g}/\text{kg}/\text{day}$) of added Mn^{2+} had normal serum levels (178). As suggested above, it appears wise to provide only 60 to 100 $\mu\text{g}/\text{day}$ to adults (Table 101.8) (179) rather than the 150 to 180 $\mu\text{g}/\text{day}$ supplement of the AMA recommendations.

The potential for excessive retention escalates when cholestasis is present (which interferes with manganese elimination from the body) and there is continued provision of the amount of manganese listed in Table 101.8 in PN. Even with normal liver function, higher dosages in infants and children (180, 181) and in a few adults (182) on long-term PN resulted in high blood levels associated with high signal intensity in T1-weighted imaging in the basal ganglia (180, 181, 182 and 182a). Levels of plasma (183) or whole-blood (180) manganese in children showed a significant positive correlation with bilirubin levels. Reducing or omitting supplementary Mn^{2+} resulted in major decreases in blood manganese over periods varying from weeks to months (180, 181 and 182) in children and adults, and the high-intensity signal on magnetic resonance brain imaging disappeared in one adult (184) and in a child (181) and was markedly reduced in another adult (182). The amounts of manganese given to patients who developed high blood levels and imaging changes (180, 181, 182, 183 and 184) were appreciably greater than those in either the AMA recommendations or Table 101.8.

The exact relation of manganese to the high-intensity signal in the basal ganglia is uncertain. Some authors postulate deposition of a paramagnetic metal (i.e., manganese) (180, 184); others suggest that the disappearance with cessation of manganese infusion is more likely to be related to manganese-induced reversible changes in the ultrastructural membrane composition (185). Also uncertain is the possible role of high levels of blood manganese per se as one of the many factors in PN that can lead to hepatotoxicity (180).

Neurologic signs were present in one adult on long-term PN containing 1 to 2 mg/day of Mn^{2+} ; these improved, and serum and urinary Mn^{2+} decreased when manganese was

omitted from PN. Nine months later the patient died from a massive GI hemorrhage secondary to her cancer. At autopsy, the Mn^{2+} content of the caudate nucleus and centrum ovale was two to three times that found in some non-PN patients ([182a](#)).

Chromium (Cr^{3+}). As noted in the 1979 AMA report, quantitative data on chromium requirements were lacking at that time, and the qualitative suggestions were based on estimates from balance data on healthy individuals ([172](#)). The current situation is not appreciably clearer, largely because of the difficulty of measuring plasma chromium levels (normally very low), lack of information on tissue levels of this ion, and lack of controlled studies on very low Cr^{3+} intake.

The relatively few cases of well-documented symptomatic chromium depletion have occurred in long-term adult PN patients receiving little or no supplementary Cr^{3+} . It has been associated with sudden occurrence of glucose intolerance, glycosuria, weight loss, and neurologic symptoms, especially peripheral neuropathy. Development of symptoms appeared to be related to prolonged glucose infusions and intestinal fluid losses—both of which increase Cr^{3+} need. The patients responded well to Cr^{3+} , often 250 μg Cr^{3+} infused daily for weeks ([186](#), [Chapter 15](#)). Cr^{3+} toxicity has not been observed, even with doses above 250 $\mu g/day$.

More analytic data on Cr^{3+} content of PN additives are now available. The total daily Cr^{3+} content of high-glucose PN formulas using a variety of PN additives from different batches and sources ranged from 2.4 to 8.1 μg , and that of a high-lipid formula, from 2.6 to 10.5 μg ([187](#)). Amino acids, especially those containing phosphate or with phosphate additives, accounted for 85 to 90% of the Cr^{3+} . British investigators found 4 to 11 μg in 3 L of a PN solution ([188](#)).

A pediatric formula containing 4 μg of Cr^{3+} as a contaminant, given over 16 months, did not produce signs or symptoms suggesting chromium deficiency ([189](#)). Children aged 1.3 to 14 years who were receiving chromium during long-term PN at 0.15 ± 0.09 $\mu g/kg/day$ had higher serum chromium concentrations than control subjects (2.1 ± 1.2 vs. 0.10 ± 0.03 $\mu g/L$). Supplementation was discontinued for 1 year (during which time the Cr^{3+} intake was estimated to be 0.05 ± 0.01 $\mu g/kg/day$), at which time the serum Cr^{3+} concentration was 0.5 ± 0.3 $\mu g/L$, and no signs of deficiency were observed ([190](#)). It was suggested that the parenteral Cr^{3+} pediatric intake should be lowered to 0.05 $\mu g/kg$ and that current values of Cr^{3+} as contaminants may be sufficient for adults. A period of 1 year of reduced Cr^{3+} intake following a period of high intake without signs or symptoms may not be an adequate test of need in long-term patients. We believe that for children and adults on long-term PN, the recommendations given in [Table 101.8](#) are still valid pending further studies. However, for periods of 1 year or less, the recommendations of Moukarzel et al. ([190](#)) may be tried with adequate precautions.

Selenium. Recommendations for selenium were not made in the 1979 AMA report. That year saw the first reports in English relating selenium deficiency to Keshan disease in China (see [Chapter 14](#)) and the report of Van Rijn et al. of a case of selenium deficiency in a patient receiving PN ([191](#)). Considerable clinical and biochemical information has accrued since then, including selenium deficiency in patients receiving

PN, with some deaths associated with cardiomyopathy and reports of muscle tenderness and weakness (see [Chapter 14](#)). As noted in [Chapter 14](#), serious deficiency in mice is associated with increased virulence of coxsackievirus.

Although deaths may occur, low plasma levels of selenium (<10 µg/mL or <0.13 µmol/L) may be present without symptoms. Cohen et al. followed five patients on HPN without added selenium for an average of 18.6 months ([192](#)). Selenium-dependent glutathione peroxidase (GSHPx) in plasma reached very low levels (<15% of normal values, 0.32 U/mL) in approximately 1 year; GSHPx in red cells reached that level (24 U/g Hb) in 1 to 2 years. At the time plasma GSHPx was at this level, plasma selenium was 0.19 ± 0.07 pmol/mL. There was no evidence of either cardiac or skeletal muscle dysfunction in this ([192](#)) or another depletion study ([193](#)). Following infusion of 400 µg of selenium as selenite, plasma GSHPx rose within 6 hours; that in red cells did not reach normal levels until 3 to 4 months later—the time required for new red cells to appear ([192](#)).

Selenious acid (as selenite salts) is available for intravenous use. Use of 40 µg/day in PN usually maintains normal plasma levels; 100 µg/day in the infusate will raise low levels in previously depleted patients receiving PN into a control range of 100 µg/mL (1.3 µmol/L) ([191](#)).

Selenoprotein P levels in plasma (measured by radioimmunoassay) correlated well with extracellular glutathione peroxidase and selenium as markers for selenium status in deficient patients on long-term PN ([194](#)).

Molybdenum. Whether a true molybdenum deficiency has been observed in several species of experimental laboratory animals is controversial because tungsten must be added to the diet as an antagonist to molybdenum uptake to induce depletion ([195](#)). A single documented case of molybdenum deficiency was reported in a patient with Crohn's disease receiving long-term PN; clinical and biochemical abnormalities were reversed by daily supplementation with 300 µg of ammonium molybdate ([196](#), [197](#)). Tissue levels of molybdenum and balance data were not obtained, nor were molybdenum-dependent enzyme activities measured. Two patients with active Crohn's disease and malabsorption had ileostomy losses of 560 and 300 to 350 µg/day of this ion.

In view of a time lapse of at least 6 months from the initiation of PN to development of symptoms in the single reported patient, the availability of simple biochemical criteria as diagnostic clues, and the reportedly high molybdenum content of PN solutions, it is recommended that molybdenum not be added at present to PN infusions in adults and that it be withheld in children with the following consideration for those receiving long-term PN ([160](#)). Serum urate and urine sulfate measurements should be made periodically to monitor a need to initiate this element. If deficiency is suspected in adults, a dose of 200 to 300 µg as ammonium molybdate appears to be safe. More data on levels of molybdenum contamination of PN solutions and its serum and urine levels in long-term PN patients are needed.

Multi-Trace Element Additives. The most commonly used commercially available trace element combination products, which contain four to five individual metals, are

listed in [Table 101.9](#) (adults) and [Table 101.10](#) (pediatric). A combination product containing six trace elements (molybdenum plus zinc, copper, manganese, chromium, and selenium) and one containing seven trace elements (iodine plus the six mentioned above) are also commercially available.

Table 101.10 Trace Element Combination Products for Pediatrics and Neonates (Content per mL)

Use of multiple trace elements in a fixed formula poses the risk of excessive dosage of one or more of the constituents to long-term patients with metabolic abnormalities who require restriction or omission. Furthermore, evidence reviewed in this chapter and recommendations in [Table 101.8](#) suggest that routine needs for some trace elements are appreciably lower than those recommended in the AMA-FDA report ([172](#)). A combination of individual trace elements or decreased volume of a given multitrace element formulation may be necessary when restriction of one or more of the latter is

indicated.

Ultratrace Elements. Ultratrace elements are reviewed in detail in [Chapter 16](#). Data are available on the contamination levels in PN additives of boron, nickel, and vanadium ([197a](#)). At present, evidence is insufficient to warrant their addition to PN solutions.

Potential Toxicity of Other Trace Elements. The issue of toxicity of parenterally administered lead, cadmium, mercury, and aluminum present as contaminants merits consideration because they bypass the normal barriers of the gastrointestinal tract ([198](#)). Twenty components of a PN solution were individually analyzed for mercury; all values were at or below the lowest quantitative detection limit ([198a](#)). The complete formulations had 0.001 µg/mL of mercury (the lower detection limit), 0.08 ng/mL of cadmium, and 2 ng/mL of lead. Potassium chloride and phosphate solutions contained 135 and 77 ng/mL of lead, respectively. Some 22 µg of cadmium was measured in a daily PN formula ([198](#)), approximately the amount estimated not to exceed reported amounts absorbed daily by normal individuals.

Aluminum. Aluminum is of special concern because its toxicity was well delineated in patients with renal disease who were treated with aluminum-containing phosphate-binding antacids and/or received aluminum-contaminated water in hemodialysis. Neurologic changes include apraxic motor abnormalities involving speech, myoclonus, seizures and dementia. Also seen is an osteomalacia refractory to therapy with vitamin D analogues, calcium or phosphate; bone pain; pathologic fractures; aluminum deposition on bone osteoid front; and a microcytic anemia without evidence of iron deficiency ([199](#), [200](#)).

Reports of serious metabolic bone disease in a group of patients receiving HPN for 6 to 72 months were followed by the discovery that the casein hydrolysate used as the source of amino acids contained relatively large amounts of aluminum (2313 ± 149 µg/L) ([201](#)). Aluminum concentrations in plasma, urine, and bone were markedly elevated in all patients studied, and the bone morphology was that of osteomalacia, ranging from mild to severe. Intense periarticular and lower extremity pain in long bones and weight-bearing joints developed within 5 months in 5 of the initial 11 patients despite improvement in their overall nutritional state. Patients with impaired renal clearance are at increased risk. As noted below, use of casein hydrolysate at this institution was discontinued, and the patients' bone status improved.

Even though free amino acid solutions have much smaller amounts of aluminum (e.g., 26 ± 20 µg/L of 10% solution), other PN ingredients may have significant amounts and may contribute to the total burden. Premature infants are at increased risk because of their poor renal clearance ([160](#)). Widely varying concentrations of aluminum have been found in the same component from different manufacturers or in different salts of the same mineral; careful selection can reduce aluminum contamination from 288 µg/L of PN solution to 10.9 µg/L ([202](#)). There is evidence from a study conducted in Cambridge in the U.K. that preterm infants given PN for a median period of 9.5 days (range, 5–15) with a solution providing 45 µg/kg/day of aluminum had dose-related reduced developmental attainment at the postterm age of 18 months, compared with a control

group who were given a solution containing only 4 to 5 $\mu\text{g}/\text{kg}/\text{day}$ of aluminum ([202a](#)).

A joint working group on standards for aluminum content of PN solutions supported the FDA proposal to set an upper limit of 25 $\mu\text{g Al/L}$ (0.93 $\mu\text{mol/L}$) in large-volume parenteral infusions; it recommended that salts of calcium, phosphate, and magnesium; trace element and multivitamin solutions; and heparin state the amount of aluminum on their label and that pharmacists and physicians be educated about the risk of aluminum ([203](#)). As noted by Klein, the FDA has not implemented action despite the recommendations of its advisory panel in 1986 and its proposed regulations published in 1990 ([200](#)). The FDA in early 1998 again requested comments on proposed regulations.

Vitamins

Formulations

The current parenteral multivitamin formulations in the United States are based on those proposed in 1975 by the Nutrition Advisory Group of the AMA for intravenous vitamin formulations ([204](#)). Its adult formulation was approved by the FDA in 1979 and is designated here as the AMA-FDA adult formula. In 1984, its recommended pediatric formula was approved. The vitamin content of the formulations per unit in the U.S. are the same regardless of manufacturer ([Table 101.11](#)). The pediatric formula provides all known essential vitamins; the adult formula omits vitamin K, which must be added separately to the PN solution at a recommended dose of 5 mg once weekly or daily at a dose of 1 mg/day. Manufacturers add excess nutrients at production time (within limits set by the FDA) to meet label requirements at the expiration date.

Table 101.11 Composition of Parenteral Multivitamin Formulations

Provision of lipid-soluble vitamins in aqueous suspension requires one or more synthetic solubilizing agents. In addition, these parenteral multivitamins contain a variety of

excipients serving as stabilizers, antioxidants, buffers, and preservatives. Their presence and concentrations in various commercial preparations of the AMA-FDA formulas are given in [Table 101.12](#). The American Academy of Pediatrics has reviewed the issue of excipients as inactive ingredients in pharmaceutical products with particular reference to infants and children ([205](#)).

Table 101.12 Excipients and Their Distribution in Commercial Parenteral Multivitamin Solutions (per daily dose) in the United States

In many other countries, other formulations are available. One (Vitalipid, adult and infant) contains fat-soluble vitamins dissolved in fractionated soybean oil emulsified with egg phospholipids similar to that used in Intralipid; accordingly, it can be infused with intravenous fat emulsions ([Table 101.11](#)). The other (Soluvit) is a solution of nine water-soluble vitamins; the pediatric formulation has the same vitamins and content as the AMA-FDA pediatric formula ([Table 101.11](#)).

Stability. Some absorption and/or destruction of individual vitamins may occur through contact with plastic containers and tubes and in passage through filters, exposure to light and heat, and interactions with other substances present in solutions. Factors affecting the solubility and stability of vitamins in various pharmaceutical preparations have been reviewed ([206](#)).

Appreciable amounts of retinol appear to be lost from solution by a combination of adsorption and photodegradation when flow through tubing is slow. This is particularly true with the increased light intensity used in neonatal nurseries ([160](#)). With exposure to bright sunlight, 100% of retinol in PN solutions can be lost in 3 hours ([207](#)). Use of polyolefin tubing rather than polyvinyl tubing reduces vitamin A loss ([160](#)). Little loss of vitamin D occurs in plastic delivery systems. DL- α -tocopherol is stable to sunlight, but 50% of vitamin K can be lost from PN solutions in 3 hours ([207](#)). Riboflavin and pyridoxine are also unstable when exposed to direct sunlight for a matter of hours ([208](#)). Thiamin, folate, riboflavin, and pyridoxine are stable under fluorescent light.

Addition of the multivitamin solution to other PN constituents presents the possibility of some loss of specific vitamins. Thiamin is split and so loses biologic activity in the presence of sulfite compounds (209) that are components of amino acid solutions in the United States; hence, multivitamin solutions should not be added directly to undiluted amino acid solutions but rather to the ultimate solution shortly before infusion into the patient. Ascorbic acid is progressively lost in the presence of Cu^{2+} and oxygen (210). Folate is stable when the PN solution has the usual pH between 5.0 and 6.0 (211).

Adult Needs

The issue of vitamin needs for the sick and injured has long been of concern. Varying amounts of vitamins have been administered to postoperative and other patients who are receiving PN, with differing intervals between the times of vitamin infusion and those of blood sampling; blood levels have been the usual criteria, although some investigators have used enzymatic methods. Few investigators have completely surveyed all 13 vitamins. Much of the published data obtained in seriously ill adult patients is based on information gathered from a few weeks to a few months, the critical time range for most patients. These data indicate a relatively narrow range of requirements for certain of these nutrients, and adequate blood levels or related enzyme activities may be attained in hypercatabolic patients with daily infusion dosages for some that are appreciably below the old MVI concentrate formula and in some cases, below, at, or not far above, the AMA-FDA adult dosages (212, 213 and 214).

The adequacy of the adult AMA-FDA formulation was tested in 16 adults with severe malabsorption or intestinal obstruction who had been receiving HPN for 1 to 9 years. These patients were studied serially over many months on this formulation (MVI-12) (210). Blood was sampled at least 36 hours after the preceding infusion of vitamins was terminated. Mean values for plasma vitamin A were near or above the upper limit of reference values, in part because five subjects had renal insufficiency; the high values were associated with elevated retinol-binding protein levels. Thiamin, pyridoxine, niacin, biotin, riboflavin, vitamin B₁₂, and folate levels were within the reference ranges for all subjects; pantothenate levels tended to be within or above the reference ranges, thiamin tended to be toward the lower half of the reference range, as did vitamin E levels. In addition to the label amount of 10 mg/dL α -tocopherol acetate, additional vitamin E was given as a constituent of the intravenous lipid. The low plasma lipid levels of these patients tended to decrease circulating vitamin E levels. A few subjects had ascorbic acid values persistently below 0.3 mg/dL, which may have been caused by loss of this vitamin during storage for 30 hours. Levels of 25-OH vitamin D and 1,25(OH)₂ vitamin D in eight individuals over 430 to 588 days on MVI-12 were within reference range, as were parathormone levels. Prothrombin times were normal, with 5 mg of vitamin K oxide added once per week (210).

In another study, the plasma vitamin E levels measured in patients over 28 to 250 days on this formulation rose from 2.1 ± 4.6 to 16.5 ± 4.6 $\mu\text{mol/L}$ (mean \pm SD) (208). In a study using some of the same patients as in ref. 210 on HPN, the same multivitamins, and twice the volume of Intralipid, plasma α -tocopherol levels of 17.5 ± 6.6 μmol in seven patients were not statistically different from values in controls (215). When a

different source of vitamin E was given to patients on long-term HPN, the average plasma α -tocopherol level was 11.14 $\mu\text{mol/L}$ (normal, 18.11 $\mu\text{mol/L}$), and there were significantly higher breath pentane levels (a measure of lipid peroxidation) than in controls ([216](#)).

The amounts of vitamin E present in Intralipid as α -tocopherol are given in [Table 101.5](#) together with concentrations of other isomers. (See [Chapter 19](#) for a discussion of vitamin E isomer activities.) In addition, as noted in this table, lipid emulsions contain appreciable amounts of vitamin K, with roughly twice as much in those containing soybean oil only. Consequently, with regular lipid infusions, separate vitamin K infusions may be reduced or eliminated ([217](#), [218](#)).

A major function of vitamin D is improved efficiency of absorption of calcium and phosphate by the small intestine. PN bypasses this route, so why is this vitamin included in parenteral solutions? Calcitriol, as the active form of vitamin D, plays an intimate role with parathyroid hormone in bone turnover; the vitamin also plays a role in cellular differentiation (see [Chapter 18](#)). Whether the current parenteral dosage recommendations are higher than necessary for these functions remains to be demonstrated.

Pediatric Needs

Greene et al. summarized research on vitamin levels in term-gestation infants and children and problems related to the needs of preterm and underweight newborn infants ([160](#), [219](#)). They concluded that the vitamin dosages suggested for children in the 1975 AMA report were adequate for continued use in term infants and children up to 11 years of age. This formulation is commercially available as MVI-Pediatric ([Table 101.11](#)). Use of this formulation for underweight infants was found to increase blood tocopherol to a high level; the manufacturer and the FDA then recommended that the daily dose be reduced successively to 65% and then to one-third of a vial for infants weighing less than 1000 g. The last level may prove too low. Further problems have surfaced in providing this formulation to very LBW infants, including large losses of retinol through the delivery sets and elevated riboflavin and vitamin B₆ plasma concentrations ([219](#)).

Greene et al. recommended a revised formulation for the very LBW infant ([160](#)) ([Table 101.11](#)); currently, this is not in production. When a European pediatric fat-soluble multivitamin formulation (Vitalipid Infant) and a water-soluble multivitamin formula (Soluvit Infant) ([Table 101.11](#)) were administered as part of Intralipid 10%, the vitamins had good stability for up to 24 hours, except for ascorbic acid (50% loss); the emulsion was stable for 24 hours ([220](#)).

Thiamin Deficiency

There continue to be reports of severe thiamin deficiency in adult patients receiving PN. This occurs despite (a) the availability and safety of its parenteral preparation in multivitamin or individual form, (b) widespread knowledge of its increased need with use of high-glucose formulas, (c) its demonstrated instability in contact with the sulfite in amino acids, necessitating minimum storage at room temperature before use ([220a](#)) and (d) the fairly rapid onset (1–2 months) of life-threatening metabolic changes

characteristic of its deficiency. Unfortunately, the problem has been complicated by periodic production difficulties in the U.S. resulting in nationwide shortages ([221](#), [221a](#), [222](#), [223](#), [224](#) and [225](#)) with four deaths ([221](#), [225](#)); 14 patients had severe lactic acidosis ([221](#), [221a](#), [224](#)), and 4 had peripheral neuropathy and/or ataxia ([221a](#), [225](#)).

COMPLICATIONS OF ORGAN FUNCTION

Complications related to vascular access, catheter-related sepsis, concentration problems resulting from formula composition, and underlying diseases are discussed above. They can be prevented or minimized by having responsibility vested in experienced physicians, nurses, dietitians, and pharmacists working as a team that closely supervises their inpatients and outpatients ([226](#)). Here we discuss certain disorders related directly to intravenous feeding, including liver dysfunction, gallstones, and decreased bone mass.

Hepatic Dysfunction

Children

Since the first description of PN-associated cholestasis and early cirrhosis in 1971 in a premature infant ([227](#)), a large and continuing literature has confirmed PN as a contributing risk factor for hepatobiliary dysfunction of varying degree and incidence. Reviews of the biochemical, clinical, and histopathologic changes in adults and children have emphasized the multifactorial nature of the problem ([228](#), [229](#)). In children, the degree of prematurity, infection, inability to consume food orally, extent of intestinal dysfunction, number of surgical procedures, duration of PN, and long-term administration of excessive calories are associated risk factors ([228](#), [229](#), [230](#) and [231](#)). Immaturity of the hepatic excretory function and the enterohepatic circulation, particularly in the neonate, is one reason for development of cholestasis. Cholestasis has been reported in various series to occur in 7.4 to 42.1% of infants, with wide variations among differing populations, criteria, hospital practices, and clinical conditions ([232](#)).

Intravenous lipid emulsions with their endogenous content of phytosterols from vegetable oils were addressed as a potential cause of cholestatic liver disease in a preliminary study of children ([233](#)). Five of 29 patients who were receiving PN and had severe cholestatic liver disease had significantly increased concentrations of campesterol, stigmasterol, sitosterol, and isofucosterol (all phytosterols); they also had elevated concentrations of cholestanol and sitostanol (a phytostanol). The 24 patients receiving PN who did not have severe cholestatic disease had normal or slightly elevated phytosterol levels. Thrombocytopenia, a common complication in patients with hereditary phytosterolemia, was clearly evident in the 5 patients with severe cholestatic liver disease. The dose of intravenous fat emulsion was substantially higher in the 5 patients with liver disease than in the other 24 patients ([233](#)). Possible relationship of high blood manganese to the development of cholestasis was mentioned above ([180](#)).

Fatty liver (steatosis), intrahepatic cholestasis, and portal inflammation can occur,

particularly in children, but also in adults. It can progress to portal tract fibrosis and infiltration, liver failure, and death.

Adults

In adults, preexisting liver and other diseases, sepsis, preexisting malnutrition, extent of bowel resection and/or damage (such as from radiation), excess nonprotein calories, little or no oral intake, and duration on PN are also associated risk factors. Increases may occur in serum transaminase, alkaline phosphatase, g-glutamyltransferase (GGT) and, less frequently, bilirubin as indicators of hepatic dysfunction.

Adult patients receiving long-term PN (median, 18 months) who were given relative excesses of carbohydrate, fat, and amino acids showed abnormal hepatic function and cholestatic changes. When the amounts of these macronutrients were reduced, jaundice was reversed and liver function tests and histologic features improved (234). Other investigators noted increasing steatosis with administration of excess calories as carbohydrate or lipid or both (235, 236). Forty-three patients who received PN were randomized to receive either glucose as the sole nonprotein calorie source or a combination of glucose and fat. The dose of nonprotein energy used in this study was moderate compared with that in many of the previous studies. Even though the patients were not dramatically overfed (1.5 times calculated basal energy expenditure), alkaline phosphatase and GGT increased significantly in both groups. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), and direct bilirubin increased more in the group receiving only glucose as nonprotein calories. It appears that liver enzyme laboratory tests are affected by administration of PN, even when used in moderate doses and when part of the energy dose is given as intravenous lipid emulsion (237).

Data from various studies strongly suggest that patients with little or no remaining small intestine are at increased risk of developing serious hepatic dysfunction with fibrotic changes; the rapidity of development and the severity of the disease vary among series (data and literature review in ref. 238). Unlike in children, actual liver failure in adults is uncommon.

Amelioration or Prevention

A variety of agents have been tested on patients receiving PN who have developed evidence of associated significant hepatic dysfunction and who require continued PN. Giving a mixture of MCT and LCT to PN patients as the intravenous lipid source did not cause a change in liver size or gray-scale value, whereas LCT infusion increased both (128). On the grounds that metronidazole could depress formation by intestinal bacteria of potentially damaging bile acids, this drug has been tested in patients receiving PN and has been reported by some to reduce increases in liver enzymes compared with untreated control subjects (229, 239). Ursodeoxycholic acid (UDCA), an epimer of chenodeoxycholic acid, has been given with benefit to adults (240) and children (241) on long-term PN who developed cholestatic liver disease. Jaundice and enzyme abnormalities regressed, and their clinical condition improved. Discontinuance of the UDCA resulted in an increase in liver enzymes, which again regressed when this drug

was administered. UDCA given intravenously for 3 weeks to newborn piglets on PN was effective in reducing cholestasis by normalizing bile flow, bile acid secretion, and the bilirubin content of liver and serum; bile composition remained abnormal ([242](#)).

Cholecystokinin in synthetic form was given intravenously twice daily from onset of PN for at least 14 days to 26 neonates on PN in a case-matched study; its use was associated with a significant trend toward lower serum direct bilirubin levels ([242a](#)). Choline as such or as lecithin has been reported to decrease hepatic steatosis, ([243](#) and [Chapter 32](#)). Treatment of hepatic complications of PN has been reviewed recently ([244](#)).

Gallstones

Sludge in the gallbladder has been observed repeatedly as a PN- and bowel rest-associated risk factor; this situation can progress to gallstone formation as the duration of PN increases. Patients who receive long-term PN maintenance because of resection or disease of the terminal ileum usually malabsorb bile salts. Thus, the bile salt pool decreases, and lower levels of bile salts are present in the gallbladder. This situation, in turn, increases the tendency of cholesterol to precipitate in the bile forming the nidus of gallstones. There is also an increase in unconjugated bilirubin and calcium, which are present in the stones that form from the accumulated sludge in the gallbladder ([245](#)). Impaired gallbladder contraction is important. Ultrasonography indicated development of biliary sludge within 12 days of starting PN in 14 of 23 patients. By 6 weeks, all had sludge, with 6 developing stones and 3 requiring surgery. The sludge disappeared 4 weeks after instituting oral feeding ([246](#)). Stasis and resulting sludge were prevented in the PN prairie dog model given daily injections of cholecystokinin ([247a](#)). When chenodeoxycholate was given intravenously to a group of prairie dogs on PN for about 40 days, they did not develop gallstone or calcium bilirubinate crystals; the controls on TPN only had gallstones (5 of 6) or crystals (6 of 6) ([247b](#)).

Gallstones are a significant problem in adults, but even more so in children on PN. For example, 9 of 29 children developed cholelithiasis; 64% of these with ileal disorders or resections developed stones ([248](#)); 6 of 13 children with less than 38 cm of small bowel remaining required a cholecystectomy ([249](#)). In a Paris hospital, the frequency of gallstones led to a policy of routine cholecystectomy whenever total or subtotal resection of the terminal ileum was performed ([250](#)). Emergency cholecystectomy in PN patients is not a benign procedure; for example, the operative morbidity was 54% and hospital mortality was 11% in 35 patients (23 adult, 12 children) with PN-associated gallbladder disease ([251](#)).

These potential problems have led to the following suggestions for management of such patients at risk: if food can be ingested safely, it should be taken orally or by tube routinely in an effort to decrease biliary stasis; ultrasonic examination should be performed periodically to detect development of biliary sludge and stones; when stones are first detected, elective cholecystectomy should be considered; if laparotomy is to be done for any reason, cholecystectomy should be considered at that time. Meanwhile,

clinical studies continue on UDCA.

Metabolic Bone Disease

Rickets has been described in infants receiving PN (252). The causative factor appeared to be a need for more calcium and phosphate in the small fluid volume required by the neonate, rather than more vitamin D.

Reference has been made above to the effects of aluminum contamination on bone (200). When contaminated casein hydrolysate was replaced by crystalline amino acids, increased bone formation occurred with reduced osteoid area, decreased amounts of aluminum at the bone surface and in plasma, and reduced calcium excretion (253).

The histomorphologic features of bone were examined in relation to formula composition in patients receiving long-term HPN who were not subsisting on aluminum-contaminated casein hydrolysate. In a prospective study in Toronto by Shike et al., bone biopsies of HPN patients initially showed a hyperkinetic pattern, possibly resulting from initial malnutrition; at 6 to 73 months on HPN, the histologic features changed, with 12 of 16 patients having some degree of osteomalacia (254). In this study, 500 IU (12.5 µg, or 32.5 nmol) of vitamin D₂ were given every other day; all other vitamins were supplied, except biotin. Because 7 of these patients were hypercalcemic and 6 had elevated 25(OH) vitamin D levels, further studies were performed on 11 patients before and after withdrawal of vitamin D₂ (and, by necessity, the accompanying vitamin A) for 6 months (255). Six of 10 patients had less osteoid and increased tetracycline uptake with the vitamin modification, but there was continuing evidence of a high turnover rate. In the three symptomatic patients, bone pain subsided, fractures healed, and urinary loss of calcium and phosphate was decreased. It was recommended that vitamin D solutions not be added to PN solutions of home patients (255). The mechanism of the postulated adverse role of this vitamin was not delineated.

Others have noted improvement in HPN patients with respect to bone fractures and pain following withdrawal of vitamin D from the PN formulations (literature review and new data in [256]). Withdrawal of vitamin D for 4.5 ± 0.2 years from nine HPN patients with low parathyroid hormone (PTH) and calcitriol levels was associated with normalization of these values and some increase in lumbar spine bone mineral; there was no decrease in the mean level of calcidiol (256).

In a study in New York City of 12 HPN patients given crystalline amino acids (with the exception of two who had been transferred from casein hydrolysate 6 years earlier), the average daily vitamin D intake over the years had been 284 IU (7.1 µg) replaced 3 to 10 months earlier by 200 IU (5 µg) daily. Histomorphometry with tetracycline labeling revealed osteopenia, subnormal osteoid volume, and normal trabecular osteoid seam width; the calcification rate was normal. Of the seven women, four were in the 66- to 77-year range, and at least one had been a heavy cigarette smoker for many years. Six patients had minor bone complaints associated with osteoarthritis or postmenopausal osteoporosis (257). Serum calcium, PTH, and calcitriol values were normal. The reasons for the marked difference in the histologic features of bone between the

Toronto and New York studies are not apparent, but there were some formula differences. The PN formulas in the New York study had appreciably fewer fat calories, proportionately more glucose calories, and a different vitamin formulation, including biotin.

A longitudinal study of bone with regional densitometry and bone biopsy was performed in 14 patients on long-term PN who had either never been on protein hydrolysate or not for at least 7 years (258). Most subjects had osteopenia with heterogeneity in bone status, complaints of bone pain, and some documented fractures while on HPN; all 11 females were amenorrheic. In the follow-up period (27 ± 14 months), some patients had improved bone mass, some had no change, and others lost bone. Serum calcium, which had been low at baseline in six, normalized in most; PTH was high in five; calcitriol was normal.

It has been suggested that PN patients lose a significant amount of bone mass early as a result of hypocalcemia that then stabilizes. Amenorrhea and/or smoking are also factors. The conclusion is that osteopenia is characteristic of long-term PN patients but that present PN formulations do not necessarily cause deterioration of bone health and may benefit some (258). A trial of antiresorptive therapy is indicated.

COMPATIBILITY OF DRUGS WITH PN SOLUTIONS

The frequency of drug interventions for coexistent illnesses or complications of PN requires ensuring that administering a drug as part of the PN solution or in conjunction with that solution will not produce incompatibility or an adverse reaction. Significant information on this issue has been summarized (259, 259a). [Table 101.13](#) contains compatibility information for PN solutions and many commonly used drugs. Both dextrose/amino acid PN solutions and TNAs are listed in this table. Drugs that can or should be administered as continuous infusions and that are compatible with PN solutions are ideal additives, especially in the critical care setting where fluid intake often must be regulated. Not all combinations of drugs and different PN solutions have been studied. Also, some drugs are compatible in traditional dextrose/amino acid PN solutions but not in TNAs (e.g., iron dextran). Still other drugs are compatible in PN solutions because they are diluted in a large volume of fluid and are incompatible when given during Y-site administration with the same PN solution. This problem undoubtedly occurs because the drug concentration is high when coinfused with PN through the same tubing. Trissel et al. (259a) found that 82 of 102 drugs were compatible during Y-site administration with PN solutions; the 20 incompatible drugs are listed in [Table 101.13](#).

Drugs compatible with PN solutions		
Dextrose		Sol nutrient admixtures
Alanine		Alanine
Glutamine		Glutamine
Fat acid		Fat acid
Hydrolyzed egg		Hydrolyzed egg
Hydrolyzed fish		Hydrolyzed fish
Hydrolyzed whey		Hydrolyzed whey
Inulin		Inulin
Leucine		Leucine
Methionine		Methionine
Phenylalanine		Phenylalanine
Threonine		Threonine
Tyrosine		Tyrosine
Valine		Valine

Drugs incompatible with PN solutions		
Dextrose		Sol nutrient admixtures
Amphotericin B		Amphotericin B
Asparaginase		Asparaginase
Hydrocortisone		Hydrocortisone
Insulin		Insulin
Penicillin G		Penicillin G
Vancomycin		Vancomycin
Chloride		Chloride
Phosphate		Phosphate

Drugs incompatible with PN solutions with amniotic PN administration		
Aspartic acid	Doxorubicin	Minoxidil
Asparaginase	Fluorouracil	Morphine
Calcitonin	Furazolidone	Propranolol
Erythropoietin	Ganciclovir	Promethazine
Epinephrine	Hydrochloric acid	Tetracycline
Enalaprilat	Methylene blue	Tris (base)
Enoxacin	Metformin	
Leucovorin	Neomycin	

Table 101.13 Compatibilities of Selected Drugs in Parenteral Nutrition Solutions

HOME PARENTERAL NUTRITION

Since the first patients were discharged from hospital to home on PN in 1969 and the early 1970s, in the United States and Canada ([260](#), [261](#) and [262](#)), HPN as primary outpatient nutritional support has mushroomed. An HPN registry for the United States and Canada was established at the New York Academy of Medicine during the years 1978 to 1983 to collect and compile the data being accrued by an increasing number of medical centers who discharged patients on HPN. Data were distributed regularly to participants and interested parties ([263](#), [264](#)). In 1984, this registry became a joint effort of the Oley Foundation and the American Society for Enteral and Parenteral Nutrition, originally designated the OASIS Registry and, more recently, the North American Home Parenteral and Enteral Nutrition Patient Registry (HPRN Registry) produced by the Oley Foundation.

Issues related to suitability, training, formulations, and home support have been extensively studied ([265](#)), and standards on organization, patient selection, and management have been developed ([266](#)). Benefits and current issues are discussed in this and other chapters.

Patient Numbers and Categories

Because Medicare in the U.S. is the largest single payer for HPN, its data provide useful information on national use, growth, and costs ([267](#), [268](#)). In 1992, an estimated 10,035 Medicare beneficiaries were on HPN of the total Medicare enrollment of 34,853,000, at an expenditure of \$156 million. Based on the figures for patients in the HPEN Registry in 1992, with 25% covered by Medicare, it was estimated that 40,000 patients used HPN therapy in that year, with 54% percent supported by private insurance ([267](#)). The age distribution of HPN changed over the period 1978 to 1988: the percentage of those 10 years of age or less roughly doubled, and the percentage of those over 65 years

tripled.

Of the 5481 HPN patients entering the registry during their first year on therapy between 1985 and 1992, the 10 top specific diagnoses in percentages were neoplasm 40.4, Crohn's disease 10.8, ischemic bowel 6.2, motility disorders 5.7, AIDS 5.5, congenital bowel disease 3.3, chronic pancreatitis 3.0, radiation enteritis 2.7, chronic obstruction 2.3, and cystic fibrosis 1.0 ([267](#), [268](#)).

Patient Outcome

Detailed data have been published for 11 diagnoses concerning survival, likelihood of rehabilitation to full and to partial function, and frequency of HPN and non-HPN complications ([268](#)). Annual survival rates of those with gastrointestinal (GI) diseases were 87% or better, with a 50 to 73% likelihood of complete rehabilitation in 1 year except for those with radiation enteritis or obstruction with chronic adhesions. In the three most common GI diseases (Crohn's disease, ischemic bowel disease, and motility disorders), survival rates over 1 year for patients 18 years or less was about 95%; for those 35 to 55, 90%; and for those 65 and older, about 70%. Younger patients were more likely to resume full oral nutrition and have more complete rehabilitation, but they had more septic admissions. The registry to 1992 lists 66 patients with these three GI diseases plus radiation enteritis who have survived 15 to 20 years on HPN. Only about 30% of cancer patients on HPN were alive at 6 months, and 20% at 1 year ([268](#)). The mortality of AIDS patients at 1 year was 90%; decreased use of HPN is likely if the reported effectiveness of newer medications in HIV patients continues.

The frequency of HPN-related complications was similar in all diagnostic groups: one to two rehospitalizations per year, one-half because of sepsis ([268](#)). Complications associated with HPN accounted for only 5% of deaths. If earlier experience continues to be true ([263](#)), a minority of patients account for a majority of rehospitalizations.

The organization, care, and outcome of PN in European countries has been summarized ([269](#), [270](#)). In certain European countries, France, Italy, Denmark, and probably others, care of HPN is restricted to approved specialist centers, and in the U.K., two adult centers managed one-half the number of registered patients ([269](#)). Adult patients ($n = 217$) with nonmalignant non-HIV chronic intestinal failure in HPN programs in approved programs in Belgium ($n = 2$) and France ($n = 7$) from 1980 through 1989 had survival probabilities of 91% at 1 year, 70% at 3 years, and 62% at 5 years, with better survival after 1987, with younger age, and with no chronic intestinal obstruction ([270](#)). In the U.K. in 1994, 4 to 5 patients per million received HPN at any one time in the course of a year. The actual number is approximately two or three times greater.

One of the more dramatic successes of HPN is the much better outcome of the newborn with abnormalities of the gastrointestinal tract requiring extensive intestinal resection. In a Los Angeles HPN program for the years 1977 to 1984, 13 children were left with less than 38 cm of remaining jejunum and ileum (JI) beginning in the first month of life; of these, 69% survived, compared with 23% previously ([248](#)). Five of these had HPN discontinued after 4 to 32 months and had normal growth and development; whereas two remained on partial HPN after 9 and 55 months, and two required PN after 66 and

68 months; these four children have grown normally. Of those with 15 to 38 cm without an ileocecal valve (ICV) and those with less than 15 cm with and without an ICV, 70% survived (compared with none in Wilmore's review of 1972 [270a]); 3 of the 10 discontinued HPN. Ultimate survival with normal growth and without HPN is now possible with as little as 11 cm residual JI and an intact ICV and as little as 25 cm JI without an ICV (248).

The course of 87 children with major resections managed from 1970 to 1988 in a Paris hospital have been analyzed. HPN was introduced in 1980. Fourteen of the 16 deaths occurred before 1980. Of those with less than 40 cm of JI who were born before 1980, 42% survived. Of those born after 1980, 94% in this category survived. The presence of an ICV did not significantly affect survival. The average time needed for adequate bowel adaptation was 27.3 months for those with less than 40 cm and 14 months for those with 40 to 80 cm (249).

Quality of Life and Support Needs

HPN presents various stresses to the patient and family members (271), including the sudden need to cope with the technical aspects, time demands, and safety issues of HPN after hospital discharge; management of handicaps resulting from primary and secondary illness and their treatments; concerns about meeting costs; patient dependency; and excessive dependence on others. A smooth transition to home care requires (a) adequate pre-discharge assessment and training of the patient and family in HPN management and (b) close support by the healthcare team via telephone contact and follow-up at home or in the physician's office to ensure that the patient's condition remains satisfactory. Dietary intake and other factors at home may require modification of the PN formulation from that deemed satisfactory in the hospital setting.

Data are available from a survey of 178 randomly selected families with a member on HPN for an average of 4.6 years, with 116 follow-up questionnaires (272). Patient and caregiver mean family scores for quality-of-life, self-esteem, life satisfaction, family cohesion, and quality of patient-caregiver relationship were similar to published norms for other healthy populations and other groups of chronically ill patients. HPN family adaptability and coping scores were higher. There were problems associated with financial strain and mild depression in patients related to increasing duration of PN and being barred from work (although able to) because of their disability classification.

Issues concerning nutritional support decision making for the competent and incompetent patient and for the terminally ill are reviewed in [Chapter 102](#) and elsewhere (265, 266, 273).

Cost-Effectiveness

Estimates of the cost of HPN vary from \$75,000 to \$150,000 per patient-year (273). Many factors enter into the total cost of maintaining a patient on HPN; such charges vary considerably, depending in part on the method used in their estimations and on differences in the perspectives chosen for the analyses, particularly the matter of estimating benefits gained and/or the effectiveness gained. Goel has discussed these

issues and has reviewed the pertinent literature relating to hospital PN and to HPN (274). Daily costs of HPN were estimated to be 60 to 70% lower than those of hospital PN. Goel has also summarized factors involved in cost-effectiveness analysis, the variability in determining precise costs, and the inclusion of effectiveness as measured by quality-adjusted life-year (QALY)—a composite measure of life expectancy and morbidity.

A cost-effectiveness analysis of HPN in a cohort of 72 patients from 1970 to 1982 in Toronto was compared with the alternative costs that would have accrued from intermittent hospital care, including PN on each admission for the same patients not receiving HPN. It was concluded that HPN was cost-effective (275). In commenting on his study (275) and others, Detsky said, “Home Parenteral Nutrition is indeed a mature technology that almost certainly provides considerable survival benefit and reasonable quality of life. The estimated incremental cost-effectiveness ratio for this technology is attractive when it is delivered in patients without disseminated cancer or advanced HIV disease” (276).

SMALL BOWEL TRANSPLANTATION

Successful small bowel transplantation was demonstrated to be technically feasible in laboratory animals in the late 1950s (277). Until the late 1980s, attempts were unsuccessful in patients because the immunosuppressive drugs available in that period could not prevent rejection of the transplanted intestine (277, 278). With the availability of cyclosporine and tacrolimus, single successful transplants (of several or more attempts) of isolated bowel were reported from Kiev and Paris (278), and a successful combined liver–small bowel transplantation was performed in London, Ontario (279). Three types of intestinal allografts are now being performed. For example, between May 1990 and February 1995, the University of Pittsburgh's transplantation group performed 71 small bowel transplantations in 67 patients: 23 received an isolate intestine, 32 a combined intestine and liver, and 23 a multivisceral transplant (280, 281).

A series of recent reviews summarize techniques, problems, advances, and results in the U.S. (280, 281, 282 and 283), and internationally (284). Of the 62 intestinal transplant patients reviewed by Lee et al., only 36 (58%) were alive at a median follow-up of 594 days, and only 31 (50%) were alive and retaining a functioning graft (281). In Grant's review of 180 intestinal transplantations performed between 1985 and June 1995, in 170 patients (two-thirds of whom were children), graft/patient survival (%) at 1 and 3 years with cyclosporine immunosuppression was, respectively, 17/57 and 11/50 for small bowel only, 44/44 and 28/28 for intestine plus liver, and 41/41 for multiviscera (284). With the use of tacrolimus the corresponding figures were 65/83 and 29/47, 64/66 and 38/40, and 51/59 and 37/43. Of the 86 survivors, 67 had stopped PN and resumed oral nutrition, 10 required partial PN, and 9 were on PN after removal of their graft. Successful small-bowel grafts can absorb oral nutrients, including fat, despite denervation and disruption of lymphatics at the time of surgery.

The review of the International Intestinal Transplant Registry concludes: “to become the standard treatment for intestinal failure, transplantation must offer greater safety, lower costs, and a better quality of life than PN.” While progress has been made, “further

refinements are needed before bowel transplantation becomes a routine surgical procedure” (284). Intestinal transplantation to date has been considered and performed in the context of serious hepatobiliary disease or loss of venous access, both secondary to PN complications (282, 283 and 284).

EFFECTS OF TROPIC AGENTS

Standard PN solutions cannot adequately support patients whose catabolic state is so advanced that they cannot develop a net positive peripheral uptake of amino acids despite adequate provision of energy and known essential nutrients (285, 287) (see also Chapter 96). Strategies that have been adopted to try to improve this situation have included (a) having the patient perform regular exercise (285); (b) providing increased amounts of such nutrients such as arginine, BCAAs, n-3 polyunsaturated fatty acids (286), glutamine (Chapter 35 and Chapter 98); (c) blocking the signals of interleukins, which initiate responses to inflammation (286, 287); (d) providing hormones and related growth factors that appear to enhance protein retention, such as recombinant human growth hormone (Chapter 96), insulin-like growth factor–1 (IGF-1) (Chapter 96), the b-adrenergic agonist clenbuterol, and low-dose bradykinin (288); and (e) a combination of the above (see Chapter 35, Chapter 96 and Chapter 98).

The concept of using trophic agents with modified diet has now been applied in an open study to selected patients with short bowel syndrome requiring HPN, in an effort to increase hyperplasia and hypertrophy. Some 47 long-term patients who had no cancer, diabetes, dysmotility, inflammatory obstructive symptoms, or active inflammatory bowel disease were hospitalized on a regimen of diet (60% carbohydrate, 20% fat, 20% protein), glutamine (0.6 g/kg/day) orally and r methionyl growth hormone (0.14 mg/kg/day) parenterally for 26 days (289). They were discharged on 30 g glutamine/day and the diet. After 4 weeks, 27 of the subjects were off PN, 14 were on reduced PN, and 6 were continued on PN. After 5 months to 5 years, 19 patients (40%) were off PN, an equal number were on reduced PN, and 9 (20%) were on their original PN formula. Multicenter trials of this therapy are under way (289).

A more-recent study of eight long-term HPN patients compared the effects on bowel function of a similar triple regimen with those of placebo in a randomized, double-blind, crossover format (289a). Although the treated patients had modest improvements in sodium and potassium absorption and in gastric emptying delay, there were no consistent improvements in small bowel morphology, stool losses, or macronutrient absorption. The two studies (289, 289a) differed with respect to duration, degree of bowel resection, hospital stay and supervision, and routes of medication administration; nevertheless, the very different outcomes indicate the need for additional well-controlled studies (289b).

Exogenous epidermal growth factor (EGF) (290, 291), glucagon-like peptide 2 (GLP-2) (292), IGF-1 (293), and TNF-a (294) have induced mucosal or mucosal cell proliferation of small animals. These peptides may prove to have value in improving human intestinal proliferation in patients with the short bowel syndrome.

[Selected Readings](#)

The widespread availability of essential nutrients in stable and safe forms and the means to administer them, by enteral tube or vein, have made nutritional support an effective therapy in many clinical situations. Much attention has been devoted in recent years to the ethical, medical, and legal aspects of providing or withholding nutrition and fluids to patients with advanced and often incurable diseases, especially those unable to make such critical decisions for themselves. These issues are considered in some detail in this chapter. First, however, consideration is given to bioethical issues related to nutritional support for other types of patients.

NUTRITIONAL SUPPORT AS AN ETHICAL ISSUE

Without clinical craftsmanship, the physician-humanist is without authenticity. Incompetence is inhumane because it betrays the trust the patient places in the physician's capacity to help and not harm.

Edmund D. Pellegrino (1)

Prevention of Undernutrition

Physicians have become significantly more sensitive to the need for remedial attention to the problem of disease-related malnutrition. However, many physicians still either overlook development of serious undernutrition in their patients or delay proper therapy in the hope that the underlying disease will soon be controlled and the “patient will again eat well”—a hope often delayed. At intervals over many years, reports of the prevalence of such hospital-based malnutrition resurface with notations of increased morbidity, delayed convalescence, and increased mortality (2). In addition to failing to recognize the need to institute adequate nutritional support, some physicians fail to oversee these modalities adequately (particularly total parenteral nutrition), with resultant adverse consequences.

Serious undernutrition has many sequelae, discussed in various chapters in this book. An ethical issue arises when the risks of serious undernutrition are either not anticipated or not treated in a potentially curable patient. One way to help such patients is to try to prevent serious undernutrition and aggressively treat existing malnutrition.

The sick may refuse food for many reasons, including the anorexia of illness, chronic nausea, depression exacerbated by fear, generalized or localized pain, medication effects, obstruction, and malabsorption. Noting and tending to relevant problems may be helpful. Food intake can be enhanced directly in a number of ways, such as making the food more acceptable in taste and appearance, providing more familiar and desirable foods, minimizing skipped meals, providing regular assistance in hand feeding when needed, and making palatable liquid supplements easily available. When indicated, tube feeding or parenteral nutrition may be necessary.

Prevention of Chronic Illness

Chronic diseases, particularly cardiovascular diseases, cancer, osteoporosis, hypertension, and diabetes, are major causes of morbidity and mortality. In recent years, it has become apparent that certain diets instituted at appropriate times and maintained can play an important role as preventive or ameliorating factors. This is clearly the case with management of hyperlipidemias in controlling coronary artery disease (see [Chapter 75](#)), efforts to minimize or delay serious osteoporosis (see [Chapter 85](#)), optimum management of insulin-independent diabetes mellitus (see [Chapter 86](#)), and assistance in controlling hypertension (see [Chapter 76](#)). In addition, because many of these diseases are exacerbated by overweight, weight control is important (see [Chapter 87](#)). Some evidence indicates that restricted protein intake can slow progression of renal disease in some groups (see [Chapter 89](#)). Increasing data from epidemiologic and intervention studies show promise for certain diets in preventing or controlling cancer (see [Chapter 79](#)).

With such information, “doing good” for the individual requires the physician's attention to the possible need for dietary and other interventions to delay, ameliorate, or prevent one or more diet-sensitive chronic illnesses. Neglect in obtaining the proper history (e.g., patient family history and dietary characteristics), in doing an adequate physical

examination, or in ordering relevant laboratory studies is as much a professional failure as is failure to diagnose an existing illness or to prescribe a correct medication. The traditional responsibilities of the physician expand as biomedical knowledge advances.

CHANGING VIEWS ABOUT MEDICAL ETHICS

Clinical ethics deals with situations in which there are strong reasons both for and against a course of action. Decisions often are difficult because ethical guidelines conflict and people of integrity and good will may disagree over what to do.

Bernard Lo (🇺🇸)

Hippocratic Tradition

The moral principles to which medical professionals are exposed during their training and in their professional organizations have a long history. The Hippocratic tradition of some 2500 years developed from interactions of ancient Greek philosophic schools and medicine with modifications of Stoic attitudes to duty and virtue. These were further modified by the views of the Galen, with subsequent religious Christian input to remove pagan influences (4). Ethical precepts from the Hippocratic tradition include beneficence and maleficence (the obligation to promote the patient's welfare while balancing benefits and harm), duty, compassion, and confidentiality as well as such prohibitions as abortion and euthanasia. The tradition combined precepts on gentlemanly conduct, education, and practical judgment including a good physician-patient relationship. These would lead physicians toward right and good decisions for their patients in situations of moral choice. Inherent in this system of medical practice and ethics was the authoritarian role of the physician; this long era has been termed one of paternalism (5) or the quiescent period (6).

“Principlism”

The traditional Hippocratic system of professional ethics was increasingly questioned in the United States in the mid-1960s in conjunction with many professional and societal changes that included depersonalization and fragmentation in many physician-patient relationships and challenges to governmental authority with the rise in the civil rights, antiwar, feminist, and consumer rights movements in a multiethnic pluralistic democratic society. As physician-patient relationships came under increasing scrutiny with claims for more patient rights, a series of principles of medical ethics were advanced (designated by some as “principlism”). These were effectively set out by Beauchamp and Childress in the first edition of *Principles of Biomedical Ethics* (7) and its successors. Its first two principles (nonmaleficence and beneficence) were similar to those in the Hippocratic ethic; the third concept, patient *autonomy*, contravened paternalism; while the fourth, *justice* (an area of diverse views often involving elements of fairness and entitlement for individuals), was completely at odds with the old tradition.

The term *autonomy* signifies the right of the competent individual to make choices freely about medical care and denotes the obligation of the healthcare provider to communicate effectively with the patient and solicit those decisions. As detailed by Beauchamp and Childress, autonomous actions require that definitions be available

including criteria so that someone could give or refuse informed consent and make other decisions. Furthermore, the principle of respect for autonomy must be evaluated in given situations in competition with the other principles (7). Widespread acceptance of principlism in the United States was circumscribed to a period of about 20 years from the mid-1960s, as other ethical concepts became more prominent (4).

Alternative Ethical Approaches

There has been increased advocacy in the past decade for alternative ethical approaches that place more emphasis on the value of a more personal decision-making interaction of physician and patient (8, 9, 10, 11 and 12). Alternative ethical approaches include casuistry (analysis of a specific case in relation to a system of principles) and cross-cultural, narrative, and virtue ethics. These gained advocacy as changes continued in society and in medical practice and care. Key examples of the latter are institution of diagnosis-related groups (DRGs) in 1983 and, more recently, the widespread movement toward managed care systems owned or directed by for-profit corporations and nonprofit organizations vying competitively, which raised serious concerns, divided physician loyalties, and imposed limitations on medical care (10).

In addition to secular ethical positions, some bioethicists have formulated their positions on the basis of particular religious traditions (13, 14) and some attempt to construct a basis for secular ethics for those “who do not share a contentful moral vision” (15).

ISSUES IN NUTRITIONAL SUPPORT OF THE COMPETENT PATIENT

Many of the ethical and legal issues concerning medical practice and patient-physician relations relate to provision of nutrition and hydration. Prior to the practical application of forced-feeding techniques, the inability to maintain adequate nutrition by mouth meant progressive body wasting until death. Except for deaths occurring very rapidly from violence, trauma, or acute overwhelming infection, the more usual direct causes of death were dehydration and starvation associated with more chronic illness. Under these circumstances, there was relatively little that a physician could do in restoring health while maintaining a good nutritional state. This situation began to change significantly in the late 19th century as effective therapies (initially surgical) and other advances in diagnosis and treatment enhanced the societal importance of the physician.

Concerning oversight of medical care in general, the prevailing judicial position in the past was that of “compelling state interest” such as preservation of life, prevention of suicide, and certification of physician education. This legal position in conjunction with the paternalistic role of the physician eventually led to contentious legal issues.

The patient's right to refuse medical treatment was not established until 1891, in a case in which the United States Supreme Court upheld the right of a personal injury plaintiff to refuse a medical examination (16). This decision established the general rights of individuals to make choices regarding bodily examination and treatment under the principle that common law guards the right of every individual to the possession and control of his or her own person on the basis of the doctrine of informed consent.

However, this only began to establish judicial decisions that more specifically defined the laws of informed consent and the rights of the incompetent patient.

In the past, the issue of provision of nutrition and fluids has caused the most controversy among adult patients, their surrogates, physicians, hospital administrators, and state courts. The right of the competent individual to decide whether or not to receive medical therapy (autonomy) was not automatically granted. Withholding or withdrawal of artificial nutrition and hydration became a contentious issue because some physicians, ethicists, theologians, and “right-to-life” groups considered such acts assisted suicide or euthanasia (and hence likely to involve criminal penalties) or were cessation of “ordinary” medical procedure.

The Bouvia Case

The Bouvia case posed the issue of the right of a competent individual to starve to death. Elizabeth Bouvia, a quadriplegic in her mid-20s, was hospitalized in California with severe cerebral palsy and arthritic pain requiring morphine injection. While able to ingest food orally with assistance, she asked that such feeding be stopped. The hospital refused to accede to her wishes, and a lower court ruling in 1984 supported the hospital (17). When her condition deteriorated to the point that feeding by nasogastric tube was necessary, the appellate court ruled in 1986 that her refusal of treatment was not a form of suicide, thus rejecting the arguments of hospital officials that removing the tube would make them a party to suicide (18). With the additional support given later by the United States Supreme Court decision in the Cruzan case (see below), the right of an irreversibly ill but competent patient to refuse artificial feeding is unlikely to be seriously challenged again.

Bouvia's condition was classified as a state of severe and permanent paralysis, which may acutely or progressively result in a “permanent locked-in state.” This was first described as a medical condition in 1966 by Cranford, as irreversible loss of motor function with preservation of normal consciousness, possible long-term survival of years or even decades, and physical and psychologic suffering of a degree that may become extreme because of the patient's awareness of the condition (19). Eleven years later Bouvia was still alive, totally dependent on others for her care and, despite several half-hearted attempts, unable to bring herself to insist on actual discontinuation of artificial feeding (19a).

Patient-Physician Interaction and Decision Making

In an incisive essay, Pellegrino stated “that a more sensitive and compelling guide to the care of the sick is to be found in the fact of illness as a human experience rather than in the assigned role of the profession. Without supplanting traditional professional ethics, the intrinsic dehumanizing nature of illness imposes additional obligations of greater sensitivity” (20). Individuals with “illness as an acute event or as a chronic accompaniment of life are deprived in varying degrees of those things which distinguish humanity from other forms of existence.” These include loss of freedom of action, freedom to make choices, and freedom from the power of others as well as threats to personal self-image. These disabilities “must be the infrangible base for the obligations

of physicians and all others who profess to heal ..., these obligations constitute the substance of professional medical ethics, ... Its rooting in the existential situation is more authentic and more human ... than the traditional one in the self declared duties of the profession ... The professional can make a valid claim for technical authority but this no longer extends to moral authority ... The patient has the human right to his own moral agency if he or she wishes to exercise it. The physician has the moral obligation to ascertain the degree to which the patient wishes to exercise his moral prerogatives and to provide the fullest exposition which will enable the privilege to be exercised” (20).

The principle of respect for autonomy of the competent patient may result in tension between a patient or the parent of a minor and the physician when the patient's decision seems inappropriate. What appears legally to be a clear-cut situation, i.e., the rights of a competent patient, may be a complex and difficult situation for all concerned with the welfare of the individual. The old Spanish proverb quoted elsewhere in this context is apt: “The appearance of the bull changes as one leaves the grandstand and enters the ring” (21). The patient's viewpoint may reflect a lucid and rational decision or an undisclosed or undiagnosed problem(s) such as depression, other mental difficulty, side effect of medication (22, 23), an unspoken complicating social problem, strong opposing family influence, misunderstanding the physician's intentions, or the patient's failure to know, comprehend, or accept the severity or irreversibility of the disease.

Disagreement may occur, for example, when the patient wishes parenteral or enteral feeding stopped and the physician believes that continued feeding is in the patient's best interest. An even more difficult situation pertains to stopping parenteral feeding in an intestinally obstructed cancer patient who has failed all therapy but is still competent and ambulatory, and for whom such continued support at home could conceivably extend life for months.

Recommendations of the President's Commission

Several recommendations on this issue were considered by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (24). It held that “health care professionals serve patients best by maintaining a presumption in favor of sustaining life while recognizing that competent patients are entitled to choose to forgo any treatments, including those that sustain life” and “the voluntary choice of a competent and informed patient should determine whether or not life-sustaining therapy will be undertaken, while healthcare institutions and professionals should try to enhance patients' abilities to make decisions on their own behalf and to promote understanding of the available options.” In such situations, members of the hospital nutritional support team, who are often and intimately involved in a major aspect of the patient's care, may be helpful in affording insight into the patient's status and expressed position. The physician's discussion of the medical situation with patient and family, the basis for the medical recommendations, the therapeutic alternatives with their probabilities of success, and the offer of a second opinion are all essential to the decision-making process.

This commission also examined the role of traditional moral distinctions as they relate to decisions about medical care and whether they are acceptable or unacceptable. It noted

that from the viewpoint of most competent patients, decisions about alternative available courses of treatment are made on the basis of factors that include treatment benefits in terms of extension of life, the nature and quality of that life, the degree of suffering involved, and the various costs to themselves and to others (24). It noted that other criteria have been used in judging the acceptability or unacceptability of life-and-death decisions and stated (24):

these bases are traditionally presented in the form of opposing categories. Although the categories causing death—by acting versus by omitting the act; withholding versus withdrawing treatment; the intended versus the unintended but foreseeable consequences of a choice; and ordinary versus extraordinary treatment—do reflect factors that can be important in assessing the moral and legal acceptability of decisions to forego life sustaining treatment, they are inherently unclear. Worse, their invocation is often so mechanical that it neither illuminates an actual case nor provides an ethically persuasive argument.

Several of the commission's conclusions about such distinctions are relevant to the issue of nutrition and hydration and have, in fact, had a significant influence on the attitudes of physicians and the courts. For example (24):

The distinction between acting and omitting to act provides a useful rule-of-thumb by separating cases that probably deserve more scrutiny from those that are likely not to need it. Nonetheless, the mere difference between acts and omissions—which is often hard to draw in any case—never by itself determines what is morally acceptable. Rather, the acceptability of particular actions or omissions turns on other morally significant considerations, such as the balance of harms and benefits likely to be achieved, the duties owed by others to a dying person, the risks imposed on others in acting or refraining, and the certainty of outcome ... A justification that is adequate for not commencing a treatment is also sufficient for ceasing it. Moreover, erecting a higher requirement for cessation might unjustifiably discourage vigorous initial attempts to treat seriously ill patients that sometimes succeed.

The guidelines of the Hastings Center also expressed concern that the terms *ordinary* and *extraordinary* “obscure ethically important questions rather than helping to resolve them. Prevalence of a treatment or its degree of technological complexity is sometimes used to make the distinction between ‘ordinary’ and ‘extraordinary’. We reject the distinction. No treatment is intrinsically ‘ordinary’ or ‘extraordinary’. All treatments that impose undue burdens on the patient without overriding benefits or that simply provide no benefits may justifiably be withheld or withdrawn. While traditional definitions of ‘extraordinary’ hinged on this comparison of benefits and burdens, the term has become so confusing that it is no longer useful” (25).

The Law Reform Commission of Canada, an official agency for evaluating and recommending reform of Canadian federal law, issued in 1983 a series of principles and recommendations for amendments to the criminal code. These amendments suggested

changing existing laws so that they would not be interpreted as requiring a physician to initiate medical treatment against the wishes of the patient or to continue such treatments when they have become therapeutically useless and not in the best interest of the patient (26). These and related amendments have not been adopted as of early 1996 (27).

Resolving Differences between Patient and Physician

When all the stated precautions and efforts have been honored in decision making but the choice of the competent and informed patient is contrary to the judgment of the physician, where does this leave the physician? “The physician too has a set of values to which he owes allegiance. He has a double obligation, to protect those of the patient and to be faithful to his own” (19). To deal humanely with the conflicts that must occasionally arise, “the physician must know enough about his own beliefs to decide when he can compromise, when he cannot, and when he must give the patient the opportunity to transfer his care to another physician whose values more closely coincide” (20). In this situation, the President's Commission took the position that “health care professionals or institutions may decline to provide a particular option because that choice would violate their conscience or professional judgment, though in doing so they may not abandon a patient” (24). In the case of the attending physician, responsibility for the care of the patient must be transferred to another physician who accepts the patient's decision and acts accordingly. Abandonment means leaving the patient without care, a serious and punishable infraction of both the legal and ethical obligations of the physician. There has been a recent emphasis on nonabandonment “as an open-ended commitment over time” (28, 29); examples include accepting competent patient decisions on demanding or stopping artificial feeding. Objection has been raised to the apparent elevation of nonabandonment to a principle rather than considering it one of the essential derivatives of medical ethics (30).

When the patient's request is opposed by the hospital administration, the solutions open to the hospital are to yield to staff pressure on behalf of the patient, to transfer the patient to another hospital willing to accept the patient, or to yield to a court order when it supports the patient. Often in the past and continuing to some degree today, it has been the reluctance of the hospital administration to discontinue tube feeding or some other life support—usually because of fear of civil or criminal penalties or on religious grounds—that has led to legal actions by patients or family members.

Distinguishing Patient Refusal from Requests

Physicians may differentiate between the competent patient's refusal of a recommended treatment and the request for a nonrecommended treatment (31). Refusals must be honored even when the physician knows that death will result. In contrast, a physician may feel that there is no moral or legal obligation to honor a request that the physician firmly believes will have an undesirable effect or result in death. This is a matter of judgment focusing on the issue of treatments deemed useless or futile by the physicians or hospital.

Denial of Treatment as Medically Futile

Statements such as those made by the President's Commission (24) and the chief counsel for the American Medical Association (AMA) (32) supporting the physician's right to deny futile treatments have been under increasing scrutiny and criticism as being too simplistic. This area has considerable relevance to artificial nutrition, especially by the intravenous route, because of its expense, increased risk of infection, and evidence of little or no benefit in advanced disease, particularly cancer unresponsive to disease-specific therapy.

Justifications for physician refusal of futile interventions for the competent patient include (a) the specific intervention proposed has no physiologic rationale; (b) the intervention has already been tried and failed to achieve any apparent benefit; (c) maximal treatment for the underlying advanced disease is a failure; and (d) the intervention(s) will not help achieve the goal of care, is burdensome, and may worsen the quality of life (3).

With respect to nutrition, how valid are these justifications? Item (a) above is obviously questionable or incorrect in the case of intravenous feeding, because it does provide essential nutrition and hydration; (b) would not hold if nutrition has not previously been given; arguments (c) and (d) may hold true. However the challenge to statement (d) rests on the answer to the question: whose goal or value is most valid—the physician's or the patient's? If the patient wishes to continue the requested treatment—even for a limited period—to achieve his or her goal (e.g., survival and additional months to see an only child married or the first grandchild born), what is the justification for saying “nay”?

Even if the likelihood of success, in the opinion of the physician, is very small, how can one know if a particular patient will or will not respond? Furthermore, can the patient be certain that the physician is fully conversant with the medical literature on this point, or has not misinterpreted the situation, or that other physicians in the same hospital or elsewhere will be in agreement? Uncertainty and changes of therapeutic options in medicine are hardly uncommon (33, 34).

The basis of physician opinion may be that the prospective benefit for the patient does not justify the required resources. However, futility is not to be confused with resource allocation (which requires well-tested clinical data plus administrative and societal decisions for acceptability), even though they do share a common purpose (35, 36). A continuum of conditions and situations extends from those that are obviously futile, to those that produce an effect but are deemed by the physician to be of no net benefit, to those in which the physician is believed to be in error by other physicians or by the patient. In the case of the incompetent patient, the same issues about futile treatments arise in the physician-surrogate relationship.

This issue has resulted in a large number of papers, letters, editorials, and conferences in the medical and bioethics literature (e.g., 32, 33, 34, 35, 36, 37, 38, 38a, 39, 40, 41, 42, 43 and 40), to the point where the question has been posed: “Is futility a futile concept?” This is based on the argument that its proponents have not paid sufficient

attention to the problematic nature of the data supporting the use of their definitions (40).

It is not surprising that strongly held differences of opinion may arise between and among physicians, patients, families, and surrogates about treatment that arguably is futile. Collaborative procedures have been advocated or instituted to help solve such problems and settle such differences constructively, short of the courts (41, 42).

Caring for the Hunger Striker

The hunger striker “is a mentally competent person who has indicated that he/she has decided to embark on a hunger strike and has refused to take food and/or fluids for a significant interval” (43). Once the physician agrees to attend a hunger striker, that person becomes his or her patient. Guidelines of the World Medical Association (WMA) include thorough examination of the patient, daily visits, information on the clinical consequences of a hunger strike, treatment of trauma and infection, and advice on fluid intake; any treatment must have the patient's approval. “Treatment or care of the hunger striker must not be conditional upon his suspending his hunger-strike” (43). Autonomy must be respected. In Israel, however, a district judge authorized force-feeding of a political prisoner on a hunger strike (43a).

Serious moral dilemmas arise when the patient is comatose when first seen and the person's wishes are not known. In that situation, the WMA, the British Medical Association, and other medical societies hold that treatment should be initiated until resuscitation has occurred and the patient's wishes are known. In the instance of a hunger striker becoming severely confused or comatose during medical observation, “the physician shall be free to make the decisions for his patient which he considers to be in the best interest of the patient taking into account the decision he has arrived at during his preceding care of the patient” (43). The problems related to management of asylum seekers on hunger strike has been reviewed (43b, 43c).

The Patient Self-Determination Act

As a result of the recommendation of the President's Commission and other similar suggestions, federal legislation (the Patient Self-Determination Act of 1990) was enacted and became law on December 1, 1991 (44). This law applies to hospitals, nursing homes, hospices, healthcare maintenance organizations, and healthcare companies receiving Medicare and Medicaid funds. At the time of admission, enrollment, or on initiating home care, they are required to inform patients about their legal rights in that specific state and assist them in making decisions concerning their medical care and formulating advance directives. Such a directive must be in the patient's medical record, indicating whether life support has been rejected. This federal law, as well as most state laws and court decisions on this subject, also allows hospitals and nursing homes to express their administrative positions on these subjects to the patient before or at admission. One goal of the statute is to encourage (but not require) adults to complete advanced directives in the form of treatment directives, a proxy appointment, or both while they are competent. Another goal is to influence both

healthcare givers and institutions to honor advance directives.

As a result of the majority decision of the United States Supreme Court on the Cruzan case (see later) and the Patient Self-Determination Act now in force, advance directives must be based on the legal requirement of individual states. Thus, standards in the United States have been established in varying degrees for truth in prognosis (45), informed consent, and advanced care directives.

The existence of advanced care directives has stimulated a number of empirical studies. It has been noted that most patients do not execute directives in part because physicians frequently fail to discuss this issue (32) or because patients fail to see the directive when it is presumably distributed on admission (46). Even when executed, only about 39% in one study wished to have the directives observed strictly by the physician (47). In addition, a significant number of directives are either ignored or overridden by the physician; sometimes more treatment is given than requested and sometimes less (32, 48).

Attitudes toward executing directives, especially by older individuals, are significantly influenced by a number of factors including dependence on family decisions, educational and economic status, religious views, ethnic backgrounds, and national origins. For example, Korean Americans and Mexican Americans were more likely to hold a family-centered model of medical decision making, rather than the patient autonomy model favored by most African American and European American respondents (49). The great majority of Navajo informants considered advance care planning a dangerous violation of their traditional values (50). To develop the understanding of and respect for cultural differences that will help avoid inappropriately paternalistic judgments, physicians do well to seek assistance from family members and others who are knowledgeable in this area (51).

Recently, a series of survey reports introduced another view of the purpose of advanced directive and planning, namely, its intent to limit life-sustaining treatments and reduce healthcare costs. Such an approach creates the potential conflict between the original purpose of advanced directives (stimulating informed consent and patient autonomy) to that of reducing medical care (51a).

Patient Choices for Life-Sustaining Treatments

Studies have been done on the process of decision making concerning medical intervention and life support of the seriously ill and the issue of quality-of-life and its expected duration. Earlier studies used measures of physiologic competence (e.g., organ function or metabolic indices), economic or environmental factors, or overall individual performance to ascertain whether any of these factors are improved by specific therapies. More recently, efforts have been spent in obtaining information on the relative importance patients assign to the value of their lives and how it may be influenced by their therapies (52, 53). The subjective health values and ratings of 1438 seriously ill but competent patients with at least one of nine diseases with a projected overall mortality rate of 50% were compared with similar ratings obtained from the patients' surrogates and their physicians. The health values of the patients varied

greatly from one to another, but the individual patient showed excellent test-retest reliability. Their preferences for living at current health levels compared with living in excellent health correlated strongly with their preferences for care that extended life even though it was at the expense of pain and discomfort. Furthermore, their individual health values and ratings were generally higher than those postulated by their surrogates and physicians. The study concluded that when it comes to the issue of resource allocation for care, the patient is the true “expert on the values of living,” whereas the value of society is that of taxpayers or insurance premium payers who often foot the healthcare bill (54).

There are important differences in the responses of elderly individuals about the use of living wills and desire for life-sustaining treatments between those who have chosen to forgo life-sustaining treatments and those who have not indicated such a preference. Those with living wills were less likely to change their expressed wishes (14%) over a 2-year period than those without (41%) (55). During the study period, patients who had been hospitalized, had an accident, become more immobile or depressed, or had less social support showed appreciable change in the stability of choice and now wanted increased treatment. Such data indicate the need for periodic review of preferences for life-sustaining treatments.

NUTRITIONAL SUPPORT OF THE INCOMPETENT PATIENT

The major medical, ethical, and legal issues on cessation of involuntary nutritional support have involved incompetent patients. More than 30 separate state court decisions on this issue between 1983 and 1995 have been summarized (56).

There are a number of causes of incompetence, ranging from serious memory loss without other physical disability, through progressive loss of cognitive ability requiring hand feeding, to one of several forms of persistent unconsciousness. The patient in the last category requires artificial nutrition and hydration to avert starvation or dehydration. Until physicians have had sufficient time to develop a firm prognosis of the individual who is unable to take sufficient food and fluid by mouth, nutrition and hydration are indicated.

Traditionally, the right of the state to preserve the life of the incompetent patient has been manifest in the requirement for a court-appointed guardian or surrogate to act on behalf of the adult patient. In the case of minors, courts have almost always affirmed the authority of the parents or (if needed) a surrogate to make decisions.

The Persistent Vegetative State (PVS)

The Multi-Society Task Force on PVS has summarized current knowledge of this state, which it defined as a “clinical condition of complete unawareness of the self and the environment accompanied by sleep wake cycles with partial preservation of hypothalamic and brain stem autonomic functions” (57). Seven diagnostic criteria were given. Facial and reflex movements, groans, and cries may occur, and small amounts of food placed in the mouth may be swallowed (19, 57). Clinical observation, the results of

positron-emission tomographic (PET) studies, and neuropathologic examination support the belief that these patients are unaware and insensate and lack the cerebral cortical capacity to be conscious of pain (58).

When this “wakeful unconscious” state persists for a month in a patient with an acute traumatic or nontraumatic brain injury (e.g., from stroke or cardiorespiratory arrest) or with one of a number of degenerative or metabolic disorders or developmental malformations, the term *persistent vegetative state* is in order. Of 257 patients, the cumulative mortality rate at 3 years was 70%, and at 5 years, 84% (58a); survival beyond 10 years was unusual, but some lived for 30 years (19, 58). Progressive spasticity and bed rest lead to muscle atrophy and limb, hand, and foot contraction (13). The term *permanent vegetative state* is prognostic, because the outcome cannot be known with absolute accuracy. It may be used after the time lapses noted, which strongly indicate that recovery is very unlikely.

The task force noted that few patients in PVS had verified recovery of consciousness after 12 months following traumatic injury, or more than 3 months after a nontraumatic injury; the few who recovered were left with severe disability (58). A British unit specializing in neurodisability reported that 40 (41%) of 97 patients with profound brain damage admitted from 1992 to 1995 had been diagnosed by the referring physician as being in a vegetative state; of these 40, 17 (43%) were considered misdiagnosed because all but one responded in some manner to a command within 16 days of admission (59). An accompanying editorial questioned the diagnosis of vegetative state in 9 of the patients and emphasized the severity of their physical, neurologic, and cognitive states despite some responsiveness (60). The need for competent and persistent serial evaluation of all vegetative patients and use of additional evaluation techniques is emphasized (60, 60a).

The prevalence of PVS is not known because it was not a codable diagnosis until recently in ID-9-CM and elsewhere. The task force referred to estimates of PVS in the United States of 10,000 to 25,000 adults and 4,000 to 10,000 children (57).

Guidelines were published recently by a multidisciplinary group convened by the Royal College of Physicians, working on the diagnostic criteria and terminology of PVS (61). This group preferred the general term “vegetative state: to describe the condition which may be transient with recovery/or which might persist to death.” The term *continuing vegetative state* (CVS) was applied when the condition persisted for more than 4 weeks and recovery from coma became unlikely. A “permanent” state exists “when the diagnosis of irreversibility can be established with a high degree of clinical certainty.” The working group accepted the U.S. Multi-Society Task Force on PVS (52) suggestion for use of the term *permanent* for adults and children with traumatic injury of 12 months duration, and 3 months for those with nontraumatic injuries.

In contrast to incompetent adults with PVS, forgoing medically provided nutrition and hydration in children has received less discussion and legal review. The current status of this aspect has been reviewed recently (62). Nelson et al. noted that pediatricians were more likely than internists to continue artificial nutrition and hydration in PVS against parental desires, even though other life-support systems had been discontinued.

They listed three major medical categories of children for whom consider it is ethically permissible to forgo such nutrition and hydration: neurologic devastation, such as PVS from severe brain injury or anencephaly; irreversible total intestinal failure, such as total bowel necrosis or neural dysplasia; and proximate death (days or weeks) in conditions such as advanced unresponsive cancer. The issue of total intestinal failure is discussed in light of the possibility of a successful bowel transplant and the presence of other serious disease in recipient and donor. Various judicial decisions concerned with cessation of artificial feeding (in the great majority of which the courts have upheld the desire by the parents for termination) are reviewed as well as federal statutory law and state laws ([62](#)).

Forgoing nutritional support in children with severe intestinal dysfunction requires careful consideration because most of these children are not in the terminal state or in PVS. Total parenteral nutrition, despite the cost and probability of complications, has proven effective in improving and maintaining adequate nutrition and a reasonably good quality of life. Despite major intestinal loss, in a number of patients the remaining bowel can often adapt to the point that parenteral nutrition can eventually be discontinued (see [Chapter 101](#)). For those who may develop severe hepatic insufficiency, bowel transplant is an increasingly successful option ([Chapter 101](#)).

The impact of PVS on the patient's family and friends is one of distress and helplessness. Psychologic consequences of seeing the loved one remain unresponsive with increasing atrophy and contractures as weeks and months pass are exacerbated by developing monetary and social problems. As noted above, a large number of such cases have led to court decisions that have focused the attention of the public, other courts, and medical societies on biomedical and ethical issues related to the requests for withdrawal of life-sustaining treatments including withdrawal of artificial nutrition and hydration. Some instructive cases and decisions affecting adults are summarized below.

The Quinlan Case

The case of Karen Ann Quinlan was a landmark effort to discontinue life support. She was a young woman in New Jersey who was in PVS on a respirator. The state's supreme court, on a reversal of a lower court decision, made medical legal history in 1976 when, at the request of the parents and despite the opposition of the patient's physician and hospital, it ruled that the respirator could be discontinued ([63](#)). When this was done, the patient was found to be able to breathe spontaneously, and she survived for 9 years on tube feeding until she died from overwhelming infection. Withdrawal of tube feeding was not considered an option by the parents. This position reflected a view then widely held, namely, that food and hydration were not in the category of a special life-support system but rather a humanitarian action necessary for the comfort of the patient.

The Barber-Nejde Case. Another troubling judicial issue was the legal liability of physicians when nutrition was withheld from an incompetent patient who was not terminally ill and who, while competent, had not clearly indicated in writing or verbally to a reliable witness a desire not to be force fed when terminally or incurably ill. This concern is illustrated by the legal developments resulting from the medical management

of Clarence Herbert, who had suffered respiratory arrest in association with routine intestinal surgery (64, 65). Following resuscitation, he remained comatose over the following several days. On the advice of physicians that prognosis for recovery was poor and with consent of family, use of the respirator was stopped. The patient then breathed spontaneously but without change in his comatose state. Two days later, again after consultation with the family, the attending physicians ordered removal of the nasogastric tube, intravenous nutrition, and air mist. The patient died 6 days later. He had not previously executed a formal directive under the California Natural Death Act, nor had he written anything concerning his wishes in such circumstances; however, he had stated to his wife that he did not want to be kept alive by machine or “become another Karen Ann Quinlan.”

A nurse reported the actions of the physicians to local authorities, who then filed criminal charges for murder against both attending physicians, Drs. Barber and Nejde. Despite a municipal court magistrate ruling that death had resulted from brain damage secondary to anoxia and that the conduct of the physicians was not “unlawful,” the district attorney appealed the case to Los Angeles Superior Court. The murder charge was reinstated by a judge who decided that there was no legal justification for the physicians' action. The physicians then appealed to the California Court of Appeals, which dismissed the criminal charges.

The Conroy Case

Another case, occurring at the same time, further delineated the complex medicolegal issues that arise when the status of an incurably ill patient is presented to different jurists. Claire Conroy was an 84-year-old woman severely ill with advanced atherosclerosis, diabetes, and organic brain syndrome (66, 67). Although the case description stated that she was not in PVS, her described behavior approximated closely the clinical description of this state. A nephew filed a petition to authorize removal of the nasogastric feeding tube from the patient, although there was no clear evidence of what the patient would have desired. A trial judge authorized removal of the feeding tube but not cessation of any voluntary or assisted oral feeding. The decision was appealed by the institution, and pending the hearing, tube feeding was continued to the patient's death.

Despite Conroy's death, the New Jersey Appellate Court heard the appeal and reversed the earlier trial judge's decision. It held that (a) she was neither comatose nor terminally ill, (b) the feeding tube was not a particularly invasive treatment as was the respirator in the Quinlan case, and (c) if the nasogastric tube had been removed in accordance with the trial judge's decision, Mrs. Conroy would have died not as a result of her condition but from a “new and independent condition: dehydration and starvation and that this would constitute murder (euthanasia).” The case was appealed to the New Jersey Supreme Court, which sanctioned withdrawal of artificial nutrition and hydration in this type of case, but with a time constraint of expected survival of 1 year or less (66).

This final decision in the Conroy case is of special interest in the context of criteria established by judges as guidelines for decisions in terminating medical care of incompetent patients. Emanuel noted that the court laid down three standards for

terminating such care and stipulated that one of them be satisfied before treatment could be stopped (67). The court designated the first a “subjective standard,” which permits termination of treatment when an incompetent patient left clear indication, such as a living will, that he or she would have refused that treatment. It called the second a “pure objective standard,” which permits termination of life-sustaining treatment for patients if the burden of the care outweighs the benefits, although they have not left indication of their preferences about life-sustaining care. For example, administering life-sustaining care would be inhumane because it would perpetuate severe pain. Others label this the “best interests standard,” in which the patient's surrogate objectively evaluates the benefits and risks of a treatment and decides what most benefits the patient. In the Conroy Case, the court, acting as surrogate, accepted this standard. The third standard, called by the court a “limited objective standard,” is a combination of the first two and permits termination of care if there is some evidence (such as remarks made during a conversation) or opinion of the surrogate that the patient would not want the treatment and if the burden and pain of continued life outweigh the benefits; this is similar to the substituted judgment standard.

The Jobes Case

A subsequent ruling by the same court involved the case of Nancy Jobes, who was in PVS following hemorrhage (68). Her husband and parents requested that a feeding tube be removed and that she be allowed to die. The nursing home refused to honor this request. When the case was brought before the New Jersey Supreme Court, the court sanctioned removal of the feeding tube but rejected as “remote,” “general,” and “casual conversation” statements by the patient's friends and relatives that she had said in conversation that she did not wish to be dependent on a respirator. The court eliminated its previous “Conroy” criterion and instead, based its ruling on the Quinlan case, ruled that the “substituted judgment standard” exercised by the family should apply to patients in a PVS, and therefore, the feeding tube could be removed. In reviewing this case, Emanuel noted that the substituted judgment standard means, in effect, that the surrogate for an incompetent patient is put into position of attempting to make a decision for the patient as if that individual were competent; this standard thus differs from the best interest standard, which is based on an objective standard of benefits and burdens (68).

The judicial and legislative history and endorsement of decision making for incompetent patients by proxy or surrogate and their ethical justification have been briefly reviewed by Emanuel and Emanuel (69). They summarize objections to proxy making on the grounds that “proxy decision makers cannot divine or implement the incompetent patient's wishes regarding the termination of life sustaining care.” Alternative solutions are suggested, with recognition that each has limitations. While agreeing with the array of concerns about proxy decision making, Lynn, in an accompanying editorial, takes the position that “a morally justifiably and pragmatic policy for decision making for incompetent adults, at this point, will have to rely heavily on appointed and family proxies, with a morally defensible and practical plan” (70) which provides options similar to those suggested by the Coordinating Council on Life Sustaining Medical Treatment Decision-Making by the Courts (71).

AMA Statement of 1986

In the midst of these and other pertinent judicial decisions, the AMA, through its Council on Ethical and Judicial, issued in 1984 (and in revised form in 1986) statements on withholding or withdrawing life-prolonging medical treatment. The 1986 statement consists of four short paragraphs that include the following, which also relate to food and fluids (72):

In the absence of the patient's choice or an authorized proxy, the physician must act in the best interest of the patient ... For humane reasons, with informed consent, a physician may do what is medically necessary to alleviate severe pain, or cease or omit treatment to permit a terminally ill patient whose death is imminent to die. Even if death is not imminent but a patient's coma is beyond doubt irreversible and there are adequate safeguards to confirm the accuracy of the diagnosis and with the concurrence of those with responsibility for the care of the patient, it is not unethical to discontinue all means of life prolonging medical treatment. Life prolonging medical treatment includes medication and artificially or technologically supplied respiration, nutrition or hydration.

The changed physician attitudes resulting from the widespread interest and discussion of these issues is evidenced by significant differences in the 1984 and 1986 statements. For example, the first version refers only to terminally ill patients, while the later one includes those in irreversible coma; the 1984 version did not define "life prolonging medical treatment," whereas in 1986, these are specifically designated and include nutrition or hydration.

The Cruzan Case

This case was the first to involve the United States Supreme Court in the issue of discontinuance of tube feeding an incompetent patient. Like the Quinlan case, it aroused widespread public and professional interest and resulted in a decision with far-reaching implications. In January 1983, at the age of 25 years, Nancy Cruzan suffered irreversible brain damage secondary to prolonged hypoxia following an automobile accident. She was then supported in the hospital by food and fluid fed through a tube. In 1986 her parents requested discontinuance of the feedings but had to resort to legal action at the insistence of the Missouri state hospital administration. In July 1988, a trial court ruled that tube feeding could be withheld; however on appeal, the Missouri Supreme Court, by a 4 to 3 decision, reversed the trial court on the grounds that no reliable evidence was presented indicating that Cruzan would have refused artificial feeding (73).

On June 25, 1990, the United States Supreme Court affirmed the reversal by a vote of 5 to 4 (74). Five justices stated that the Constitution did not prohibit Missouri from choosing to rule as it did. Three of the four dissenting justices stated that incompetent as well as competent patients had the constitutional right to be free of unwanted medical treatment and the fourth stated that the Constitution required that the best interest of the

patient be followed. Six of the nine justices explicitly found no distinction between fluids and nutrition delivered artificially and other medical treatments; none of the other three found a constitutionally relevant distinction (74, 75). Six months later, nearly 8 years after the parents' first request, a judge in Missouri Circuit Court, in a brief order, authorized the parents as coguardians "to cause the removal of nutrition and hydration from our ward, Nancy Beth Cruzan" (76). This was done, and Cruzan died 12 days later.

While some bioethicists felt that the Supreme Court's opinion would make a constitutional right to refuse artificial nutrition more difficult to achieve in the future (77, 78), others believed that the decision had important positive aspects. These were summarized in a statement by physicians, nurses, lawyers, and bioethicists (79). The best evidence of the impact of the Supreme Court's decision was the rapid collapse of the medical, institutional, surrogate, and legal opposition in Missouri to discontinuing Cruzan's feedings. Another effect of the Cruzan decision was the speed with which many states enacted health proxy legislation (80). Problems still remained, however, because of the variability in important requirements among state laws. As a result of publicity about the Cruzan case and variability of relevant state laws, some families in similar situations have requested that physicians not start artificial feedings because they and the patient may become prisoners of technology and state law (19). This type of request presents a professional problem for physicians who are hesitant to start or to stop such treatment before the prognosis seems certain. To help resolve this dilemma, Cranford proposed that the family be assured that once a diagnosis and prognosis were established with great certainty, physicians would be willing to discontinue artificial nutrition and hydration, thus freeing the family of the fear that the patient and family would be held hostage by medical technology (19).

The problem is further complicated by family members or surrogates who, despite physicians' recommendations, insist that life-support systems be continued in patients in a PVS (e.g., cases of Wanglie [81] and of Baby K [82]). While various recommendations have been offered in an effort to increase legal support for medical decisions, in the United States, the legal outcome in a suit depends on state court decisions as they arise.

In some other countries, the highest national courts have upheld the right of physicians to withdraw lifesaving treatment in specific instances of patients in PVS. In the United Kingdom, the House of Lords made that decision on February 4, 1993, in the case of Anthony Bland, who had suffered severe brain damage in 1989 (83); the wording of this decision led the Royal College of Physicians to provide standards for decision making by physicians that will have High Court or Parliamentary approval (58).

The Irish Supreme Court by a 4 to 1 majority ruled that a gastrostomy feeding system could be withdrawn from a 45-year-old woman in "near permanent" vegetative state for 23 years and that she be allowed to die (84). In recent years, courts in New Zealand and South Africa have ruled it lawful to discontinue treating PVS patients (85).

Patients with Progressive Neurologic Deterioration

In addition to the state of severe and permanent paralysis ("locked-in syndrome")

described above in the Bouvia case) and PVS, a third syndrome, dementia, is in the category of disabling neurologic conditions with the potential for prolonged survival and the resulting issue of life-sustaining medical treatment. Dementia includes Alzheimer's disease, the most common cause in the elderly, with its variable destruction of the neocortex; multiinfarct and other vascular dementias with variable cognitive deficits (19, 23); and the variants of Creutzfeldt-Jakob disease and dementias associated with parkinsonism and progressive supranuclear palsy (85a). These disorders are characterized by gradual onset of progressive neurologic deterioration occurring over years to decades, with time to prognostic certainty usually months to years, and with suffering decreasing with increasing impairment of cortical function.

The PVS is the ultimate and terminal form of dementia as the result of complete loss of neocortical function (19, 57). An estimated 4 million patients in the United States have various stages of dementia, of whom 1.3 to 1.9 million have Alzheimer's disease (23).

The President's Commission (24), the American College of Physicians (86), the AMA (87), and other relevant organizations draw a distinction between the incompetent patient in PVS and one in a "conscious" state but with severe, irreversible, and deteriorating mental impairment. The critical difference between these states is retention until late in the disease of self-awareness, motor function, and feelings of pain and suffering (57). At what stage and on what grounds is the family or surrogate to make the decision to accept or forgo further life-sustaining treatments?

There are major differences in the judgmental criteria of various medical ethicists. One opinion is that the decision should be that which the patient when fully rational would have made, based on what Dworkin calls "critical interests" (88, 89 and 90), which is equivalent to the "substituted judgment" standard mentioned above. An opposing opinion is based on the proposition of an existing awareness on the part of the patient and the possibility that his or her interests and wishes might have changed. In this situation, the family, surrogate, and physician should attempt to understand the experiential world of the patient by observation and testing so as to better weigh the benefits and burdens of current treatment (88, 89 and 90). This is essentially the "best interest," "objective," or "benefit burden" judgment standard.

The situation changes when the patient becomes unable to eat voluntarily and swallow adequately when hand fed and has minimal consciousness. In such circumstances, some bioethicists have favored withholding nutrition and hydration (19, 68, 90). Undoubtedly, this issue will receive increasing medicolegal scrutiny as long as such conditions remain irreversible and family members or surrogates continue efforts to erase the distinction between PVS and severe dementia.

Attitudes and Beliefs Influencing Decisions

The major professional societies, most bioethicists, and many state legislatures and courts support withholding or terminating artificial feeding for the competent patient who requests it. Some states still limit parental authority or advance directives for the incompetent terminally ill patient or for children and adults in a PVS (reviewed in 62 and 93). The attitudes of physicians about artificial feeding vary. As mentioned above,

physicians may be unaware of advance directives or do not make serious efforts to obtain them or may undertreat or overtreat despite directives, and pediatricians are believed to be more reluctant than internists to discontinue feeding with PVS (62).

Long-term comparative data are not available on attitudes and behavior of large numbers of physicians concerning the issue of artificial feeding. However, some data on physician attitudes are at hand. A national survey of 169 neurologists and 150 nursing home medical directors indicated general concurrence (89%) that it was ethical to withdraw artificial nutrition and hydration from patients with PVS in an irreversible stage (94). In a survey of 32 internists familiar with tube feeding, 80% favored withdrawing tube feeding and the remaining 20% opposed it when presented with a case of a woman in PVS for 1 year who was being fed via gastrostomy (95).

A more complex study was conducted with 456 university internists presented with the issue of withdrawing life support; preferences were obtained on withdrawal of eight different life-support systems including TPN, enteral feeding, and intravenous fluids in relation to 13 attributes including cost, invasiveness, patient discomfort, rapidity of death. The order of preferences of withdrawal of specific supports was marked. Physicians were much more likely to withdraw TPN before tube feeding before intravenous fluids—the latter two being classed with artificial ventilation. Older physicians were less likely than younger ones to prefer withdrawing a number of such supports. The authors concluded that “even when physicians may have agreed that life support should be withdrawn, the choices that they make about the manner of withdrawing life support reflect other moral, social, and clinical goals” (96). A study of actual patterns in withdrawing life-support systems for dying patients indicated a stepwise retreat in forgoing different types of support until death occurred; enteral and parenteral nutrition and, finally, ventilatory support were the last to be withdrawn (97).

Patients, surrogates, and physicians may hold religious beliefs that influence their decisions on terminating artificial nutrition. Leading church figures and other theologic scholars have stated their opinions. The Archbishop of Canterbury concluded in 1977 that extending life by artificial means was distinct from euthanasia and that removal of life support was acceptable if it would be better for the patient to be allowed to die (98). The National Conference of United States Catholic Bishops in 1992 restated the Pope's earlier view that Catholics are not obliged to use extraordinary or disproportionate means when there is no hope for recovery and only the burden of care remains (99).

For Orthodox Jews, the legal ethical system known as halacha governs most aspects of daily life, including the medical ethic that the “Sanctify of life, the halachic, the imperative to preserve life, supersedes, with a few exceptions, quality-of-life-considerations” (100). Freedman states that the concept of duty and obligation rather than rights is important and that Halachic Judaism has a concept of informed consent and guidelines for individual medical decision making (14). In his review of relevant rabbinical decisions, an Orthodox Jewish theologian-ethicist has noted differing positions on artificial feeding and concludes that “the question of withholding and withdrawing artificial nutrition and hydration—tube feeding—is not clear cut in halacha” (100). His own opinion is that in geriatric patients, advance directives should be limited to withholding nutrition and hydration as opposed to withdrawing it. In

Israel, the preservation of life in the sick has been embodied in parliamentary legislation that empowers hospital ethics committees that can overrule a patient's expressed will (43a). At the same time, its Supreme Court has recognized the right of a terminally ill suffering patient to reject intrusive and uncomfortable therapy that cannot cure the basic illness (43a).

The physician and hospital must each make their positions clear to patients and surrogates concerning such end-of-life issues so that, if necessary, alternatives can be found without rancor and undue distress. It is equally important that physicians, nurses, and other members of the healthcare team “be skilled in the two essential aspects of good clinical care of dying patients—technical issues in the compassionate withdrawal of life-prolonging therapy and counseling and emotional support for patients, families, and staff during this process” (101).

Physiologic Responses to Restriction

Young, healthy, active individuals in negative water balance develop thirst, dry mouth, and headache, followed by fatigue; cognitive impairment occurs as dehydration progresses and becomes severe with abnormal electrolytes, rising blood urea, and hemoconcentration. Renal failure ensues unless water is available. In healthy elderly people, in contrast, reduced thirst may occur with water deprivation (102).

Those involved in palliative care of terminally ill patients have reported frequently that the conscious competent patient with an advancing severe illness unresponsive to therapy and in little or no pain becomes progressively weaker, with decreasing communication, increasing anorexia, decreased desire for fluids, and progressive apathy. In such patients with little intake of fluids, signs and symptoms of dehydration appear: dryness of skin and mouth, decreased urinary output, and occasional thirst. Nausea, vomiting, or cramps are reportedly rare in this situation, and the dehydrated patient rarely needs oral pharyngeal suction; this is in contrast to the hydrated patient (19, 103, 104 105 and 106). Obtundation usually progresses to a peaceful death.

There are a significant number of reports (summarized in ref. 92) that many terminally ill patients have relatively few of the changes in blood and urine chemistry that indicate clinical dehydration and that thirst is usually absent. In a brief report about terminally ill patients, no differences were noted in biochemical parameters and state of consciousness in those given intravenous fluids and those given only oral fluids (107). In their detailed study of 32 competent terminally ill cancer patients, McCann et al. concluded that “food and fluid administered beyond the specific requests of patients may play a minimal role in providing comfort to terminally ill patients”; 97% either did not experience hunger at all or only initially, 66% either did not experience thirst or only initially, and the rest were comfortable with mouth care and sips of water (108). The relationships among symptoms, laboratory evidence of dehydration, and medications were studied in 82 individuals dying of cancer in a hospice; none were given artificial fluid therapy, and the time from entry into the study to death ranged from 1 to 5 days (median, 2 days). Fifty percent had normal serum osmolalities below the upper limit of normal and a urea concentration below 11.0 mmol/L, which was not considered evidence of dehydration. The others had evidence of dehydration. There was no

statistically significant relationship between hydration status and the symptoms of dry mouth and thirst noted by about 85% of those able to respond clearly to questions. Almost all of the latter group were on medications known to cause dry mouth and/or had other causes for this condition such as mouth breathing, candidiasis, and past treatment with chemotherapeutic agents and radiotherapy (109). Such reports put into question the use of tube and orally administered fluids to the dying patient.

The common use of intravenous isotonic glucose—with or without electrolytes or vitamin additives—in this situation also seems less defensible because this prevents ketosis and inhibits some dehydration, thereby overcoming their contribution to comfort and prolonging the dying process.

In the management of such patients with the stated goal of comfort, one must also consider some of the undesirable effects of tube feeding, whether via nasal or gastrostomy tube. These include increased agitation, accidental or self-extubation often requiring restraints, and aspiration pneumonia (110, 111); in addition, leakage, diarrhea, or impaction may occur. As Cranford has stated “to a large extent limiting nutrition and hydration is more a medical than a moral issue” (19).

Management of symptoms that may arise when artificial nutrition and hydration are withheld or withdrawn is outlined in [Table 102.1](#).

Symptom	Management
Thirst (rare)	Sips of fluids (patients commonly take much less than required for physiologic volume replacement)
Dry mouth (common)	Glycerine swabs, ice chips, sips of fluid; review medication list for any that cause dry mouth
Dry mouth if aggravated by glycerine or lemon swabs)	Artificial saliva, petroleum jelly, lip balm
Mouth debris or poor hygiene	Nonalcoholic mouthwashes, dilute hydrogen peroxide
Oral inflammation	Diphenhydramine liquid, viscous lidocaine; antimonial therapy
Pain, restlessness (rare)	Morphine or benzodiazepines in titrated doses
Nausea (rare)	Antiemetic drugs

CHAPTER REFERENCES

Note: The references to judicial decisions follow the form generally used in legal writing. Following the case name, the first number refers to the volume of the reporter series for the decisional court; the reported series follows as an abbreviation, then the number of the first page of the printed judicial decision, and finally the year of the decision. For example, *Smith v Jones*, 261 F2d448 (1990) can be

found in vol. 261 of the second series of the Federal Reporter beginning on page 448.

Published court decisions are generally available to the public through state, county, or city bar association libraries or law school libraries. West Publishing Company and Mead Data Services also provide case text databases on a fee-for-service basis to libraries and law firms.

EVOLUTION OF THINKING AND UNDERSTANDING

Perceived Purposes of Standards

From ancient times man has known that health and physical well-being depend on diet and that particular foods have special virtue for curing diseases (1). More than 2000 years ago, liver was known to cure night blindness. There was, and still is, an abundance of information about diet and disease in the folklore of almost every culture. Unfortunately, in modern times in North America, that folklore continues to expand. The work of Lind (1753) was a milestone for human nutrition for it is perhaps one of the earliest recognized applications of the methods of science to the claims of folklore. Lind, with his now-famous treatise (2), established the relationship between diet and scurvy, validating what had been folklore. The first “dietary standard” given any sort of official status was created in 1862 at the request of the British Privy Council (3). That standard was intended “to prevent starvation diseases” and was to serve the purpose of evaluating estimated intakes in the first dietary surveys conducted in Britain shortly thereafter. [Table 103.1](#) provides a brief summary of some markers of the changes in

perceived purposes of dietary standards.

Year	Organization	Stated Purpose of Standard
1924	USDA	To prevent disease
1942	USDA	To prevent disease through the provision of a dietary standard
1943	USDA	To provide information on the nutrition of a dietary standard
1944	USDA	To provide information on the nutrition of a dietary standard

Table 103.1 Changing Purposes of Dietary Standards—Some Markers

Since these early works, much has changed, slowly at first and then with ever-increasing speed. Today that speed is feverish. Even as this chapter is being written, it is being superseded by events. The changes have been in many areas. First, our knowledge concerning the diverse functions of nutrients has increased phenomenally. However, this rapid progress has not necessarily improved our ability to estimate human nutrient needs; rather, it has fostered an evolving concept of what we hope to achieve (the markers of “inadequacy” are changing). Change is also evident in shifts in the type of evidence used in attempts to estimate human needs. The earliest requirement estimates were based on epidemiologic observation—the intakes of healthy versus sick people. Gradually this gave way to experimental approaches seen as more respectable—balance studies, planned deprivation and repletion studies, and theoretical modeling based on experimentally established functions of nutrients. It was soon recognized that estimates based on experiments conducted under controlled conditions had to be confirmed under field conditions; thus, epidemiologic evidence came back into its own.

We have now gone full circle and are starting again. Epidemiologic evidence currently suggests relationships between consumption of certain types of foods and some forms of cancer, cardiovascular disease, and other noncommunicable chronic diseases. Unfortunately, although the dietary associations seem clear, identifying the active factors in the foods is not clear. For that reason, attempts to develop estimates of human needs for fat, specific fatty acids, carotenoids, tocopherols, ascorbic acid, and “antioxidant substances,” and to incorporate this knowledge into public health policy has faced many difficulties and much controversy. It is not necessarily that we know too little; perhaps we know too much. Yet we cannot seem to put all the pieces together into a coherent whole (for discussion of these issues, see Garza et al. [17]).

Another phenomenal and highly problematic evolution, particularly since World War II,

has been in the scope and sheer divergence of applications of the recommended dietary allowances (RDAs). A few years ago, the Food and Nutrition Board (FNB) established a committee to identify and catalogue the then-current uses of the RDAs. The 1983 report of that committee was never published, though a summary of the findings was included in the FNB 1994 report (18) "How Should the Recommended Dietary Allowances be Revised?" That summary (reproduced verbatim as Table 103.2) did not imply endorsement by the FNB of these uses and, as stated, they certainly are not all endorsed by the present author. What is not apparent from the table is that many of these applications have been given a legal dimension by being incorporated into regulations issued by federal and state bodies. This has further complicated a tangled situation. For example, the Food and Drug Administration (FDA) established the U.S. recommended *daily* allowances, derived from the 1968 recommended *dietary* allowances, as a reference point for food labeling. Numerically and conceptually these two sets of numbers are very different, although they were, at one time, related. The most confusing aspect is that the abbreviation *RDA* applies to both. In fact the name used by the FDA is identical to the name used in the first FNB report on RDAs (19).

Table 103.2 Reported Uses of the RDAs

With the growth of scientific knowledge about the function of nutrients as well as about factors likely to affect requirements, inevitable pressure developed to alter the criteria of adequacy, the specification of "requirement for what?" The nutrition community adopted the vague and unmeasurable goal of establishing "optimal intake." The North American public has monumental expectations of the relationship between diet and all aspects of their health and well being. Although these expectations may be unrealistic, they are now a part of the climate (and folklore?) in which the nutritional scientist must work. This phenomenal belief in the power of nutrients has led to massive growth in the use of nutritional supplements and pressure to allow health claims for dietary supplements (20). As criteria of adequacy shifted, requirement estimates tended to increase. In some cases, as the base of knowledge increased, requirement estimates actually decreased, either because previously accepted evidence was found inappropriate or incorrectly interpreted or because committees felt comfortable in lowering the "margin of safety,"

sometimes called the “margin of doubt.”

Another rapidly evolving feature of the estimation, description, and application of human nutrient requirement estimates is the use of statistical concepts. The need to address the distribution of both requirements and intakes has been progressively realized. When assembling evidence to estimate human requirements, one must be aware of exactly what each type of evidence actually estimates. It could be the average of individual requirements for a class of individuals; it could be the required concentration of nutrient in a diet consumed ad libitum by subjects in an experimental study; it could be a necessary group mean intake in an epidemiologic study. These estimates are not the same conceptually or numerically. Nevertheless, they can all be related by proper application of statistical concepts concerning univariate and bivariate (joint) distributions of intakes and requirements. In parallel, given the appropriate construct and the relevant information, one can move from estimating human nutrient requirements to specifying the necessary concentration of nutrients in the diet or to estimating necessary group mean intakes.

Only relatively recently (in the last 20–25 years) has there been a real effort to merge the evolving biologic and statistical knowledge bases concerning estimation and application of human nutrient requirements. Most experimental scientists and even many epidemiologists, consider statistics a tool used to test hypotheses about effects or associations, which it is. Statistics can also be used to understand and describe relationships; in the past this has received too little recognition. The Food and Agriculture (FAO)/World Health Organization (WHO) series of reports on nutrient requirements, and the report of the eighth Joint Expert Committee on Nutrition (21) chronicle the progressive integration of statistical concepts into the estimation, description, and application of nutrient requirement estimates. Specifically, one can follow the attempts to describe and work with distributions of nutrient requirements and gradually see conceptual development of approaches to concurrently dealing with distributions of requirements and of intakes. At first this involved assessing the apparent adequacy of diets in population groups. Gradually, merging of nutrition and statistics led to estimation of necessary nutrient:energy ratios and, in 1996, to estimation of necessary group mean intakes (16).

In 1945, when Canadian and U.S. committees charged with developing a Dietary Standard and Recommended Dietary Allowances, respectively, disagreed and went their own ways, a major issue was the stated goal and suggested interpretation of the 1945 revision of the U.S. RDAs (22):

The allowances are intended to serve as a guide for planning an adequate diet *for every normal person* of the population and not for the average member of the group categories . . . In order to meet the needs of the whole population it is necessary to satisfy the requirements of those with less efficient usage. Because the allowances take into consideration the requirements of those at the upper level of the normal range of requirements, they allow a factor of safety for persons who have an average or less than average requirement. In most categories this factor of safety is approximately 30%, but for many persons the allowances cover only the amounts needed for maintenance . . . When the tables are used to estimate the per capita needs of population groups and the agricultural production required to supply such groups, the allowances should be weighted by the composition of the population according to the categories and ages. When the allowances are weighted in this manner the average allowance for each individual [the per capita allowance] is lower than that for a man for all factors except calcium. . . . Even when weighted in this manner, the allowances are greater than the average or the mode of the need for many factors because the allowances are planned to be sufficiently high to meet the needs of normal

persons who are less efficient in utilization.

The apparent disagreement between Canadian and U.S. committees at that time appeared to relate more to a difference in philosophy and approach than to any real difference in scientific judgment. In the United States, strong emphasis was placed on the individual and ensuring adequacy for every individual. In Canada, greater emphasis was and, until relatively recently, continued to be, placed on the group or population. Parallel differences between U.S. and Canadian perspectives and approaches can be seen in aspects of their respective healthcare systems and, for example, approaches to asymptomatic hypercholesterolemia screening (favored in the U.S. and opposed, except for high-risk individuals, in Canada). The open debate appears to have centered on how the U.S. RDAs were to be applied to population groups. Both Canada and the U.S. accepted the reality of variation in need among individuals, but the Canadian group felt that a more realistic estimate of needs could be developed if factors believed to affect requirement (and hence explaining part of the variation among individuals) were built into the dietary standard (13). Unfortunately, that Canadian report (13) described the figures as representing a “nutritional floor beneath which maintenance of health in people cannot be assumed.” That phraseology generated major reaction and for years split the two communities. Had the report, instead, said that the numbers “indicate a nutritional floor above which maintenance of health [with reference to the tabulated nutrients] could be assumed,” the debate might have been much less acrimonious, and harmonization of standards might have followed many years ago instead of still being discussed today.

What is interesting and important is that, by 1945, the major issues that have plagued the development, interpretation, and application of the RDAs were already on the table. A paper written in that era captures the crux of one of the major issues—the need to marry statistical and biologic concepts. In 1945 Pett et al. (23) noted four basic uses of dietary and nutritional standards:

- i. for use in calculating the nutrient requirements of a population in connection with a national food and nutrition policy for health.
- ii. for use in evaluating the dietary status of a group of people from the total and average quantities of foods eaten, or providing foods for such a group.
- iii. for use in establishing regulations under the Foods and Drugs Act [a Canadian Act] governing the contents of foods, dietary supplements or drugs and of allowable claims for them.
- iv. for use in evaluating the dietary status of an individual person from the foods eaten, or from the foods purchased.

The authors commented (13) (absolutely correctly), “it is not likely that a single set of figures in a table could be used properly for all these purposes . . . Nevertheless it is possible to marshal information about requirements in a manner that forms a uniform basis for various calculations suited to different purposes . . . It is thus apparent that the problem of arranging and interpreting figures for human requirements is basically statistical.” The paper went on to speak of “the probability of the individual's suffering from a serious deficiency or from a suboptimal state of nutrition” and “the likelihood of finding specific medical signs in any particular individual.” They pointed out that “Medical evidence is necessary before the story is known about any individual. However, if the

[intake and requirement] curves are properly determined it would indeed be possible and correct to estimate the proportions of the population receiving an insufficient amount of any nutrient.” Those authors had the elements of the puzzle in hand and mapped out a solution. However, at the time, the story fell on “stony ground” (L.B. Pett, personal communication, 1989), and there was little or no follow-up.

It has taken the rest of us 50 years to reach the insights expressed in that paper. We are finally there, this time equipped with more complete scientific knowledge and statistical concepts and tools that are more widely accepted and applied. We still have a long road to follow before the nutrition community and other users of the RDA reports are ready to use the new insights and new techniques they bring. The FNB (18) has indicated that in the current revision of the RDAs, under way as this chapter is being written, the board will direct major effort to developing a guidelines report relating to interpretation and application of whatever Dietary Reference Intakes (DRIs) or RDAs it chooses to publish. Perhaps the dream of Pett and his colleagues will finally be realized. Perhaps also we will see a much greater willingness to harmonize nutrient requirement reports around the world. It is amazing that in an international community of knowledgeable scientists, misunderstandings rather than true scientific disagreements have persisted for so long.

This chapter attempts to document and illustrate some of the major evolutions mentioned above. In so doing, the author hopes that the reader will recognize that while new concepts and approaches at first seem complicated and nonintuitive, the benefits of understanding and applying them correctly are great, and before long they become the accepted norm, and old approaches are forgotten.

Scientific Basis of Estimated Human Nutrient Requirements and RDAs

In the 8th edition of this book, Harper (24), who formerly chaired an FNB/RDA committee, reviewed the progressive increase in the scope and scientific security of estimates of human nutrient requirements. In [Table 103.1](#), the first report cited (Lind, 1753), concerned only one food factor, and its chemical identity was unknown. When Smith (3) prepared his report for the British Privy Council, human needs were described in terms of energy, carbon, and nitrogen. von Voit (5) believed that a complete diet was supplied by protein, fat, and carbohydrate, reflecting the advances in chemistry and proximate analyses. Much later, classical nutritional science began exploring and identifying the “accessory food factors,” which included first the essential minerals and then the vitamins. This began the era of true experimental nutrition that characterized the mid-20th century. Much of this work was initially conducted in small animals, then confirmed in humans. Some was initially based on observation of now-classic deficiency diseases in farm animals.

In its 1943 report on recommended dietary allowances (12), the FNB commented: “The difficulty [in establishing goals for good nutrition and a yardstick to measure progress toward these goals] lies in the lack of sufficient experimental evidence on which to estimate requirements for various nutrients with any great degree of accuracy. Judgments as to requirements are necessarily based on incomplete and often conflicting reports of research and clinical observations and from data derived from work

on animals. Experiments with the various vitamins also differ with regard to procedure and interpretation. These variables explain the wide divergence in 'requirements' as set forth in current literature in nutrition".

Earlier, the National Research Council's (NRC) Committee on Food and Nutrition arranged for a critical appraisal of the literature on each of the recognized dietary essentials, formulated tentative allowances, subjected them to review by the original contributors, and then presented them for comment and criticism to the larger community of nutrition scientists. A final, slightly revised version was adopted in May 1941 (11, 19). The report addressed allowances for energy, protein, two minerals (calcium and iron), and six vitamins (vitamin A, thiamin, riboflavin, niacin, ascorbic acid, and vitamin D), a total of 10 nutritional variables. The tabulated allowances were related to 12 age/sex/physiologic state categories, and for adults, three levels of physical activity were considered. In the 10th revision of the RDAs (25), the tables present numeric estimates of RDAs "designed for the maintenance of good nutrition in practically all healthy people in the United States" for energy, protein, four fat-soluble vitamins, seven water-soluble vitamins, and seven minerals. In addition, "Safe and Adequate Daily Dietary Intakes" were offered for two vitamins and five trace elements. The text of the report also addressed needs for nine amino acids, dietary guidelines for fat and cholesterol, the function and role of linoleic, linolenic, and arachidonic acids, dietary guidelines for carbohydrate and fiber, and needs for water and three electrolytes, a total of at least 45 nutritional variables. The age/sex/physiologic state categories had grown to 16, and energy needs were exemplified (for adults) by five categories of activity. This is an amazing change in only 48 years!

By 1989, the science base supporting estimated human nutrient requirements was clearly becoming very strong. This did not mean an end to disagreements on judgments about how *dietary allowances* should relate to *nutrient requirement estimates* or about what information justified changes in allowances from one revision of the RDAs to the next; such controversy was a prominent feature of the 10th revision. The 1989 report (25) also directed major attention to possible upper limits of desirable or safe intakes. In the revision of the RDAs now under way, the FNB has established a special subcommittee to look explicitly at safe or desirable upper limits of nutrient intakes, since this has become important both in establishing fortification guidelines and policies and in considering the safety of the ever-increasing use of minimally controlled, and often high-potency, pharmaceutical supplements and food extracts and concentrates. Historically, the greatest demand for knowledge related to preventing inadequate intake; today, in North America, the demand for knowledge is increasingly directed toward safe upper limits of intake, whether of macronutrients such as fat or of vitamin and mineral micronutrients (18). What the 1941 RDA report said about nutrient requirements might today be said about nutrient excesses. It is to be hoped that we will see an equally encouraging growth of knowledge in this area. Perhaps not too long after the turn of the century we will finally be able to describe safe and suitable ranges of nutrient intakes, will have dropped the search for the nebulous "optimal intake," and indeed may be able, with good evidence, to restore the public's faith that one can obtain "good nutrition" from reasonable and acceptable dietary practices—certainly a goal well worth achieving.

The above discussion has centered on the increasing volume and quality of evidence and the evolution of focal issues. However, the scope of evidence brought to bear in the

final estimation process has also changed. We no longer rely on isolated pieces of information about a specific nutrient. Rather, we look for congruence of information arising from several lines of evidence. That congruence ([Fig. 103.1](#)) gives confidence to our judgments.

Figure 103.1. Nutrient requirements and recommended intakes are based on multiple types of evidence. Congruence of lines of evidence gives confidence in the estimates. However, such a blending and synthesis of evidence is feasible only when there is an understanding of the function and use of the nutrient and a coherent theoretical construct for integration that has strong statistical components. (From Beaton GH. *J Nutr* 1996;126:2320S–8S, with permission.)

Terminology and Concepts

As successive committees in different countries have attempted to deal with evolving concepts, they have often changed terminology in hopes of persuading users to check their text to see the intended meaning. The changed terminology has not necessarily added clarity. For many years, the term *recommended intake* was applied to what in the United States has been called *recommended dietary allowance*, even within the RDA reports. Recently, there has been growing disavowal that the tabulated numbers are actually “recommended” as intakes for all citizens.

Conceptual Development

In its 1969 report, the U.K. Panel on Recommended Allowances of Nutrients ([26](#)) again identified and described very clearly the conceptual issue that was then emerging for many committees; in essence, the same issue raised by Pett et al. ([23](#)) a quarter century earlier. The U.K. report states:

For nutrients, distributions of intake may be quite unrelated to distributions of need. The recommended intakes, which are judged to be sufficient for practically all individual members of population, must of necessity be in excess of the requirements of most of them. If an individual is taking more than the recommended intake, he is almost certainly obtaining more than he requires; but if the average intake of a group is greater than the recommendation,

one cannot be sure that there is no malnutrition because of uncertainty about the distribution of intakes within the group. Equally, it is not legitimate to deduce the presence of malnutrition in a population merely on the basis of a survey in which the average intake of nutrient is less than the recommendation. But malnutrition is more likely to be present the further average intake falls below the recommendations.

That paragraph touched upon three distinct issues, each of which has been addressed in the 25 years since it was written:

1. Almost all committees have addressed requirements of *individuals*, not populations. The numeric recommendations relate to usual intakes of individuals. Terminology changes were intended to better reflect actual meanings, not to mark conceptual shifts. An FAO/WHO committee (27) had already followed that route, encouraging others to rethink the nomenclature.
2. Since one can only estimate the precise requirements of a particular individual by intensive study, the published requirement estimates can be applied to a particular person only on a probability basis, and observed intake can only be assessed on a probability or risk basis. This was finally examined in detail in a seminal report issued by an FNB committee in 1986. That report (28) merged biologic and statistical concepts and fostered development of theory-grounded approaches to resolution of issues that had fomented for nearly 50 years.
3. Setting guidelines for population mean intakes requires considering the distribution of both requirements and usual intakes among individuals. This issue was identified earlier by the Joint FAO/WHO Committee on Nutrition in its eighth report (21). Procedures have since been developed and were applied in a 1996 FAO/WHO/International Atomic Energy Agency (IAEA) report on trace elements (16).

Terminology Shifts

In 1973, an FAO/WHO committee (27) dealing with protein and energy requirements expressed concern that its recommendations for protein intake were well *below* usual intakes and noted that it did not intend to *recommend lowering* intakes to these levels. That committee abandoned use of the term *recommended intake* and adopted the term *safe level of protein intake*, which elicited strong objection from those concerned with food safety from the perspective of toxicity rather than inadequacy. A Canadian committee used a terminology shift to address another issue that had gained prominence in assessment of nutrient intakes. It had been the practice in Canada to publish “Recommended Daily Nutrient Intakes” (RDNIs), but these were being taken too literally, as an intake to be achieved *each* day rather than persisting over time, as intended. In 1983, the name was changed to *Recommended Nutrient Intake (RNI)* (29) (see Appendix [Table II-A-3](#)). In 1989, the United States dropped the word *daily*, which had been introduced in the 1953 revision of the RDAs (see Appendix [Table II-A-2-b](#)). Between those editions, the summary tables carried the heading “Recommended Daily Dietary Allowance,” itself a revision from the much earlier “Recommended Daily Allowance” (19), a term that is identical with the current U.S. recommended daily allowance used by the FDA. Another change, reflecting new British terminology, has been proposed for the RDA revisions in progress (18) (see Appendix [Table A-3-a](#)).

Perhaps the most heretical shift in terminology was introduced in the United Kingdom in

1991. The U.K. committee (30) abolished the use of “recommended” as part of the name and adopted instead the concept and terminology of reference values. It went a step further and formally incorporated the probability concept. In the U.K. approach (30), the “Reference Nutrient Intake” (RNI) represents the upper tail of the nutrient requirement distribution “that is enough for almost every individual, even someone who has high needs for the nutrient. This level of intake is, therefore, considerably higher than most people *need*. If individuals are consuming the RNI of a nutrient, they are most unlikely to be deficient in that nutrient.” The British group then defined a “Lower Reference Nutrient Intake” (LRNI), representing the lower tail of the requirement distribution, as “the amount of the nutrient that is enough for only a small number of people with *low* needs. Most people will need more than the LRNI if they are to eat enough. If individuals are habitually eating less than the LRNI they will almost certainly be deficient.” The report also defined the “Estimated Average Requirement” (EAR), noting that “clearly many people will need more than the EAR and many people will need less.” Unfortunately, as discussed below, the U.K. committee did not probe deeply enough into how these reference values should relate to groups rather than individuals. In that regard, they shared the shortcomings of U.S. (25) and Canadian (31) reports.

The reader must recognize that these name changes have no direct bearing on the scientific basis of nutrient requirements estimates. The choice of points on the distribution of requirements reflects judgments about desirable levels of intake *for a randomly chosen individual whose true requirement is unknown* and about how best to incorporate the concept of a distribution of requirements among seemingly similar individuals.

The U.S. (25) and U.K. (30) committees accepted the scientific basis of the estimation of human adult protein requirements presented by the earlier FAO/WHO/United Nations University (UNU) committee (32). The most recent Canadian committee (31) found it necessary to make some adjustments in the FAO/WHO/UNU approach (32) and also adjusted for the estimated quality of Canadian diets. [Figure 103.2](#) portrays the estimated distributions of adult protein requirements, expressed per kilogram body weight, and the points on the distributions singled out by the respective committees; the nomenclature used is shown. All of the names (except the British LRNI and EAR) are based upon the same scientific (evidence and are clearly supposed to carry identical conceptual meanings in the eyes of the parent committees. In choosing names, each committee was attempting to address either what it saw as a particular application of the numbers or a frequent misuse of previous reports (the stated purpose of the U.K. change [30]). If one were to consider something other than protein, there might be some major differences among the committees, relating more to judgments than to science. None of the committees is entirely consistent in its approach across nutrients.

Figure 103.2. Existing descriptions of adult protein requirements and recommendations. The figure shows the estimated distributions of requirement per kilogram (identical for FAO/WHO/UNU, the U.S., and the U.K. but slightly different for Canada) and the levels singled out for tabulation in the respective reports. In spite of differences in names, the “Safe Level of Intake,” “Recommended Dietary Allowance,” “Recommended Nutrient Intake,” and “Reference Nutrient Intake” have identical conceptual meanings.

Further, there is an unfortunate similarity of names with very different intended meanings. The U.K. committee (30) decided to use “Safe Intake” to indicate that there was not enough information to estimate requirements (the term is unhappily close to the “Safe Level of Intake” applied by FAO/WHO committees (27, 40) to describe well-grounded requirement estimates. In the U.K. report, “a Safe Intake is one which is judged to be adequate for almost everyone’s needs but not so large as to cause undesirable effects.” The U.S. committee (25) chose a different term for the same sort of situation; it refers to “Safe and Adequate Daily Dietary Intakes,” often expressed as a range. The notes make it clear that this is intended to be treated as a safe range of intake and that chronic intake above this range should be avoided. FAO/WHO/UNU presented a conceptual framework for a “safe range of protein intakes” referred to the individual but did not provide estimates of the upper limit of the safe range. It appears that the current U.S. committee may attempt to define such a range or at least to present estimates of safe upper limits to intakes (18); a separate subcommittee was established to address this.

Other Modes of Expression of Requirements

For some purposes, it may be desirable to consider protein:energy ratios, a diet quality measure, rather than absolute protein intakes. Many uses for such ratios have been proposed, but there has not always been consistency about how the reference value (i.e., a level “adequate” or “safe” for almost all individuals) should be computed (32). Two requirement distributions must be estimated and combined in a joint distribution of nutrient and energy requirements. The FAO/WHO/UNU report (32) presents a mathematical probability-based formula (developed by committee member Will Rand, a statistician) for computing the “safe protein:energy ratio.” There is a distribution of

required P:E ratios, and the safe ratio is a point in the upper tail of that distribution (a conceptual parallel to the portrayals in [Fig. 103.2](#)). Since many have difficulty internalizing the equation presented in the FAO/WHO/UNU report ([32](#)), an empirical example of computation of the distribution of P:E ratios is presented below.

The 1994 phase of the most recent U.S. Department of Agriculture (USDA) survey ([33](#)) reported the body weights of 2269 adults. For each of these subjects, an energy requirement was computed as a random member of the distribution of requirements for persons of that age, sex, and weight as described in the 1989 revision of the U.S. RDAs ([25](#)). This required computing an average basal metabolic rate (BMR) for a person of the specified age, weight, and sex, using the FAO/WHO/UNU prediction equations ([32](#)). The estimated BMR was multiplied by the activity factors specified in the U.S. report ([25](#)) (between 1.55 and 1.67 depending on age and sex). To this was added a random normal deviate with SD equal to 440 kcal for women and 580 kcal for men (variabilities taken from the U.S. report [[25](#)]). These estimates of daily energy need were then converted to kilocalories per kilogram by dividing by weight, yielding

Simulated energy requirements:

Adult males ($n = 1145$) 37.15 ± 7.93 kcal/kg/day

Adult women ($n = 1124$) 33.32 ± 7.87 kcal/kg/day

In the case of protein, the simulation was simpler. For each subject, a protein requirement was generated as 0.6 plus a random normal deviate, with SD equal to 0.075. The resultant distributions were

Simulated protein requirements:

Adult males ($n = 1145$) 0.60 ± 0.075 g/kg/day

Adult women ($n = 1124$) 0.60 ± 0.076 g/kg/day

In this simulation, each of the 2269 adult subjects was assigned an energy requirement and a protein requirement. The plot of the joint distribution of these requirements is shown in the upper panel of [Figure 103.3](#). To convert this into the distribution of P:E ratios, the protein requirement was multiplied by 4 kcal/g, divided by the energy requirement, and then multiplied by 100 to express the ratio as the more familiar term, protein energy as a percentage of total energy need. The derived distributions are portrayed in the lower panel of [Fig 103.3](#). Mean values plus SD

Figure 103.3. Derivation of required protein:energy ratios. The *upper panel* displays a simulation of the joint distribution of protein and energy requirements for 2269 U.S. adults, assuming that energy and protein requirements per unit body weight are essentially independent (low correlation) and that energy and protein requirements were correctly estimated and described in the most recent U.S. RDA report (25). The *lower panel* simply converts the joint distribution to a univariate distribution of the ratio of protein:energy requirements, expressed in the familiar form of protein as % energy. The 95th centile of that distribution is identified as the likely RDA recommended under existing practices. Note that both panels refer to the needs of individuals.

Simulated distribution of required P:E ratios

Adult men ($n = 1145$) 6.78 ± 1.78 % energy as protein

Adult women ($n = 1124$) 7.68 ± 2.39 % energy as protein

The distribution of the ratios is skewed. In this situation one might set the equivalent of the RDA as the level that meets or exceeds the expected needs of 95% of individuals (the 95th centile of the distribution). For men, for women, and for the two sexes combined, the 95th centile is about 11% energy as protein.

The point of this exercise is simply to illustrate that for special purposes, other modes of estimating and describing requirements can be applied. Because the derived requirements expressed a new way still constitute a distribution, it is still necessary to establish how best to apply the distribution to the purpose at hand.

ESTIMATING AND DESCRIBING GROUP NEEDS

Most of the above discussion has related to estimation and description of the requirements of individuals. However, as noted, confusion and controversy exist about how the numbers should be related to large groups or whole populations. The most common suggestion is that the mean (or median) intake of a group of persons of one

sex and about the same age should approximate the RDA or RNI. For groups heterogeneous with regard to sex, age, or other variables affecting the requirement, it has been suggested that the demographically weighted average of the RDAs or RNIs should serve as a reference for comparison of the observed or planned mean intake. Although these approaches are specifically suggested or implied in several recent national reports, they are scientifically flawed approaches as illustrated below.

Homogeneous Groups

Consider first the simpler case of a homogeneous group (e.g., young adult men). The task is to estimate the average protein intake to offer the group (e.g., in an institutional setting). In the 1994 round of the USDA Continuing Survey of Food Intake by Individuals (CSFII) (34), the distribution of estimated usual protein intakes (35) is associated with an expected prevalence of about 1% of individuals with usual intakes below their actual (but unknown) requirements, as estimated by the probability approach (28) (top panels, Fig. 103.4). Almost all those interested in public nutrition and certainly health planners would consider this acceptable. However, the estimated requirement distribution has a mean of $0.6 \pm \text{SD } 0.075 \text{ g/kg/day}$, and this distribution is taken as Gaussian. In contrast, the estimated intake distribution has a mean of 1.39, a median of 1.34, and an SD of 0.42 g/kg/day . That is, the mean and median intakes are *well above the RDA* of 0.75 g/kg/day .

Figure 103.4. Illustration of the relationship among requirement distributions, intake distributions, and numbers of individuals with intakes below their own requirement (protein used as the example). Figures on the *left* present frequency distributions and the estimated prevalence of inadequate intakes (probability assessment [28]); those on the *right* portray simulated joint distributions and counts of individuals with intakes below their requirements. The two sets of prevalence estimates are very close but not identical. *Top panels* portray the apparent current situation in the United States. In the *next panel*, the intake distribution has been shifted slightly so that inadequate intakes have been virtually eliminated. The *bottom panel* portrays the erroneous advice offered for many decades, namely, that the mean or median intake should approximate the RDA (here, median intake = RDA). Clearly this is not a satisfactory or desirable situation for the group; existing advice must be wrong.

According to the principle that characterized the early RDA reports and is said to still hold for nutrient RDA figures, each individual should be at low risk of having an intake below his or her actual requirement. Thus, many users of the RDA report, particularly those involved in one-on-one dietary counseling, seem to feel that the goal is to have *every individual* achieve an intake at or above the RDA. To establish this condition, the intake distribution would be shifted upward until there is very little, if any, overlap between the distributions of intakes and requirements (middle panels of [Fig. 103.4](#)) (intake distribution: mean, 1.53; median, 1.48; SD, 0.42 g/kg/day). Here the expected prevalence of inadequate intakes is only 0.1%.

A moment's consideration, however, reveals that this is very wasteful. Almost all individuals would have protein intakes that greatly exceed their actual requirements. *The 1986 FNB report (28) shows that the proportion of intakes falling below the average requirement gives a good empirical estimate of the proportion of individuals expected to have intakes below their own true (but unknown) requirements.* (The empirical observation has been supported on theoretical grounds by A. Carriquiry and colleagues at Iowa State University in a presentation to the FNB, 1995). This approach does not identify the individuals with inadequate intakes, only the proportion or expected prevalence of inadequate intakes in the group. If covering all but 2.5% is taken as satisfactory (the arbitrary value adopted when looking at individual needs and setting an RDA), the required group mean or median intake is defined by positioning the intake distribution so that the 2.5 centile approximates the average protein requirement. If the intake distribution is approximately Gaussian, the satisfactory group mean intake would be *mean requirement plus 2 SD of intake*. In the examples at hand, that might suggest 1.44 g/kg/day ($0.6 + 2 \times 0.42$) as a group mean intake target. In fact, because of the skewed distribution, this is a bit higher than necessary, but in the absence of detailed knowledge of the actual usual intake distribution, it remains a useful approximation.

In contrast, the recommendation offered frequently in national reports and formerly in FAO/WHO reports was that “the group mean intake should approximate the RDA.” This situation is illustrated in the bottom panels of [Figure 103.4](#). The median intake has been set equal to the RDA, 0.75 g/kg/day, the generated mean intake is 0.80 with an SD of 0.42 g/kg/day. Here the estimated prevalence of individuals with intakes below their actual requirements is 33.4%. This situation is vastly different from the assumption made by the authors of the recommendation. *The common advice that the group mean intake should approximate the RDA is seriously flawed.* As Pett et al. (23) pointed out 50 years ago, no single number published in a table can possibly serve both applications.

The illustrations in [Figure 103.4](#) contain no assumption about normality of the distribution of usual intakes. The top panel represents an estimate of the existing situation in young adult males. The intake distribution has been adjusted using the Iowa State University (ISU) methodology (35) to reduce the effect of day-to-day variation on the apparent distribution of usual intakes. This distribution was then shifted by addition or subtraction of constants to generate the examples shown in the other panels. In [Figure 103.4](#), the panels on the left side portray frequency distribution curves (intake

and requirement). The panels on the right portray simulated joint distributions of intakes and requirements under the assumption that protein intake and protein requirement per unit body size, are essentially unrelated (very low correlation).

There is no excuse for continuing to misinterpret and misuse the RDAs, *when they have been based on estimates of actual requirements*. However, the arguments presented within specific sections of the reports indicate that for some nutrients, the published numbers refer to group mean intakes not intakes of individuals; individual requirements were not estimated (Beaton, unpublished report to the FNB, 1995). That is the case for the early FAO/WHO group that examined calcium requirements and proposed “Suggested Practical Allowances” (36). These practical allowances were ranges of group mean intakes deemed appropriate for four different age groups. The Canadian RNI for calcium is explicitly described as related to the group mean intake (31, 33). Of course, for energy, all reports worldwide seem to be in agreement that the published numbers refer to group mean intakes or expenditures of adequately nourished groups (also assuming that for energy, and for energy alone, there is high correlation between chronic intake and chronic expenditure or requirement such that energy balance is closely approximated on a chronic basis).

Heterogeneous Populations

Just as there has been monumental confusion about applying the RDAs to individuals versus applying them to groups, there is an even more serious potential for misunderstanding and major error in applying requirement estimates and RDAs to heterogeneous groups (males and females, adults and children, etc).

It had been common practice to estimate population per capita nutritional needs as a weighted average of the recommended intakes (RDAs). This approach came from approaches developed for estimating per capita energy needs. Although commonly applied during the past 50 years, such an approach for nutrients (but not for energy) is seriously flawed. The limitation was pointed out in the applied section of the FAO/WHO report on iron requirements (37). That report acknowledged the then-conventional approach to estimating population needs but noted that “studies in many countries . . . have shown that although national per capita intake of iron is usually above the average national recommended allowance, iron deficiency often remains an important public health problem.” As the report pointed out, the reason for this apparent contradiction lies in the great disparity between the iron requirements of men and women. In practice, iron intakes are likely to be distributed within households in roughly the same manner as the total supply of calories is distributed. In most populations, women probably receive less iron than men, since they eat less food. Requirements for iron are unaffected by caloric intakes. Thus, even though the per capita supply of iron may seem adequate, individuals with high iron needs (women) can be expected to have lower intakes than men, who have low requirements. Iron deficiency continues to be a prominent problem in certain population groups.

[Table 103.3](#), taken directly from that FAO/WHO report, illustrates this issue. Although one can question the estimates of energy and iron needs that existed in 1970, the point of the table is clear. Conventional approaches to estimating and applying a

demographically weighted per capita nutrient requirement completely ignored issues of the distribution of intakes. Serious errors resulted. If the iron intakes were adjusted to levels expected to meet the needs of the persons with the highest needs (here, adult women), obviously, the iron intakes of adult men would greatly exceed estimated needs.

	Family Member						Average
	Reference Male	Reference Female	14 years Male	12 years Female	6 years either sex	10 months either sex	
Caloric allowance kcal ¹	3200	2400	2200	2000	1300	1000	2200
Recommended iron intake mg ²	5	14	12	5	5	5	7.7
Distribution of iron intakes mg ³							
Population 4 ⁴	12.2	10.2	8.4	7.5	5.0	3.8	7.7
Population 5 ⁵	18.6	14	12.6	11.6	7.5	5.8	11.7

²Based on FAO/WHO, Iron, a WHO Technical Series 46, Geneva, World Health Organization, 1970.

³Based on FAO/WHO, UL, average per day of a mixed diet.

⁴Younger age males is included in proportion to caloric intake.

⁵Protein-to-iron intake ratio equals iron-to-recommended iron.

⁶Protein-to-iron intake ratio of the adult women equals the recommended ratio of the reference woman.

Table 103.3 A Theoretical Example of Iron Distribution in the Family (A Comparison of the Inequities in Distributions of Intakes and Needs)

This issue was picked up again by the FAO/WHO Joint Expert Committee on Nutrition in its eighth report (21) the following year. As noted above, the FAO/WHO/UNU committee that considered protein and energy requirements directly addressed the joint distribution of energy and nutrient needs and its implication for estimating the “safe protein:energy ratio.” A conceptual framework now existed to allow examination of the sort of problem that the iron committee had identified. We can estimate a nutrient:energy ratio need for the heterogeneous population, and through this, we can begin to estimate per capita nutrient needs. This is illustrated below.

Recently, Beaton (“Fortification of Foods for Refugee Feeding,” unpublished report to the Canadian International Development Agency, 1995) conducted such an analysis for a very specific situation. In the early stages of establishing a refugee camp, the refugees may depend almost totally on food made available through the World Food Program and the United Nations High Commission for Refugees. These food packages barely contain enough total energy to meet the estimated per capita needs for sedentary activity (39). Beaton estimated that provision of nutrients fell grossly below estimated requirements. Classic deficiency diseases were periodically reported. Major interest existed in improving micronutrient intakes, and one possible approach was fortification of the staple cereal being distributed. Consideration of this approach required developing a profile of needs for extra nutrient, which implied the need for a reference requirement pattern, applicable to the demographically mixed population, with which per capita supplies could be compared.

Under the unusual circumstances of the refugees, it was reasonable to assume that

food distribution within a “household unit” would parallel energy needs of the individuals. Hence the germane question became “what is the profile of required nutrient densities in the distributed food ration so that almost all individuals in the household (and, by analogy, in a heterogeneous population) meet their individual nutrient needs when consuming the available food in proportion to energy needs?” This query follows directly from, but goes well beyond, the iron committee model. In essence, the approach taken by Beaton was to estimate the average nutrient:energy ratio required in the ration for each class of individuals, with the proviso that the expected prevalence of inadequate intakes in that age and sex group would be below 5%. This is the calculation that was developed in the FAO/WHO/UNU report (32). The estimation was repeated for each of 12 different age and sex reference groups (excluding infants and children under 2, who really require a different diet and would not be expected to share the ration in the same sense as others). Then, selecting the highest of these ratios as a reference for the refugee ration would give reasonable assurance that nutrient intakes would be adequate for all age/sex groups. Although calculations were made for pregnant and lactating women, pregnant women were not included in selecting the final reference nutrient density. It was unreasonable to attempt to meet estimated iron and folate needs of pregnant women by diet alone. If direct supplementation was needed, then the requirements of pregnant women clearly should not drive the dietary nutrient density reference. Below, Beaton's approach for iron is described; the original report considered 16 nutrients.

To implement this approach, iterative models were developed such that the mean and variability of requirements for iron and for energy and the expected variability of the nutrient:energy ratio in the diets of individuals could all be taken into account. With each iteration, the test nutrient density was increased until the target condition (≤5% individuals at risk of inadequate intake) was met. These models were run using the estimates of need for usable iron described by the FAO/WHO committee (40). [Table 103.4](#) shows that excluding pregnant and lactating women, adolescent females who were still growing but had started menstruation required the highest-quality diet. If their needs were met, the needs of the other groups would also be met. The apparently necessary 1.35 mg of usable iron per 1000 kcal of the total mix of foods offered to refugees could be translated to dietary iron by using FAO/WHO estimates of iron availability in different diets. Beaton's report recommended dietary fortification with sodium iron EDTA. This chelated iron is well absorbed, and EDTA is believed to strongly enhance absorption of iron from other dietary sources (41). Beaton suggested that iron availability of the total diet (added an indigenous iron) might be in the range designated “moderate availability” by the FAO/WHO committee (i.e., about 15%), which yielded an estimate of the necessary average iron density of about 9 mg/1000 kcal. This was expected to prevent anemia in the menstruating females and to meet all functional needs in the other groups; it would *not* meet the estimated needs of pregnant women, but would suffice for lactating females. The point of this example is simply to indicate that while not easy, we do have conceptual and methodologic frameworks that allow us to develop reasonable (not perfect) approaches to estimating per capita nutrient intake targets for heterogeneous population groups.

Sex and Age Group	Estimated Requirements (Refugee)		Necessary Average Iron:Energy Ratio* at Usual Iron Intake (1000 kcal)
	Iron (mg) [†]	Energy (kcal) [‡]	
M 2-5 years	0.55	1.000	0.55
M 7-9	0.55	1.400	0.55
M 12-14	1.10	1.800	1.00
M 15-17	1.10	2.200	1.00
M 18-24	0.55	2.600	0.46
M 25-54	0.55	2.600	0.46
F 2-5	0.55	1.400	0.55
F 7-9	0.55	1.800	0.55
F 12-14	1.10	2.200	1.00
F 15-17	1.10	2.600	1.00
F 18-24	1.10	2.600	1.00

*Based on estimate of an established refugee situation (24). †Based on estimate of 1000 kcal for the average refugee. ‡Based on estimate of 1000 kcal for the average refugee. ††Based on FAO/WHO (25) 5% of requirement is taken as 10% average for individual iron intakes. From the distribution of intake iron taken as the mean, and means of requirement distribution were found using the formulae of the FAO/WHO report (25). Approximate error is three percent in the Food and Nutrition Board report (25), and used in the assessment of intake. ‡‡Based on FAO/WHO (25) iron, average distribution body weight typical of populations in Africa. For other children, adolescents, and adults, average intake was estimated as 1.5 × calculated body. The CV of requirement for total body weight was taken as 10%, 1 kcal = 4.184 kJ. †††To use iron this average refugee intake would be adequate to meet the iron needs of all but 5% of individuals of the specified age and sex. For method of calculation, see text in 10.10. The corresponding average ratio of nutrient requirement/average requirement divided, the comparison takes into account selection of requirement and population variation of intake. ††††Median intake. †††††Estimation of requirement is taken as top normal. ††††††If this is the highest nutrient density available to any of the age-sex groups, it may also be the highest nutrient density available to the population for all other groups.

Table 103.4 Estimating a “Safe” Nutrient-Energy Ratio for a Heterogeneous Population: Reference Iron:Energy Ratios for Refugee Rations

For many years, committees charged with estimating human nutrient needs and “recommended intakes” have worried about estimating the requirement variability when there are too few data to provide reliable estimates. In the absence of data-based estimates, they have adopted judgments, sometimes referred to as the “margin of safety” or even “margin of ignorance.” In the 10 years since the FNB report on assessment of nutrient adequacy (28), the variability of requirement has become much less important for many applications than the variability of usual intakes. The mean or median requirement is the critical estimate, along with the knowledge (or reasonable assumption) that the requirement distribution is approximately symmetric, not necessarily Gaussian. This implies that we have ample data and well-advanced methodology for estimating the distribution of usual intakes, for the examination of intake variability (35). It is reasonable to expect that the next 10 years will see major development of methods related to application of requirement estimates in human population groups, small and large, with further integration of biologic and statistical principles. As we refine application procedures, we also open the door for new ways to “test” requirement estimates (47). We increase the scope of evidence that can be brought to bear on requirement estimation. Thus, for example, tentative requirement estimates can be applied to population data. If they suggest a major problem of inadequate intakes in the population, but there is no such evidence, there is reasonable basis for at least questioning the requirement evidence. Thus, development of the constructs and approaches for application can and will also offer the opportunity to improve nutrient requirement estimates (the generation of congruent evidence enhances reassurance; see Fig. 103.1). Again, by shifting attention from the variability of requirement to the variability of intake, we can gradually replace a remaining area of opinion and judgment with data and science.

ADDRESSING UPPER LIMITS TO NUTRIENT INTAKE

The concept of a safe range of intakes is not new. It has long been recognized that excessive intakes of many nutrients are detrimental to health and well-being if not

blatantly toxic. We know, for example, that very high doses of iron, vitamin D, and vitamin A can cause acute and/or chronic toxicity. In Canada, steps were taken to limit possible excessive exposure to vitamin A and vitamin D by limiting the degree of fortification of multiple foods with these nutrients and/or by regulating the levels that could be included in nonprescription over-the-counter nutrient supplements. Excessive intakes of a number of other nutrients over long periods can have detrimental effects. Furthermore, because of known nutrient:nutrient interactions, excessive intake of one nutrient may have a negative impact on the absorption or use of another. When the FAO/WHO/IAEA committee was established to consider trace elements in human health (16), therefore, both “requirement” and “toxicity” were to be considered in framing recommendations and guidelines. Traditionally, concern about high intakes of trace elements has been left mostly in the hands of food toxicologists.

A potentially serious conflict was on the horizon. The nutrition community had a strong tendency to increase what it perceived as a margin of safety and to recommend higher and higher levels of intake. At the same time, there was also a tendency among toxicologists to increase what they saw as a margin of safety and to talk about lowering the acceptable intake levels. There was a very real possibility that the two groups would come into direct conflict, with intakes recommended by nutritionists approaching or exceeding levels deemed unsafe by toxicologists. This situation did not actually emerge but it set in motion a serious attempt to consider both ends of the spectrum (inadequacy and excess) concurrently and within a common conceptual framework. The U.S. FNB has now taken up the challenge and will attempt to offer guidance on suitable intakes. Merging concepts from nutrition and toxicology will not be easy; persons working in these fields generally come from quite different backgrounds, have quite different concerns, and perhaps work with quite different conceptual frameworks.

Given the propensity of the North American consumer to purchase and use high-potency nutrient supplements, there is growing concern about safe upper limits of intake. Conceptually there should be a direct parallel between establishing reference levels that define “undesirably high” and reference levels that ensure nutrient needs. That is, there is every reason to believe that the biologic mechanisms associated with the detrimental effects of high doses exhibit variable individual tolerances just as biologic mechanisms lead to variable individual requirements. Conceptually, we then have risk or probability curves relating to both risk of inadequacy and risk of excess. Such theoretical curves, applied to usual intakes of individuals, were presented by the FAO/WHO/UNU committee (32) and have since been widely reproduced. That committee also coined the phrase “safe range of intake.”

The FAO/WHO/IAEA committee (16) took the conceptual framework a step further. They were interested in establishing reference levels for populations and large groups as well as for intakes of individuals. In many parts of the world, where inadequate trace element intakes were presumed to exist, only group mean intake data (at best) were available. The FAO/WHO/IAEA report (16) provides approaches to estimating both a *safe range of intakes* (individuals) and a *safe range of population mean intakes*. From the discussions above in this chapter, it should be apparent that the safe range of population mean intakes is numerically narrower than the safe range of intakes for

individuals.

If conceptual frameworks already exist, then what challenge do we face in the coming decades when attention focuses upon these upper limits? First, we will need a much stronger database relating to detrimental effects of high intakes, and we shall have to bridge concepts. As mentioned above, we are entering the domain of toxicology, which has operated with its own conceptual frameworks. Originally, much of that work derived from studies with mortality as an endpoint. This has changed to include concern about detrimental, but nonfatal, effects. Much of the toxicology literature is conceptually based on “dose-response curves,” and the notion that subjects vary in response to the same dose is a relatively recent entry into that literature. In nutrition, the dose-response curve was historically very important and remains important today, but once the criterion of requirement has been set, the nutrition community's interest turns more to the issue of variability in the intakes necessary to meet that criterion. The toxicology community has not really addressed such issues as the relationship between fat intake and heart disease. They might correctly consider that this is not really a “toxic effect” and thus not their concern. Nevertheless, the nutrition community is concerned about safe upper limits of fat intake as related to chronic diseases. For effective bridging to develop between the nutrition and toxicology communities, both communities must give careful consideration to definitions of “requirement for what function” and “detrimental to what function.” In essence, we *must* get rid of the nebulous concept of optimal intakes and begin to think about *ranges* of “acceptable intakes,” “desirable intakes,” “safe intakes,” or whatever other term we apply. Intakes falling in these ranges carry low risk of detrimental effects attributable to either inadequacy or excess. One of the greatest challenges will be to eliminate the notion of “margin of safety” from our thinking and replace it with meaningful and estimable variables. Unless this is done, many in the nutrition community will continue to argue that the “optimal” intake is likely to be *higher*, often much higher, than existing intakes, while some in the toxicology community are more likely to think of “optimal” as *lower* than existing intakes. We need conceptually consistent frameworks if we are going to be able to draw on science in resolving these emerging issues.

CRITERIA OF REQUIREMENT AND ADAPTATION

Whether considering intakes required to prevent manifestations of inadequacy or intakes likely to generate effects of excess, one *must* clearly define the physiologic criteria of adequacy or excess. Failure to do so leads to irresolvable debate about requirements (42). This was illustrated in a recent commentary by V. R. Young (43) on the RDA for vitamin C. This was written in response to a pharmacokinetic analysis indicating that measures of body levels of ascorbic acid continued to respond to intakes well above the published RDA, suggesting that since this might be important, the RDA should be as high as 200 mg. In responding, Young illustrated the expected prevalence of inadequate intakes in the U.S. population if the mean requirement was set at different levels. If the FNB truly believes that the requirement for vitamin C should be defined by the highest achievable level of any measure of body vitamin C, then it must also believe that the suggested prevalence of inadequacy in the U.S. population also marks a health problem that warrants immediate and drastic public health action. That is, not only is there a scientific need to carefully set meaningful criteria of requirement (or of excess),

there is also an ethical responsibility to do so before advising whole populations about nutritional needs. Young's closing sentences were "Only in this way [by examining the population implications of a requirement estimate] can a sound judgement be reached on the RDA for ascorbic acid for use by health policy makers and for the design of effective national nutrition programs. Regardless of what policy decisions are made, it is essential that the requirement values provided for this purpose are based on rigorous scientific evidence and critical thought."

A parallel picture holds when one rereads the longstanding debates about the importance of *nutritional adaptation* and asks how it affects the estimation of human nutritional requirements. In a 1984 symposium on nutritional adaptation, John Waterlow (44) tried to present his concept of nutritional adaptation as a range of dietary situations over which physiologic mechanisms allow adjustments that serve to preserve a body function (not necessarily all body functions). To make this concept operational, he was forced to accept that there must be other (external?) criteria to mark the limits of adaptive capacity. At these limits, the function(s) declared important is no longer maintained. Seemingly, this parallels the concepts embodied in setting criteria for "deficiency" (perhaps a lower limit to adaptation in the Waterlow schema) or "excess" (the upper limit of adaptation?). In both instances, the estimation of "safe" ranges of intake and the discussion of ranges of human adaptability, one must carefully define the functions to be preserved (the criteria to be met). Dr. Waterlow emphasized that the adaptation and functional markers he discussed were physiologic, recognizing that there are also behavioral adjustments that can, for example, reestablish or maintain energy balance if intake is altered. Setting limits on these sorts of adjustments requires assigning value judgments to certain human behaviors and even modification of social structures (45). The need to address normative desirable activity levels before estimating human energy requirements was presented in the report of the FAO/WHO/UNU committee (32) and immediately became a topic of considerable controversy. In general, nutritionists and physiologists prefer to avoid discussing behavioral adaptations to dietary change because they lack self-assurance in judging meaningful limits to those adaptations. Thus, any discussion of energy *requirements* evokes a great deal of ambivalence and hedging.

Perhaps iron represents a classic example of nutritional adaptation, with associated implications for estimation of requirements. There are well-described physiologic processes by which the human organism adjusts to, adapts to, or accommodates, different levels of chronic iron intake. These mechanisms can be seen as increasing the efficiency of dietary iron use at the low end of the intake range (protecting against loss of a function) and decreasing the efficiency of iron use, increasing waste, at the upper end (protecting against toxic manifestations). With iron, hematopoiesis has gained the greatest attention as the function to be preserved. An FAO/WHO committee (40) judged that maintaining this physiologic function would preserve all other physiologically important functions. Of course, health consequences might not become apparent until anemia developed, so one could use the appearance of anemia to mark the limit of adaptation to low intake. In the case of high intake, the concern is the effects of high concentrations of iron in tissues and necrotic changes in those tissues. The most frequently cited manifestation of iron overload is hemochromatosis, but in dealing with safe upper limits, criteria related to the beginning of a detrimental process are preferable

to presentation of overt clinical disease.

The nutrition community has long argued that it is “desirable” to maintain substantial stores of body iron. They may have no immediate functional importance, but they serve as a reserve against future need (e.g., to offset the heavy iron demands of pregnancy [37]). Clearly, movement of iron into and out of storage is a central adaptive mechanism. So far no evidence suggests that a specific level of iron storage has particular physiologic advantage. Stores approach zero before the hematopoietic function is compromised (40). The second major adaptive mechanism is alteration of dietary iron absorption efficiency (conditioned by the nature of the diet and its effect upon bioavailability).

Faced with this situation, it is impossible to estimate iron requirements without first clearly defining the criterion of adequacy, the “requirement for what?” Once this is done, one has also defined the lower limit to adaptation in John Waterlow's scheme. For example, if it is judged important to maintain iron stores of at least x amount, then reduction of stores below x cannot be considered an “adaptation”—it marks the failure of adaptation. Adaptation to higher levels still continues. An important feature of the adaptive processes involved in iron homeostasis is the rapidity of their response to change in diet or in the internal milieu (e.g., response of iron absorption to phlebotomy).

The FAO/WHO committee (40) addressed the problem of adaptation in iron metabolism by defining three levels of iron requirement: a normative level that maintained a desirable level of iron stores without functional markers; a basal level that preserved the hematopoietic function; and a level that prevented anemia as defined by WHO. In fact, they estimated and published requirement estimates for only the last two classes of requirement, noting that for many populations, it was unrealistic to advocate dietary intakes high enough to support iron storage levels that were often suggested to be desirable but that were nearly impossible for most women living in developing countries to achieve and of questionable benefit if achieved.

More recently the FAO/WHO/IAEA committee (16) had to address adaptation in the context of zinc requirements. They developed two levels of requirement estimates, one relating to the “adapted” state and the other to the nonadapted state. In the judgment of that group, there was no immediate functional difference between the two states but as for iron, the normative requirement estimate (nonadapted state) was consistent with temporary protection against future intake shortfalls or increased need.

The early literature suggests a different sort of “adaptation” for calcium. People maintained chronically on different levels of calcium intake show a capacity to alter their efficiency of calcium absorption and retention. Also, when intakes are changed under controlled experimental conditions, compensatory adjustments require a long time to become established. It was once thought that perhaps this adjustment of absorption efficiency was not fully reversible or that populations exposed to high calcium intake in early childhood might persist in exhibiting lower absorption efficiencies as adults, even when on a low calcium intake. Malm (46), working with Norwegian prisoners, placed 26 adult male subjects on a diet providing 450 mg of calcium per day. Prior to this, the men had been maintained on a high-calcium diet providing 950 mg/day for an average of 7

months. The low-calcium regimen was continued for as long as 1.5 years (average, 240 days). Of the 26 apparently healthy men age 20 to 69 years, Malm found 10 with a faculty for rapid adaptation (38%); 12 with a much slower and less marked faculty (46%); 1 with evidence of adaptive capability but not sufficient to establish zero balance (4%); and 3 with no evidence of adaptation (12%). The important feature to note is the large variation in the time required to reestablish equilibrium (to adapt) with the new lower intake.

Many reviewers have commented, as did an FAO/WHO committee (36), that the major determinant of calcium requirement is the habitual intake of calcium. In populations where intakes are high at all ages, calcium requirements (to preserve balance) also appear high; conversely, where intakes are habitually low at all ages, evidence suggests that very low intakes suffice to maintain calcium balance. We have then what appears to be a direct impact of “adaptation” on nutrient requirement. Exposure to high intakes for long periods results in changes in body processes to establish equilibrium among intake, absorption, and excretion to maintain body calcium metabolism within physiologic norms. However, because we also have evidence that these changes are reversed slowly to adjust to lower intakes or may even be irreversible in terms of accommodating very low intakes, we can reasonably state that the process of “adaptation” has influenced nutrient requirement.

Perhaps the only generalization that can be made is that offered in the opening of this section. To set nutrient requirements we must first decide on the criterion of adequacy (requirement for what?). Having done this, we have also defined the limit to adaptation and, with few exceptions, have set aside concerns about the impact of adaptation in setting nutrient requirements.

DIETARY REFERENCE INTAKES

In August 1997, after this chapter had been submitted for publication, prepublication copies of the uncorrected proofs of the first volume of the new dietary reference intakes (54) were released. This volume addresses calcium, phosphorus, magnesium, vitamin D, and fluoride. It is understood that changes will be made (particularly in the calcium chapter) prior to release of the final version of the report (see Appendix Table II-A-2-b). Nevertheless, it is relevant to compare aspects of the DRI report with discussion in the present chapter. The report follows very closely the structure and conceptual framework of the United Kingdom report (30), although terminology is not identical, and the DRI report extends further. The DRI report deals with four different estimates, with the following definitions:

Estimated average requirement (EAR): “the nutrient intake value that is estimated to meet the requirement defined by a specific indicator of adequacy in 50 percent of the individuals in a life-stage and gender group.” Note that this actually describes the median requirement, but if the requirement distribution is symmetric, mean and median are the same (they can be expected to differ for iron requirements of menstruating women [40]).

Recommended dietary allowance (RDA): “the daily intake level that is sufficient to meet the nutrient requirements of nearly all (97 or 98 percent) individuals in the life-stage and gender group. The RDA applies to individuals and not to groups. The EAR serves as the foundation for setting the RDA.”

Adequate intake (AI): “If sufficient evidence is not available to calculate an EAR, a value called an AI is used instead. The AI is based on observed or experimentally determined approximations of the average nutrient intake,

by a defined population or subgroup, that appears to sustain a defined nutritional state, such as normal circulating nutrient values or growth . . . The AI is expected to exceed the RDA for the same specified end points of nutritional adequacy.”

Tolerable upper intake level (UL): “the maximal level of nutrient intake that is unlikely to pose risks of adverse health effects to almost all individuals in the target group. The term *tolerable intake* was chosen to avoid implying a possible beneficial effect . . . The UL applies to chronic daily use.” The important feature to note is that as described and derived in the DRI report, the UL is an estimate of the lower tail of the distribution of individual susceptibilities—it has conceptual parallelism to the RDA (an estimate of the upper tail of the distribution of individual requirements) in this regard.

The EAR and RDA are entirely consistent in concept with the portrayal presented in [Figure 103.2](#) and hence with prior U.S., Canadian, and U.N. reports. The other two estimates are unique to the DRI report although the ideas are not.

As defined, the AI is similar to the concept of the early German standards developed by Voit and Rubner—descriptions of existing diets believed to be adequate and estimated as the group mean intake ([Table 103.1](#)). The AI is also conceptually similar to the necessary group mean intake discussed above in this chapter but differs in one very important feature. While the necessary group mean intake is derived from knowledge of the EAR and characteristics of the intake distribution, the AI will more often be based on observation of adequate intakes (descriptive epidemiology) and could exceed the necessary group mean intake. It is possible (but not likely) that experimental data could lead to an estimate of the AI without allowing estimation of an EAR. From the first volume of the DRI reports, it is clear that there will be major inconsistencies in the approach to derivation, and hence interpretation, of the AI. Perhaps its most important attribute is that it represents a clear declaration that the body of scientific evidence does not yet support estimation of requirements for that nutrient in the particular life-stage gender group. Prior reports have tended to overlook the demand for explicit evidence and instead offered informed judgments under the heading of an RDA. Creation of the AI can be hoped to end that practice, even though it declares the existence of major problems for interpretation and application. Meaning and intended interpretation of the AI are heavily clouded by the suggestion within the DRI report that the AI, derived as an estimate of the adequate group mean intake, “may be used as a goal for nutrient intake for individuals.” Seemingly, with the AI, the DRI report has gone full circle and has again suggested that a single numeric estimate can serve all purposes (see early critique by Pett et al. [\[23\]](#)).

The truly unique and evolutionary step of the DRI reports (and the feature that in the end may cause the greatest trouble for the authors) is that there is a concerted attempt to describe nutrient requirements for the prevention or delay of chronic diseases, many of which are multifactorial. In such a venture, epidemiology should constitute a major cornerstone of the evidence linking nutrient and disease. Unfortunately, the DRI process seems to continue to place the major emphasis and greatest weight on experimental studies, sometimes to the exclusion of epidemiologic evidence. As the reports on other nutrients emerge, it will be interesting to see if the committees become more successful in linking what can be studied under controlled experimental conditions with what happens in free-living populations where chronic diseases actually develop.

The introduction to this volume of the DRIs again offers assurance that “the DRI committee intends to issue a subsequent report that will focus on the uses of the DRIs

in various settings.” At the time of writing, it is understood that funding for the preparation of such a report has not been identified, and it remains more a hope than an actual plan. In the meantime, some suggestions about possible applications of the EAR, RDA, AI, and UL are included, but these do not go into the depth necessary to achieve a change in understanding and use of what many will see as merely another iteration in the series of RDA reports. In fact, the DRI reports represent a major evolutionary step in thinking and approach to the derivation and application of human nutrient requirement estimates. We can hope that the aspirations of those in charge of the DRI process come to fruition and that a detailed applications report will emerge. It is desperately needed.

A welcome change in these DRI reports is the presentation for each nutrient of a detailed review and assessment of the evidence used to derive the presented estimates. This allows others to evaluate the evidence and, more importantly, offers the opportunity to identify gaps or weaknesses that require future research—an incentive for progress in nutritional science. The authors of this first DRI report are to be congratulated for breaking new ground and opening new vistas.

A second DRI volume in prepublication form was distributed in April 1998 and covers 8 B vitamins and choline (55) (see Appendix [Table II-A-2-c-1](#), [Table II-A-2-c-2](#), [Table II-A-2-c-3](#), [Table II-A-2-c-4](#) and [Table II-A-2-c-5](#)).

EPILOGUE: POSSIBILITIES AND LIMITATIONS FOR APPLICATION

This chapter emphasizes conceptual issues. Statistically based approaches to facilitate application of biologic concepts and knowledge to populations and individuals are a part of nutritional science both today and tomorrow. However, one must not ignore valid criticisms and limitations of these approaches. The most serious criticisms are not conceptual; they relate to our limited ability to estimate dietary intakes. Numeric estimates of desirable intakes may be formulated with great scientific accuracy and precision and may be used in recommending what people should do. However, we must be able to estimate and evaluate existing food and nutrient intakes more effectively to know what people are doing and progress toward scientifically defined nutritional goals. Our limited ability to estimate dietary intakes limits application of our scientific knowledge and the use of any statistical model.

The 1970s saw a sudden upsurge in interest in the “day-to-day variation” in intake (47, 48 and 49) that prompted committees around the world to emphasize that their estimates of requirements referred to usual intakes (the average intake persisting over moderate periods of time). At that time approaches to population assessments (counting the proportion of persons with intakes below some cutoff, often using 1-day data) yielded estimates of the magnitude of problems that were potentially seriously biased, simply because the “tails” of the intake distribution were inflated by the day-to-day variation (50). In 1986, the FNB (28) issued a report that proposed, in addition to a probability assessment approach to evaluation, a statistical approach to adjusting the distribution of observed intakes, to eliminate or at least attenuate the impact of day-to-day variation. This methodology has since been greatly improved by a team at Iowa State University (35). Consequently, we have new methodologies to overcome one of the perceived limitations in estimating and assessing the distribution of intakes of

populations or large groups.

But, no available methodology can reliably estimate the usual intake of a particular individual. It may become possible to estimate intake for a finite period of time without error, but unless that period extends for a long time, an important error remains in estimating an individual's *usual* intake. This is illustrated in [Table 103.5](#). To appreciate the impact of this factor, recognize that human protein requirement is thought to have a coefficient of variation of about 12.5% ([25](#), [30](#), [31](#) and [32](#)). Thus, the 95% confidence interval in estimating the true protein requirement of an individual approximates the average requirement $\pm 25\%$. [Table 103.5](#) suggests that with 1 day of intake data, the confidence interval of apparent protein intake as an estimate of the individual's usual intake might be about $\pm 50\%$. If the observed intake equaled the RDA (0.75 g/kg), then the individual's usual intake could be as low as 0.38 or as high as 1.12 g/kg/day, i.e., the confidence band associated with the intake estimate encompasses the whole range of estimated requirements. One could not assign any confident assessment to the observed intake. With more days of data ([Table 103.5](#)), the situation improves, but even with the equivalent of 2 weeks of data and a mean intake equal to the RDA, one could only say that the usual intake is likely to lie between 0.55 and 0.965 g/kg/day. Hence, the assessed risk of the intake being inadequate would lie between 0 and 0.5. As a consequence of this characteristic of dietary data, severe limitations exist in our ability to assess the intake of particular individuals, although these limitations have been largely overcome for group assessments.

Number of Days of Intake Data Pooled	Expected 95% Confidence Interval for Estimate of Usual Intake of the Individual ^b
1	Observed $\pm 50\%$
3	Mean $\pm 29\%$
7	Mean $\pm 19\%$
14	Mean $\pm 13.3\%$
21	Mean $\pm 10.9\%$
28	Mean $\pm 9.5\%$

^aAssumes that days of data collection are independent of one another.

^bAssumes that within person CV of estimated protein intake is 25%, a variability estimate consistent with many published reports but not necessarily applicable to all situations.

Table 103.5 Impact of Number of Days of Data Collection on the 95% Confidence Interval of the Estimate of Usual Intake^a

What has reemerged as a potentially serious limitation to assessment of observed intakes is an alleged and almost certain bias toward underreporting or undercapture of actual intake. This can be documented only for total energy intake ([51](#), [52](#)). If total intake is underestimated, at least some nutrient intakes are certainly underreported as well. Unfortunately, even if we can use external validity measures to estimate the possible overall degree of underestimation of energy intake, we cannot assume

proportional underreporting of all aspects of the diet. We would have to know what components of the diet are missing or underreported. Without question, this is a serious problem. There are some potentially encouraging signs. One “external validity” check is to compute the expected BMR from age, weight, and gender data for each individual. The observed energy intake may then be expressed as a ratio to BMR. The group mean energy:BMR ratio may then be computed and compared with the expected ratio (believed to be a function of physical activity). Beaton et al. (48) computed these ratios for young adult females in the 1985 USDA survey and in a recent Dutch national survey. He then reported the data on the basis of weight (BMI) status (Table 103.6). The approach has now been applied to data from adults of both sexes included in the 1994 wave of the most recent USDA Continuing Survey of Individual Food Intakes (34). The results are shown in Table 103.7. Group mean ratios are compared with the ratios assumed to apply when the RDAs for energy were being developed (25). The values for males are low, albeit reasonably close to expected group means. The means for females are far below those expected. The 1985 and 1994 data, therefore, indicate that underreporting of food and energy intake may be a serious issue for adult females but perhaps not for adult males, at least by use of current USDA dietary methodology. Because of the high prevalence of dieting among American women, part of the apparent underreporting is likely to be true low intake on the days sampled. Based on analyses of USDA data, Ballard-Barbash and colleagues (personal communication) have convincingly argued that this practice explains part of the low intakes seen among overweight women.

	BMI Status		
	Thin	Normal	Overweight
USDA			
n	23	376	198
BMR kJ/day	4466	5182	6275
Energy:BMR	1.67	1.28	0.97
Dutch			
n	52	915	218
BMR kJ/day	5316	5768	6379
Energy:BMR	1.85	1.58	1.37

Table 103.6 Apparent Ratio of Energy Intake: BMR in Adult Women in Two National Surveys: An Approach to External Validation?

Age Group (years)	Females		Males	
	n	Ratio Energy Intake:BMR ^a	n	Ratio Energy Intake:BMR ^a
20-29	270	1.28 (1.60)	267	1.52 (1.67)
30-39	287	1.17 (1.55)	309	1.45 (1.60)
40-49	288	1.15 (1.55)	303	1.31 (1.60)
50-59	278	1.09 (1.50)	266	1.18 (1.50)

^aValues in parentheses are the expected ratios, as proposed in the RDA calculations, for light-to-moderate physical activity (25).

Table 103.7 Computed Ratio of Energy Intake:BMR in Adults Included in the 1994 Wave of the USDA Survey

It is to be hoped that continuing refinement of data collection methods will yield high-quality data in national surveys. Until data quality can be documented (e.g., through comparative studies of energy expenditure and estimated energy intake, using doubly labeled water), application of the approaches discussed in this chapter (or any other application of the RDAs) is seriously constrained.

Do these constraints imply that we should not worry about getting our conceptual frameworks and approaches to application correct? Certainly not. We must be optimistic about successfully addressing the problems of dietary intake estimation and be ready. Further, only some of the applications of the RDAs are compromised by problems of intake estimation. The other applications also require the basic conceptual framework in the formulation of RDAs or RDIs. Finally, only with the availability of scientifically valid and coherent conceptual frameworks can we identify the sources and potential impact of existing constraints. We must continue to move forward.

DEDICATION

This chapter is dedicated to Lionel Bradley Pett and his counterparts in many other countries who attempted to struggle with conceptual frameworks and consistent approaches to application of the RDAs in the early stages of this evolution. Their work may not have had the immediate impact it deserved, but it has come to fruition. The chapter acknowledges also the many scientists who participated in national and international nutrient requirement estimation and application committees and, through their work, contributed to the evolution of the concepts.

THE NEED FOR DIETARY GUIDELINES

Nutrition research is ultimately paid for by taxpayers (if it is funded by national research institutes or councils or public universities) or by consumers (if funded by food or pharmaceutical companies). In other words, it is paid for by the great majority of men and women in the community. They are not scientifically trained in nutrition, but the politicians and administrators who allocate money to nutritional research on their behalf must believe that nutritional science has three objectives:

- Healthier foods
- Healthier food choices
- Healthier food consumption

All the research results and interpretations in this book and in the reference lists for each chapter, and in the wider literature of nutritional science cannot help the great majority of people in our countries until this mass of data is translated into information that most people can understand and accept.

Food consumption patterns can become healthier in two ways: from change in the foods that are available and affordable or from change in the foods people choose to eat and in the way they prepare them. What is needed ideally as the foundation of nutritional

education and national food policy is a set of nutritional recommendations or dietary guidelines that are evidence-based, authoritative, and comprehensible.

Evidence Based

Scientific communication to the nonscientific majority of people often consists of “breakthroughs” and news snippets on television or radio, in newspapers and women's magazines. These items of news—and documentaries as well—are selected by producers and editors because of newsworthiness (1), not because they are good for you. Mere statement of an unsubstantiated hypothesis or a pilot case-control study, being new, is more likely to be in the news than completion of a systematic review or metaanalysis. News about nutrition is often negative, undermining confidence in traditional foods (2) rather than emphasizing the principles of a sensible diet. We have to live with a Tower of Babel of nutrition breakthroughs and threats.

Nutritional recommendations for a nation should therefore be based on objective, unbiased, and thorough reviews of all the evidence relating the nutrients, food components, and foods to health or disease risk. Evidence-based medicine is now encouraged (3), and metaanalysis is a recent powerful method in epidemiology (4), but systematic reviews of nutrition and health have been appearing since the 1960s (5), at first focused on diet and heart disease.

Authoritative

Food and drink companies advertise their products, and most advertising is for products that make the largest profit (e.g., carbonated soft drinks and alcoholic beverages). Food companies and associations defend products that nutrition scientists consider less healthy. Vested interests are academic as well as commercial. Some nutrition researchers like to publicize their new results and opinions; this may help them obtain funding for more research. Specialized journalists with some background for interpreting nutrition news are rare. In the postmodern world there is no longer universal agreement that there is one truth waiting to be revealed: it is constructed by people, always provisional, and influenced by context and power (6). As well as orthodox, scientific nutritionists, who read this book, there are alternative nutritionists, naturopaths, and herbalists (see [Chapter 110](#)). Alongside the mainline grocery supermarket is the “health food” store. In all cities, there are many different ethnic restaurants alongside fast food chain outlets.

For most people to take notice of and accept national dietary recommendations, the recommendations have to be credible and be prepared by a committee of experts convened by a government department, national academy of science, or professional association. Membership of the committee should have broad coverage (of scientific area and constituency), adequate independence, and minimal commercial bias. The best model is the committee that prepared the “Diet and Health” report for the U.S. National Research Council (NRC) in 1989 (7). It had 33 experts on the main committee and another 76 specialists recorded as providing input.

Comprehensible

Every branch of knowledge and every occupation has its technical terms. Nutrition is the same. But everyone has to eat, and everyone has an opinion about which foods are good for them. Dietary guidelines have to be comprehensible to the general public (8), who are confused about terms like *cholesterol*, *fat*, *fiber*, *polyunsaturated*, and *energy*. Guidelines must also be available in language meaningful to health professionals who can explain the above and other technical terms and the meanings of *moderate in*, *low in*, and *plenty of* for individuals.

In public health nutrition, two major sets of messages are sent from a consensus of nutritional scientists to the rest of the population—politicians, government departments, food industry, farmers, health professionals, economists, journalists, school teachers, supermarkets, caterers, shoppers, and consumers. *Recommended dietary intakes* (RDIs; see [Chapter 103](#) and Appendix [Table A-2-a-1](#), [Table A-2-a-2](#), [Table A-2-a-3](#), [Table A-2-b-1](#), [Table A-2-b-2](#), [Table A-2-b-3](#), [Table A-2-b-4](#), [Table A-2-b-5](#), [Table A-2-b-6](#), [Table A-2-c-1](#), [Table A-2-c-2](#), [Table A-2-c-3](#), [Table A-2-c-4](#), [Table A-2-c-5](#), [Table II-A-3-a](#), [Table II-A-3-b](#), [Table II-A-4-b](#), [Table II-A-4-c](#), [Table II-A-4-d](#), [Table II-A-4-e-1](#), [Table II-A-4-e-2](#), [Table II-A-4-f](#), [Table II-A-5-a](#), [Table II-A-5-b](#), [Table II-A-5-c](#), [Table II-A-5-d](#), [Table II-A-6](#), [Table II-A-7-a](#), [Table II-A-7-c](#), [Table II-A-7-a](#), [Table II-A-7-d-1](#), [Table II-A-7-d-2](#), [Table II-A-7-d-3](#), [Table II-A-7-d-4](#), [Table II-A-7-d-5](#), [Table II-A-7-d-6](#), [Table II-A-8-a-1](#), [Table II-A-8-a-2-a](#), [Table II-A-8-a-2-b](#), [Table II-A-8-a-2-c](#), [Table II-A-8-a-3](#), [Table II-A-8-b-2](#), [Table II-A-8-b-2-a](#), [Table II-A-8-b-3](#) and [Table II-A-8-b-4](#)) are the first and older set. They advise the quantities of the essential nutrients that people ought to consume. These technical numbers have to be converted for ordinary people to educational devices such as food groups, meal plans, or exchange lists, or to food enrichment, subsidies etc. In underdeveloped countries and communities, food and nutritional policy must concentrate on striving to reach the RDIs for as many people and as many nutrients as possible.

In affluent countries, intakes near the RDIs can be taken for granted for most people. Other sets of authoritative statements, *dietary guidelines*, have emerged since the late 1960s and advise how to select from the many combinations of foods in adequate diets to give the best chances of long-term health. The variety of food products is bewildering, and the whole food system needs signposts—guidelines to healthier diets that can be used in nutritional education, planning by food companies, and national nutrition policy.

FEATURES OF DIETARY GUIDELINES OR GOALS

Dietary guidelines aim to reduce the chances of developing chronic degenerative diseases rather than to provide enough of the essential nutrients (that is the purpose of RDIs). While there is never more than one RDI (or RDA, recommended dietary allowance) committee and report in a country, there can be several sets of dietary guidelines at a time (5).

Dietary goals or guidelines start not from zero intake (as RDIs do) but from the present

estimated national average diet. They deal with the optimal proportions of the energy-yielding macronutrients: how much carbohydrate? fat? protein? alcohol? and which types? They are not usually expressed as nutrients, but as food components, food groups, or even eating behavior. So, they are often a hybrid collection of recommendations.

Dietary goals or guidelines are not usually expressed as weight of nutrient per day; but as semiquantitative advice on consumption of a food component or on people's eating behavior. If expressed quantitatively, this is mostly as a percentage of total energy, that is, nutrient density (e.g., total fat intake should be 30 to 35% of total energy).

Dietary guidelines are targets for the population to aim for some time in the future. In some sets, the year is given or goals are progressive (e.g., total fat: intermediate goal, 35% energy; ultimate goal, 20–30% [9]). RDIs by contrast are needed now and every day (although there are reserves in the body—large for some nutrients, small for others).

A few sets of dietary guidelines draw a distinction between general advice for the whole population and (usually more radical) advice for groups at risk. For example, the U.S. Surgeon General's report (10) has five recommendations for most people and another four for some people. The recommendations of the World Health Organization (WHO) Europe (9) give intermediate goals separately for the general population and for the cardiovascular high-risk group.

Although most RDIs are relatively well established scientifically, guidelines are more provisional, being based on indirect evidence about the complex role of food components in causing multifactorial diseases with very long incubation periods. Dietary goals and guidelines, which primarily examine macronutrients, rely more on epidemiologic data than RDIs do. In addition, they depend on using food consumption patterns. The NRC Committee on Diet and Health (7) observed that

the term *insufficient data* could perhaps be applied to most issues concerning nutrition and health. In particular it characterizes many of the relationships between diet and certain chronic diseases. The lack of certainty about causal associations and mechanisms of action is common and stems in part from attempts to relate a complex mixture such as diet to complex, multifactorial chronic diseases for which the pathophysiological, environmental, and genetic predisposing factors are imprecisely understood ... Despite such limitations, a large body of evidence has emerged in the past four decades concerning chronic diseases and their relationship to general dietary patterns or specific dietary components (7).

Unlike RDIs, which give separate numbers for males and females and for different age groups and physiologic states, dietary guidelines have usually appeared to be the same for every man, woman, and child. Of course adjustments have to be made at the implementation stage. An international WHO symposium in Japan (11) concluded that while countries could usually share their RDIs, dietary guidelines are most effective if the target group is defined. New Zealand has different dietary guidelines reports for infants (12), children (13), adolescents (14), most adults (15), healthy pregnant women (16), and healthy older people (17). (Most of these reports [except ref. 15] do not appear to be the work of a large, representative committee). In Australia, there is a general dietary guidelines report (18) and a separate report for infants, children, and adolescents (19). Canada has a separate report on fat recommendations for children

(40).

Although they are more recent than RDIs, dietary guidelines are better known by the general public. Their summary recommendations, written in deliberately simple language about major food components or food habits appeal to journalists, consumer organizations, and cookbook writers.

GOALS OR GUIDELINES?

The classic *Dietary Goals for the United States* (20) was addressed to the nation, and the recommendations were expressed in such technical terms as “increase the consumption of complex carbohydrates and naturally occurring sugars from about 28% of energy intake to about 48% of energy intake” (20)—not a calculation the shopper can manage in the aisle of a supermarket! These dietary goals were followed by *Dietary Guidelines for Americans*, published by the departments of Agriculture and Health, in which the corresponding recommendation in the 1995 edition (21) is headed “Choose a diet with plenty of grain products, vegetables and fruits.” In Australia, “dietary goals” was also used for statements on nutritional policy, “Increase consumption of complex carbohydrates and dietary fibre ...” (22), while dietary guidelines came later in a mass-produced booklet, written in less technical language for consumers, “Eat more bread and cereals (preferably wholegrain), vegetables and fruit” (23). Helsing (24) has suggested that recommendations are needed at three levels: quantitative nutrient goals for scientists and health professionals, quantitative food goals for politicians and food producers, and dietary guidelines expressed as advice to individual consumers. The report *Diet, Nutrition and the Prevention of Chronic Diseases* by a WHO committee (25) defines population nutrient goals as the range in which population average intakes are judged to be consistent with a low prevalence of diet-related diseases in the population. The report sets out goals for 11 nutrients in numerical terms, e.g., total average carbohydrate for a population should be between 55 and 75% of energy. It stresses the difference between population nutrient goals and individual nutrient intakes, e.g., if the population's total carbohydrate intake is 60% of energy, individual intakes might range from 45% to 75% of energy (see Appendix [Table II-A-9](#)). The contrasting concept of dietary guidelines was well explained by Robbins (26) in a commentary on the first proposed nutritional guidelines for Britain: “Guidelines express the goals in terms of foods (or combinations of foods) which are to be eaten by individuals ... Guidelines need not be quantified but need to be based on goals. Many different dietary patterns can be compatible with a given set of dietary goals.” For instance, the goal of reducing total fat intake can be achieved by drinking skimmed milk, by eating less fatty meat, or by reducing hard cheese and biscuits.

HISTORY OF DIETARY GOALS AND GUIDELINES

Nordic Synpunkter (1968)

The first set of dietary goals were *Mediciniska synpunkter på folkkosten i de Nordiska landerna* (medical viewpoints on people's food in the Nordic countries). “Nordic” and “Scandinavian” are often used interchangeably, but the original meaning of

“Scandinavia” was the peninsula comprising Norway and Sweden. “Nordic” includes Denmark, Finland, and Iceland. These goals were developed by Professor Arvid Wretling and other nutrition professors in Sweden, Finland, Norway, and Denmark and published in 1968 (27, 28) (Table 104.1). Ancel Keys arranged for an English translation to be printed in *Nutrition Reviews* 4 months later (29).

The calorie supply in the diet should in many cases be reduced to prevent overweight.
The total fat consumption should be reduced from the present around 40% to between 25 and 35% of total calories.
The use of saturated fat should be reduced and consumption of polyunsaturated fat increased simultaneously.
Consumption of sugar and sugar-containing products should be reduced.
One should increase consumption of vegetables, fruit, potatoes, skimmed milk, fish, lean meat, and cereal products.
From the medical and nutritional standpoint it is essential to emphasize the importance of regular exercise habits from childhood for all individuals with mainly sedentary work.

Translated by the author from Medicinska synpunkter på folkkostens i de Nordiska länderna. *Vår föda* 1968;20:31-5 and Medicinska synpunkter på folkkostens i de Nordiska länderna. *Läkartidningen* 1968;65:2152-3.

Table 104.1 Medical Viewpoints on People's Food in the Nordic Countries (1968)

The first idea behind these recommendations was that mechanization had reduced physical work and with it, caloric consumption. Consumers with low caloric intakes needed to increase the density of iron, calcium, and other critical nutrients per 1000 kcal if they are to obtain their RDIs. Meanwhile, the proportion of dietary fat had risen in Sweden from 29% of energy at the end of the 19th century to 42% in the mid-1960s (30). “Simple calculations showed that a diet ensuring the requirements of the low calorie groups is practically impossible to achieve without reduction of the fat consumption ... to, at most, 35% of calories” (31). In addition, replacement of saturated fats by polyunsaturated fats should lower plasma cholesterol levels, and reduction of sugar and confectionery should help reduce dental caries. The Nordic viewpoints met considerable local opposition from conservative professionals and food companies, but they were the foundation for the 1972 “Diet and Exercise” campaign in Sweden and the Norwegian nutrition policy (32).

Meanwhile, evidence was accumulating for the dietary fat hypothesis of coronary heart disease that Ancel Keys started to develop in 1952 (33, 34). The American Heart Association has been publishing diet-heart statements since 1961, and these statements have become progressively less tentative, with a stronger scientific infrastructure. Since 1970, other scientific and professional bodies in the United States, Australia, New Zealand, the Netherlands, the United Kingdom, Germany, and Canada (in temporal order) have published expert committee statements on diet and coronary heart disease. So, by the mid-1970s, there were two lines of reasoning for general dietary advice to the public in affluent countries. The Nordic recommendations aimed primarily to replace empty-calorie foods (fats and refined sugars) with a mixture of

nutrient-dense foods because people were expending less energy and, as a consequence, eating less food than their grandparents. The followers of Ancel Keys aimed primarily to bring down the plasma (total) cholesterol concentration. Their advice concentrated on eating less saturated fat and cholesterol.

Dietary Goals for the United States (1977)

Dietary Goals for the United States (1977) was a pivotal document. It added to the above two concepts a third group of miscellaneous ideas: the dietary fiber hypothesis; the possible relationship of high fat intake to breast and large bowel cancer, and the possible role of sodium salt in causing essential hypertension. *Dietary Goals* was written by a group of staff members and associates without specialized nutritional experience under committee chairman, Senator George McGovern. Some expert input was provided by Professor Mark Hegsted before publication. The report contains no major blunders, although the references are few and some of them, unconventional. The first edition (20) was revised before the end of 1977 (35) (Table 104.2) in response to objections cited in group 8 of Table 104.3. The other objections were of a more political or philosophical nature. Committees that draft dietary guidelines have to keep these possible objections in mind (Table 104.3) and work to minimize them. Never again have there been so many published comments and criticisms of nutrition recommendations as followed the first edition of *Dietary Goals for the United States* One collection of commentaries runs to 889 pages (36).

Dietary Goals, Feb. 1967 (20)		Dietary Goals, Dec. 1967 (35)
↑ Carbohydrate		Avoid overweight
↓ Total fat		↑ Complex carbohydrates
↓ Saturated fatty acids	↑ PUFA	↓ Sugars
↓ Dietary cholesterol		↓ Total fat
↓ Sugar		↓ Saturated fatty acids
↓ Salt to 3 g/day		↑ PUFA
		↓ Dietary cholesterol
		↓ Salt to 5 g/day

PUFA, Polyunsaturated fatty acids.

Table 104.2 Recommendations from *Dietary Goals for the United States*, 1st and 2nd editions, in Abbreviated Form and Original Order

Assessing not scientific enough, based more on intuition than science; reassuring not a scientifically sound review; should be reassured by expert bodies: IHT, FICHA, LECHA, NACU, etc.
 Not needed: America's health is improving; the committee has generated a fiasco by claiming that Americans are suffering from an epidemic of killer diseases.
 The need more research, too soon, the link hypothesis of coronary heart disease not yet proven; the relation between salt and hypertension not yet proven; we are only on the threshold of discovery in nutrition; it's unwise to base recommendations on food/disease-prevalence data; proteins too much; the politicians are over-selling nutrition.
 Political, politically motivated, a political, "big brother" approach; it's unwise to tamper with the diets of the great majority of people; for high-risk groups, diets should be individually prescribed by medical practitioners or dietitians.
 Problems of recommending for all age-sex groups; these look like guidelines for food intake by overweight middle-aged men; neglects children, pregnant.
 Member interests; my advice wasn't asked or that of our professional association; our industry may be affected (oil, dairy, sugar, egg, cornmeal).
 There could be adverse effects; we are concerned that increased intake of polyunsaturated fat could have side-effects; if less meat is eaten, iron deficiency may increase.
 Amino acids were omitted and corrections are required; left out alcohol (although prohibited in Iowa); should add a goal about obesity; should add encouragement of water foundation; the goal of 3 g NaCl per day is far too low.
 Based mainly on reference diets, an overstatement in Nutrition Today.
 The committee's report was an attempt to do a job that should be done by the government. Many of the recommendations were a mixture of guesses and some of the advice repetitive, redundant, contradictory, often made obsolete in course of the review process.

Table 104.3 Objections to *Dietary Goals for the United States* (1st Edition)

Nevertheless, the first independent comment overseas, an editorial in *The Lancet* (37), generally welcomed *Dietary Goals*. The goals were never an official U.S. government statement, although most nutritionists outside the country did not realize this. The ideas in *Dietary Goals* have been modified and reused—or rediscovered—in subsequent official or authoritative sets of guidelines in the U.S. and in many national sets of nutritional recommendations around the world.

CURRENT GUIDELINES IN THE UNITED STATES

Dietary Guidelines for Americans

Now in its fourth revised edition (21), *Dietary Guidelines for Americans* first appeared in 1980. The fourth edition is a 43-page booklet, 10 × 22.5 cm, which can conveniently slip into a handbag or pocket. It is published with the joint authority of the U.S. Departments of Agriculture and Health and Human Services. It is intended for all healthy Americans over 2 years of age and is written, as far as possible, in nontechnical, reader-friendly language. Table 104.4 shows the headings of the seven guidelines. They are similar to the 1977 dietary goals (Table 104.2) except that variety of food consumption has been added as a first principle plus a guideline on alcohol consumption. *Dietary Guidelines for Americans* has been revised and updated about every 5 years. It is instructive to compare the wording of headings in the fourth (1995) edition with those of the first (1980) edition (Table 104.4). Much care has gone into the wording, which must be brief as well as clear. “Avoid too much fat” turned out to be rather meaningless and has been replaced by “Choose a diet low in fat and saturated fat and cholesterol,” with simple semiquantitative advice in the body of the booklet. *Dietary Guidelines* is Home and Garden bulletin no. 232, widely distributed and written for ordinary consumers. It is not written for health professionals, but they should have a copy and note how simply it presents the main conclusions of modern nutritional research.

1980 (1st edition)	1995 (4th edition)
Eat a variety of foods	Eat a variety of foods
Maintain ideal weight	Balance the food you eat with physical activity—maintain or improve your weight
Avoid too much fat, saturated fat, and cholesterol	Choose a diet with plenty of grain products, vegetables, and fruits
Eat foods with adequate starch and fiber	Choose a diet low in fat, unsaturated fat, and cholesterol
Avoid too much sugar	Choose a diet moderate in sugars
Avoid too much sodium	Choose a diet moderate in salt and sodium
If you drink alcohol, do so in moderation	If you drink alcoholic beverages, do so in moderation

Table 104.4 Headings from *Dietary Guidelines for Americans*

The Surgeon General's Report on Nutrition and Health

The Surgeon General's Report on Nutrition and Health (of 1988) is a large review (10) of 727 pages, which had 90 contributors and 171 reviewers. There are five recommendations for most people:

- Reduce consumption of fat (especially saturated) and cholesterol
- Energy and weight control
- Increase consumption of whole-grain cereal foods, vegetables, and fruits (complex carbohydrates and fiber)
- Reduce intake of sodium
- Take alcohol only in moderation (no more than two drinks per day), if at all

There are another four recommendations *for some people*:

- Community water systems should be fluoridated
- Children should limit consumption and frequency of use of foods high in sugars
- Adolescent girls and adult women should increase consumption of foods high in calcium
- Children, adolescents, and women of childbearing age should be sure to eat foods that are good sources of iron

The National Research Council's 1989 *Diet and Health* Review

A substantial, large book (7) of 750 pages, *Diet and Health* was written by a committee of 33 persons, with contributions or advice of a further 76 specialists acknowledged. It is the most thorough review of the evidence on which dietary guidelines are based. Its recommendations are

- Reduce total fat intakes to 30% of calories or less. Reduce saturated fatty acid

intake to less than 10% of calories and dietary cholesterol to less than 300 mg daily. Polyunsaturated fatty acid intake should stay at about the present 7% of calories (and not be above 10% of calories in individuals). Concentrated fish oils are not recommended (for the general public).

- Eat five or more servings of a combination of vegetables and fruits each day (especially green and yellow vegetables and citrus fruits). Also, increase intake of starches and complex carbohydrates by eating six or more servings of a combination of breads, cereals, and legumes. Increase of added sugars is not recommended.
- Maintain protein intake at moderate levels, i.e., less than twice the RDA.
- Balance food intake and physical activity to maintain appropriate body weight. Increased abdominal fat carries a higher risk for chronic diseases than comparable fat deposits in the hips or thighs. All healthy people should maintain physical activity at a moderate level. Neither large fluctuations in body weight nor extreme restrictions in food intake are desirable.
- The committee does not recommend alcohol consumption. For those who do drink, limit consumption to two standard drinks a day. Pregnant women and women attempting to conceive should avoid alcoholic beverages.
- Limit total daily salt intake to 6 g (sodium chloride) or less.
- Maintain adequate calcium intake, but the potential benefits of calcium above the RDA are not well documented.
- Avoid taking dietary supplements in excess of the RDA.
- Maintain an optimum intake of fluoride, particularly during the years of primary and secondary tooth formation and growth, i.e., fluoridated water or (if not available) fluoride supplements.

Guidelines to Prevent Cancer

To reduce dietary factors that appear to contribute to development of cancer, recommendations in a large review by an NRC committee ([38](#)) were initially published in 1982 and updated in 1989. Summarized briefly these are

1. Reduce fat (unsaturated as well as saturated) to 30% total energy or less
2. Frequently consume fruits (e.g., citrus) and vegetables (especially carotene-rich and cruciferous)
3. Reduce consumption of salt-cured and smoked foods
4. Continue efforts to minimize contamination of foods with carcinogens from any source
5. Make further efforts to identify mutagens in foods, test them for carcinogenicity, and minimize their concentration
6. If alcoholic beverages are consumed, do so in moderation.

The American Cancer Society's 1997 guidelines are compatible with these, but they add encouragement to eat grain products and to be physically active. Consumption of meats (especially high-fat meats) should be limited ([38a](#)).

The United States is a large country with by far the largest investment in nutritional research in the world. It is not surprising that there have been more than one set of

authoritative dietary guidelines in the country since 1977. There are other important sets not reviewed here, such as those of the American Heart Association and of the American Dietetic Association (guidelines for women). The different sets of recommendations agree closely, with no serious conflict.

DIETARY GUIDELINES IN OTHER COUNTRIES

Most major countries formulated authoritative sets of dietary guidelines following the 1977 appearance of *Dietary Goals for the United States*. Dietary guidelines are popular with governments. They are inexpensive, involving only a few committee meetings and a small secretariat. Nutritional scientists are pleased to be asked their opinions. Most food companies accept guidelines if they are seen to be balanced and objective; they can assist companies in developing new products and forward planning. The expectation must be that if a country has dietary guidelines agreed on by representative experts, they will be used in school education programs for the nation's future shoppers and food preparers. Nutrition and food professionals will use them in advising members of the general public, and when there is a query or dispute about nutritional messages or the nutritiousness of a food, the guidelines are there for reference.

[Table 104.5](#) lists sets of authoritative dietary guidelines known at the time of writing this chapter ([9](#), [15](#), [18](#), [19](#), [39](#), [40](#), [41](#), [42](#), [43](#), [44](#), [45](#), [46](#), [47](#), [48](#), [49](#), [50](#), [51](#), [52](#), [53](#), [54](#), [55](#), [56](#), [57](#), [57a](#), [58](#), [59](#), [60](#), [61](#) and [62](#)). There may be others, and certainly other sets of guidelines have been proposed by individual nutritionists that have not been through the full process of committee, consultation, and approval by a government department.

Table 104.5 Authoritative Dietary Guidelines Outside the United States

A Selection of Guidelines for Developed Countries

There is only space to record the headings and add a few brief notes.

Australia (1979, Revised 1992)

The first set of dietary guidelines, published in 1979 (23), were well accepted by nutritionists, health authorities, and the food industry. In the 1992 revised set of guidelines (18), the elements have been reordered and reworded with more emphasis on a low-fat diet, and two guidelines on specific nutrients have been added. The ten guidelines are (a) enjoy a wide variety of nutritious foods; (b) eat plenty of breads and cereals (preferably whole-grain), vegetables (including legumes), and fruits; (c) eat a diet low in fat and, in particular, low in saturated fat; (d) maintain a healthy body weight by balancing food intake and regular physical activity; (e) if you drink alcohol, limit your intake; (f) eat only a moderate amount of sugars and foods containing added sugars; (g) use salt sparingly and choose foods with little added salt; (h) encourage and support breast-feeding; (i) eat foods containing calcium; this is particularly important for girls and women; and (j) eat foods containing iron; this is particularly important for girls, women, vegetarians, and athletes.

Canada (1990)

The Canadian diet (39) should (a) provide energy consistent with maintenance of body weight within the recommended range; (b) include essential nutrients in amounts recommended; (c) include no more than 30% of energy as fat and no more than 10% as saturated fat; (d) provide 55% of energy as carbohydrate from a variety of sources; (e) contain reduced sodium; (f) include no more than 5% of total energy as alcohol, or two drinks daily, whichever is less; (g) contain no more caffeine than the equivalent of four regular cups of coffee per day; and (h) community water supplies containing less than 1 mg/L should be fluoridated to that level.

For children (40) from the age of 2 until the end of linear growth there should be a transition from the high-fat diet of infancy to a diet that includes no more than 30% of energy as fat and no more than 10% of energy as saturated fat.

Europe (1988)

In a report for WHO Europe (9), goals (not guidelines) are given for the general population; (intermediate goals) and ultimate goals: complex carbohydrates (>40 en%) 45 to 55 en%; protein 12 to 13 en%; sugar 10 en%; total fat (35 en%) 20 to 30 en%; saturated fat (15 en%) 10 en%; P:S ratio (£0.5) £1.0; dietary fiber (30 g/day) >30 g/day; salt (7 to 8 g/day) 5 g/day; dietary cholesterol <100 mg per 4.2 MJ (1000 kcal); fluoride 0.7 to 1.2 mg/L. (For cardiovascular high-risk groups, the intermediate goal for fat and saturated fat is the same as the ultimate goal for the general population).

Germany (1985)

In *Ten Guidelines for Sensible Nutrition* (1985) (46) recommendations are to (a) use variety in the choice of foods; (b) eat not too much and not too little; (c) eat small meals more often; (d) eat sufficient protein; (e) avoid too much fat; (f) eat sweets seldom; (g)

eat fresh food (fruits, juices, vegetables, milk) and whole grain products daily; *(h)* prepare foods properly; *(i)* use salt sparingly; and *(j)* use restraint with alcohol.

Hungary (1988)

Recommendations (47) are to *(a)* eat a variety of foods; *(b)* avoid too much fat; use vegetable oil and margarine; *(c)* avoid too much salt; *(d)* reduce sugary snacks; *(e)* drink half a liter of low-fat milk per day; *(f)* eat fresh fruits, vegetables, and salads more often; *(g)* always have whole-grain bread on the table; choose potatoes over rice; *(h)* eat four or five meals daily, none too rich or too light; *(i)* quench thirst with water; it's best to avoid alcohol and it is forbidden for children and pregnant women; and *(j)* good nutrition means a balanced diet—in other words, no food is prohibited, but some are to be preferred and others to be eaten less frequently.

Italy (1988)

Guidelines for a healthy Italian “alimentation” (50) are headed *(a)* watch your weight; *(b)* less fat and cholesterol; *(c)* more starch and more fiber; *(d)* sweet foods: not too much; *(e)* salt? much less; *(f)* alcohol: with moderation; *(g)* variety of foods and six food groups.

Japan (1985)

Recommendations (51) are *(a)* obtain well-balanced nutrition with a variety of foods; eat 30 foodstuffs a day; take staple food, main dish, and side dish together; *(b)* take energy corresponding to daily life activity; *(c)* consider the amount and quality of the fats and oils you eat: avoid too much; eat more vegetable oils than animal fat; *(d)* avoid too much salt, not more than 10 g a day; *(e)* happy eating makes for happy family life; sit down and eat together and talk; treasure family taste and home cooking.

South Korea (1986)

Korean recommendations (52) are *(a)* eat a variety of foods; *(b)* keep ideal body weight; *(c)* consume enough protein; *(d)* keep fat consumption at 20% of energy intake; *(e)* drink milk every day; *(f)* reduce salt intake; *(g)* keep in good dental health; *(h)* moderate alcohol and caffeine consumption; *(i)* keep the harmony between diet and daily life; and *(j)* enjoy meals. (Those in Western countries who think a target of 30% energy from total fat too stringent should ponder the fourth Korean recommendation.)

Netherlands (1986)

The Dutch recommendations (55) are *(a)* achieve or maintain a normal body weight; *(b)* diet should be balanced and supply adequate amounts of all essential nutrients; *(c)* average total fat intake of 30 to 35% dietary energy; *(d)* saturated fat should be around 10% total energy, and polyunsaturated fat 50 to 100% of saturated fat; *(e)* dietary cholesterol should not exceed 33 mg/MJ; *(f)* carbohydrates (total), 50 to 60% of energy; sugars, 15 to 25% of energy; *(g)* protein, 10 to 15% of energy (as at present); *(h)* dietary

fiber target, 3 g/MJ; (i) current alcohol consumption is far too high in many cases; (j) salt, upper level 8 g/day.

There is also advice for special groups, e.g., about vitamin D and fluoride for children.

New Zealand (1991)

The food and nutrition guidelines (15) are (a) eat a variety of foods from each of the four major food groups each day; at least three servings of vegetables, two of fruit, six of bread and cereals, two of milk and dairy products (especially low fat), one of lean meats or poultry, fish, eggs, nuts, or pulses; (b) prepare meals with minimal added fat (especially saturated fat) and salt; (c) choose preprepared foods and snacks that are low in fat (especially saturated fat), salt, and sugar; (d) maintain a healthy body weight by regular physical activity and by healthy eating; (e) drink plenty of liquids each day; (f) if you drink alcohol, do so in moderation.

Nordic Countries (1989)

These are the first set of guidelines (56) agreed for the countries of a region, *Denmark, Finland, Norway, and Sweden*. The report contains RDIs as well as guidelines. For adults and children over 3 years (a) protein ought to provide 10 to 15% of the total energy intake; (b) fat should not provide more than 30% of the total energy intake. The decrease from most people's present intake should be primarily by reducing saturated fat, which will generally be accompanied by a desirable decrease in dietary cholesterol. Total fat should not, however, be below 20 to 25% energy. Essential fatty acids should contribute 3 to 10% (at least 4.5% for pregnancy and 6% for lactation). Both linoleic (w-6) and linolenic (w-3) are essential, but requirement of the former is greater. Linolenic and long-chain w-3 acids should provide at least 0.5% of energy; (c) carbohydrates should provide 55 to 60% of energy. Sugar should not provide more than 10% of energy (i.e., refined, not naturally occurring sugar). The intake of dietary fiber should be at least 3 g/MJ (12.5 g/1000 kcal), which for adults is 25 to 30 g/day. (d) It is desirable that the sodium intake gradually decrease to a level corresponding to 5 g NaCl per day; (e) consumption of alcohol should be avoided or be moderate. During pregnancy alcohol should be avoided entirely.

Singapore (1989)

Recommendations (59) are to (a) eat a variety of foods; (b) maintain desirable body weight; (c) restrict total fat intake to 20 to 30% of total energy intake; (d) modify composition of fat in the diet to one-third polyunsaturated, one-third monounsaturated, and one-third saturated; (e) reduce cholesterol intake to less than 300 mg/day; (f) maintain intakes of complex carbohydrates at about 50% of total energy intake; (g) reduce salt intake to less than 4.5 g a day (1800 mg Na); (h) reduce intake of salt-cured, preserved, and smoked foods; (i) reduce intake of refined and processed sugar to less than 10% of energy; (j) increase intake of fruit and vegetables and whole-grain cereal products, thereby increasing vitamins A and C and fiber; (k) for those who drink, not more than two to three standard drinks (about 40 g alcohol) per day; (l) encourage

breast-feeding of infants until at least 6 months of age.

United Kingdom (1990, 1991)

After considerable earlier controversy ([63](#), [64](#), [65](#) and [66](#)), dietary guidelines and goals are now accepted by the British establishment. The Ministry of Agriculture published in 1990 a thin book ([61](#)) for the general public (without scientific background). The eight guidelines are (a) enjoy your food; (b) eat a variety of different foods; (c) eat the right amount to be a healthy weight; (d) eat plenty of foods rich in starch and fiber; (e) don't eat too much fat (we don't need saturates at all); (f) don't eat sugary foods too often; (g) look after the vitamins and minerals in your food; (h) if you drink, keep within sensible limits.

The next year, quantitative population goals for fats and carbohydrates were included in the new report on dietary reference values ([62](#)). Of the population's average percentage of total energy (including alcohol), total fat should be 33%. Of total fatty acids, saturated fatty acids should be 10%; *cis* polyunsaturated fatty acids, 6% (not more than 10%); and *trans* fatty acids not more than 2%. Nonstarch polysaccharides should be 18 to 24 g/day (corresponding to around 30–35 g/day dietary fiber) and “nonmilk extrinsic sugars” should average 60 g/day (“data in support of any specific quantified targets for non-milk extrinsic sugars were scanty”).

Guidelines for Less-Industrialized Countries

Dietary guidelines were originally introduced to meet the nutritional problems of affluent communities. Until the end of the 1980s, there were no (published) proposals to apply them in developing countries, where the dominating nutritional problem is that many people can't afford or grow all the food they need. However, in these developing countries, (a) coronary heart disease and cancers are increasing their share of mortality as infections come under control ([67](#)); (b) the affluent middle class in a country like India may only be 5% of the population, but it comprises 40 million individuals who play a major part in the development of the country ([49](#)); (c) developing countries had a bad experience when they followed industrial countries and abandoned breast-feeding; (d) now is a good time to try to prevent the consequences of further increases in fat intake; and (e) low-income countries cannot afford to add the burden of medical care of degenerative diseases to their health budgets.

Dietary guidelines are a low-cost measure. If they have official status they can be written into nutritional material, adopted by multinational companies for their staff, and accepted by voluntary and international agencies as well as by national health workers. Two conditions that make formulation of dietary guidelines specially challenging in low-income countries are the scarcity of food composition data (food analysis is very expensive) and the wide range of nutritional status, from undernutrition among the poor to overnutrition in the affluent class.

For India, Gopalan proposes two sets of guidelines ([49](#)). For the relatively poor, diets should be least expensive and conform to tradition and cultural practices as far as possible. Some pulses (legumes) should be eaten along with the high-cereal diet, and at

least 150 mL/day of milk and 150 g/day of leafy vegetables. Energy from fat and oil need not exceed 15%, and that from sugar need not exceed 5% of total calories.

For affluent Indians, he proposes (49, 68) restricting energy intake to levels commensurate with sedentary occupations; giving preference to undermilled cereals; including green leafy vegetables in the diet; limiting edible fat to no more than 20% of total energy and restricting ghee (clarified butter) to special occasions; restricting intake of sugar and sweets; and avoiding high salt intake, especially by those prone to hypertension.

For Latin America, Bengoa et al. (53) propose an alternative model, dietary goals that can apply to all, rich and poor, “metas nutricionales.” These then have to be converted into focused guidelines for different segments of the population. Energy and protein requirements are derived from the FAO/WHO/UNU report (69). Fat should be 20 to 25% of dietary energy, with the ratio of fatty acids, saturated:monounsaturated:polyunsaturated, equal to 1:1:1. Omega-3 fatty acids should be 10% of total polyunsaturated fatty acids. Carbohydrate should provide 60 to 70% of total energy, with the emphasis on less-refined cereals and products. Sugar contributes to dental caries, but it can be useful for increasing the caloric density of diets, particularly for young children. Most adults in Latin America can only take moderate amounts of milk because of lactase insufficiency. Fiber (recommendation, 8 to 10 g/1000 kcal) only needs to be encouraged for the more affluent. Attention to biologic interactions among nutrients can enhance availability of limited micronutrients. Salt intake should be below 10 g/day. There are separate recommendations for different age groups, including of course breast-feeding for infants and adequate calcium for adolescents and pregnant women.

With goals like this, some people need to be helped to eat more fat, while other sections of society should bring their fat intake down to 20 to 25% energy that Bengoa, and Scrimshaw and colleagues think are the optimal range for health. Dietary goals like this might eventually be developed, after wide consultation, into international dietary goals. A WHO Study Group (25) has proposed *population* nutrient goals for the whole world, expressed as ranges, including: total fat between 15% of energy (lower limit) and 30% of energy (interim goal); saturated fatty acids between 0% (lower limit) and 10% (upper limit); polyunsaturated fatty acids, 3 to 7% of energy; total protein, 10 to 15% of energy; total carbohydrate, 55 to 75% of energy; “complex” carbohydrates, 50 to 70% of energy; “free sugars,” 0 to 10% of energy; dietary fiber (expressed as nonstarch polysaccharides) 16 to 24 g/day; fruits and vegetables (lower limit), 400 g/day; salt, 0 to 6 g/day (25).

WHERE SETS OF GUIDELINES AGREE AND WHERE THEY DISAGREE

There is *almost complete agreement* on the following six recommendations:

1. Eat a nutritionally adequate diet from a variety of foods
2. Eat less fat, particularly saturated fat
3. Adjust energy intake and/or physical activity to maintain or achieve healthy body weight

4. Eat more complex carbohydrates and fiber *or* eat more cereals/grains, vegetables, and fruits
5. Reduce salt intake
6. Drink alcohol in moderation, if at all

The Japanese recommendations (51) suggest 30 different foods a day to give a numerical expression to the concept of *variety*. A more usual way to explain variety is advice to eat foods from each of the five (three to seven in different countries) nutritional food groups each day and to make regular changes of foods within each group.

The target for *total fat* is sometimes not quantitative. If a number is stated, it ranges between 35 (62) and 20% (52) of total energy. (Note that fat percent energy is a somewhat lower number if total energy includes alcoholic drinks as well as food, and it is also lower if fat is expressed as fatty acids, instead of fatty acids plus glycerol.) The recommendation to increase complex *carbohydrates* and fiber is stated in different ways and is less likely to be expressed quantitatively.

The recommendation to reduce *salt* is often not expressed quantitatively, but when it is, the target upper limit ranges between 4.5 (59) and 10 g/day (51). The NRC (7) sets 6 g salt per day, which corresponds in Australia to the upper end of the RDI range of 100 mmol sodium (70).

Where the quantity of *alcohol* is stated (for those not pregnant), it has usually been two drinks per day.

A *second group* of recommendations is more controversial; these give advice about polyunsaturated fats, dietary cholesterol, and sugar. When polyunsaturated fats are mentioned, the usual upper limit for individuals is 10% of energy (7, 18, 56, 62), but guidelines more often concentrate only on reduction of saturated fat, usually to 10% of energy. A few guidelines mention w-3 and w-6 polyunsaturated fatty acids.

Some U.S. guidelines and Singapore recommend reducing dietary cholesterol (to less than 300 mg day) (7, 59), but most committees do not mention dietary cholesterol in their headings. Indeed, the U.K. committee states that “dietary cholesterol has a small effect on serum cholesterol levels. The effect of dietary cholesterol in raising serum cholesterol is minimized when saturated fatty acid intake represents a small proportion of energy” (62).

On sugar(s) (other than those naturally occurring in milk and fruits, etc.), there appears to be the largest difference of opinion. Canada (39) recommends 55% of energy from carbohydrates from a variety of sources and does not mention sugar. Japan (51) and Korea (52) do not mention sugar either. At the other extreme, the Nordic recommendations (56) and Singapore (59) advise restricting refined sugar to less than 10% of energy. In between are several different opinions: “Do not increase sugar consumption” (7), “decrease sugar intake” (not quantified) (42), “limit total sugar intake to 15–25% of energy” (55), “cut down sugary snacks and sweets between meals” (46, 47), and “eat only a moderate amount of sugars and sugary foods” (18, 21).

A *third group* of recommendations appears only in a small number of guideline sets: encourage breast-feeding ([18](#), [59](#)); do not ingest too much protein ([7](#)); preserve (by good preparation) the nutritive value of foods ([46](#), [61](#)); drink fluoridated water (or use fluoride tablets) ([7](#), [10](#), [39](#)); make sure you get enough calcium (or milk) ([7](#), [10](#), [47](#), [52](#)); reduce intake of salt-cured and smoked foods ([59](#)); limit the intake of *trans*-unsaturated fatty acids ([62](#)); limit caffeine intake ([39](#)); foster happy eating for happy family life ([51](#)); enjoy your food ([61](#)).

SCIENTIFIC BASES OF GUIDELINES

The original hypotheses underlying dietary guidelines were mentioned in describing their history. After 30 years of evolution, how well are current guidelines justified by scientific knowledge? The six guidelines on which there is general agreement have clearly been reasoned by large numbers of experienced scientists, independently, in more than 20 different countries, and examined at greater length than is possible in this chapter. The evidence they used is, of course, also discussed in different places in this textbook. The following brief notes are intended to help link the six major guidelines with these scientific bases.

Eat a Nutritionally Adequate Diet from a Variety of Foods

A nutritionally adequate diet means eating all (or nearly all) the RDAs of those nutrients for which there is an RDA. A varied diet, if built around the food groups of nutritional education, is a fundamental principle of nutrition, older than dietary guidelines. It maximizes the probability of eating all the RDAs as well as minor nutrients that lack an RDA. At the same time, variety minimizes the risk of toxins and pathogens from food and drink. Food variety, how to quantify it, and associated health experience is the subject of a small but growing literature ([71](#), [72](#) and [73](#)).

Eat Less Fat, Particularly Saturated Fat

Fats in food provide more calories than any other food component, and much of this is hidden in attractive dishes and products. Reducing fat is the most important way of reducing excess energy intake. Many fatty ingredients in foods contain few other nutrients. If they are replaced by lean meat, low-fat milk, and vegetable foods, the intake of essential nutrients is improved. Saturated fat raises plasma total and LDL (low-density lipoprotein) cholesterol. The importance of limiting these is explained in [Chapter 74](#) and [Chapter 75](#).

Adjust Energy (Calorie) Intake to Expenditure and Avoid Overweight and Underweight

“Don't eat too much or too little” ([46](#)) is the fundamental quantitative principle of nutrition; it long antedates dietary guidelines. Mortality and morbidity are increased in people who are too thin (see [Chapter 41](#) and [Chapter 59](#)) or too fat (see [Chapter 63](#) and

[Chapter 87](#)).

Eat More Food Containing Complex Carbohydrates and Fiber

The terms *complex carbohydrates* and *fiber* are both imprecise. “Complex carbohydrates” is presumably used here to mean starchy foods and naturally occurring sugars (as in milk and fruits). “Fiber” presumably covers nonstarch polysaccharides and resistant starch. While this heading reflected the thinking in nutrition science in the 1970s, it is now realized that foods containing complex carbohydrates and fiber very likely contain a cocktail of other potentially protective substances: carotenoids other than b-carotene, folate, flavonoids, phytoestrogens, glucosinolates, alliin and allicin, limonoids, etc. (74) (see [Chapter 81](#)). The older heading is therefore being replaced by “Choose a Diet with Plenty of Grain Products, Vegetables and Fruits” (18, 21) ([Table 104.4](#)).

From the preceding guidelines, these plant foods should of course be eaten in variety and without added fat. They should also be eaten as whole foods (i.e., not refined), because they are intended not only to replace fat-rich foods but also to provide generous intakes of essential nutrients and a mixture of apparently protective other substances (mentioned above).

Reduce Salt Intake

Reducing salt intake is recommended in an attempt to reduce the prevalence of essential hypertension and (a firmer epidemiologic index) mortality from cerebral hemorrhage (see [Chapter 76](#)). The evidence may not be as strong as that for saturated fat and plasma cholesterol, but a taste for salty food is an acquired one, handed down from the era before refrigerators. Most societies consume several times more sodium than people need; no harm, and possibly some benefit, could result from intakes of 50 to 100 mmol sodium per day (3–6 g NaCl). In explaining this guideline, it is important to stress that “most sodium or salt intake comes from foods to which salt has already been added during processing or preparation” (21).

Drink Alcohol in Moderation, if at All

Drinking alcohol in excess causes road accidents, domestic violence, raised blood pressure, cirrhosis of the liver, fetal alcohol syndrome, and many other complications (see [Chapter 94](#)). While it appears that two or three standard drinks per day give some protection against coronary heart disease, this benefit is only of value in older adults and in communities with high risk of coronary heart disease. It has a smaller beneficial impact on the whole population than the adverse impact of alcohol in young people, since more person-years are lost from alcohol among people less than 35 years old than are saved in the older age group (75).

PRODUCTS OF DIETARY GUIDELINES

Dietary goals and guidelines have most impact on peoples' lives when they are

incorporated into policies, nutrition education handbooks, food labeling, modified foods, and health claims.

A National Food and Nutrition Policy. The Plan of Action of the World Declaration of Nutrition adopted by ministers of 159 states at the FAO/WHO International Conference on Nutrition (Rome, December 1992) states as the first of the strategies, “incorporating nutritional objectives, considerations and components into development policies and programmes” (76). For “nutritional objectives,” read dietary goals.

There is a big difference between a government report that induces no action and a policy that is followed through and supported with education, subsidies, tariffs, etc. The best-worked policy has been the Norwegian Nutrition and Food Policy (77).

In Britain a major government “white paper,” “Health of the Nation” (78) has four nutrition targets among its 10 risk-factor targets. These are to reduce saturated fat consumption, to reduce total fat consumption, to reduce the prevalence of obesity, and to reduce the proportion of people who drink too much alcohol. Ways of achieving these objectives are proposed. Healthier nutrition also is featured in the cancer section. These nutritional targets are naturally derived from the nation’s dietary goals.

In the United States, there are 21 nutrition targets in the large volume of national health promotion and disease prevention objectives (79). The first group of these relate to dietary guidelines and the later ones to services.

Food Guides. FAO and WHO have produced a recent report, *The Preparation and Use of Food-Based Dietary Guidelines* (8). The underlying idea of the consultation that prepared the report is that dietary guidelines need to be expressed in terms of foods and in ordinary language. Meanwhile, new food guides, centered on a colored diagram or poster have been produced (Fig. 104.1) in Canada (a quarter rainbow) (80), in the U.K. (a plate with food sectors) (81), and in the U.S. (the black pyramid [82], which is similar to the earlier Australian pyramid (83). These food guides use a simple visual form to show the groups of foods that provide the RDAs and, in the same picture, to show the dietary guidelines.

Figure 104.1. Recent food guides for nutrition education. A. Canada (Health Canada):

quarter rainbow (80); B. United Kingdom (Health Education Authority): plate (81); C. United States (U.S. Department of Agriculture): black pyramid (82); D. Australia (Australian Nutrition Foundation).

Nutrition Labeling. The food components in dietary guidelines—calories, fat, saturated fat, cholesterol, carbohydrate, sugar, fiber, and sodium (salt) are the main items in nutrition labeling of processed foods (“Nutrition Facts”).

Modified Foods. Special foods have been developed to help consumers follow dietary guidelines, namely, foods with reduced calories, reduced fat, reduced saturated fat, reduced sugar, increased fiber, increased calcium, reduced salt, or increased iron. Food standards have to be revised to include *standards* for these foods modified in line with dietary guidelines (i.e., definitions of “reduced fat,” “low fat,” “reduced salt,” “low salt,” etc.).

Health Claims. Eight health claims are allowed by the U.S. FDA in 1997 under the Nutrition Labeling and Education Act (1990) (NLEA) (see [Chapter 115](#)). The wording is regulated and so is the definition of appropriate foods. A typical claim essentially states the dietary guideline in its first sentence and, in the second sentence, states that this product is appropriate. For example, “Diets low in sodium may reduce the risk of high blood pressure, a disease associated with many factors. This product can be part of a low-sodium, low-salt diet that might reduce the risk of high blood pressure (hypertension)” (84).

Only one of the permitted health claims on foods in the United States is not based on a current dietary guideline, the claim about folate and prevention of neural tube defects. This is not yet a dietary guideline because the conclusive evidence was accumulated after the last major review for *Diet and Health* (1989) (7). This folate function will presumably belong with dietary guidelines in the future. In March 1996 the FDA authorized a health claim for folic acid and neural tube defects (see [Chapter 115](#)). Some other countries are discussing whether to adopt similar sorts of health claims.

SOME PROBLEMS AND QUESTIONS ABOUT DIETARY GUIDELINES

Keeping up to Date

As illustrated by folate, *trans*-unsaturated fatty acids, coffee (kahweol and cafestol) and plasma cholesterol, glycemic index of foods, resistant starch, phytoestrogens and bovine spongiform encephalopathy—none of which feature in most 1996 sets of dietary guidelines—nutritional research rolls on, and practitioners have to modify and add to authoritative guidelines, while committees should regularly revise (or at least add to) the last set of guidelines.

How Much Should I Eat?

Defining the amounts of food components and the foods that contain them in dietary guidelines is difficult. These recommendations are not medical prescriptions or diets for sick people but are intended for the healthy majority, people with a wide range of energy expenditures and intakes. Thus, it is almost impossible to hit the happy medium between being too vague and too detailed. *Servings* are being used as a semiquantitative indicator (85), but they work better for discrete foods than for mixed dishes.

Consider Sustainability, the Environment, and the World Food Problem

Two of the four principal objectives of the Norwegian Food and Nutrition Policy (1975 to 76)(32) were far ahead of their time: “the policy should aim at increased production and consumption of domestic food and at strengthening the ability to increase rapidly the degree of self-sufficiency in the food supply” and “for regional policy reasons the highest priority should be placed on utilizing the food production resources of the economically weaker areas” (of Norway).

Sooner or later national food and nutrition policies will have to consider the costs in energy and water consumption of the different dietary recommendations. It costs much more energy to ship fruit by air, to catch deep-sea fish, and to produce stall-fed beef than to grow plant foods in open fields (86, 87). It costs much more water to produce a kilogram of beef than a kilogram of chicken and more water to produce rice than wheat, maize, or potatoes. Gussow has written about dietary guidelines for sustainability (88, 89). A widely supported nutritional recommendation is to eat “five servings a day of fruit and vegetables.” Many do not eat this at present (90). If everyone did, the impact on agriculture, including the increased demands on ground water and for agrochemicals, would be enormous (91).

Dietary Guidelines or Idealized Traditional Cuisine(s)

Dr Elizabeth Helsing, who directed the WHO Nutrition Office for Europe in Copenhagen, declared at the 7th European Nutrition Conference in Vienna in 1995 that the “Mediterranean diet” is a more effective educational concept than dietary guidelines. Professor Willett of Harvard also prefers the concept of an idealized Mediterranean diet to the NRC's dietary guidelines (92), and he has collaborated in designing a different pyramid from the U.S. Department of Agriculture black pyramid (Fig. 104.2). An ideal, traditional Mediterranean diet has interested many nutritional scientists in recent years, and excellent symposia have been published on it (93, 94 and 95).

Figure 104.2. Alternative nutritional education pyramid, designed by Willet et al. (92), based on an ideal traditional Mediterranean diet.

Two other traditional diets should be considered in helping to make the results of nutritional research more palatable. One is the Japanese diet, initially a variant of classical Chinese cuisine, but now distinct and associated with the world's best life expectancy. Its fish consumption would not be sustainable for wider adoption, however, and the traditional salt content is too high.

The third ideal diet concept is the hunter-gatherer's diet. Our human ancestors' bodies presumably had time (50,000 generations) for genetic adaptation to diets of this type, which all humans ate until agriculture started only 10,000 years ago. These hunter-gatherers' diets contained a great range of parts of plants and animals but did not contain cereals or milk (after early childhood), sugar, salt, or alcohol (96, 97). To look backward at such diets is probably of more philosophic than practical value.

CHECKLIST FOR DIETARY GUIDELINES

- Dietary guidelines are recommendations about foods or food components other than essential nutrients. Are standards for essential nutrients included as well?
- Are dietary guidelines defined solely in terms of food components and foods (usually food groups) or do they also include eating behavior and food habits?
- Are recommendations expressed as *change* from the estimated present average diet in the country (“eat less —”) or in absolute terms (“choose a diet low in —”)?
- Are the recommendations qualitative, quantitative, or mixed? If quantitative, are the limits intended for individuals or for the population's average intake?
- Are they published by an authoritative group (e.g., the Ministry [Department] of Health) with minimal likelihood of commercial or other bias?
- Are they for a single country, for a region, or for the whole world (including low-income countries)?
- Are the goals and guidelines for now or for some date in the future?
- Are they addressed to everyone in the population or are some recommendations

for one subgroup?

- Are they written in technical language and/or in language that ordinary people can understand?
- Are they ranked in order of importance or priority? This may vary between different subgroups of the population.
- Do they include special advice for at-risk subgroups (e.g., people with atherosclerotic diseases, overweight and obese people)?
- Are they focused on the general population or on prevention of specific diseases (e.g., heart disease, cancer, diabetes)?

[Selected Readings](#)

The nutrition-monitoring program in the United States is considered the most comprehensive in the world. A model national nutritional program has been described as one that possesses such features as a coordinated set of activities that responds to the diverse needs of its data users, provides data on a continuous basis, supports reliable inferences about all population groups and geographic areas, and assists state and local nutrition-monitoring activities (1). The present National Nutrition Monitoring and Related Research Program (NNMRRP) in the United States is continually evolving. Yet, it has known limitations with respect to these model features. For example, it does not completely describe the current dietary and nutritional status of selected subgroups of the United States population, such as Native Americans residing on Indian reservations, Alaska natives, persons without a place of residence (homeless persons), institutionalized persons, and persons with particular physiologic and nutritional characteristics. National nutritional surveys provide data representative of the entire country and of major geographic regions but not of states, counties, and cities.

Although various national surveys have been conducted since the 1930s, Congress and the executive branch of government did not mandate a comprehensive strategy for a coordinated program to strengthen existing national monitoring efforts until 1990. This strategy was designed to review and integrate the various federal surveys to provide timely, useful information that systematically addresses questions concerning the dietary and nutritional status of the American population. Thus, the National Nutrition Monitoring and Related Research Act of 1990, a public law (PL 101-445), was enacted to place the existing monitoring system composed of interacting federal groups under an expanded program that includes related research. This program was designated to be guided by a specific 10-year plan under which action would be taken toward a goal of comprehensive national nutrition monitoring.

The National Nutrition Monitoring and Related Research Act defines nutrition monitoring

as “the set of activities necessary to provide timely information about the role and status of factors that bear on the contribution that nutrition makes to the health of the people in the United States” (2). Nutrition monitoring is characterized by regular data collection, analysis, and interpretation to provide a description of nutritional conditions in the population, and linkages with policy making and research. Monitoring provides a database for public policy decisions related to such issues as public health intervention programs, fortification, safety and labeling of the food supply, food assistance programs, and federally supported food service programs (3). It also assists in identifying health and nutritional research priorities of public health significance such as food security/insecurity, thereby strengthening the research base for monitoring and policy making.

The five components of the United States National Nutrition Monitoring System (NNMS) were specified in the 1987 Operational Plan as follows: (a) nutritional and health status measurements; (b) food consumption measurements; (c) food composition measurements and nutrient data banks; (d) dietary knowledge and attitude measurements; and (e) food supply and demand determinations (4). Although the titles of these components have been modified slightly in the 10-year plan for the NNMRP, the content of these components remains essentially the same (see Table 105.1 for revised names).

Activity	Agency	Survey Design
Nutritional and Health Status		
National Health and Nutrition Examination Survey	NCHS, CDC	Multi-stage, stratified probability sample of household occupants in office
National Health and Nutrition Examination Survey	NCHS, CDC	Continuous, stratified, multistage probability sample of individuals in households
National Health and Nutrition Examination Survey	NCHS, CDC	Probability sample of households, aged 0 to 18 years in 1971-1973, 1981-1983, and 1989-1991
National Health and Nutrition Examination Survey	NCHS, CDC	Continuous, stratified probability sample of 15-19 years of age, 1985-1991
Pregnancy Nutrition Surveillance System	NCHS, CDC	Continuous, stratified probability sample of pregnant women who participate in publicly funded prenatal and food assistance programs
Older Americans Resource Survey	NCHS, CDC	Older Americans resource survey
Food Consumption		
Continuing Survey of Food Intakes by Individuals	BHWC, ARS	Multi-stage, stratified, seven probability sample of defined populations
Continuing Survey of Food Intakes by Institutions	ARS, ARS	Strata with specific diets
Food Composition and Nutrient Data Banks		
National Health and Nutrition Examination Survey	NCHS, CDC	Multi-stage, stratified probability sample based on 10000 households
National Health and Nutrition Examination Survey	NCHS, CDC	Probability sample of 40000 grade students, one national and 39 state surveys
National Health and Nutrition Examination Survey	BHWC, ARS	Probability sample of 100000 children of age 6-17 years in 1989-1991
National Health and Nutrition Examination Survey	BHWC, ARS	Probability sample of 100000 children of age 6-17 years in 1989-1991
National Health and Nutrition Examination Survey	ARS, ARS	Continuous, stratified probability sample of households
Food Supply and Demand		
National Health and Nutrition Examination Survey	ARS, ARS	Multi-stage probability sample of other population strata using computerized data linkage to NCHS, CDC
National Health and Nutrition Examination Survey	BHWC, ARS	Strata with specific diets
National Health and Nutrition Examination Survey	BHWC, ARS	Strata with specific diets
National Health and Nutrition Examination Survey	BHWC, ARS	Strata with specific diets
National Health and Nutrition Examination Survey	BHWC, ARS	Strata with specific diets

National Health and Nutrition Examination Survey	BHWC, ARS	Strata with specific diets

Table 105.1 Principal NNMRP Activities, Sponsoring Federal Agencies, and Survey Designs

This chapter provides a brief account of the historical development of the NNMS and the current NNMRP (Table 105.2); describes the cornerstone surveys of the NNMS, giving special attention to survey design; discusses some of the limitations of the current program; and recognizes provisions in PL 101-445 that may enhance the program. In the context of nutrition monitoring, related health status refers to health conditions that may be associated with nutritional variables, such as diabetes and obesity, or osteoporosis and calcium. The terms *dietary status* and *nutritional status*, although often used interchangeably, have different connotations. Nutritional status encompasses

anthropometric, biochemical, clinical, dietary, and sociodemographic factors. Dietary status is a more limited term that refers to intake of foods, beverages (nonalcoholic and alcoholic), and nutrients, including supplements.

1977	Food and Agriculture Act (PL 95-113)

Table 105.2 History of Nutrition Monitoring in the United States

HISTORICAL OVERVIEW

In the late 1960s, concerns about the nutritional status of the United States population emerged as reports about the existence of hunger and malnutrition were released (5). Between 1969 and 1977, the Senate Select Committee on Nutrition and Human Needs investigated not only the extent to which hunger existed in the United States but also how effective the federal government was in measuring this problem. Recognizing serious deficiencies in federal nutrition-monitoring efforts and identifying the need for a coordinated comprehensive national nutrition monitoring system, Congress sought to remedy the situation by legislative action.

The Food and Agriculture Act of 1977 (PL 95-113) (6) required the secretaries of agriculture and of health, education and welfare (currently health and human services) to

formulate and submit to Congress ... a proposal for a comprehensive nutritional status monitoring system, to include: (1) an assessment of a system consisting of periodic surveys and continuous monitoring to determine: the extent of risk of nutrition-related health problems in the United States; which population groups or areas of the country face greatest risk; and the likely causes of risk and changes in risk factors over time; (2) a surveillance system to identify remediable nutrition-related health risks to individuals or for local areas, in such a manner as to tie detection to direct intervention and treatment ...; and (3) program evaluations to determine the adequacy, efficiency, effectiveness and side effects of nutrition-related programs in reducing health risks to individuals and populations.

The proposal for a comprehensive national nutrition monitoring system was submitted by the Department of Health, Education and Welfare and the United States Department of Agriculture (USDA) to Congress in 1978 (7). This proposal reviewed current federal,

state, and local agency activities in the areas of nutritional and dietary status assessment, nutritional quality of foods, dietary practices and knowledge, and the impact of nutritional intervention programs. It acknowledged the deficiencies in existing nutritional and dietary assessment methods, recognized delays in data analysis and the publication of results, pointed out the inadequate coverage of certain target groups and geographic areas, and recognized the inadequate evaluation of nutritional intervention programs. Although the proposal contained a series of recommendations for improving and expanding the scope of federal nutrition-monitoring activities, it lacked a set of priorities; assignment of tasks and a timetable for completion; a prospective plan; a reporting component to monitor progress of the NNMS; a timetable for publications; assignment of responsibility for implementation; identification of costs; and identification of the relationship to the Joint Subcommittee on Human Nutrition Research (8).

At the request of the Committee on Science and Technology, the proposal was reviewed by the General Accounting Office, which recommended that the departments develop an implementation plan for a national nutrition monitoring system to provide specific information on how and when the system could be implemented and on its cost. The Department of Health and Human Services and the Department of Agriculture (DHHS-USDA) Joint Implementation Plan for a Comprehensive NNMS was submitted to Congress in 1981 (9). The plan made the assistant secretary for food and consumer services, USDA, and the assistant secretary for health, DHHS, responsible for implementing compatible survey plans. It also identified and described the current efforts in nutrition monitoring conducted by the USDA and DHHS and proposed major goals and objectives for the NNMS. The two major objectives were (a) to achieve the best possible coordination of the National Health and Nutrition Examination Survey (NHANES) and the Nationwide Food Consumption Survey (NFCS) and (b) to develop a reporting system to translate the findings from these two national surveys and other monitoring activities into periodic reports to Congress on the nutritional status of the American population. The plan described how to implement the first coordinated NHANES-NFCS survey in 1987. However, certain critical features were never fully addressed, which inhibited achieving a comprehensive system (8).

In 1982 and 1983, the Subcommittee on Science, Research, and Technology and the Subcommittee on Department Operations, Research, and Foreign Agriculture jointly held hearings to review the system. They noted that coordination had improved but was still inadequate. The NNMS lacked a central focus, a provision for continuous monitoring, and a mechanism for evaluating food assistance programs.

In 1983, the Joint Nutrition Monitoring Evaluation Committee (JNMEC) was appointed. This federal advisory committee, jointly sponsored by the USDA and DHHS, was responsible for the first progress report to the Congress, as stipulated in the Joint Implementation Plan. The report, published in 1986, contained information on the nutritional status of the United States population and made specific recommendations to improve the monitoring system (10). The JNMEC reported that the principal nutrition-related health problems experienced by Americans arose from overconsumption of fat, saturated fat, cholesterol, and sodium. Intakes of iron and vitamin C were low in certain population groups. In addition to reviewing available data, the committee made 14 recommendations on how to improve nutrition monitoring

efforts.

In 1987, the DHHS and the USDA published an operational plan for the NNMS, a revision of the 1981 Joint Implementation Plan (4). The operational plan described the goals of the operational phase, progress during the implementation phase (1981 to 1986), and proposed activities for the operational phase (1987 to 1996), including a calendar of events. The specific goals were to achieve a comprehensive system through coordination among NNMS components, thereby improving both information dissemination and exchange between data generators and users and Congress, as well as the research base for nutrition monitoring.

The operational plan did not stipulate a time for implementation of the comprehensive, coordinated system sought by the Congress. Given the lack of legislative mandate to establish such a system, it was unclear how this operational plan would be any more successful than the 1981 Joint Implementation Plan. In 1988, the Interagency Committee on Nutrition Monitoring (ICNM) was formed (11). The committee was cochaired by the assistant secretary for health, DHHS, and the assistant secretary for food and consumer services, USDA. The purpose of this committee was to increase the effectiveness and productivity of federal nutrition-monitoring efforts by improving planning, coordination, and communication among the agencies engaged in nutrition monitoring. The membership included representatives from Public Health Service (DHHS) agencies, USDA agencies, the Agency for International Development, the Bureau of Labor Statistics, the Census Bureau, the Department of Defense, and the Veterans Administration.

In 1989, the second progress report on nutrition monitoring, prepared by an ad hoc expert panel, was transmitted to Congress. This report provided (a) an update to the 1986 report on the dietary and nutritional status of the United States population and (b) an in-depth analysis of the contributions of the NNMS to the assessment of iron nutriture and of dietary and nutritional factors related to cardiovascular disease (12). The expert panel concluded that the principal nutrition-related health problems experienced by Americans were related to overconsumption of selected nutrients, particularly food energy, fat, saturated fatty acids, cholesterol, sodium, and alcohol. Iron deficiency was cited as the most common single nutrient deficiency. The expert panel also made several recommendations to improve the NNMS.

Between 1984 and 1990, several attempts were made to pass a legislative bill to establish a coordinated national nutrition-monitoring and related research program (8, 13). This proposed legislation included developing a comprehensive plan to assess both the nutritional status and dietary intake of the United States population and the nutritional quality of the food supply. Provisions for conducting scientific research were also included. Finally, on October 22, 1990, the National Nutrition Monitoring and Related Research Act (PL 101-445) was signed into law (2).

The key monitoring provisions of this bill (Titles I and II) were

1. To establish an Interagency Board for Nutrition Monitoring and Related Research (IBNMRR) jointly chaired by an assistant secretary from the USDA and an

- assistant secretary from the DHHS.
2. To establish a National Nutrition Monitoring Advisory Council of nine voting members who are not federal employees.
 3. To develop and implement a 10-year comprehensive plan for a coordinated program designed to assess and report on a continuous basis the dietary and nutritional status of the United States population, particularly infants and children, the aged, disadvantaged persons, minorities, and women; to develop and update nutrient data banks; to sponsor and conduct research to develop uniform indicators and methods for conducting and reporting nutrition-monitoring activities; and to assist state and local government agencies in developing procedures and networks for nutrition monitoring and surveillance.
 4. To publish at least once every 5 years or sooner a report to the Congress on the dietary, nutritional, and health-related status of the American population and the nutritional quality of food consumed in the United States.

In 1991, the IBNMRR was established through expansion of the Interagency Committee on Nutrition Monitoring. As shown in [Figure 105.1](#), the IBNMRR is the central coordination point for the federal government's nutrition-monitoring program. About 20 agencies are members of the board ([14](#)). Board responsibilities include coordinating scientific reports that describe the nutritional and health status of the U.S. population, providing mechanisms for increased communication and collaboration among member agencies, and developing the annual budget report.

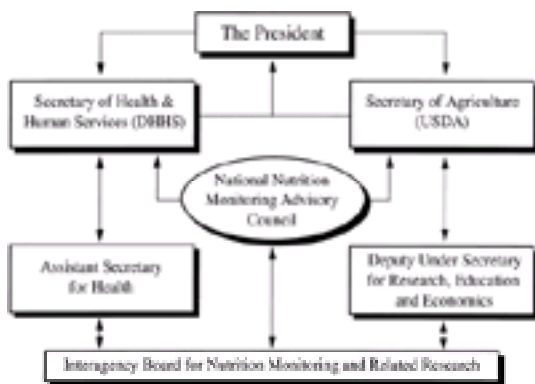

Figure 105.1. Structure of federal coordination of the National Nutrition Monitoring and Related Research Program.

The National Nutrition Monitoring Advisory Council, composed of nine nonfederal members with expertise in the areas of public health, nutrition-monitoring research, and food production and distribution, was established in 1992. The cochairpersons of the IBNMRR are ex officio nonvoting members of the council. The council is charged with providing scientific and technical advice on the development and implementation of the coordinated NNMRR Program and advising the secretaries of the USDA and DHHS. It

is required to report to the secretaries annually on the effectiveness of the NNMRR Program and to offer recommendations for enhancing the program's effectiveness. Since its formation, the council has identified six priorities for the NNMRRP: identifying ways to include high-risk subgroups of the population; integrating federal, state, and private data needs; determining the cost-effectiveness of the NNMRRP; providing timely data dissemination; assessing nutrition-monitoring research activities; and determining trends in NNMRRP data, especially those relating to measures of the food supply and to consumers' knowledge and attitudes toward nutritional and dietary guidance (15).

The Ten-Year Comprehensive Plan for the NNMRR Program describes national nutrition-monitoring activities for the period 1992 to 2002. A proposed plan was compiled by members of a DHHS/USDA working group and published on October 29, 1991 (16). After subsequent public comment and departmental revision periods, the plan was finalized. It was signed by the president and forwarded to Congress in January 1993 and published in the *Federal Register* on June 11, 1993 (17). This plan is intended to be the guidance mechanism to provide direction to the federal and state agencies participating in the national nutrition monitoring program. It discusses a tentative course of action designed to address some of the recognized deficiencies in the NNMS. For a detailed presentation of the proposed national nutrition monitoring activities and the agencies responsible, the reader is encouraged to refer to the 10-year comprehensive plan (17).

The plan includes three objectives at the national level and three at the state and local levels. The national objectives are to provide for a comprehensive NNMRR Program through continuous and coordinated data collection, to improve the comparability and quality of data across the NNMRR Program, and to improve the research base for nutrition monitoring. For each national objective, activities within the five components are delineated. The state and local objectives are to develop and strengthen state and local capacity for continuous and coordinated data collection that complements national nutritional surveys; to improve methodologies to enhance comparability of NNMRR Program data across federal, state, and local levels; and to improve the quality of state and local nutrition monitoring data.

Chartbook I: Selected Findings from the National Nutrition Monitoring and Related Research Program was published in 1993. This resource highlighted dietary intake data from the Hispanic HANES and the 1989 and 1990 Continuing Survey of Food Intakes by Individuals (CSFII), changes in the food supply, progress in developing food composition analysis methods, and selected dietary knowledge and attitudes of the U.S. population (18). Chartbooks that display data with graphics and brief narratives are proposed intermediates to the scientific reports to Congress by DHHS and USDA. They are designed to keep users of nutrition-monitoring data up to date on the latest findings and research of the NNMRR Program.

In 1995, the third report on nutrition monitoring prepared by the Life Sciences Research Office (LSRO) and a group of expert consultants was transmitted to the president and Congress (19). This two-volume report updated the 1989 report. Special emphasis was placed on the dietary and nutrition-related health status of Americans, and concerns for low-income and high-risk population subgroups were expressed. The expert consultants

noted that a considerable gap existed between what Americans eat and what they should eat and that some Americans do not get enough to eat. The increasing prevalence of overweight and the high proportion of the population with high serum cholesterol levels and hypertension are cause for public health concern. The expert consultants also provided recommendations for strengthening each component of the NNMRR Program and indicated ways to overcome some of the limitations of the present program.

NATIONAL NUTRITION-MONITORING CORNERSTONE SURVEYS

Between 1896, when the first food composition tables were published, and 1991, over 100 federal nutritional surveys and surveillance activities have been conducted. A chronologic listing categorized by measurement components was published in the comprehensive plan for national nutrition monitoring and related research ([16](#), [17](#)). Although many surveys and surveillance activities have been sponsored by a variety of agencies in the federal government, three in particular, the NFCS, the CSFII, and the NHANES, were regarded as the cornerstones of national nutrition monitoring. Because the NFCS was discontinued in the early 1990s, the two cornerstone NNMRRP surveys are the CSFII, sponsored by the Agricultural Research Service (ARS) of the USDA and the NHANES, sponsored by the National Center for Health Statistics of the DHHS.

Nationwide Food Consumption Survey

The involvement of the federal government in nutrition monitoring actually dates back to 1893, when the USDA received the first appropriation to conduct human nutritional research. The first national survey of household food consumption and dietary levels was conducted in 1936 to 1937 as part of the Consumer Purchases Study ([20](#)). Between 1942 and 1955, three nationwide studies on household food consumption (NFCS) were conducted by the Human Nutrition Information Service ([21](#)). These surveys included collecting information on household food use over 7 days and reflected food use from an economic perspective; that is, it included food used, whether it is eaten, discarded, or fed to pets. The person primarily responsible for food preparation in a given household provided this information. Food distribution among members of the household was not taken into account. In the 1965 and subsequent NFCS (1977–78 and 1987–88), data were obtained on dietary intakes and patterns of individuals as well as on household food use. Information on food consumed by individuals both at and away from home was collected for 1 day in the 1965 NFCS and for 3 consecutive days in the 1977–78 and 1987–88 NFCS. Nutrient content of food used by households and of food consumed by individuals was estimated from food composition data files developed from the National Nutrient Data Bank ([22](#)).

The objectives of the NFCS were to describe current food consumption behavior, to identify changes in diet since the previous NFCS, and to assess the nutritional content of diets for their implications on policies relating to food production and marketing, food safety, food assistance, and nutritional education. More specifically, data from the NFCS have been used to develop the *Dietary Guidelines for Americans* ([23](#)) and the “Thrifty Food Plan” ([24](#)), which is used as the statutory basis for the Food Stamp Program; to evaluate the achievement of the 1990 Health Objectives for the Nation ([25](#)): and to help

develop the nutritional objectives included in *Healthy People 2000* (26).

The NFCS was designed to provide a multistage stratified area probability sample representative of the 48 conterminous states (22). The stratification plan takes into account geographic location and degree of urbanization. In the 1987–88 NFCS, households were drawn from nine geographic divisions and three urbanization classes as defined by the Bureau of the Census (27). This NFCS included two probability samples—one for the basic survey of the general population (households and individuals with all incomes), and one for the low-income survey (households with incomes consistent with eligibility for the Food Stamp Program).

The 1987–88 NFCS involved three visits with participants (28). The initial visit identified respondents and provided them with materials needed to keep notes on household food used during the survey period. The next visit, 7 days later, consisted of a 2- to 3-hour personal interview to conduct the household phase of the survey, to obtain a 1-day dietary recall from individual members, and to leave these individuals a 2-day dietary record to complete. The final contact with respondents was 2 days later, to collect the 2-day dietary record. In addition to obtaining information on food use/intake, questions were asked about household characteristics; individual characteristics such as self-reported height, weight, and health status; participation in food assistance programs; and diet-related topics such as supplement use, alcohol consumption, use of salt at the table, and dieting (27). To reduce data processing time and make NFCS results more readily available, laptop computers were used in these household interviews.

The target sample for the basic 1987–88 survey was about 6000 households and their approximately 15,000 individual members. The low-income survey targeted 2500 households and about 6000 individual members (22, 29). The household response rate was 38% for the basic sample and 42% for the low-income sample (30). The individual response rate for the basic sample was 31% for individuals completing 1 day of intake and 25% for individuals who completed all 3 days of intake (29).

A national survey is designed to represent the United States population; if response rates are extremely low, it is questionable whether the data provide an unbiased estimate of the dietary and nutritional status of the nation. USDA contracted with the LSRO of the Federation of American Societies for Experimental Biology (FASEB) to conduct an independent review of the impact of nonresponse on the estimates of food and nutrient intakes. LSRO convened an expert panel of statisticians who noted that it was impossible to determine the extent to which nonresponse bias influenced the interpretation of the data. This panel consequently recommended that persons using the 1987–88 NFCS data should exercise great caution and should recognize that the respondents might not be completely representative of subgroups when group comparisons are made. Comprehensive evaluations of the possible effects of nonresponse in the NFCS and of potential limitations in using the collected data have been published (29, 31).

Continuing Survey of Food Intakes by Individuals

The first CSFII was conducted in 1985, the second in 1986. These two surveys constitute series I. Series II began in 1989 and includes the 1990 and 1991 CSFIIs. Series III began in 1994 and continued through 1996. This 3-year survey is popularly known as the “What We Eat in America Survey.” The purpose of these surveys is to provide information on the dietary status of the United States population and to monitor changes in dietary intakes. In addition, individuals identified as main meal planners/preparers in the 1989 to 1991 CSFIIs were contacted to participate in the Diet and Health Knowledge Survey, another NNMRRP activity sponsored by the USDA. The dietary data collected in the CSFII was then linked to an individual's nutritional knowledge and attitudes.

“Usual” intakes were assessed in the 1985 and 1986 CSFII by multiple 24-hour dietary recalls over a 1-year period. A 1-day dietary recall in an in-person interview and a self-administered 2-day dietary record were used in the second CSFII series (32). As in the NFCS, nutrient intakes were calculated from the National Nutrient Data Bank. The dietary data collection method for the 1994–96 CSFII consisted of two nonconsecutive 1-day recalls of food intake through in-person interviews.

The target population for series I and II CSFII consisted of individuals selected by sex and age residing in the 48 conterminous states in households with incomes at all levels (basic sample) and with incomes at or below 130% of poverty guidelines (low-income sample). The 1985 CSFII included men and women aged 19 to 50 years and children 1 to 5 years of age (33, 34 and 35), whereas the 1986 CSFII included women 19 to 50 years of age and children 1 to 5 years of age (36, 37). For the series I CSFII, the basic sample included approximately 1300 households and their 2000 individual members. The 1985 low-income sample included about 1900 households and their 3400 individual members, whereas the 1986 low-income sample had about 1200 households and 2100 individual members. Individual response rates for women and children completing 1-day recalls were 71% for the basic sample and 65% for the low-income sample in 1985 and 66% for the basic sample and 75% for the low-income sample in 1986 (38).

The 1989 to 1991 CSFIIs were designed to obtain information on food intakes from all household members (men, women, and children of all ages). Like the 1985 and 1986 CSFII, they had basic and low-income samples. Approximately 6700 households and their 15000 individual members were included in the samples. Overall household response rate for the 1989 to 1991 CSFII was 67%. Individual response rates were 58% for those completing 1 day of dietary recall and 45% for those completing 3 days (19).

The sample size for the 1994–96 CSFII was projected to include approximately 15,000 to 16,000 respondents, about 5,500 individuals each year. In 1994, 5,540 individuals completed 1 day of intake recall, and 5,263 completed both days of intake recall (39). Notable design changes from the first two series include a target population of noninstitutionalized persons in all 50 states, oversampling of the low-income population rather than a separate low-income survey, larger samples of young children and older adults, subsampling within households, and collection of 2 nonconsecutive days of food intake data through in-person interviews rather than 3 consecutive days of food intake

data using a 1-day recall and a 2-day record ([39](#), [40](#)).

National Health and Nutrition Examination Survey

In 1967, the Senate Subcommittee on Employment, Manpower, and Poverty of the Committee on Labor and Public Welfare noted in a letter to President Lyndon Johnson that malnutrition and widespread hunger had reached emergency proportions. In response to these concerns and the lack of a monitoring system to determine the magnitude of the problem, Congress mandated, in Section 14 of the Partnership for Health Amendments of 1967, that the secretary of health, education, and welfare, in collaboration with other federal government and state officials, was to conduct a comprehensive survey to assess the incidence and location of serious hunger, malnutrition, and health problems. This action authorized the National Nutrition Survey, better known as the Ten State Nutrition Survey.

The Ten State Nutrition Survey, 1968 to 1970, was designed to select families randomly from the 1960 Bureau of Census enumeration districts, where the highest percentage of families had incomes below the Orshansky Poverty Index in the states of California, Kentucky, Louisiana, Massachusetts, Michigan, New York, South Carolina, Texas, Washington, and West Virginia. The sample population included middle- and upper-income persons who, because of changes in residential patterns subsequent to 1960, were living in selected enumeration districts. Nutritional status was assessed on the basis of dietary intakes and food patterns, dental examinations, and anthropometric and biochemical measurements. Information on nonnutritional factors that affect food intake (e.g., socioeconomic characteristics, health status, and income) was also gathered. The findings indicated nutritional problems in selected age and sex groups ([41](#)).

While the Ten State Survey was still under way, in 1969, President Richard Nixon asked the secretary of the Department of Health, Education, and Welfare to expand it to describe the extent of hunger and malnutrition in the entire United States. In response, a Task Force on Nutritional Surveillance at the National Center for Health Statistics (NCHS) was formed and asked to plan and implement a survey to provide an effective nutritional surveillance system. To minimize duplication with other surveys conducted by the NCHS and to permit nutritional variables to be correlated with other health status measurements already being collected in the National Health Examination Survey (NHES), a nutritional assessment component was added to the NHES to create the first NHANES. Conducted between 1971 and 1974, NHANES I was the first health survey to assess dietary intake and other measures of nutritional status in a nationally representative sample of persons aged 1 to 74 years in the civilian, noninstitutionalized population in the United States ([42](#), [43](#)).

A major objective of the NHANES is the periodic assessment of the health and nutritional status of the United States population and monitoring changes in status over time. The second NHANES was conducted from 1976 to 1980 ([44](#)), and the third NHANES, from 1988 to 1994. The Hispanic HANES (HHANES) was conducted from 1982 to 1984 ([45](#)). This special survey included three Hispanic groups: Mexican Americans residing in five southwestern states; Cubans in Dade County, Florida; and

Puerto Ricans in the New York City metropolitan area.

Each of the NHANES surveys has used complex, multistage, probability, cluster sampling to select a representative sample of the civilian noninstitutionalized population residing in households in the United States. Special oversampling techniques were used to ensure adequate representation of subgroups considered at high risk of malnutrition. NHANES II statistically selected a sample of 27,805 individuals to represent the entire United States population and selected subgroups. About 91% of those selected agreed to be interviewed, and 73% agreed to be interviewed and examined (38). In the full 6 years of data collection for the NHANES III, 1988 to 1994, approximately 40,000 individuals were selected, of whom 86% were interviewed and 78% were examined. The age range for NHANES III was expanded to begin at 2 months with no upper age limit.

The NHANES is unique because it collects data on the health and nutritional status of Americans through interviews and direct physical examinations. The household interview is administered in four parts:

1. A household screener questionnaire is used to determine household eligibility and select sample persons.
2. An adult household questionnaire is used to assess health status and practices, including reported health conditions, use of health and dental services, meal program participation, and use of vitamin/mineral supplements and medications.
3. A child household questionnaire contains items similar to those asked of adults plus questions on infant feeding practices, weight status, breast-feeding history and status, and other nutrition-related questions.
4. A family questionnaire is used to determine relationships of persons in the household, to obtain basic demographic data, and to assess participation in income assistance programs, including the Food Stamp Program and Women, Infants and Children (WIC) Program.

After completing the household interview, sample persons are invited to Mobile Examination Centers where the NHANES staff administer standardized examination and laboratory tests.

Nutritional status is evaluated from data generated through interviews and direct physical examinations. Listings of the major parameters measured by sex and age have been published (46). Briefly, the interviews include a single 24-hour dietary recall; a food frequency questionnaire for persons 12 years of age or older; questions related to eating habits, lifestyle, and other nutrition-related practices; and a medical history. NHANES III includes a quantitative measure of intake of vitamins and minerals from supplements and a series of food sufficiency questions. Physical examinations include such components as anthropometric measurements, hematologic and biochemical assessments, and physical and dental examinations. The survey design and implementation strategies have been described in various reports (46, 47), and a compendium of all data collection instruments for the NHANES III has been published (48).

The NHANES is designed as a multipurpose survey. Some examples of the major uses of the data include assessment of selected conditions (e.g., growth retardation, exposure to lead, prevalence of overweight [49], hypertension [50], and high blood cholesterol level [51]), evaluation and development of nutritional policy (e.g., *Healthy People 2000* [26] and the *Dietary Guidelines for Americans* [23]), and assessment of food fortification policies.

OTHER NUTRITION-MONITORING ACTIVITIES

In addition to the core components, CSFII and NHANES, several other survey and surveillance activities constitute the NNMRRP. Approximately 50 monitoring activities that will provide information on the five measurement components are planned between 1992 and 2002 (17). The activities conducted on a regular basis and their sponsoring federal agencies are shown in [Table 105.1](#). The periodicity of the activities varies. For example, food supply estimates are conducted annually, whereas the Food Label and Package Survey is done biennially. Many special surveys, such as the Vitamin and Mineral Intake Survey, the Navajo Health and Nutrition Survey, and the National Maternal and Infant Health Survey, are also conducted periodically as needs arise. A comprehensive compilation of all NNMRRP activities with descriptions about survey design and objectives, sample sizes, and response rates is provided in the *Directory of Federal and State Nutrition Monitoring Activities* (30) and the comprehensive plan for national nutrition monitoring and related research (17).

LIMITATIONS OF THE NATIONAL NUTRITION-MONITORING SYSTEM

The five components of the NNMRRP provide much valuable information. Recommendations for strengthening each component of the NNMRRP are published in the *Third Report on Nutrition Monitoring in the United States* (52). In general, there is a need for improvement, especially with regard to components that have not been functionally integrated into a coordinated and comprehensive system. Both the USDA and the DHHS have made serious efforts to improve and coordinate their individual nutrition-monitoring activities. To improve communication and coordination among the NNMRRP member agencies as well as to oversee the activities delineated in the 10-year comprehensive plan, three staff working groups in the areas of survey comparability, food composition data, and federal-state relations and information dissemination and exchange, were established.

In 1992, a report on comparability of selected population descriptors was published (53). The purpose of this report was to standardize collection and reporting of key socioeconomic variables and to enhance data linkages across NNMRRP surveys and surveillance systems. With completion of the population descriptors report, the Survey Comparability Working Group has focused on documenting selected nutritional and nutrition-related health variables across the NNMRRP and identifying specific assessments that would constitute a minimum set of indicators for nutritional status.

USDA and DHHS are continually collaborating to improve dietary information and

linkage of dietary data. The same food codes and nutrient database were used to analyze data collected in the NHANES III and the 1994–96 CSFII. Development of automated procedures for tracking food composition changes to facilitate analysis of trends in nutrient intakes and expansion of the Survey Nutrient Data Base to include foods reported in national dietary intake surveys is planned. Additionally, the Food Composition Working Group has started evaluating the effectiveness of the food composition data component in meeting the needs of the NNMRRP.

A survey of primary users of NNMRRP data, including persons in federal, state, and local government, academic institutions, and for-profit businesses such as food industries and hospitals, indicated that most were satisfied with the quality of NNMRRP data and the degree to which these data meet their needs. Despite their satisfaction, the respondents noted changes that would increase their confidence in, or substantially increase their use of, NNMRRP data. Common themes for improvement were more detailed information on racial, ethnic, and age groups; data that can support estimates for small geographic areas; improved timeliness and documentation of data; continuous or more-frequent data collection; and increased dissemination of the data in general formats that facilitate access and analysis (54). Some of these shortcomings are discussed below.

Population Subgroup Coverage

The core components (CSFII and NHANES) provide data representative of the civilian, noninstitutionalized population in the United States. Groups excluded from these surveys include active-duty military personnel residing on military installations and persons in institutions, such as long-term care hospitals, homes for the aged, convents, monasteries, and penal and mental institutions. Homeless people with no address are excluded from all household surveys because lists of addresses within census tracts are used as the basic unit for sampling.

As shown in [Table 105.1](#), a complex, multistaged, stratified probability method of sampling is used in the core national surveys. This method either limits or eliminates the sample size of some subgroups that may be at higher risk for nutritional problems. For example, selected subgroups (e.g., pregnant or lactating women) and ethnic minority groups (e.g., Asians and selected Hispanic subgroups) do not occur in the population in sufficient numbers to yield adequate representation in the survey sample for reliable detailed estimates of their nutritional and health status. To capture all population subgroups, other approaches need to be implemented (55). Special surveys, such as the Hispanic HANES or the CSFII low-income sample, can be conducted.

Oversampling, a technique used to increase sample size, can help improve the precision of estimates for nutritional and health variables. For example, NHANES III oversampled African American and Mexican American persons, children under 6 years of age, and adults aged 60 years or older.

The nutrition objectives in *Healthy People 2000*, give a high priority to obtaining more data on the nutritional status of seven selected groups: people in hospitals, nursing homes, convalescent centers, and institutions such as those for the developmentally disabled; physically, mentally, and developmentally disabled individuals in community

settings; children in child care facilities; Native Americans on reservations; old and very old individuals living independently; people in correctional facilities; and the homeless (26). PL 101-445 also cited the need to gather data on these groups (2). More specifically, this current legislation mandates that the comprehensive plan include components to incorporate, in survey design, military and (where appropriate) institutionalized populations; to sample representative subsets of identifiable low-income populations such as Native Americans and the homeless; and to collect dietary and nutritional status measurements on preschool and school-age children, pregnant and lactating women, elderly individuals, low-income populations, blacks, and Hispanics. The *Third Report on Nutrition Monitoring*, prepared by the LSRO with input from expert consultants, recommended focused studies of these high-risk populations using data collection techniques comparable to national surveys. This approach seems to be the most economical way to assess these groups (52).

Geographic Coverage

Many users of NNMRRP data request that federal agencies provide information on defined geographic areas, such as cities, counties, and individual states. The design of federal surveys uses primary sampling units consisting of a county or a contiguous group of small counties that are stratified by characteristics such as urbanization and income. However, confidentiality restrictions prohibit release of data with identification of limited geographic areas. Areas are selected randomly within regions to provide the most representative sample while minimizing operational costs. Both NHANES and CSFII are designed to provide a picture of the nation. The USDA also reports the findings from CSFII by the four major geographic regions of the country (Northeast, North Central, South, and West), as defined by the Bureau of the Census. Data from NHANES III can be analyzed and reported by these four regions. Data from the NHANES I and II were available by region; however, the regions were not identical to those defined by the Census Bureau (44). Although regional data are available, representative state and local (city) data cannot be obtained from the core surveys.

Surveillance activities at the Centers for Disease Control and Prevention (CDC) effectively target high-risk populations in narrow geographic areas. These activities include the Pediatric Nutrition Surveillance System (PedNSS) and the Pregnancy Nutrition Surveillance System (PregNSS), whose target populations consist of a convenience sample of low-income children and pregnant women, respectively, who participate in publicly funded health, nutrition, and food assistance programs. Participation in the CDC system is voluntary. In 1995, 43 states, 5 Indian tribes, the Intertribal Council of Arizona, and Washington, DC, and Puerto Rico participated in the PedNSS, and 26 states, Washington, DC, the Navajo Nation, the Intertribal Council of Arizona, and American Samoa participated in the PregNSS. The states involved in these two surveillance activities receive the data analysis results on a monthly, quarterly, or annual basis for use in program planning, management, and evaluation.

The comprehensive plan for the NNMRRP in PL 101-445 requires that the federal government provide scientific and technical assistance, training, and consultation to state and local governments for the purposes of obtaining dietary and nutritional status data; developing related databases; and promoting development of regional, state, and

local data collection services so they might become integral components of a national nutritional status network. A grant program to encourage and assist state and local governments in developing their capacity to monitor and oversee nutritional status, food consumption, and nutritional knowledge and to enhance nutritional services is also a provision of PL 101-445 (2). However, this legislation has no statutory provision for additional funds to establish such programs. Therefore, as part of the related research provision of this law, innovative ways must be developed to help smaller areas meet their needs for information about the nutritional status and health of their residents.

Timeliness of Data

Timely data are essential for both policy makers and researchers. National surveys involve large sample sizes and oftentimes relatively long periods for data collection. In the past, one of the major limitations of the NNMS was inordinate delays in processing and release of data from both the core and ancillary surveys (56). With improved technology and use of automated data collection systems, such as an automated system for assigning food codes that was used in the NHANES III, data from future NNMRP activities should be disseminated faster. Indeed, some results from NHANES III, a 6-year survey conducted from 1988 to 1994, were analyzed and published after the first 3 years of data collection (49, 50, 57, 58 and 59). The full 6-year data were available for public release and analysis on a CD-ROM in 1997. Electronic bulletin boards are used to distribute nutrition-monitoring publications and survey data, and CD-ROMs are used to distribute survey data. The data from the 1994 series III CSFII was released in March 1996 on a CD-ROM at a USDA-sponsored users conference. Although progress has been made toward more timely release of survey data, further improvements are needed to meet the needs of public health administrators and nutritional policy makers.

CONCLUSIONS

The future direction of the NNMRP will continue to be largely determined by the interpretation of PL 101-445 and by the various federal agencies that sponsor monitoring activities and contribute to the 10-year comprehensive plan. The law provides many windows of opportunity to enhance the current NNMRP by increasing involvement at the state and local levels. The law authorizes carrying nutrition-monitoring activities into nonfederal areas, with the potential to expand monitoring beyond the core components of DHHS and USDA. The 10-year plan is ambitious and includes new activities. The extent to which these proposed initiatives are carried out and realized will largely depend on adequate allocation of resources.

Organizations and programs are currently changing both to become more efficient and effective in conducting their activities and to minimize duplication of efforts. Although the impact that reorganization, program restructuring, and resource reallocation will ultimately have on the NNMRP is uncertain, such changes can have potentially far-reaching implications. With governmental reorganization, some agency units inevitably disappear as they are combined with other divisions for greater efficiency. Other units are selected to reorient their ongoing nutrition-monitoring activities. For example, at the time of this writing, discussions are under way within the IBNMRR by

representatives of USDA and DHHS to explore implementing a joint survey and research project that would incorporate CSFII and NHANES components into a single national survey. Although the outcomes of these discussions are not yet final, these are precisely the type of negotiations that the NNMRR Act of 1990 was designed to foster.

With potential decentralization of programs from the federal government and increasing empowerment of the states through block grants and other financial and administrative mechanisms, current nutrition-monitoring approaches may need reevaluation. Because of potential changes in the methods used to administer food assistance programs and the movement toward managed health care, nutrition-monitoring activities may increasingly focus on providing information that can be better applied and interpreted at the state and local levels.

Finally, some monitoring activities have become more sophisticated. Nutrition-monitoring databases, for example, are becoming much larger, and computerized methods allow rapid, selective retrieval of desired information. However, the full potential of these advances may not be realized if fiscal constraints restrict their use. The 10-year plan was ambitious, optimistic, and visionary. A review of the plan was scheduled to begin in 1997. To what extent the goals and objectives of this plan will be met by the year 2002, when it is scheduled to be completed, depends largely on the availability and judicious allocation of adequate resources to support the activities and projects described in it.

The NNMRRP is still evolving and probably still surpasses the nutrition-monitoring activities in any other nation. Taken together, the many national nutrition-monitoring components provide an opportunity for comprehensive and coordinated evaluation of the dietary status and the nutritional status of the U.S. population and of selected subgroups considered at high-risk for developing nutrition-related health problems.

HISTORICAL CONTEXT

For centuries, vegetarian diets have been used to meet nutritional needs, perhaps most often out of economic necessity in underdeveloped countries. Nonetheless, even in ancient times some advocated such diets for a variety of health-related, religious, or ethical reasons. Pythagoras is considered the founder of the vegetarian movement; advocates included other ancient Greeks. Eastern religions, including Buddhism, Zainism, and Hinduism, also promoted vegetarian diets and continue to urge preservation of animal life; vegetarians are found among their adherents.

In the 18th century, Benjamin Franklin was perhaps the most famous of the scientists, physicians, and philosophers who supported vegetarian diets. The vegetarian movement expanded considerably in the 19th century with the formation of societies, establishment of health care facilities, publication of books, and opening of restaurants, all promoting vegetarian diets. The 20th century witnessed a further expansion of interest and knowledge. Details of the history of vegetarian dietary practices can be found in recent reviews ([1](#), [2](#)).

A 1994 survey reported that some 12.4 million people in the United States call themselves vegetarians ([3](#)). This represents approximately 7% of the population and a near doubling in number of reported vegetarians over an 8-year period. It is predicted that 10% of all Americans will consider themselves vegetarians by the year 2000 ([4](#)).

The growing vegetarian population necessitates that health professionals be informed about the potential benefits and risks associated with these dietary practices. Position papers and scientific reviews have been published, as well as the proceedings from two international congresses addressing this topic ([5](#), [6](#), [7](#) and [8](#)); proceedings from the third, held in 1997, are under review. A recent monograph addresses virtually all topics related to the nutritional status of vegetarians and provides useful summaries of the literature as well as dietary suggestions for different conditions ([9](#)).

DEFINITIONS AND RATIONALE FOR VEGETARIAN DIETARY PRACTICES

The term *vegetarian* encompasses a wide range of dietary practices with potentially differing implications for health. It is not uncommon for individuals who call themselves vegetarians to consume meat. It was recently reported that 20% of vegetarians said they ate meat at least once a month ([4](#)). Consumption of fish or poultry is even more common.

The varied dietary practices result in differing nutritional intakes and necessitate that health professionals ascertain what actually is eaten rather than depend on what persons call themselves. Unfortunately, there is no consistent definition for vegetarian in the various scientific studies, although researchers may classify subjects on reported dietary intake rather than on what the subjects call themselves or their diets.

Cereal grains, fruits, vegetables, legumes, nuts, and seeds form the basis of vegetarian diets, with varying amounts of dairy products, with or without eggs. The types of animal products included frequently are used to identify the kind of vegetarian diet. Lactoovovegetarians (LOVs), sometimes called ovolacto vegetarians, and lacto vegetarians are the largest subgroups. Both exclude meat, poultry, fish, and other seafood.

It is quite common for nonvegetarians to believe that vegetarians eat fish; while this may be true in some cases, it is not true of all vegetarians. Those who include fish may be called pescovegetarians, and those who include poultry may be called pollovegetarians;

however, they are more commonly classified as semivegetarians, with individuals who are occasional or infrequent meat eaters.

Persons who exclude all animal products may be called strict, total, or pure vegetarians. However, these descriptors are also sometimes used, albeit inaccurately, to mean simply exclusion of flesh foods. The term *vegan* is explicitly used to define individuals who do not use any animal products. Some vegans also refrain from using honey and animal products such as leather or wool. Only 4% of vegetarians report they are vegans (4).

Additional subgroups of vegetarians or near vegetarians have been reported in recent years. In the 1970s, individuals who did not belong to vegetarian groups common at the time and who did not fit the usual definitions for vegetarians were classified as “new” vegetarians. The rationales for their dietary practices and actual food choices differed considerably among them.

Macrobiotic diets are often classified as vegetarian, although they may include fish. The macrobiotic diets of today are an outgrowth of a 10-step approach to eating that culminated in a diet composed almost exclusively of brown rice. This diet resulted in severe nutritional deficiencies and has since been modified. Although it still emphasizes brown rice and other whole grains, it also includes sea vegetables, legumes, and root vegetables. Animal foods are limited to white-meat fish, once or twice a week. Standard macrobiotic diet recommendations include 50 to 60% whole grains, 20 to 25% vegetables, 10% beans and sea vegetables, and 5% soups. Locally grown fruit may be consumed occasionally in season. Meat, poultry, eggs, dairy products, butter, yogurt, sugar, honey, and artificial sweeteners are to be avoided.

Occasionally, a fruitarian may be encountered or an individual who consumes only raw foods. The fruitarian diet consists of fruits (including those vegetables botanically classified as such), nuts, and seeds. A raw food diet, also called “living food diet,” includes uncooked, fermented, or sprouted plant foods and the juice made from sprouts.

Thus a broad spectrum of dietary practices may be classified as vegetarian. Regardless of how persons identify themselves, so far as dietary practices are concerned, actual dietary intake must be ascertained before effective nutritional intervention can take place. Knowledge of why an individual follows particular dietary practices is also helpful in developing an appropriate counseling approach.

Although, historically, vegetarian diets were associated with certain religious practices, currently, health appears to be the primary reason for adopting a vegetarian diet (4). The second reason encompasses ecologic and environmental issues relating to the large differences in resources necessary to support animal- and plant-based diets. The third currently most common reason relates to ethical concerns about the treatment of animals and may extend to the use of animals for clothing or research. In many cases, however, multiple reasons underlie vegetarian dietary practices.

The differing reasons for adopting a vegetarian diet may affect food choices and subsequently nutritional status. In addition, the rationale for a particular diet may be

associated with other lifestyle practices that can affect health. Thus, ascertaining these reasons and associated practices is an important aspect of a patient's history.

DIETARY INTAKE AND NUTRITIONAL STATUS AMONG VEGETARIANS

There are many and varied ways to meet nutrient needs, and the adequacy of a diet depends not on what it is called but on the foods that are included. A vegetarian diet need not be deficient in nutrients; however, the more foods eliminated from any diet, the greater the risk of deficiency.

Most vegetarians ingest an adequate diet; however, those following restrictive dietary patterns may not, and these engender significant concern, especially when they include pregnant and lactating women, infants, children, and the elderly. As our understanding of both beneficial and problematic aspects of vegetarian dietary practices grows, it allows us to focus our attention on those issues of greatest consequence for preventing disease and promoting health. Thus, our attention here addresses those questions that are most frequently raised.

Dietary Intake

Energy

Energy Intake and Weight Status. Some, but not all, investigators report that vegetarians weigh less than nonvegetarians, with the difference being least among the LOVs and greatest among the vegans. The lower weight among vegetarians is consistent with the lower intake of calories often reported. The energy-yielding nutrients of protein and fat are generally consumed in somewhat greater amounts by nonvegetarians, while larger amounts of carbohydrates are consumed by vegetarians. The result of this difference is that vegetarians may more closely approximate dietary recommendations for the distribution of macronutrients than do omnivores, and they may be closer to desirable weight.

A variety of other reasons have been suggested for the weight difference. In addition to the higher intake of carbohydrates, which may be less efficiently converted to body fat, they include perhaps greater control of food intake, possibly greater physical activity, and greater intake of fiber, which may enhance satiation ([10](#)).

Although overweight is a frequent concern in the general population, maintaining adequate weight through appropriate caloric intake may be a concern to some vegetarians. Those at risk include children, adolescents, the elderly, and those who include no added oils or fat in the diet.

Vegetarian Diets and Weight Loss. The general understanding that vegetarian diets are associated with lower weight status may be the rationale for some females to adopt such a diet in hope of weight loss. Vegetarian dietary practices have been found among anorexia nervosa patients, although most were not vegetarians prior to the anorexia. It

was suggested that vegetarian diets are a convenient and socially acceptable way to reduce caloric intake (11). A recent study of eating behavior found that vegetarian women had lower dietary restraint scores, indicating they were not motivated by weight loss to adopt the vegetarian diet (12). Thus, it is inappropriate to conclude that vegetarians are more prone to eating disorders than the general population.

Protein

One of the most frequent questions regarding the nutritional adequacy of vegetarian diets relates to protein, yet there is little supporting evidence for such concerns with usual dietary intake in healthy vegetarians. However, the inadequate energy intake seen in some vegetarians may compromise protein status.

Nutritional Quality of Plant Proteins. The nutritional quality of plant proteins may be underestimated in studies of animals, because animals have greater protein needs than humans. More relevant human data confirm the adequacy of plant proteins to meet the needs of both adults and children. Plant foods are often said to lack certain indispensable amino acids and thus be of lesser quality than animal foods. Although a certain plant food may be low in a specific amino acid, it is inaccurate to say it is incomplete. A single plant food, if fed as the only protein source, may prove inadequate; however, this is likely to occur only in a research setting. Appropriate mixtures of plant foods are equivalent to animal protein in quality and are commonly consumed.

Limiting Amino Acids. Two amino acids are of particular interest in vegetarian diets: lysine, the limiting amino acid in cereal grains, and methionine, the limiting amino acid in legumes. Lysine occurs in significant amounts in the intracellular spaces of the skeletal musculature where it is deposited after a protein-rich meal (13). Subsequently, it is available to buffer a low-lysine amino acid mixture resulting from consumption of a meal deficient in this amino acid.

Methionine is of interest because it is the limiting amino acid in soy and other legumes, often a major source of protein in vegetarian diets. Soy protein isolates have been used successfully to refeed children recovering from malnutrition; they provide a protein quality comparable to that of milk. They may be used as the sole source of protein for adults and children; however, modest supplementation with methionine may be appropriate for soy-based infant formulas, although the amount needed is lower than predicted from rat studies (13).

Complementation. Protein complementation occurs when a food low in a particular amino acid is combined with a food containing an adequate amount of that amino acid. Animal studies have influenced our attitudes toward combining complementary proteins within one meal. In these studies, an amino acid otherwise absent from the diet was added several hours later. Such a delay in providing a supplementary amino acid to rapidly growing rats and pigs affects protein use. Similar effects were not seen in human adults when the plant protein was distributed among several meals. The supplementary effect was somewhat lower in young children when the proteins were fed at intervals longer than 6 hours; however, this is a longer period than usual in young children, and meals are not entirely devoid of an amino acid as in the laboratory studies (13). It can

be concluded that combinations of plant foods consumed throughout the day provide adequate amino acids for nitrogen retention and use.

Digestibility. Plant proteins in their natural form are, in general, less digestible than animal protein sources. Well-processed soy isolates, however, are as digestible as egg protein (13). Processing methods may have beneficial or detrimental effects on the nutritional quality of plant proteins. Consuming a broad variety of foods prepared in many different ways ensures adequate intake of amino acids.

Protein Intake. Vegetarians, in general, consume less total protein and even less animal protein than omnivores; however, studies consistently show they more than meet the recommended dietary allowances (RDA) and the recommended 10% of calories as protein. In addition, they more than meet the needs for the indispensable amino acids. Current evidence suggests that lower animal protein intake is beneficial and may lower urinary calcium excretion and slow the progression of renal disease. In addition, compared with animal protein, plant sources contribute less total fat, saturated fat, and cholesterol and more carbohydrate and fiber. In more restrictive diets, where variety or energy intake is limited, greater attention must be given to providing an adequate protein intake, especially in pregnant women, infants, growing children, and the elderly.

Hematologic Status

Iron

Nonheme iron from plant foods is less available than heme iron, and plant foods contain a variety of substances known to reduce iron availability; thus, the iron status of vegetarians is often questioned. However, plant foods also contain other substances that enhance iron uptake, and well-planned vegetarian diets often contain more iron than omnivorous diets.

Some studies suggest that long-term LOVs, even with a higher fiber intake, maintain iron status no different from omnivores (14). Other studies, however, indicate vegetarians may have reduced iron stores, even though iron deficiency anemia as determined by hemoglobin levels is no more prevalent than among omnivores (15). However, although there was no significant difference in iron intake, a recent study found significantly lower hemoglobin levels in vegetarian children in England (15a). The authors suggested dietary advice was needed to ensure optimal absorption of iron. Another recent study found lower serum ferritin levels in both male and female vegetarians than in omnivorous controls, although the vegetarians consumed significantly more iron (16). Although lower iron stores increase risk of deficiency, the optimal storage level continues to be debated, particularly in view of evidence of an association between elevated iron stores and coronary heart disease.

The high levels of iron in well-planned vegetarian diets combined with the frequent intake of vitamin C–rich fruits and vegetables appear to protect against iron deficiency, which is more likely to be encountered among those on restrictive vegetarian diets, such as macrobiotic. Iron deficiency is also more prevalent in developing countries where

dietary choices are limited and there is greater reliance on unleavened and unrefined cereal products (14).

Folate

Intake and blood levels of folate are often higher in vegetarians than omnivores because of their greater use of fruits and vegetables. Elevated folate is of concern in individuals whose vitamin B₁₂ intake is low because folate may delay the appearance of megaloblastic anemia and thus mask a developing vitamin B₁₂ deficiency with its potentially irreversible neurologic effects (17).

Vitamin B₁₂

Vitamin B₁₂ is of particular interest because the usual dietary sources of this vitamin are animal products. Persons who include only plant foods in their diet, such as vegans, are at increased risk of deficiency unless care is taken to include a reliable source of vitamin B₁₂. Vitamin B₁₂ deficiency can result in serious and irreversible neurologic and neuropsychiatric abnormalities, and these potentially significant consequences necessitate giving attention to this vitamin in any discussion of vegetarian diets.

In addition, inactive analogues of this vitamin occur in foods and are found in the body. However, they are not differentiated in the usual microbiologic assays used to assess either vitamin B₁₂ status or its content in foods, which are likely overestimated unless a method specific for cobalamin, the active form, is used (18).

Sources. Plants do not synthesize or store vitamin B₁₂. The ultimate source of this vitamin is microbial synthesis. Vitamin B₁₂ occurs in plants only if they are contaminated by bacteria producing it (18). Such contamination is more likely where sanitary procedures are not followed in handling food and may be a reasonable explanation for the limited vitamin B₁₂ deficiency occurring among vegan populations in developing countries. Animals either ingest the vitamin or absorb what is produced by bacteria in their intestines, thus becoming a source of vitamin B₁₂ for those who consume animal products.

As noted, the microbiologic assays often used to assess vitamin B₁₂ content determine the inactive vitamin B₁₂ analogues, as well as cobalamin, the active form of the vitamin. Labels on many food products give values for the nonactive analogues rather than for cobalamin. This is misleading and causes confusion for the consumer. Assays specific for cobalamin indicate that many food products commonly thought to be sources of vitamin B₁₂ in actuality contain mostly inactive analogues (18); these include spirulina, tempeh, other fermented foods, and most sea algae. It was suggested that individuals relying on spirulina as a source of vitamin B₁₂ might develop a deficiency more rapidly because some of the analogues contained in it actually block vitamin B₁₂ metabolism

(18).

Intake and Status. Serum vitamin B₁₂ levels in vegans are generally lower than those in omnivores, with intermediate levels found in LOVs. Recently, individuals adopting a vegan diet showed a more rapid drop in serum vitamin B₁₂ levels than anticipated, and those using vitamin B₁₂ supplements or vitamin B₁₂ fortified foods had higher mean serum levels over time (19). Similarly, serum vitamin B₁₂ levels declined over a 2-year period in six of nine subjects adhering to a “living food diet” (20).

It is remarkable that there are so few reported cases of vitamin B₁₂ deficiency even among vegans. Observations, however, suggest that suboptimal vitamin B₁₂ status may occur well before the deficiency is discovered. Reasons for the low incidence of vitamin B₁₂ deficiency include the very small requirement, relatively large stores, and a very efficient enterohepatic circulation that recovers most of the vitamin B₁₂ excreted in the bile. Intestinal bacteria produce vitamin B₁₂; however, most of this occurs below the ileal site for vitamin B₁₂ absorption and it is excreted in the feces (18). Some evidence indicates that small amounts are produced in the small intestine; however, it is unclear how much of this is the active form (18). Some vegans may consume the vitamin in foods eaten outside their homes. In developing countries, food and water contaminated with vitamin B₁₂-producing bacteria, in conjunction with poor hygienic practices, may contribute to vitamin B₁₂ intake.

There is limited evidence that some seaweeds may contribute active vitamin B₁₂, presumably from contamination with plankton. Vegans consuming *Chlorella* or Nori seaweed had serum vitamin B₁₂ concentrations twice as high as those not consuming these seaweeds (20). In another study, increased consumption of seaweeds by a mother led to normalization of urinary methylmalonic acid (MMA) in her breast-fed infant (21). In contrast, ample consumption of seaweed by vitamin B₁₂-deficient infants did not improve their abnormal hematologic indexes and there was no relationship between algae consumption by macrobiotic adults and their vitamin B₁₂ status (22, 23). Reliable sources of vitamin B₁₂ must be ensured to prevent deficiency in individuals who consume no animal foods.

Other Nutrients

Calcium and Vitamin D

Adequate calcium and vitamin D intakes are important to ensure optimal bone status over the lifetime. Recent evidence suggests that calcium also may be important in regulating blood pressure and preventing colon cancer. Milk and dairy products supply 70% of calcium in U.S. diets, and questions regarding adequacy are often expressed when intake of these foods is limited, as in vegan diets.

Intake. Calcium intake among LOVs appears to be similar to that of omnivores,

whereas vegans take in less. The long-term impact of this lower intake on bone health is not yet known, although some evidence warrants concern (24). In addition to the lower intake of calcium, vegans also consume lower levels of vitamin D. The low consumption of vitamin D may be further exacerbated in some cases by limited exposure to sunlight. Low vitamin D concentrations and secondary hyperparathyroidism were documented during the winter in vegans living at northern latitudes (25). Vitamin D deficiency was also documented in British Asian vegetarians and is a frequent concern among macrobiotic children (26, 27). The Institute of Medicine recently released new recommendations for intake of nutrients related to bone health (27a).

Factors Affecting Calcium Status. Besides vitamin D, a variety of other dietary factors also influences calcium status. A consistently lower intake of protein, as often seen among vegetarians, may decrease calcium requirements (28). Numerous studies demonstrate that increases in animal protein intake result in increased urinary calcium excretion. This relationship is not seen with plant protein (28). In addition, the ratio of dietary calcium to protein is thought to be important (29). This ratio in milk and dairy products is very favorable to a positive calcium balance (29). It is higher in LOVs than in omnivores and even higher than in vegans.

Similarly, a high intake of sodium increases calcium excretion (29a). There is some evidence that vegans consume less sodium than LOVs or omnivores. However, it was suggested that the characteristically increased consumption by vegans of oxalate- and phytate-containing foods may offset the benefits of their lower intake of protein and sodium (24).

Although lower rates of hip fracture are reported in populations worldwide with much less calcium intake than the United States where fracture rates are higher, genetic and lifestyle factors may play important roles. Optimal calcium intake under different dietary and lifestyle conditions remains to be determined.

Sources. Obtaining adequate calcium intake, as with all nutrients, depends on food choices. Individuals consuming relatively large amounts of animal protein, even though dairy products are not excluded, may need to give special attention to calcium intake. Vegans also may need to give attention to supplying an appropriate intake, especially during periods of growth. In general, few other foods provide as concentrated a calcium source as dairy products; however, it is relatively widely distributed among plant foods. The bioavailable calcium from various food sources has been calculated and may be useful in guiding food choices (24). The calcium in high-oxalate vegetables such as spinach, Swiss chard, and beet greens is largely unavailable; however, kale, broccoli, Chinese cabbage, and mustard and turnip greens provide substantial amounts of available calcium. Legumes and some nuts and seeds also contribute to calcium intake. Unfortified soy beverages provide negligible amounts, whereas calcium-set tofu and fortified soy milks are rich sources.

Zinc

Meat, fish, and poultry provide 40 to 45% of the zinc in the U.S. diet; dairy foods and grain products each contribute a little less than 20%. Nonetheless, reported zinc intake

among vegetarians is similar to that of omnivores. However, its lesser availability from plant foods may result in somewhat lower zinc status among vegetarians than among nonvegetarians. A lower zinc intake was found among vegetarian children and adolescents, but it did not affect their growth; vegetarians were slightly taller than nonvegetarian controls (30). A recent study of adolescent female vegetarians found no difference in dietary zinc intake by LOVs, semivegetarians, or omnivores (31). Further, the investigators found no differences in mean values for any indicator of zinc status among the groups. Nonetheless, 24% of LOVs, 33% of semivegetarians, and 18% of omnivores had low serum zinc levels. Attention should be given to ensuring an adequate intake of foods that supply this nutrient.

VEGETARIAN DIETS IN THE LIFE CYCLE

Risk of nutritional deficiencies is greatest during periods of growth and adequate intake of all nutrients should be ensured at these times. The impact of vegetarian diets on various stages of the life cycle was recently reviewed (6).

Pregnancy and Lactation

LOV diets provide adequate nutritional support during pregnancy and lactation, but special attention is needed to obtaining certain nutrients when following a vegan or macrobiotic diet. These include energy, iron, vitamin B₁₂, calcium, and vitamin D.

Vegetarians are more likely to breast-feed their infants and to do so longer than the general population. This necessitates continued attention to dietary intake. Guidelines for counseling pregnant vegetarians also have broader application to other groups (32).

The few reports of pregnant vegetarians suggest a possible increased risk of earlier labor and lower birth weight in those following a more limited diet, although no difference in incidence of pregnancy complications was seen (33). More-concentrated energy sources may be necessary than are usually consumed on a vegan diet to ensure appropriate weight gain. Low serum ferritin levels are associated with increased risk of prematurity and low birth weight, and therefore care should be taken to ensure adequate iron intake for all pregnant women.

Normally, enough vitamin B₁₂ is deposited in the fetus to last from 6 to 12 months after birth, yet a number of cases of vitamin B₁₂ deficiency have been reported in infants of vegan mothers, with the deficiency frequently developing before 6 months of age (34, 34a, 34b). The infants were totally breast-fed by vegan mothers who showed no clinical signs of deficiency, although later testing confirmed they had low vitamin B₁₂ status. Low maternal serum vitamin B₁₂ levels were reflected in low values in milk (35). It is suggested that it is currently ingested vitamin B₁₂ that is available for placental transport and secretion in the breast milk (36). Thus, totally breast-fed infants born to vegan mothers are at increased risk of vitamin B₁₂ deficiency because of decreased stores at birth and low milk values.

Certain features are characteristic of infants developing a vitamin B₁₂ deficiency:

increased fretfulness and apathy, decreased socialization and activity, and regression in motor control. The infants are generally very small for their age and show serious neurologic deficits. Upon testing, the vitamin B₁₂ deficiency is apparent. The usefulness of MRI (magnetic resonance imaging) in diagnosis and follow-up of patients with suspected diseases of myelination was recently emphasized (34a). In most cases there is rapid improvement with administration of vitamin B₁₂. Unfortunately, however, there appear to be long-term neurologic deficits in some cases (37). Vegan women *must* understand the importance of consuming a reliable source of vitamin B₁₂, at least during pregnancy and lactation, and it must be included in the diets of infants and children.

Low vitamin D status and low calcium intake were found in lactating macrobiotic women (35). In view of the increased calcium needs in pregnancy and lactation, this could result in maternal bone demineralization. Adequate calcium and vitamin D must be ensured at these critical stages of the life cycle.

Essential fatty acids and their derivatives play important roles in fetal development, especially of the retina and central nervous system, and parturition (33). Docosahexanoic acid (DHA, 22:6n-3), while found in fish, occurs in only small amounts in eggs and is absent from commonly consumed plant foods. In contrast to the low level of DHA, vegetarian diets contain high amounts of linoleic acid (18:2, n-6). DHA can be synthesized in the body from linolenic acid (18:3, n-3); however, high levels of linoleic acid inhibit this process.

In comparison to omnivores, a lower proportion of DHA was found in plasma and cord artery phospholipids, as well as in the milk of vegan mothers (33). As expected, the erythrocyte lipids of their infants contained a lower proportion of DHA than those of infants breast-fed by omnivorous mothers or fed cow's milk formula. It was suggested that vegans use soybean or canola oils, which have a lower ratio of linoleic:linolenic acid, to facilitate the body's synthesis of DHA.

Infancy and Childhood

Concerns have been expressed regarding vegetarian diets for children whose vulnerability is great for nutrient deficiency, yet there is little evidence that physical or intellectual growth has been harmed (6). The growth of Seventh-day Adventist LOV children is the same as that of omnivores, with no greater evidence of nutritional deficiencies (30). While vegan children weighed less and were shorter than controls, their growth was within normal ranges and catch-up occurred by about age 10 (38). The lower growth appeared related to the high bulk and low energy density of some vegetarian diets combined with the small stomach capacity of young children. Recently, investigators reported significant catch-up in height and arm circumference for age in boys and girls combined who had followed a macrobiotic diet in early childhood. However, both boys and girls were still significantly below reference values for height, and girls were below reference for weight-for-height and arm circumference for age (38a). Multiple regression analysis showed that inclusion of moderate amounts of dairy products improved growth of vegan children.

Inadequate weaning foods deficient in calories, vitamin D, calcium, iron, and vitamin B₁₂ may be used by some vegan or macrobiotic parents, resulting in low growth and nutritional deficiencies. Similar diets continued into preschool years resulted in impaired growth, rickets, iron deficiency anemia, and vitamin B₁₂ deficiency (39). Vegetarian food guides are available and can be helpful in planning diets for children and other age groups (40).

Adolescents

The few studies describing the nutritional status of vegetarian adolescents were recently reviewed, and suggestions were made for dietary management (41). Not everyone adopting a vegetarian diet understands the nutritional implications of excluding animal products, and care must be taken to ensure adequate intake, especially of vitamin B₁₂, calcium, and vitamin D, as well as iron and other trace elements.

Preadolescent LOV females were shorter than omnivores, but were taller than omnivores later in adolescence (30). This suggests a delay in the pubertal growth spurt. They were also reported to experience a 6-month delay in onset of menarche. These findings appear to represent a delay in physical maturation that may be of benefit in adult life, particularly in relation to decreased risk of breast cancer (30). Recent investigations in Europe also found that vegetarian children grow at least as well as omnivorous children, and both were close to the 50th percentiles for both height and weight (41a).

Compared with omnivores, LOV adolescents reported significantly greater intake of fruits, vegetables, and starchy foods and lower intake of dairy products, junk foods, and (as expected) meat (30). Thus, their dietary pattern more closely approximated current recommendations than that of the omnivorous controls. As noted previously, a larger proportion of LOVs and semivegetarians had low serum zinc levels than omnivores, although there was no difference in intake (31). Similarly, more LOVs and semivegetarians than omnivores had low iron stores. They were, however, more likely to consume greater amounts of antioxidants and other protective phytochemicals.

Adult and Elderly Vegetarians

Adults may adopt vegetarian diets to lose weight, to decrease risk of chronic disease, or as part of a therapeutic regimen to control disease. As noted, vegetarians, and especially vegans, generally weigh less and have lower serum cholesterol levels and lower blood pressure. If no animal products are included in the diet, attention is warranted for those nutrients noted above as at risk. Low vitamin D levels were reported in some elderly vegetarians as well as marginal iron and zinc status (6, 16, 42). Adequate vitamin D is particularly important in maintaining bone health in aging women and care must be taken to ensure an adequate intake and/or exposure to sunshine.

Impaired absorption makes vitamin B₁₂ deficiency increasingly common with advancing

age in both vegetarians and omnivores. Possibly, vegetarians, if they have reduced stores, may be at risk for earlier manifestation of the deficiency. Further, vitamin B₁₂ deficiency in the elderly is rarely accompanied by anemia or megaloblastosis, and serum vitamin B₁₂ levels in the elderly are often within the currently defined normal range (43). It was suggested that the cutoff for suspecting a vitamin B₁₂ deficiency should be below 258 pmol/L (<350 pg/mL) rather than below 148 pmol/L (<200 pg/mL). Because there is a limited window of time for effective intervention in a vitamin B₁₂ deficiency, attention must be directed to the status of this vitamin in elderly persons.

HEALTH IMPLICATIONS OF VEGETARIAN DIETARY PRACTICES

The association of vegetarian diets with lower risk for several chronic diseases is well documented, and various studies investigating the relationships have been reviewed (10, 44). The standardized mortality ratio (SMR) for all-cause mortality is greatly reduced among vegetarians who are known to consume more fruits, vegetables, and polyunsaturated fatty acids and less saturated fatty acids, cholesterol, and alcohol than the general population (5, 6, 7, 8 and 9, 44, 44a). They also smoke less, have a lower body mass index (BMI), and may exercise more.

The specific health-promoting factors associated with a vegetarian lifestyle continue to be investigated, with particular attention currently focused on phytochemicals and the foods that contain them. These nonnutritive substances include a wide range of chemicals found in plant foods and are reviewed elsewhere (45, 45a). These substances can alter various hormone actions and metabolic paths in beneficial ways. The advantages of fruits and vegetables are so well accepted that recommendations to include more of them in the diet are heard with increasing frequency. Some of the positive health effects of vegetarian diets may be due to the increased intake of these foods.

Several major epidemiologic studies focus on Seventh-day Adventists, a conservative religious denomination. Adventists follow a broad range of dietary practices, from total vegetarian to usual American diets. Approximately half are vegetarians, with the great majority of these being LOVs. Certain lifestyle characteristics, such as smoking and alcohol consumption, which can confound or modify the effects of other factors, are largely absent from this population. The Adventist Health Study provides opportunity to compare vegetarian and omnivorous dietary practices within a population with great similarity of other lifestyle factors. Overall mortality rates are lower among Adventists than in the general population. Although they die of similar diseases, they appear to develop these diseases at a later age (46).

Cancer

The German Vegetarian Study found death from all cancers in vegetarians was reduced by 52% in men and 26% in women compared with expectations (47). More specifically, the SMR for colon cancer was found to be 44 in men and 78 in women. Longer duration of vegetarian practices decreased risk of cancer mortality.

The risk of death from cancer is considerably lower among Adventists as a whole than in an appropriate reference population (48). Lower risk would be expected for those sites associated with cigarette smoking or alcohol; however, the reduction in risk included nearly all major cancer sites, with a greater reduction for males than for females.

The relationships between dietary components and specific cancer sites were investigated in the Adventist population and recently reviewed (46). Multivariate analysis was used to control for factors other than the variable of interest.

Frequent consumption of fruit (>1/day vs. <3/week) was associated with a 75% reduction in risk of lung cancer, independent of past smoking status. The risk of stomach cancer was also greatly reduced in those who consumed fruit frequently. Raisins, dates, and other dried fruit provided significant protection against prostate cancer. Frequent consumption of tomatoes and dried beans also may protect against prostate cancer, while consumption of fish more than once a week may increase risk. No association with dietary factors, including animal fat, was found for breast cancer.

Striking protection against pancreatic cancer was afforded by frequent consumption of legumes, with those consuming dried beans and peas more than twice a week having only 1/30th the risk of those who consumed these foods rarely or not at all. An 80% reduction in risk of this cancer was associated with frequent consumption of raisins, dates, and other dried fruit.

Individuals who ate beans more than twice a week had a 42% lower risk of developing colon cancer than those who ate beans less than once a week. A similar reduction was seen in those who consumed more fiber. In contrast, a somewhat greater risk was associated with eating meat, fish, or fowl several times each week. After adjusting for age, sex, and smoking history, frequent consumption of beef was associated with a more than twofold increase in risk of bladder cancer.

These results suggest that, with the exception of bladder and perhaps colon cancer, dietary factors other than the absence of meat are the protective agents in the reduced risk of cancer seen among vegetarians (46). Others reported an inverse relationship between milk intake and incidence of breast cancer (49). Thus, increasing attention is being focused on foods commonly consumed by vegetarians and the protective compounds they contain.

Coronary Heart Disease

Lower risk of death from coronary heart disease (CHD) among vegetarian populations is well established and not surprising given their dietary and lifestyle characteristics resulting in lower body weight, lower blood pressure, and lower serum lipid levels (6, 7, 8 and 9). An LOV vegetarian diet in an African American population was also associated with a more favorable profile of blood lipid risk factors for premature CHD than the omnivorous diet (50). Multiple factors undoubtedly play roles in decreasing the

risk seen among vegetarians.

An association of meat consumption and fatal ischemic heart disease was described in the Adventist Mortality Study, and more recently, data from the Adventist Health Study confirmed that relationship (51). Risk of fatal CHD was nearly twice as great in men who ate beef up to three times a week than in men who never ate any, and in men consuming beef three times a week or more, risk was more than twofold greater. Meat eating did not change the risk of CHD for women.

The same analysis revealed other intriguing relationships. The risk of both nonfatal and fatal CHD was lower in those who consumed mainly whole wheat bread than in those who ate mainly white bread (51). Similarly, the risk of both nonfatal and fatal CHD was lower in those who ate nuts frequently than in those who ate nuts less than once a week. The protective effect of frequent consumption of nuts was found consistently among various subgroups including both vegetarians and nonvegetarians.

A carefully controlled dietary trial was subsequently conducted to investigate these relationships further (52). Moderate quantities of walnuts were incorporated into a National Cholesterol Education Program Step 1 isocaloric diet in place of fatty foods, meat, and visible oils, while maintaining fat at 30%. This resulted in a more favorable lipoprotein profile. The possible mechanisms mediating the beneficial effect of nuts have been reviewed (53).

To date much of the research investigating the relationships between diet and CHD has focused on dietary factors related to modifying serum lipids. Rapid expansion over the last decade of our understanding of various plant constituents has led to rethinking the relationship of diet to heart disease (54). Whereas great emphasis was placed on dietary fat, it is now suggested that other factors, such as higher intake of antioxidants, may play important, if not deciding, roles. This is not to suggest fat intake should be ignored, but other factors should also receive attention.

Hypertension

Cross-sectional studies often report that vegetarians have lower blood pressure and lower incidence of hypertension than omnivores. This was also documented in African Americans, a population with a well-recognized increased risk of hypertension (50). Confirmed hypertension occurred in significantly fewer vegetarians than semivegetarians and omnivores. Mean systolic blood pressure was significantly lower in black vegetarians than in black nonvegetarians but was higher than in white vegetarians or nonvegetarians, suggesting that vegetarian dietary practices do not completely offset the risk of hypertension in the black population (50).

In contrast, the Health Food Shop Users cross-sectional study found no difference in blood pressure between vegetarians and omnivores (44). It was suggested that lifestyle factors other than avoidance of meat may be shared by vegetarians and other health conscious individuals and may affect blood pressure.

Randomized controlled trials introducing an LOV diet to meat eaters were reviewed (55). The review indicated that the reported blood-pressure-lowering effect of vegetarian diets is between 5 and 10 mm Hg in systolic blood pressure and is independent of effects of changes in body weight.

The relationships between vegetarian diets and decreased risk of hypertension are complex because of the myriad dietary and lifestyle components that interact in this, as in other, chronic diseases. None of the characteristics of the vegetarian diet alone—absence of meat, type of protein, high polyunsaturated:saturated fat ratio, or high fiber, potassium, or magnesium intakes—has been identified as the active agent (56). The combined effect of several specific foods and/or nutrients may be responsible for the lower blood pressure seen in vegetarians.

Diabetes

Vegetarians may be at less risk for developing diabetes than omnivores. Among Adventist Health Study volunteers, vegetarians have lower rates of diabetes than omnivores. Nonvegetarian men, after adjusting for age and weight, were 1.8 times more likely to die from diabetes than vegetarian men. No difference, however, was seen among women (56). Further, an increased risk of diabetes appearing on the death certificate was seen with increased meat consumption in men, i.e., there was a dose response; in women, increased risk was seen only with meat consumption more than six times a week.

Various factors found among vegetarians have been suggested as protective for diabetes. Among these are lower body weight, lower serum cholesterol levels, high complex carbohydrate and fiber intake, and lower fat and animal protein intake. The benefits of high-carbohydrate, high-fiber diets in treating diabetes have been demonstrated (57).

Osteoporosis

Studies of bone mineral status in vegetarians and omnivores were reviewed (58). No differences were found in either cortical or trabecular bone in recent studies. However, an earlier report suggested postmenopausal vegetarian women were protected against bone loss and that their lower protein intake might be a major beneficial factor (58). A recent prospective study reported a small but significant increase in risk of forearm fracture for women who consumed more than 95 g/day of total protein, compared with those who consumed less than 68 g (59). A similar increase in risk was seen for animal protein, but no association was found with vegetable protein. Those who ate five or more servings per week of red meat had a higher risk of forearm fracture than those eating fewer than one serving a week.

Concern was expressed about the bone status of vegans (24). Recent reports lend support to that concern, although to date there are few studies specifically of vegans. Obese postmenopausal omnivorous subjects placed on a low-calorie, high-fiber diet for

6 months lost significantly more bone from the lumbar spine than nondieting obese controls (60). Whether the loss of bone was due to the loss in weight, dietary factors, or a combination is not known. However, the fiber, calcium, and protein intakes reported in this study would not be uncommon among vegans. Since leanness is also a risk factor for osteoporosis and since vegans are often leaner than the general population, it would be wise to give attention to their bone status. Investigators recently reported a higher risk of exceeding the lumbar spine fracture threshold and of being classified as osteopenic in vegan than in lactovegetarian postmenopausal Taiwanese women (60a). Others reported significantly lower bone mass at several sites in Dutch adolescents who had followed a vegan macrobiotic diet in childhood (60b).

Bone density was compared with dietary intake in five counties in China with widely differing calcium intakes (61). Bone density was approximately 20% higher from the fourth to well into the eighth decade of life in areas where dairy products were consumed (Ca intake 724 mg/day) compared with those where dairy products were not used (Ca intake 230–359 mg/day). Protein intake in the former was 75 g/day versus 49 to 57 g/day in the latter counties. The lower protein intake reported in these Chinese did not confer protection against low bone density when the calcium intake was very low.

The dietary and lifestyle factors related to risk of osteoporosis have been reviewed (62). Many factors other than calcium affect bone status and risk of fractures; however, a consistently low calcium intake combined with low vitamin D status and high fiber intake may place vegans at greater risk for low bone density. On the other hand, their lower protein intake, and common consumption of soy foods that contribute phytoestrogens may be protective. Studies are needed to clarify these issues.

PHYSIOLOGIC RESPONSE TO VEGETARIAN DIETS

Metabolic Rate

The reduced risk of disease found among vegetarians suggests biologic processes are influenced by the diet. Vegetarians generally weigh less and have less body fat than omnivores. However, the exact reason for the differences remains to be resolved. Possibilities include lower total energy consumption or differences in resting metabolic rate (RMR) and the thermic effect of a meal (TEM) that could ultimately affect energy expenditure. High fiber intake and meditation, both possibly observed more frequently among vegetarians, appear to decrease postprandial thermogenesis, a finding that would not, however, contribute to the lower weight in vegetarians (63, 64). Vegetarians had a higher RMR than nonvegetarians, as well as a higher plasma norepinephrine concentration and a faster rate of norepinephrine appearance (65). The investigators concluded that macronutrient composition and plasma norepinephrine may be independent modulators of RMR, but the effect appears to be small.

The Colonic Milieu

Lower cancer incidence among vegetarians has led investigators to study various factors thought to be related to particular cancers. Some, but not all, reports suggest

vegetarians have a lower concentration of total bile acids in their stools than nonvegetarians. A recent investigation found no difference in bile acid concentration in total feces of vegetarians and omnivores, but the vegetarians did have a lower concentration in fecal water (66). The latter may be of greater significance, because it is the fecal water that is in contact with the colonic mucosa. Further, vegetarians had a higher ratio of primary to secondary bile acids and a lower concentration of deoxycholic acid in fecal water. These findings are similar to those of other studies comparing populations at low and high risk of colon cancer. Deoxycholic acid is thought to be a promoting factor for colon cancer, and its concentration appears to be influenced by dietary saturated fat (66). Vegetarians also have higher wet fecal weight and a higher defecation frequency. In addition, a significant decrease in mutagenic activity in urine and feces was recently reported after shifting from an omnivorous to a lactovegetarian diet (66a). Similarly, switching from a diet rich in fat and meat and poor in dietary fiber to a vegetarian diet poor in fat and rich in dietary fiber resulted in a marked decrease in formation of hydroxyl radicals in the feces (66b). All of these factors may contribute to the lower frequency of colon cancer found among vegetarians.

Colonic epithelial cell proliferation was investigated in populations at differing risk for colon cancer. Compared with omnivores, vegetarians had a lower rate of cell proliferation (67). The possible association between cell proliferation and various dietary factors was investigated in healthy vegetarians and omnivores (68). Increased intake of calcium appeared to be associated with a reduced rate of cell proliferation, although not all studies agree.

Hormonal Effects

The relationship between dietary fat intake and breast cancer has prompted numerous studies, some among vegetarians, many looking at various hormonal associations. Results of studies investigating menstrual differences among vegetarians are inconclusive, with some showing more ovulatory disturbances and some reporting less (69). These differences are likely due to different study designs. Some were of short duration; dietary components including fat, fiber, and carbohydrate differed; and the definition of vegetarian was not consistent.

An inverse relationship between dehydroepiandrosterone sulfate (DHS) and breast cancer has been suggested in premenopausal women. A study of adolescents found higher DHS levels in vegetarians than in omnivores (70). However, no association was found with any nutrient, and caution was urged until more definitive data are available.

The biologic effects of soy protein, a common ingredient in vegetarian diets, were investigated in premenopausal women (71). The menstrual changes found in response to the inclusion of soy protein may be beneficial with respect to risk of breast cancer and may help to explain the lower risk in populations who consume significant amounts of soy.

Antioxidant Status

Much attention is currently focused on the benefits of dietary antioxidants. It is not

surprising that vegetarians, in view of their diet, are reported to have higher blood levels of b-carotene, vitamin C, and vitamin E, nutrients thought to play important roles in the prevention of chronic disease (72).

The various modifications to the physiologic milieu will continue to be investigated as reasons are sought for the beneficial effects of vegetarian diets.

VEGETARIAN DIETS IN THE TREATMENT OF DISEASE

Vegetarian diets have been proposed, and used, as treatment for various disease conditions. Macrobiotic diets are claimed to be helpful in treatment of serious disease; however, evidence supporting the claims is limited (6).

Coronary Heart Disease

A number of clinical trials have investigated diet and lifestyle changes in the treatment of coronary heart disease, with or without drug intervention. Regression of atherosclerosis has now been shown in patients with advanced disease in multiple studies, which were recently reviewed (73). Generally, the diets used were similar to vegetarian diets, viz., low in fat, saturated fat, and cholesterol, and high in fiber. Lifestyle factors were often incorporated in the treatment and included exercise and stress management. Recently, a very low fat, vegetarian diet was used as part of a comprehensive treatment approach. Quantitative coronary angiography demonstrated regression of atherosclerosis in subjects after a year, but progression in controls (74). Frequency, duration, and severity of angina were reduced in subjects, while controls experienced increases. Just as vegetarian diets appear to provide primary prevention against coronary heart disease, they also contribute to secondary prevention and the reversal of CHD.

Diabetes

A vegetarian diet may be helpful in managing diabetes. Current recommendations for diabetics include reducing total fat, saturated fat, and cholesterol, as well as increasing fiber intake. This may result in a food pattern similar to a vegetarian diet, especially if significant sources of plant proteins are included. Because diabetics are prone to diabetic nephropathy, this may be particularly appropriate. Evidence from insulin-dependent diabetics suggests that isocaloric substitution of vegetable for animal protein results in beneficial effects on renal function (75).

Low-fat, high-fiber diets effectively reduced serum glucose and cholesterol levels in diabetics (57). In addition, such diets may help control weight. Thus, evidence indicates that vegetarian diets are not only compatible with therapeutic diabetic regimens but may be beneficial in controlling the metabolic aberrations associated with diabetes. The Diabetes Care and Education Dietetic Practice Group of the American Dietetic Association recently published a comprehensive resource for diabetes management in vegetarians (75a).

Renal Disease

The importance of protein in the management of renal disease is recognized. Although a low-protein intake is desirable, the use of vegetarian diets is often questioned because of their high phosphorus content relative to the quality and quantity of protein they contain. However, a recent review of the impact of vegetarian diets on renal disease provides evidence from both animal and human studies of potential benefits from such diets (76).

Plant proteins exert significantly different renal effects from animal proteins; the effects seem comparable to those achieved by reducing the total amount of dietary protein. In subtotaly nephrectomized rats, soy protein resulted in less proteinuria, reduced glomerular filtration rate, milder renal histologic damage, and longer survival than casein. In patients with diabetic nephropathy, an LOV diet that provided 1 g protein/kg/day reduced proteinuria while maintaining good nutritional status over 8 weeks. In addition, plant-based diets exert beneficial effects on the hyperlipidemias associated with renal disease, and soy-based diets reduce serum cholesterol independent of dietary fat (76). A carefully designed vegan diet used successfully to manage mild chronic renal failure may be the diet of choice when the conventional low-protein diet is poorly tolerated (76a).

Because plant foods provide more nonessential amino acids than do animal proteins, they generate more urea. Consequently, it may be more difficult to minimize uremic toxicity on a strictly plant-based diet in severe chronic renal insufficiency (76). Fewer problems will be encountered on an LOV diet. In addition, a vegetarian diet may require an increase in phosphate binders in end-stage renal disease or dialysis, and attention should be directed to using lower potassium fruits, vegetables, and grains to compensate for the higher potassium content of some legumes, nuts, and seeds. Guidelines for planning a vegetarian renal diet are available (77).

Other Conditions

Rheumatoid Arthritis

Claims are frequently made that special diets, including vegan or LOV diets, can alleviate the symptoms of rheumatoid arthritis. A recent review suggested this is part of “the folklore of the disease” (78). Although a number of studies have been reported, most were poorly designed, did not include controls, and were not adequately blinded. Often the subjects held a strong belief in the intervention. Clinically demonstrable improvements rather than subjective responses were not always used. Nonetheless, some patients may benefit from a vegetarian diet (79).

Cancer

Claims continue to abound that a macrobiotic diet can cure cancer. Unfortunately, there is little supportive scientific evidence; however, recent reports suggest survival may be

greater in some cases (80). Considerable concern exists that individuals may delay appropriate treatment for their disease and that the diet may contribute to malnutrition and weight loss (81).

COUNSELING ISSUES AND DIETARY GUIDELINES

Careful investigation of the dietary practices of individuals calling themselves vegetarians is essential for the health professional to provide optimal counseling, and general lifestyle practices that may affect health should be evaluated as well. The beliefs and attitudes that support these practices may affect a patient's willingness to follow suggestions. Those adhering to more restrictive dietary practices, such as macrobiotics, may be less willing to seek or follow the advice of health care professionals. The attitude of the health professional will be perceived quickly, and a nonjudgmental approach is of utmost importance in establishing a productive relationship.

Issues to be considered in counseling pregnant vegetarians are described above and are applicable to others as well (32). Vegetarian food guides are available, as are specific applications for vegetarian adolescents (40, 41). Food sources for the nutrients most likely at risk are included in these guides. Bioavailable sources of calcium are also described (24). A vegetarian diet manual is available for use in various clinical conditions (82).

The basic principles for planning a vegetarian diet are the same as those for planning any other diet, with variety a key component. A diet restricted in either variety or amount can limit the intake of essential nutrients. Energy intake to maintain appropriate weight must be considered. Obtaining adequate calories may be a challenge on a vegan or macrobiotic diet, while avoiding excess calories may be equally challenging on an LOV diet that relies on full-fat dairy products (40). An emphasis is appropriately placed on unrefined foods in any diet.

There are many different ways to obtain the essential nutrients, and the health care provider should be aware of alternate sources for those nutrients commonly supplied by foods excluded from a given diet. A registered dietitian can be very helpful in providing guidance, information, and counsel. An adaptable, creative, and sensitive approach will be most successful in providing dietary suggestions for individuals whose dietary patterns and beliefs differ from our own.

CONCLUSION

Current dietary recommendations call for increased consumption of plant foods in all diets. Evidence from populations consuming plant-based diets supports these recommendations. As one researcher said, "vegetables and fruits ... are chemical powerhouses that produce dozens if not hundreds of unique and complex organic compounds, many of which are biologically active" (54). The potential health benefits, as well as issues of concern regarding vegetarian diets, have been described. The health professional has a responsibility to be informed regarding both, to encourage those

dietary and lifestyle practices that promote health, and to provide alternatives to those that may be detrimental.

ACKNOWLEDGMENTS

The generous reading of the manuscript and insightful suggestions of Ella Haddad and Joan Sabatç, are gratefully acknowledged.

INTRODUCTION AND CONCEPTUAL FRAMEWORK

Modern Nutrition in Health and Disease (MNHD) is an influential textbook, frequently updated to absorb and distill the avalanche of ongoing discovery in the areas of human and clinical nutrition. Nutrition is a discipline that has derived from various influences, including biochemistry, animal sciences, dietetics, clinical medicine, epidemiology, and public health. [Table 107.1](#) provides a convenient working outline of the hierarchy of levels of nutritional concern—both basic and applied—when the issue is primarily the nutritional health of *human beings*. Both implicitly and explicitly, the body of information in textbooks such as *MNHD* is based upon these interacting levels. However, in planning space allowances and selecting topics and contributors, this and other texts must make choices of emphasis. The extent to which these choices make the contents

more or less useful for different readerships is a legitimate concern of editors.

Basic Nutrition
Nutritional biology, biochemistry, physiology
Normative human nutrition
Clinical nutrition
Effect of patients' disease on nutritional status
Producing deficiency
Producing excess
Effect of imbalance of individual's nutrient intake and use
Producing deficiency states
Producing excess states
Nutritional and dietary therapeutics
Public health nutrition (public nutrition)
Effects of endemic diseases and environmental conditions on nutritional status
Effects of subadequate dietary nutrient intake in producing endemic nutritional deficiency states
Effects of excess dietary nutrient intake in producing endemic nutritional excess states
Interaction of dietary patterns and prevention and production of chronic diseases
Prophylactic and remedial public health interventions

Table 107.1 Outline of Various Interacting Levels of Concern in Understanding Nutrition of Human Beings and Promotion of Nutritional Health

This author has commented on a breach between the center of gravity of the selections in this textbook and the center of gravity of nutrition and health for the practitioners and populations of developing countries (1). For instance, acute gastroenteritides accost toddlers and preschoolers in billions of episodes annually, but *MNHD VIII* devoted much more text to nutritional management of celiac sprue and Crohn's disease (1). This chapter represents both a practical and conceptual approach, which tries to harmonize the emphases in *MNHD* with a profile of priorities for the so-called developing countries of the world at the dawn of the 21st century.

DEFINITIONS AND APPROACHES

This is not the first time that a commentary on nutritional priorities for developing countries has come forth. A commission of the U.S. National Research Council published the *World Food and Nutrition Study* (2) in 1977. This panel cited the highest priority research areas for developing countries as the relationship of nutritional status to performance, the role of dietary components in health and nutrition, nutritional interventions, and policy aspects of nutrition. Philip R. Payne (3), in a symposium titled Strategy for Nutrition Research at the 324th scientific meeting of the Nutrition Society in 1978, whose paper was subsequently published in the *Proceedings of the Nutrition Society*, was assigned the topic nutrition research priorities for the Third World. This was no doubt a daunting challenge for someone occupying a chair at the London School of Tropical Medicine and Hygiene in the capital city of an affluent Western democracy. He concluded that the highest priorities were estimating the magnitude of and trends in malnutrition, determining the relationship of malnutrition to infectious diseases, and orienting research in food science and agriculture to the problems of the neediest. It is no less daunting to attempt a similar exercise from a capital in the highlands of Central America. As discussed below, the diversity of national realities and

the dynamics of social, demographic, and environmental change do not permit any single individual's perspective to encompass the entire problem. If this contribution can serve as a framework for discussion and analysis of how nutritional knowledge can be produced and can be applied to meet the concerns of different international regions, it will have begun the appropriate process.

Developing countries is a term used to designate a set of nations situated primarily in a belt bounded by the Tropics of Cancer and Capricorn and located in Africa, Asia, Latin America, and Oceania. They are characterized by high fertility rates; low levels of education and literacy; unequal distribution of wealth, with large sectors living in poverty; and underdeveloped infrastructure and public services. Classically, manufacturing and service industries in urban centers have been rare. Thus, most populations have been dedicated to agricultural pursuits (subsistence, commercial, or both), to nomadic pastoral lifestyles, or to tribal hunter-gathering activities. Developing countries have historically had high infant and under-5 mortality rates, alarming morbidity statistics for acute and infectious diseases, and life expectancies grossly inferior to those of the industrialized nations.

This chapter is based on a number of premises. One is that there is only one fundamental nutritional science for all geography and all humanity. The scientific methodology applies equally in the north and in the south. Stated another way, the first heading of [Table 107.1](#), "Basic Nutrition," is universal. Globalization of communication reaches toward globalization of information; a core body of nutritional knowledge receives and incorporates contributions from all over the globe. This chapter's focus also recognizes that clinical and therapeutic concerns in nutrition must be understood and addressed in the context of Third World nations; to the extent that these considerations have been neglected, the utility of *MNHD* in addressing these issues is diminished.

However, there is a valid need for geographic differentiation; this chapter is also predicated on that need. Distinctions between developed and developing countries are based on the relative wealth, political history, and climate and ecology of each of the regions. [Table 107.2](#) outlines the sources of differentiation and diversity across countries that tend to produce different realities in nutrition and health. These, in turn, influence the priorities for research and application in all branches of human-related nutrition. Although the *principles* of nutrition are universal, the *prescriptions*, as we shall see, may require regional distinctions.

Genetic and ethnic makeup
Infrastructure and natural resources
Academic institutions and traditions
Dietary patterns
Climate and physical environment
Cultural beliefs and practices
Economic status and distribution of wealth
Degree of urbanization and industrialization

Table 107.2 Sources of Diversity That Differentiate Developing and Developed Countries, and Developing Countries from One Another

A few examples can illustrate the different textures in human nutrition. For instance, the most often reported parable about the influence of parasites on human nutrition is that of human vitamin B₁₂ deficiency caused by the fish tapeworm *Diphyllobothrium latum*. This, however, is a cold-water marine fish, irrelevant to tropical climates. On the other hand, various species of parasitic flukes that reside in human visceral organs, such as *Fasciola* and *Schistosoma*, worms unknown in temperate latitudes, can produce nutritional disturbances in the tropics and subtropics. The dietary issues of cystic fibrosis, celiac sprue, and inflammatory bowel disease are relevant in industrialized countries with populations of European ancestry, but the genetic makeup of most developing countries makes these topics irrelevant. Dietary management of patients with persistent diarrhea and visceral leishmaniasis (Chagas' disease) are more relevant in the tropics. Tuberculosis and HIV infection are present in both industrialized and preindustrialized regions, but ecologic—and even genetic—factors, as distributed in different regions, characterize the clinical and public health dissemination of these two pandemics as well as their mutual interaction.

Not only is diversity across countries important in international nutrition, but diversity *within* communities is an important reality. There has been a prevailing myth of the monolith. It is common to characterize the diets of the Third World's poor as “monotonous”; we tend to see uniformity in the levels of poverty. [Table 107.3](#) highlights variables that differ *within* communities and are often even more polarized than in affluent populations. A seminal contribution to the eventual understanding is the concept of “positive deviance” (4), which notes that not all of the poor are malnourished or ill. It seeks to characterize the coping strategies and other factors that allow some to do better than others in situations of deprivation.

Height
Body weight
Respiratory infections
Enteric infections
Geohelminthic infestations
Dietary pattern
Nutrient intake

Table 107.3 Interindividual Variables That Can Differentiate and Characterize Nutritional Status within Poor Communities

From a pragmatic, utilitarian perspective, findings made in developing countries have often served to unravel clinical mysteries in affluent settings. Manifestations of human copper deficiency described in children recovering from kwashiorkor in 1964 (5) led to recognition of an iatrogenic form of this deficiency in patients undergoing total parenteral nutrition (TPN) (6, 7). Similarly, Keshan disease is endemic to parts of China. Linkage of its selenium deficiency manifestations with problems occurring in TPN patients led to the recognition that this nutrient was deficient in human cardiomyopathies (8, 9).

From a humanistic point of view, making the benefits of nutritional knowledge available to most of the world's population—not only to an affluent elite—has intrinsic merit. From an intellectual and academic standpoint, the huge number of individuals interacting with various climates, diets, environments, and endemic disease patterns will provide new insights. The sphere of the nutrition community that produces and traditionally uses *MNHD* would be expanded and enriched by a better understanding of the issues of the tropics.

PUBLIC HEALTH NUTRITION (PUBLIC NUTRITION)

In the balance among the topics in [Table 107.1](#), it is virtually self-evident that the public health aspects of nutrition have been the dominant concern. Epidemiologic and community nutrition remain the principal focus of nutritional research, at least as expressed in the international English-language literature. How developing country priorities are considered in developed countries can be viewed, in part, from the perspectives of scientific offerings in nutrition journals. In 1992, the *Journal of Nutrition (JN)* created a subcategory of “Community and International Nutrition.” Over the ensuing 4 years, 37 papers from developing countries were published under that heading. Ten of these related to vitamin A in terms of prevalences of hypovitaminosis A or its consequences, deficiency manifestations, or dosing. Eight papers related to growth or body composition, and two additional papers to energy expenditure. Five papers considered topics in dietary intake. Minerals were the topic of five papers: three

principally about iron and two about zinc, with folic acid, vitamin B₁₂, and other trace elements variously included. Individual papers on the prevalence of lactose maldigestion, the impact of breakfasting on cognitive function, and indicators of food security rounded out the 4-year roster of contributions. Four papers included geohelminths as an interactive factor, three from Kenya and one from Jamaica. Most papers were exclusively about children ($n = 23$) or women of childbearing age ($n = 7$), including the pregnant and lactating; seven papers covered other adult segments of the population.

The *American Journal of Clinical Nutrition (AJCN)*, by virtue of its name and its being the official organ of the American Society for Clinical Nutrition, would be expected to attract clinical and metabolic studies to a greater extent than the *JN*. The *AJCN* reestablished a category of “international nutrition” with its June issue in 1994. Through the end of 1996, 20 original articles appeared under that heading. All were community-based field surveys in nature; none was clinical. Eight publications concerned vitamin A; four were about iron; three related to growth, body composition, or both; two were about iodine; and one each concerned zinc, vitamin B₁₂, and energy expenditure. All but two were focused exclusively on women (in three instances, pregnant women) or children. Thus, nutrition in *populations*—and in the groups relevant to maternal and child health—continue to be the expressed priority of researchers in this field.

Fads and fashions will always dominate scientific interest during a defined era. The relative frequency of topics considered under “international nutrition” in the 1990s suggests an emphasis on micronutrients in general and on vitamin A in particular. Since the end of World War II, so-called international nutrition has gone through a series of topical concerns. The first was protein-energy malnutrition and the “protein gap”; the United Nations' major permanent nutrition panel was the Protein Advisory Group. In the 1970s, when the factual pillars about a worldwide protein shortage were corroded by evidence (10), the new concern became the issue of total food and a potential “energy gap” (11), which reigned from the mid-1970s to the mid-1980s. This gave rise to the Nutrition Collaborative Research Study Project (12). In the mid-1980s, a field study in Indonesia reported that administration of oral vitamin A produced a 34% reduction in juvenile death from childhood illnesses (13). On the basis of their minute weight in the daily diet, the term *hidden hunger* (14) was coined at the Micronutrient Conference in Montreal in 1991 (which emerged from the World Summit on Children in 1990) for a constellation of micronutrient deficiencies common to preschool children. With this development, the last decade of the 20th century had identified its dominant nutritional paradigm. Child growth and development and maternal and child health seems to be an enduring context.

These consensus agendas are set by academics and agencies on the basis of legitimate advances in new knowledge. Generally, the loudest voices in a given era affix their personal discoveries to the central agenda. The topics become “fads” when consolidated and maintained by the donor community. In an international context, these donations have generally originated in United Nations organizations such as the World Health Organization (WHO), Food and Agriculture Organization (FAO), and United Nations Children's Fund (UNICEF). Bilateral assistance from the foreign-assistance or

research-fomenting agencies of specific donor nations has followed in lock step with the dominant consensuses. Fads and trends are not necessarily totally negative, as they provide for an intensive burst of research and focus the discussion of an entire professional community into a common idiom. Such intense scrutiny should eventually separate the myths from the realities, as has occurred with the “protein gap” theory. On the debit side, fashions can delay the diversification and broadening of interests toward other important areas. For developing countries, these narrowly focused mandates within the confines of public health concerns have undoubtedly retarded development, expression of other clinical and therapeutic concerns, and application of advanced biologic concepts and technology to community problems in nutrition and health.

Effects of Endemic Diseases and Environmental Conditions on Nutritional Status

As noted, Third World countries are characterized by poor health statistics, poor sanitation, and widespread and common infections. There is a well-known synergistic interaction of infection and malnutrition (15). The clinical syndrome of kwashiorkor, conventionally ascribed to protein deficiency, is most often precipitated by a single attack or a series of infectious episodes.

Based on data from the early 1980s, Walsh (16) estimated the burden of tropical disease in terms of the prevalences (or incidences) and mortality from communicable illnesses in Africa, Asia, and Latin America, a population of about 4.5 billion people. She estimated that 1.5 billion of them are infected with tuberculosis (seropositive), with malaria affecting close to 1 million persons annually in these zones. The roundworms, *Ascaris* and hookworm, infect close to 1 billion people each, but with a low mortality. In terms of cumulative annual mortality, Walsh estimated that diarrheal disease, respiratory infections, malaria, schistosomiasis, and pertussis each cause a million or more deaths. The second tier comprised tuberculosis, hepatitis B infection, and tetanus, with about half a million deaths from each annually. Following the humanistic imperative, linkage of these very common and widespread diseases to their nutritional consequences would have greater impact than more esoteric concerns. The linkage to malnutrition is well understood for hookworm, and malaria and tuberculosis are also understood to impair nutrition.

The acquired immunodeficiency syndrome (AIDS) was barely recognized in the era for which the above estimates of worldwide mortality and morbidity were calculated. The AIDS pandemic is now over 15 years old, and the greatest rates of increase in incidence now occur in the developing countries of Africa, Asia, and Latin America. Since wasting is such a dominant feature of AIDS, mediated by inappetence, malabsorption, and catabolic reactions, Tomkins (17) suggested that we shall have to unlearn all of the conventional epidemiologic lessons about underweight and wasting in populations of developing countries and relearn them in the context of the AIDS factor.

Growth deficit, reflected in short stature and stunting, has been treated as synonymous with “chronic malnutrition.” However, any deficit accumulates largely prior to 36 months of age, after which growth rates parallel those in affluent societies. Poor growth can only be explained in part on a dietary basis and further by recurrent infections such as diarrhea. Solomons et al. (18) postulated that an important factor in growth deficit is

chronic stimulation of the immune system. Thus, the constant low-grade activation of the acute-phase response by the sheer number of microbes in the environment signals white cells to activate catabolic processes, thereby increasing nutrient requirements and enhancing nutrient deficits.

The interplay of pollution and nutrition is an emerging paradigm. As populations grow, environmental regulations get set aside, and long-lived and poorly degradable compounds increase in our environment (19). Soil, water, and air are the vectors for contaminants. Even forms of radiation such as solar and ionizing radiation and noise are polluting the environment. Some formats for understanding the interaction of contaminants and nutrition exist. The influence of lead on hematologic status by interfering with iron metabolism is the classic example. A committee of the International Union of Nutritional Sciences is beginning to explore paradigms to examine and understand the interrelation of pollution and nutrition.

Effects of Subadequate Dietary Nutrient Intake in Producing Endemic Nutritional Deficiency States

Public health nutrition has traditionally dealt with endemic nutrient *deficiencies*. In view of the shift away from interest in protein and energy undernutrition and the rise of the “hidden hunger” paradigm, recent concern has focused on micronutrients. The principal micronutrient deficiencies of interest have been those of vitamin A, iron, and iodine. Those of zinc, selenium, riboflavin, and vitamin B₁₂ have become the subject of more recent research in developing countries.

In the past decade, no micronutrient has received more attention than vitamin A. After the protective effect of this vitamin in toddlers and preschoolers was established, questions about mortality in relation to marginal vitamin A deficiency were extended to younger ages (20). The relationship of morbidity to both vitamin A supplementation (21, 22) and vitamin A deficiency and growth (23, 24) has been explored. The picture is not consistent, and there are various textures; specific ecologic features of each geographic region may characterize the response to vitamin A. Better diagnostic assessment tools are being sought, among them the conjunctival impression cytology test (25, 26) and the modified relative dose-response test (27, 28). The field still suffers from the lack of a definitive diagnostic test for vitamin A status of the individual (29).

Iron deficiency is the most widespread of all nutritional deficiencies (30). Recent interest in iron has focused on its relation to growth. Studies from Tanzania suggest that iron has a trophic effect on growth (31). On the other hand, supplementing iron to children in Indonesia with a normal iron status tended to reduce their ponderal growth (32). Serum ferritin has been the indicator of iron status for two decades, but it is sensitive to confounding by infection and inflammation. Soluble transferrin receptor in serum appears to be an alternative index (33).

What had earlier been classified as “endemic goiter” was reclassified as iodine deficiency disorder (IDD) in 1987 (34). IDD has a negative impact on learning ability and cognitive function (35). Refinements in assessing iodine status have been explored. The use of creatinine measurement to normalize for urinary iodine was discarded in favor of

simply assaying its elemental concentration (36). Ultrasound measurements can assess thyroid size by use of portable units, as an alternative to visual inspection and manual palpation. In recent years, the threshold for declaring a public health problem with IDD has been lowered to a rate of five goiters detected per 100 persons examined.

Zinc is a nutrient involved in both growth and host defenses. Shrimpton (37) has queried whether zinc deficiency is endemic in developing countries. The approaches have largely consisted of population intervention trials to see whether zinc is associated with growth (38). A byproduct has been a reduced incidence of diarrheal episodes in the zinc-treated wings of the trials (39, 40).

Vitamin B₁₂ is uniquely associated with foods of animal origin in the human diet, as plants are devoid of this vitamin. For reasons of both economics and culture, flesh and dairy products are absent from the diets of a large number of individuals in developing societies. Allen et al. (41) uncovered an unexpected prevalence of B₁₂ deficiency in a central Mexican rural population.

Riboflavin deficiency, reaching the stage of showing the overt manifestations of hyporiboflavinosis, rarely occurs in free-living people in the community. On the other hand, submaximal saturation of tissues with flavin coenzymes is widespread in developing nations (42, 43). Whether low riboflavin status interacts with iron metabolism to the detriment of hematologic status remains unanswered.

Effects of Excess Dietary Nutrient Intake in Producing Endemic Overnutrition (Nutrient Excess)

Poverty is more likely to produce scarcity than excess. However, a few endemic excessive nutritional states are recognized as unique to specific regions of the developing world, such as African-type hemosiderosis (44) and Indian childhood cirrhosis (45). Excessive iron intake causes the former, but a specific genetic predisposition interacts with the custom of consuming iron-laden home-brewed beer for expression of this iron overload condition (44). Just drinking the beer will not produce the syndrome. Excessive exposure to copper, presumably in the diet because of the use of copper cookware, is the precipitating factor in the juvenile cirrhosis observed in parts of the Indian subcontinent (45); whether any genetic component is involved has not been determined.

Prof. Barry Popkin, a nutritionist and epidemiologist, has characterized a phenomenon associated with demographic transition and globalization that he terms *nutrition transition*. It is defined as a situation in which “problems of under- and overnutrition often coexist, reflecting the trend in which an increasing proportion of people consume the types of diets associated with a number of chronic diseases” (46). It is the irony of the poor and powerless that, when the lowest end of the totem pole is one of scarcity, their lot is undernutrition, but when the bottom of the barrel contains high-energy foods with empty calories, the consequences of their consumption also befalls the lowest social strata.

The 1992 International Conference on Nutrition in Rome (47) yielded enlightening statistics on worldwide obesity in the preschool years. Of the 34 countries included in the analysis, 15 had a rate greater than the 2.7% expected in the standard reference population. These included Italy and Canada in the developed world, and in ascending order of prevalence in the developing world: Zambia, Venezuela, Panama, Peru, Barbados, Honduras, Lesotho, Bolivia, Trinidad-Tobago, Iran, Mauritius, and Jamaica. In the last two nations, the obesity rate for preschoolers was over 10%. Again, insights from Popkin et al. (48) may be relevant. In examining large survey data sets from countries in the developing world, he found that the risk of fatness was highest in persons of shortest stature. As the process of stunting continues apace, but nutritional transition transforms the pattern of diet, overweight may be accentuated in persons of short stature in the developing regions of the world.

Interaction of Dietary Patterns and the Prevention and Promotion of Chronic Diseases

In the context of public health nutrition in developing countries, deficiency and undernutrition have been emphasized to the virtual exclusion of overnutrition, dietary excess, and substances potentially active in preventing chronic diseases. In 1990, the National Research Council published the committee report *Diet and Health: Implications for Chronic Disease* (49). Its 28 chapters contain 5951 references, of which less than 0.2% derive from research or observations in developing countries. Either research performed in the Third World was ignored as irrelevant to conclusions for U.S. populations, or there is a paucity of dietary and disease research on these issues from developing societies; the latter is more likely.

The falling of trade barriers will allow a major influx of Western processed foods, bringing a very different macronutrient balance to less-institutional countries. The effect of drastic and dramatic changes in the nature of foods and food patterns, especially in individuals who began life in the setting of poverty and scarcity, is of concern. The “virginal” nature of some populations relative to both the dietary and environmental risk factors of chronic diseases provides a unique setting to verify theories about the multifactorial determination of degenerative conditions. Are the same dietary correlates for diabetes and hypertension found in Bangkok as in Boston, in Singapore as in Salzburg?

The “diet and disease” paradigm, however, should be broadened beyond *chronic* disease to include acute illnesses as well. The work of Fawzi et al. (50, 51) in the Sudan is seminal. In this study, involving a randomized trial of retinyl palmitate or placebo, the chemically pure vitamin had no effect on diarrheal or respiratory disease risk or mortality, but the patterns of the underlying diets were strong predictors of well-being and survival.

Prophylactic and Remedial Public Health Interventions

Just as clinical nutrition goes beyond description and diagnosis to therapy, public health nutrition is concerned with interventions at the population level that promote adequate

nutrition. For vitamin A, a primary issue is delivering more of the vitamin to populations with endemic hypovitaminosis A. A strictly food-based strategy is limited by poverty. The major sources of the vitamin are edible plants, and the efficiency of conversion of provitamin A in foods to the active vitamin has probably been overestimated (52, 53). Fortification of a common vehicle, such as sugar, with vitamin A is practiced in Central America with promising results.

Periodic supplementation of vitamin A, either in special “campaigns” or as part of the routine immunization series, has been advocated to break the cycle of marginal vitamin A deficiency and child mortality (54, 55). The younger the child, the lower the apparent benefit and the greater the risk of adverse reactions and consequences. Simultaneous vitamin A administration may interfere with developing immunity with some vaccines. Supplementation of the lactating *mother* can potentially enhance the vitamin A intake during the first 6 months of life (56).

Public health delivery has focused on two modalities: fortification and supplementation. Some of the adverse characteristics of inorganic salts, such as metallic taste, oxidation of food, and poor absorption, may be eliminated by the iron chelate iron-sodium EDTA, which can be added to table sugar (57). Pregnant women usually receive high-dose iron supplements. Compliance is a problem due to intolerance. Several approaches exist: the “gastric delivery system,” in which the ferrous salt is combined with a hydrocolloid matrix that dissolves after ingestion and floats on the gastric contents (58), and weekly—rather than daily—prescription of two or three times the usual daily dose (59). In areas endemic for hookworm infections, antihelminthic treatment may complement iron-folate tablets to control anemia (60).

Most authorities feel that universal iodization of salt would be a panacea, eliminating IDD throughout the world. However, the will to enforce fortification laws is often absent. Alternatives to salt fortification include placing iodine in water or fertilizers and either injecting iodine intramuscularly or administering it orally. The role of chemical goitrogens in goitrogenesis is still not clear. The effect of some goitrogens can be overcome competitively by additional iodine, but those that are noncompetitive can produce goiter regardless of the level of iodine intake.

Environmental pollution may play an important role in nutritional health and in the interaction of diet and health (19). Some elements of contamination that influence nutrition are both well known and relatively constant. Some agents that have traditionally been absent are now increasing. Some agents are common to ecosystems in industrialized nations, whereas others are uniquely endemic to tropical, developing regions.

Breast-feeding and its relationship to complementary weaning foods represent a public health concern, especially in developing countries in which early and improper artificial feeding can prejudice both health and nutritional status. The WHO recommends exclusive breast-feeding for 4 to 6 months. When exclusive breast-feeding ends, weaning begins. The timing (when), content (what), and pattern (how) of complementary feeding have occupied the attention of scientists, technologists, and public health professionals. The age at which weaning begins has always been multifactorial. It is

generally believed that in more traditional times, a community consensus based on cultural norms governed the transition from the breast or bottle to nonliquid foods. Factors such as family composition, religion, household income, use of health services, mother's age, parental literacy, and maternal work outside the home clearly influence the age at which complementary foods are introduced (61). These foods consist both of items especially concocted for the weanling, such as gruels and porridges, and scaled-down versions of the adult diet. Issues of microbiologic safety, nutrient content, and nutrient density are predominant concerns (62). The bulkiness in terms of fibrous matrix or hydration of adult foods often means that the infant cannot consume sufficient volume to meet his or her macro- and micronutrient needs. Two strategies—more frequent feedings or greater nutrient density—are debated as programmatic options (63).

Finally, however, some nutritional public health concerns in affluent countries may *not* be reflected in developing countries. A case in point is increased folic acid intake and prevention of spina bifida and neural tube defects in the developing fetus. In the United States, a call has been made to increase folic acid intakes (64). The genetic makeup of nonwhite ethnic groups may make them less susceptible to poor folate transport to the fetus, making the ambient folic acid intake sufficiently protective.

BASIC NUTRITION

Nutritional Biology, Biochemistry, and Physiology

The basic biology of nutrition advanced along the lines of nutritional biochemistry (i.e., the chemistry of the nutrients) until the date of publication of the previous edition of *MNHD*. Since then, the decade of progress in molecular biology and biotechnology has caught on in the nutritional sciences. Prof. Ed Harris (65), commenting on the differential display polymerase chain reaction (PCR) technique, stated: "A missing dietary component can leave an indelible mark on biologic systems, such as a failed enzyme or an impaired physiologic function. Today, nutrition science has a new tool for spotting effects caused by missing nutrients. [It can be] put to the task of examining which genes are and which are not being expressed." Important fruits of genetic probes have been insights into the cellular regulation of nutrient metabolism. The iron regulatory element is a mechanism at the level of the messenger RNA for proteins, specifically ferritin and membrane transferrin receptors, which themselves regulate the systemic and cellular metabolism of iron (66, 67). A metal regulatory element that involves zinc regulates metallothionein expression (68). "Zinc finger" proteins, dependent on adequate zinc status of the host, are a class of transcriptional modifiers, with over 100 thus far identified in the human genome. Some act to regulate transcription whereas others serve as nuclear membrane receptors for steroid and thyroid hormones (67). When a pathway is regulated, the tools to uncover how the information is transmitted are available to the nutritionist. Animal models with dietary manipulation represent the current locus of nutritional molecular biology. At the level of human research, Third World populations may come into play because of the spontaneous occurrence of deficiency states.

The same technology has brought the interaction of nutrients into the regulation and

metabolism of individual cells. The acute-phase response (APR) to injury, a complex component of the immune response, is responsible for a catabolic nutritional response (69). That the APR is relevant to populations in developing countries is evident from the high incidence of microbial contamination of the environment and recurrent infections. The APR is mediated by hormones known as “cytokines,” produced by monocytes and tissue macrophages. How nutrients influence cytokine production and activity is an important new vista (70). What basic biology may contribute to nutrition in poor countries is an understanding of how nutritional status influences the acute-phase response.

A third example of basic biology is the inquiry into free radicals and oxygen-reactive species (71, 72). Nutrients are involved both in oxidation and free-radical generation (Cu, Fe) and in antioxidant protection and free-radical quenching (carotenoids, tocopherol, ascorbic acid, Mn, Zn, Cu). The issue is the balance between free-radical generation and their control (73). How cellular hydration and metabolism are influenced by the balance between oxidative and antioxidant actions is an important consideration for developing country populations, as the additional stresses of infection and microbial contamination are superimposed. A challenge to basic nutritional science with profound implications for developing countries is the linkage from systemic to cellular levels of the immune response and oxidative processes.

The topic of biomarkers is a final area of basic science development with profound, medium-term ramifications for developing countries. Since the final, pathologic outcomes in chronic disease, morbidity and mortality are prolonged in their evolution, epidemiologists seek to measure the earliest changes that herald eventual illness. These are called biomarkers. As discussed, the role of chronic disease in the profile of Third World pathology is increasing. Linking advances in biomarker identification to the demographic transition carries the potential for predicting and monitoring the emergence of chronic diseases that are not yet seen as endemic in regions of the developing world.

Normative Human Nutrition

Normative human nutrition relates to free-living populations without nutritional disease or other forms of pathology. Whereas the *principles* of nutritional science are universal, the *prescriptions* may not be universal or general, and what is prudent for affluent nations may not be so for poor populations. This may find its validation in the area of nutrient requirements.

One area in which prescriptions from one region may not be applicable to another is that of recommended dietary intakes. Recommended nutrient intakes have traditionally been linked to nutrient requirements. While nutrient requirements have been touted as universal for all people—at least this is the message of the recommendations of the UN agencies (74, 75)—what is probably correct, within certain limits, is that the effect on pool size or tissue reserves of a given nutrient intake is similar from population to population. To the extent that environmental stressors cause wastage and poor utilization of nutrients, more than the usual amounts of the nutrients may be needed in tissues. However, the circumstances of genetic constitution and environmental

conditions set up a tradeoff situation in developing countries.

Adaptation is the concept that has been lost in the equations for analysis of nutritional recommendations (76). This concept has been discussed with respect to trace elements (77). “We must confront the nutritionally heretical hypothesis that sometimes lower intakes or stores of nutrients are adaptively favorable for the species in process of evolution.” Weinberg (78) introduced the concept of “nutritional immunity,” based on an antagonistic interaction of malnutrition and infection. Especially, with iron (but also with other trace elements), deprivation of the mineral blunts proliferation of intracellular pathogens. Selenium deficiency retards *Salmonella* infections, and a low antioxidant state may reduce the parasitemia of malaria by causing infected host red cells to collapse.

Adaptive responses apply not only to trace elements and vitamins but to macronutrients as well. Nutritionists and biological anthropologists tend to diverge. Whereas the former see growth as the end, the latter see growth as the means to the end (76, 79). When being smaller is adaptive, nutritional deficiency may mediate modulation of size. A classic quandary is the issue of promoting in utero growth for babies in wombs of small mothers. Low birth weight has recognized adverse implications for survival, health, and development of infants (80). On the other hand, fetal-pelvic disproportion can lead to obstetric complications difficult for traditional midwives to resolve. In summary, recommended intakes might be better set to maximize the adaptation to group survival than to achieve a given size, tissue concentration, or body store.

The relations of body composition, nutrition, and health is an important area. Traditionally, such physical measurements of the body as height, weight, skinfold thickness, and circumferences have been the tools of body composition assessment. New models for the levels of composition of the body from that of its elements to that of its organs are important to body composition evaluation. Change in the “quality” of lean tissue may be a marker for ill health (81). A host of tools—isotope dilution, multifrequency bioelectric impedance spectroscopy, imaging techniques, and in vivo neutron activation—are being developed. The former two approaches have already been applied in developing countries to move assessment of body composition beyond anthropometry (82). Two imaging techniques may eventually make assessment of nutritional anemia a matter of noninvasive imaging. The *Erlangen* microlight-guided photometer (EMPHO) technology, from Germany, has already been explored in Indonesia to provide a functional index of oxygen transport (83). Magnetic resonance imaging (MRI) can differentiate metals in vivo, and it is a matter of time before iron reserves can be determined by this form of diagnostic radiology. Metal concentrations in other tissues may likely also be accessible by MRI.

The effect of aging is an aspect of normative nutrition. It is latent in developing countries in which 5% or less of the population is over 60 years of age. The elderly in the Third World, born in 1938 or before, are survivors from an era of high infant mortality rates; they have endured pestilence and famine and have witnessed major social and political changes, such as decolonization of their nations. Much is to be learned about what is intrinsic senescence (chronobiology) and what is an accumulation of insult (pathology). Comparative study of elderly from different regions may well provide insight into this

issue. This process has begun to embrace preindustrialized and emerging nations in large multicenter studies ([84](#), [85](#)).

CLINICAL NUTRITION

It is appropriate, given limited resources and widespread and endemic diseases, that the dominant strategy in developing countries has been at the public health level. Nonetheless, individuals contract exotic diseases or show severe manifestations of common diseases. More than its relationship to disease, I view clinical nutrition as a process based on the interaction between an individual and a health practitioner. The aforementioned resource constraints have produced a dearth of hospitals, a paucity of physicians trained in clinical nutrition, and a shortage of diagnostic and therapeutic modalities. For this reason, the focus of *MNHD* must be linked with the health circumstances of the vast majority of the world's population. Following the outline in [Table 107.1](#), we can examine priority loci for this interfacing.

Effect of Patients' Disease on Induction of Nutritional Deficiency

Many of the diseases discussed in detail in *MNHD* are rare or nonexistent in developing countries because they are genetically linked to European ancestry, they occur in extreme age, or they are related to a lavish and affluent lifestyle. Some diseases such as cancer, renal disease, tuberculosis, and AIDS are found in both developed and developing countries. But many diseases that come to a physician's attention in the Third World have not been discussed in detail in the present volume of *MNHD*.

For those diseases that are universal, both north and south, some factors in [Table 107.2](#) intercede to differentiate the situation. Different dietary patterns and ethnic makeup may precipitate or protect against the collapse of adequate nutrition in the face of acute and chronic infirmities. Diseases specific to tropic regions are a matter for research, either library inquiry or direct clinical studies with patients.

Effect of Patients' Disease on Induction of Nutritional Excesses

In industrialized nations, clinical entities such as Prader-Willi syndrome and acromegaly would cause excess accumulation of tissue. Wilson's disease, a hereditary disturbance of copper storage, and hemochromatosis are also rare outside European populations. The ethnic makeup and associated genetic constitution in developing nations make the specific aforementioned entities and others of their class rare to nonexistent. Only by careful prospective research might pathologic conditions that lead to nutrient accumulations in nonwhite populations be identified. We would tentatively conclude, however, that this issue is of disproportionately greater concern in the north than in the south.

Effect of Imbalances of Individual's Nutrient Intake and Use in Producing Clinical Deficiency States

As noted, nutrient deficiency has been the obsessive concern of nutritionists in

developing countries, but only in the *public health* context. In clinical contact with health practitioners, individual deficiencies may be identified in consulting individuals. Such recognition calls for therapy, and the practitioner must then decide whether “general” factors for endemicity are at play or more specific and exotic causes are present. Anorexia nervosa and fear-of-food syndromes (86) are recognized causes of weight loss and marasmus. With a “westernization” of culture, especially in urban areas, such psychogenic eating disorders may emerge in developing countries. Diets that are essentially vegetarian (vegan) in composition are a consequence of poverty, religious practice, or both. Consequences such as macrocytic anemia may result.

Aside from the aforementioned psychogenic or culturally based causes of undereating, the appearance in one's office of patients with specific nutrient deficiencies should be viewed by the medical practitioner as a potential warning. Occasional abnormal cases of clinical deficiency imply the existence of a potentially vast submerged problem at the preclinical, endemic stage.

Effect of Imbalances of Individual's Nutrient Intake and Use in Producing States of Overnutrition

In Western nations, obesity—rather than underweight—is the major issue of primary malnutrition. If indeed, as noted above, short stature is a factor for obesity in urban settings, practitioners should begin seeing overweight and obese patients in increasing numbers in developing countries. Moreover, the iron (44) and copper (45) overload conditions mentioned above have environmental causes, but practically speaking, the solution is in case finding and treatment in the clinical context.

NUTRITIONAL AND DIETARY THERAPEUTICS

In earlier editions of this textbook, *MNHD* was subtitled “Dietotherapy,” which implied the modification of diet as an adjunct in treatment of diseases. That dietary prescription is an essential feature of overall therapy in clinical medicine can be proven from a litany of conditions common in affluent nations: diabetes mellitus, chronic renal insufficiency, hypertension, obesity, allergy, and peptic disease. In the area of therapeutics, the question of whether the prescriptions for affluent countries are *feasible* or *prudent* for less-industrial countries, is joined.

Feasibility and Prudence

The *feasibility* of concocting diets as a prescription for the aforementioned conditions in most developing societies is high. The required tolerances for sodium, carbohydrates, protein, stimulant substances, liquid volume, and total energy can be achieved with almost any combination of regional foods. In fact, the traditional rural diets in most regions of the world are closer to those prescribed in industrialized countries for all of the mentioned conditions—with the exception of those for allergies and peptic diseases—than is the usual fare of affluent societies. What is needed for precise adjustments is an understanding of local cuisines and data on their nutrient and chemical composition. In the latter respect, modern data on food composition are often

lacking for diets in developing countries. An initiative of the United Nations University's Food and Nutrition Programme, called INFOODS, has been working to create or update food composition data on regional diets throughout the world.

In terms of *prudence* in prescribing therapeutic diets based on Western medical practices, the differences between regions ([Table 107.2](#)) are influential. The situation of the nutritional management of a patient with a malignant tumor is illustrative. Much has been written recently about whether to deprive the tumor of certain nutrients, at the risk of undernutrition to the host, or whether to counteract the effects of the tumor on host nutrition with compensatory nutrition ([87](#)). The former option is relevant when modern chemotherapy is being brought to bear on malignancies, and a short-term nutrient deficit for the host might be a reasonable tradeoff to allow a remission. When aggressive palliative or curative therapy is not available, as is the situation for most cancer patients in low-income nations, then supporting the nutrition of the patient—irrespective of its proliferative effect on the tumor—would be the situational option.

Nutritional and dietary therapy for AIDS is another illustration. In recent years, in North America and Europe, combined antiviral therapy has extended survival and improved the quality-of-life of persons infected with HIV. The logistics and expense involved in antiviral therapy limit its accessibility to AIDS patients in developing countries. Malnutrition is a major mediator and predictor of death from AIDS ([88](#)). Another interesting therapeutic aspect of AIDS management relating to nutrients is the report that vertical transmission of the virus in pregnant, seropositive women can be attenuated by supplementation with vitamin A ([89](#)).

Parenteral and Enteral Nutrition

Use of parenteral and enteral nutrition in nutritional therapy is fraught with difficulties. The nutritive solutions for both modalities can either be created from primary materials in hospital pharmacies or be purchased from commercial pharmaceutical houses. The high cost of commercial purchase limits this source of parenteral and enteral solutions. This raises the temptation to attempt individualized production of media for artificial nutrition in the kitchens and pharmacies of local healthcare facilities in developing countries.

A sensible aphorism is “If the gut works, use it.” Hence, when either parenteral or enteral approaches could be used in a patient's situation, the latter is the practical option for reasons of both physiology and safety. Enteral nutrition can be less safe where resources are scarce. Scarcity may begin with the nonavailability of appropriate low-irritant, small-bore feeding tubes or with the difficulty of maintaining tubes securely in place via the nasal and percutaneous (gastroscopy, jejunostomy) routes that permit long-term enteral feeding. Formulation of enteral fluids should minimize cost, minimize osmolarity, provide adequate macro- and micronutrient nutrition, and respond to the digestive and absorptive capabilities of specific patients. For this reason, formulations from elemental to polymeric to liquified food exist in the pharmaceutical marketplace. When made in dietary kitchens of individual hospitals, quality control from osmolarity to nutrient balance can become an issue. Milk powder as the protein base may be inappropriate in most Africa and Asian countries because of the high prevalence of

lactase nonpersistence (90, 91). Moreover, bacterial contamination increases with the amount of time the bags or bottles of liquid formula are left hanging. In hot, humid, and contaminated environments, microbiologic safety is even more rapidly compromised. In developing countries, the solution is encouraging local or regional commercialization of low-cost, high-quality, *prepackaged* products that can be fed orally or by tube.

When the gut does not work, the parenteral route is sought. In TPN, all nutrients are delivered by large-bore intravenous catheters into central veins. This approach magnifies the limitations discussed for the enteral route. The products are more expensive per calorie delivered; the premium on sterility and antisepsis is much higher; the paraphernalia for administration are expensive and uncommon; and the appropriate osmolarity and nutrient and electrolyte composition are critical. It is tempting to use parenteral nutrition in common situations such as protein-energy malnutrition (PEM) and persistent diarrhea. Experience with TPN in PEM has produced disastrous results (92), and most cases of kwashiorkor and marasmus can be managed much better by oral and tube feeding (93). Experience in noninvestigative settings in persistent diarrhea is not well characterized.

Oral Rehydration Therapy

Clinical nutritionists in developing countries must recognize that managing infantile diarrheal disease is more than just using fluids to replete and maintain the fluid and electrolyte balance until the purging subsides. Issues of *nutritive* feedings during the episode are important. Both conventional and folk wisdom often recommend “starving” the diarrhea. Without oral intake, there would be little fecal output. Modern concepts of the pathophysiology of secretory and invasive diarrheas give no credence to this notion.

Conventional oral rehydration solution (ORS) based on glucose and salts provides only 80 kcal of metabolizable energy per liter. This falls far short of meeting the basal energy needs of the small child or the superimposed stress of infection in a diarrheal episode. Brown (94) has reviewed the concepts behind introducing semisolids and solid foods early in the course of treatment and the progress that has been made in producing hypercaloric diets based on rice or other cereals as the source of glucose to promote absorption of fluids for rehydration. These prevalences have advantages both in lowering osmolalities and in protecting the general nutriture. Indeed, there might be something unique about rice as a carbohydrate source. Recently, Macleod et al. (95) isolated a low-molecular-weight antisecretory substance in extracts of rice that actively inhibits chloride secretion by blocking cyclic AMP channels. Such substances may provide the mechanistic basis of the positive effects of rice-based oral rehydration solutions on childhood diarrhea. Finally, micronutrients (specifically, zinc) added to ORS may also reduce the rate of fluid secretion and speed recovery in secretory diarrheal episodes (96).

DISCIPLINARY ORGANIZATION AND PROFESSIONAL TRAINING IN NUTRITION

For nutritional science and practice to progress in developing countries, the local

nutritional communities and their constituent professionals must have the tools to guide such progress. Specifically, with respect to the perceived needs of low-income populations, debate has arisen about what format for professional training should be emphasized and what type of professional produced in the area of nutrition. It is a most timely discussion.

The Western academic model has been experienced by many contemporary faculty leaders from low-income countries, who have subsequently devised curricula modeled on the nutritional training in *developed* countries. Dietetics and public health epidemiology applied to nutrition are prominent in these curricula. Indeed, this combination is often offered under the title “community nutrition.” Laboratory research and clinical nutrition are represented to a lesser extent. All of these diverse components, however, are based on nutritional biology, quantitative analysis, or both.

Nutritional Engineers and Public Nutrition

The first salvo of a reconsideration came from Alan Berg in 1993 (97). In an indictment of the present direction of training and investment in nutritional research in, and for, developing countries entitled “Sliding towards Nutritional Malpractice. Time to Reconsider and Redeploy,” he called for creation of “nutritional engineers.” He argued that the balance between research and applied investment had been overly shifted toward the former. A sector of opinion went so far as to assert that all of the knowledge needed to alleviate and eradicate undernutrition problems afflicting the Third World had already been gathered (98, 99). The same individuals later met in Bellagio, Italy, where they forged a programmatic definition for a “new” discipline of training and professional development in nutrition in developing societies (100). Programs in “Public Nutrition” have emerged as the suggested focus for training nutritional professionals in and for developing countries (101). The main argument is to drop “health” from the title and reach beyond the academic forum of nutrition departments in schools of public health or tropical medicine and hygiene.

A central premise of this new program is that nutrition goes beyond the biologic and health issues. Agricultural production, distribution of the food supply, and aspects of food security are consistently prominent. Advocacy and mobilization of opinion for change is a major role of the new public nutritionist. Breadth (rather than depth) and application (rather than inquiry) should be the tenets of training and of the professional mission. In my opinion, this discussion merits continuation.

Nonetheless, I see a danger in the marginalization of the health focus of nutrition and its fundamental scientific underpinnings with an excessive broadening and diffusion of the scope. What this chapter demonstrates, however, is how neglected the clinical and biologic aspects of nutrition for developing country populations have been. An exclusive focus on *under* nutrition, as populations are urbanizing and undergoing nutrition transition, is not without peril, as one can miss the already manifest health problems derived from nutrient excess and overload. The fact that undernutrition in early life may condition susceptibility to chronic disease in later life is another reason to broaden the focus beyond one strictly adhering to macro- and micronutrient *deficits*. Thus, whether it is in the context of a new program or in the present format of training, it is urgent to

strengthen the ability of professionals serving low-income countries to adapt to, and to adopt, modern clinical nutrition. Grounding in the scientific method, a fund of basic nutritional biology, and experience in research activities are as vital to the progress of clinical nutrition in developing nations as they are in more affluent ones.

New Realities in Nutrition and Health Care

When it comes to applied nutrition, many public health nutritionists have been laboring with a model of action that is somewhat a relic of the past. The current “working” model for intervention features both a postulated universal common solution and the presumed need for a highly centralized administration. National ministries of health had prevailed as the exclusive loci for action on health initiatives; they envision investing public funds into operations conducted by public servants of the central governments. For crop and food initiatives, a similar model existed, centralized in ministries of agriculture. Coordination and logistical support from U.N. or bilateral sources was part of the model.

The phenomenon of economic structural readjustment has rendered such centralized and concerted actions somewhat unrealistic and obsolete. With disincorporation of state projects and decentralization of resources and responsibilities, modalities such as private insurance, fee-for-service, and nongovernmental organizations become part of a mosaic for nutritional action in developing countries. These *new* realities point to clinical nutrition and therapeutics as an important part of the emerging picture and lead to the diametrically opposite conclusion of those (98, 99) who would place a moratorium on research in and for the Third World.

CONCLUSION

It is said that armies are always trained and equipped to fight the *last* war. If we can extend this metaphor to the science of nutrition, in both its investigative and applied facets, nutrition for the developing countries may be based on past realities that have ceased to be true or that were false perceptions that were never really valid.

There is only one humanity and only one nutritional biology. Progress in relieving suffering and maximizing human and social development is tied to the extent to which nutritional science is brought to bear on the problems in low-income nations. Past nutritional activities have been expressed primarily in public health and epidemiologic terms; most research publications reflect this context. While population diagnosis and collective prevention and redress will remain important, differentiation of individual health problems and recognition of disease in the clinical setting make clinical nutrition and therapeutics an increasingly important focus for developing and transitional nations.

The advances in basic biology provide tools to unlock new information relating nutrition to health and disease. This is true in both the north and the south. The principles and lessons in clinical nutrition in this textbook are universal and relevant across the globe. But, populations in the world possess much genetic polymorphism, great variety in dietary habits, and substantial diversity in disease patterns, and most of this diversity is expressed in the 70% of the earth's population living in low-income countries. This

diversity is truly a challenge, as it makes populations in developing countries different from the reference groups in affluent nations upon which many diagnostic and therapeutic norms are based. Clearly, much work needs to be done to adapt modern nutritional concepts and the insights of clinical nutritional research and service to the needs of the developing world.

- [Chapter References](#)

The social sciences' approach to human nutrition complements those of the biologic and physical sciences. The latter approaches have been used in other chapters of this book to describe the biologic mechanisms by which hunger and satiety are regulated in the organism, as well as the nutrient levels required for health and function. Despite a fair degree of uniformity among humans in these regulatory pathways and in nutrient needs, there is considerable variety in *what* humans eat and the extent to which they are *successful* in meeting their nutrient needs. Social sciences focus on these issues.

This chapter describes social and cultural approaches to explaining why people eat what they eat. The goal is to show that understanding the social and cultural aspects of food consumption is critically important if nutritional scientists are to understand why groups of humans differ in nutritional status and how dietary change can be effected to correct problems of under- and overnutrition. Attempts to change dietary habits cannot depend solely on nutrition education. Rather, they must recognize the way dietary habits are embedded in the social structure and culture of groups and design interventions that are culturally appropriate.

This presentation begins by expanding the contrast between nutritional and social science approaches to food consumption and then gives an overview of the theoretical approaches used to study human dietary choices: materialist, ideationist, and social interactionist approaches. Data collection and analysis methods particular to such approaches are briefly summarized. The perspective then changes to an examination of the effects of social and cultural factors on food consumption and nutritional status. Whether social groups are defined at the level of family, social class, or world system, the patterning of these is evident in nutritional measures ranging from dietary quality to obesity to stature.

CONTRASTING NUTRITIONAL AND SOCIAL SCIENCES APPROACHES TO FOOD CONSUMPTION

Humans achieve and regulate their nutritional status by consuming *foods*, substances (vegetable, animal, mineral, or combination) that supply *nutrients*. Although food is composed of nutrients, cognizance of these nutrients and their relationship to health and biologic functioning is neither necessary nor usual. What is—and what is *not*—food is defined socially and culturally. Thus, while some societies consider insects good to eat, others view them with disgust; some societies relegate maize to cattle feed, and others celebrate its harvest as a food for people. Nutritional science and the social sciences differ considerably in their approach to food consumption and the importance they attribute to contrasts such as these. The social science approach goes beyond food to focus on patterning of foods into meals and the meanings (both social and biologic) of such patterning ([1](#), [2](#), [3](#), [4](#) and [5](#)).

The nutritional approach, which has been dominant in most research on food consumption, views food and eating in relation to the nutrient composition of foods and their instrumental roles in the physiologic functioning of the human body. Eating practices either promote development and function and should be encouraged or they impair these processes and should be discouraged. The nutritional perspective is functionally oriented, viewing food consumption as a means to an end. This perspective makes food habits and preferences secondary to the biologic activity of foods. The social and cultural factors surrounding food consumption become, thus, a barrier to the objectives of nutrition, consumption of a health-promoting diet.

Conceptually, the approach of social scientists (both anthropologists and sociologists of food) is quite different. Anthropologists and sociologists view food consumption as the “completion (most usually) of a culturally appropriate sequence of interpersonal cooking, feeding, and eating, involving social intercourse that leads towards culturally recognized consequences on bodily and mental life” ([6](#)). Thus, food consumption is a considerably more complex act than a nutritional/biologic perspective implies. Analytically removing it from social and cultural contexts eliminates the nonbiologic qualities it embodies and transmits to the consumer.

While the anthropologic and sociologic perspectives are not important to understanding the biology of nutrition, they are central to addressing questions that bear on the nutritional status and health of populations: How do food preferences and food habits arise? How do they become established in a society? How are they transmitted and changed? What role do such diverse factors as gender and economics play in determining food consumption patterns? How do the symbolic aspects of food relate to consumption patterns? Why do variations in cultural or social factors correlate with variations in nutritional status?

UNDERSTANDING WHY PEOPLE EAT WHAT THEY EAT: THEORETICAL APPROACHES IN THE SOCIAL SCIENCES

As social and behavioral scientists have studied food consumption, it has become clear that many interconnected factors influence consumption. To help make sense of them, they have been organized into logically connected groups that constitute theoretical approaches. As in any science, the value of these theoretical approaches is in their power to generate predictions and hypotheses concerning food consumption in diverse circumstances, as well as to explain observations. For nutritionists, familiarity with some of the major theoretical approaches can be useful in understanding the causes of food consumption patterns they observe, as well as for predicting the outcome of interventions to change food behavior. [Table 108.1](#) shows these approaches, as well as their key concepts.

Name	Approach	Key Concepts
Materialism	Interactions of physical, cultural, social, and historical environments predict food consumption	Foodways
Ideationism	Food consumption reflects the way people conceptually organize the world and their social relations	Social order, rules
Social constructionism	Food-related discourse produces subjective knowledge and self-understanding	Subjectivity, power

Table 108.1 Theoretical Approaches to Food Consumption

Materialist Approaches to Food Consumption

Materialist approaches to food consumption are grounded in cultural ecology theory. Cultural ecology takes a systems approach to food consumption, modeling the interactions of the physical, cultural, and historical environments in producing food consumption patterns. Its focus on the physical environment leads some to classify it as *geographic* (7). Cultural ecology sets food consumption within the broader concept of “foodways.” These characterize populations and consist of all information surrounding the ways food is obtained, distributed, and processed, as well as consumed by a particular population (8, 9). Foodways are limited by the resources available within a specific environment. They can be considered adaptive to the extent that they promote health and functioning or maladaptive to the extent they prevent this. The history of maize consumption and deficiency disease provides illustration.

Katz et al. documented cross-cultural patterns in the techniques used to process maize for human consumption (10). They showed that dependence on maize as a primary staple occurs only when alkali processing techniques are used (e.g., soaking the kernels in lye or a wood ash solution before drying and grinding). Viewed biologically,

this process alters the amino acid balance by enhancing the bioavailability of niacin. However, from a cultural standpoint, the importance for the consumer lies in the ability of the altered maize to be satisfactorily shaped into tortillas and other culturally preferred forms.

Katz et al. could find no examples of maize dependence without alkali processing. However, historians of medicine have identified significant health consequences of failure to carry out such processing under conditions in which economic deprivation rendered foods other than maize unavailable. The pellagra epidemic in the southeastern United States in the early 20th century is a case in point (11). Mill workers and tenant farmers who were forced by poverty to subsist on a diet of maize (made palatable by small amounts of salt pork and molasses) had high levels of pellagra as a result of niacin deficiency. Goldberger's studies of pellagra made possible the ecologic analysis, situating the pellagra-inducing food consumption pattern in the economic context of cash-cropping (cotton) in lieu of subsistence cropping (gardening) (12). The cultural ecology analysis of pellagra in the South links food consumption to the socioeconomic environment of social stratification and poverty.

Other food consumption patterns analyzed from the perspective of cultural ecology include such food taboos as the Hindu proscription of beef consumption and the Jewish and Moslem, of pork (13), as well as the prohibition of fish consumption in Africa (14).

Differing somewhat by drawing on world systems theory, but still squarely in the materialist domain is Mintz's analysis of the remarkable increase in British sugar consumption in the 18th and 19th centuries (15). He links the system of indentured servitude on the sugar plantations of the Caribbean to changes in work and income in England. Sugar consumption, he argues, increased not so much because of a desire for sweets, but because of the working class's need for affordable calories.

Despite their utility in placing food consumption in context, materialist approaches have been criticized as overly functional explanations, relying too heavily on an attribution of rationality to human societies and better suited to post hoc explanation than prediction. Other theoretical perspectives focus far less on linking cultural practices to favorable biologic outcomes and center more on how societies *think* about food.

Ideationist Approaches

Rejecting functionalist or economic explanations for food consumption patterns, many anthropologists and sociologists have approached food consumption as a complex set of rules corresponding to the ways people organize their thinking about the world as a whole and reflecting the social interactions in which they engage. Such explanations avoid the pitfalls of teleologic thinking inherent in many materialist analyses, but their tendency to focus on aesthetic aspects of food or mundane details of eating sometimes results in their importance being overlooked by nutritionists.

Mary Douglas's studies of British meal patterns are classic structural analyses connecting the ordering of foods into daily, weekly, and annual cycles with ordering of social systems (16, 17). Based on observations carried out in British households of

varying social class, Douglas declared meal consumption to be a ritual activity with rules regulating the order in which foods of different tastes, temperatures, and textures were permitted. Changes to the pattern (e.g., a single food for the evening meal rather than a central meat with starch and vegetable) create disharmony and unease for the participants, challenging their sense of order. From the most basic units of eating—tea and biscuits—Douglas showed how meals are used to symbolize and order social interactions. Principles of inclusion or exclusion and of hierarchy operated. In British households, beverages were shared with strangers and casual acquaintances, in contrast to meals, which were shared with family and close friends. Thus, to be invited into a home for a meal encoded a high degree of affiliation (literal or figurative kinship). To be offered only a drink excluded a guest from this circle and signified a social threshold that the guest had not crossed (16). By maintaining social boundaries, food consumption patterns helped create and reinforce the social order (17). Similar analyses differentiating “proper meals” from snacks and other eating events have been conducted more recently by Murcott (18) in South Wales and by Quandt, Roos, and colleagues in the United States (19, 20). They too found that meals are defined by where and with whom food is eaten, in addition to by what is eaten.

Other ideationist analyses of food consumption patterns point to how the history of a people shapes present eating by providing organizing codes (21). Some show that the past is not so much a blueprint for present eating as a source of symbols or meanings that can be called upon in a somewhat arbitrary way. One example of this is the use of African foods by contemporary African Americans in the U.S. in the context of Kwanzaa to enhance the sense of African heritage and reinforce their separateness from European Americans. Few if any of the African dishes have been retained through time in the Americas. Rather, they have been researched and reintroduced for their symbolic value. Another example is the popularity of large “country” breakfasts in the U.S. Though often consumed in relatively anonymous urban settings, they give the consumers a link to the agrarian past, with its connotations (accurate or not) of family, abundance, and a simpler, easier life. Quandt, Roos, and colleagues have studied older adults in the southeastern U.S. and noted the meanings attached to such meal patterns and the sense of loss often experienced as women living alone shift to a cold, uncooked breakfast (19, 20).

Even within meals, there are rules by which foods are combined or separated. A recent study by Drewnowski demonstrated the cognitive categories within which American adults think about common vegetables (22). Asking subjects to judge the similarity of pairs of vegetables as well as to rate the vegetables along attribute scales (e.g., weak to strong flavored, nutritious to nonnutritious) Drewnowski discovered that adults use the dimensions of calories, color, and convenience to think about vegetables. Vegetable preference is most closely linked to convenience, but compatibility of vegetables is associated with color contrast. Thus, vegetable combinations such as broccoli and cauliflower were more acceptable than broccoli and brussels sprouts.

The ideationist approaches to uncovering the grammar of food consumption patterns show that unwritten rules govern the seemingly mundane, everyday activity of eating. These rules vary from culture to culture, and indeed, they are often maintained by subgroups (e.g., ethnic groups) as a way of creating and reinforcing group identity. Social scientists using ideationist approaches to study food point to the implications this

has for attempting dietary change (22). While substitution of one type of food for another might create what more biologically oriented nutritionists would consider a better meal (e.g., replacing meat with fish or vegetables), such a change may be met with resistance because it violates the eater's sense of propriety (23), unless an effort is made to find cognitively acceptable substitutes.

Social Constructionist Approaches

Recently, the analysis of food consumption has shifted to one that views preferences and choices as more fluid, marked by discontinuities and paradoxes. This “social constructionist” approach, like the ideationist approach, recognizes the importance of food as a domain in which individuals define who they are in contrast to others. However, it focuses less on fixed patterns of food use and their reinforcement of social hierarchy and more on the way discourse, the patterning of language and behavior, around food produces meaning for individual consumers. Two concepts stand out in this approach. The first is *subjectivity*, the ways individuals use experiences in their lives to understand themselves. This understanding is flexible, less rigid than “identity,” depending on experiences with food and eating over time to create a subjective understanding of oneself. The second concept is *power*, a property that runs through food-related interactions between individuals and groups, creating subjective knowledge and self-understanding. Both these result, among other things, in foods having relationships to gender, to age, and to life histories.

Gendered Foods

Contemporary Western society as well as many non-Western societies has a large body of assumptions about what foods are appropriate for men and what are appropriate for women. Women are expected to like sweets more than men do and to use them to achieve certain ends (e.g., to make children behave [24]). The concept of “light” foods is also used to describe women's foods, so that salads, rather than potatoes, and chicken, rather than red meat, should be consumed (23, 24 and 25). Bourdieu highlights gender differences in preferences for fish among the working class in France (26). He notes that fish is considered women's food, as it has to be eaten in small mouthfuls, in the front of the mouth rather than the back, and with considerable restraint to avoid bones. Such an eating style is antithetical to the understanding of a male body as powerful and large. Red meat and strong cheeses are considered more manly. By serving these to men and taking only small portions or eating fish or salads herself, women reinforce gender identities in the context of food. Such gender differences in foods are frequently and consistently reported by lay persons. Lupton, for example, surveyed residents of Great Britain and found a consistent association of “lighter” foods for women and “heavier” for men (23).

The notion of gendered foods is borne out in food consumption surveys (27). Women eat more fruit, more sweets, and less meat than men. Men also tend to eat larger quantities and frequently exaggerate their food consumption in surveys, while women underreport theirs.

Such patterns of gendered food ideology and consumption develop in the day-to-day

interactions in which people engage. Mealtimes in Western households center on the serving of food, usually by women, in ways that meet expectations of men and children. DeVault in her study of American families documented the “invisible, caring work” women, particularly wives and mothers, do in catering to tastes, preferences, and schedules of family members (28). Hers and numerous other studies have shown that women often subordinated their own preferences to those of men (24, 29, 30, 31 and 31a). Gittelsohn's detailed observations of intrahousehold food distribution patterns in Nepal extended the concept of gendered food interactions beyond Western cultures (32). He showed that at an early age, girls learn to eat only when served from the common pot, while boys learn to ask for more. As adults, these females eat last after the largest and choicest portions have gone to men and boys.

This pattern of social interactions over food shaping female and males notions of relative power and status is replicated across many cultures. While studies tend to emphasize the normality and uniformity of such interactions, their linkage to gender relations is highlighted in the exceptions, domestic disputes. Several studies of divorced couples and of domestic violence note the role played in precipitating problems by discontinuities between male and female behaviors and expectations related to food. In these studies, women not subordinating their own tastes to husbands' or not preparing foods as expected evoked violence on the part of husbands (33, 34).

The social interactions surrounding food and the way that notions of gender are conveyed through them have been linked in Western society to the preponderance of eating disorders in women, compared with men. Susan Bordo argues that Western culture demands self-control for all adults, but especially for women. Girls learn this through interactions concerning food and its relationship to their body shape from an early age. Bordo contends that their bodies come to symbolize the arena in which control must be maintained, and women who are not thin embody a lack of self-control. Self-starvation gives women a strategy for establishing control of the feminine emotions and appetites (35).

Age-Appropriate Foods

The domain of food is also used to differentiate age groups. Several studies have examined the interaction of parents and adolescents over food and the way adolescents use this interaction to declare their independence. Although many dictums about feeding children have changed (e.g., forcing children to clean their plates is now recognized as creating the potential for overeating in adulthood), parents in Western societies are still expected to control their children's food intake. Through the discourse surrounding this control, children learn to define themselves within families and relative to adults (36, 37). Because eating is a domain used to reinforce relationships, it becomes one in which to redefine them. Hence, adolescents, particularly females, resist parents by such acts as becoming vegetarian, skipping meals, and preparing their own food (23, 24, 38). Prättälä studied Finnish teenagers and found that they used “junk” food to differentiate themselves from adults (39). While they knew well the nutritional benefits of the food served at family meals, they opted for “junk” food when with friends. This dual food preference was articulated in the contrast between parents and peers, and it helped to establish teens' subjective knowledge of themselves as leaving

childhood. Roos studied preadolescents in the U.S. and found that they used age as the primary distinction around which to group food; “kid” food was always their stated preference, not “adult” food (40).

Food and Life History

Social constructionist approaches have also been used to study the transmission of food habits from one generation to the next. Sharman studied dietary choices and allocation of resources in low-income African American households, with special attention paid to the effects of federal food programs (41). After analyzing life histories from the women in these households, Sharman found that differences between women in the use of food derived in part from their experiences with it. In particular, she noted that the birth order of a woman—whether she was the oldest daughter or one of the youngest children of her mother—determined how much she was taught about food shopping, preparation, and meal formats. Eldest daughters knew more about these because they had been taught to assist their mothers; younger children had not needed to know these things and came to adulthood with a different set of food-related knowledge, skills, and values. These formed the basis for food habits in households but were modified in the context of current activity patterns related to strategies for survival. For example, even women who preferred traditional cooked meals resorted to processed and quickly prepared foods when the demands of holding multiple low-wage jobs made it impossible to prepare the traditional meal. Such studies demonstrate that even within the same family, there are differences in what ideas about food are transmitted. In addition, they show that dietary intake may not reflect nutritional knowledge or food preference, a finding of importance to nutrition educators.

Another study of the transmission of dietary practices through time focused on Italian American communities (42, 43 and 44). In this ethnic group, the interactions of social networks composed of adult sisters produced continuity of some food traditions, particularly for holiday or communally prepared meals. However, outside this continuity, the experiences of members of individual households contributed to change in meal patterns consumed at everyday meals. A major factor determining dietary intake was the tradition of food exchange and regularly feeding persons besides household residents. In households monitored by the researchers, guests were present at meals or other food events from 30 to 50 times per month, and food exchanges between households occurred 16 to 29 times per month. For nutritionists this study is important in demonstrating how households overlap in determining the dietary intake and nutritional status of residents. Understanding the history of households as well as ethnic-specific values related to reciprocity and obligations helps to make sense of these food consumption patterns.

Ethnic Foods

Foods and cuisines are frequently categorized popularly or by nutritionists into “ethnic” or “regional” food patterns (e.g., Mexican food or Southern cuisine). Such labeling creates expectations of what foods will be eaten by members of a particular group or in a certain locale, expectations that are frequently not met as foodways change. Social scientists' current view of ethnicity as a *process* rather than a *thing* is useful in

understanding why ethnic and regional foods are maintained and why they may change over time (45). Social scientists view self-ascribed membership in an ethnic group or in a regional population as a means by which individuals establish an identity (46). This identity can be reinforced by any number of symbols or behaviors, from eating particular foods, to wearing characteristic clothing, to proclaiming one's allegiance to a particular sports team. As individuals or groups choose to invest in a particular ethnic identity or reject it, they frequently do so through the symbols of food (47).

For this reason, those studying the changes in foodways with immigration note generational differences in food consumption patterns that are not necessarily a continuum from native to American cuisine (48). While members of the immigrant generation frequently try to maintain their foodways, the second generation rejects them in favor of newly available foods as they attempt to differentiate themselves from their parents. Then, in third and subsequent generations, there may be a conscious return to foods that provide identity with the original group or homeland. The content and context of such foods are often quite different from those of the immigrant generation, however. Substitutions are made on the basis of available ingredients, ethnic foods may be consumed only on special occasions or as an accompaniment to foods of the dominant culture, or higher status foods of the ethnic group may be substituted for those actually consumed by the immigrant generation.

Two factors complicate attempts to predict the food use of groups on the basis of presumed ethnicity. First, ethnicity is frequently confounded by such variables as income, occupation, and education, making it impossible to know if an ethnic group's consumption of a particular diet represents choices made to symbolize identity or simply limitations dictated by what is affordable. Epidemiologists currently argue that one must exclude the possibility that health-related behaviors do not reflect economic constraints before categorizing them as products of ethnicity (49). Those studying food use would do well to use similar caution.

The second factor complicating the prediction of food use on the basis of ethnicity is that choosing so-called ethnic foods is a behavior readily open to anyone. In their analysis of eating in America, Root and de Rochemont argue that American eating reflects social relations (50). Ethnic foods (with the exception of perhaps German, Dutch, and British) have not melted into a single pot. Rather, they remain distinct and highly available. Consumption of foods from different ethnic groups (e.g., the spread of Vietnamese restaurants in the U.S. in the past two decades) symbolizes acceptance of the ethnic group, rather than membership in the group.

Methods for Studying Social and Cultural Influences on Food Consumption

Methods used by social scientists to study food consumption differ substantially from those in which most nutritionists are trained (51). In the studies cited above, the two principal data collection methods are open-ended interviewing and participant observation. Both methods rely heavily on qualitative data, rather than the quantitative data familiar to most nutritionists.

Open-ended interviewing is a technique designed to reveal how persons talk about a

particular subject, the meaning they attach to it, and how they relate it to other aspects of their lives (52, 53). These are topics that when approached directly, most people cannot articulate. Thus, the analysis and interpretation of the text a person produces in response to open-ended questioning becomes the source of such insight. Open-ended interviewing can be conducted with one informant at a time or with groups. One-on-one interviewing is usually called “key-informant interviewing” because the informant has been chosen for being particularly knowledgeable about a specific domain of information. For example, a midwife with years of experience in a town might be interviewed about infant feeding practices, rather than a new mother. In key-informant interviews, one can delve into how that person thinks about food without their responses being influenced by others.

It is important to conduct a number of such interviews and to be aware of the type of sample such persons comprise. In contrast to most quantitative research, which depends on a random or probability sample, most qualitative work uses an ethnographic sample. In such a sample, persons are chosen to provide breadth. Hence, the data produced are designed to give a better idea of the range of variation than of the central tendency (Fig. 108.1) (54, 55). For example, qualitative interviewing with an ethnographic sample can uncover the range of foods people classify as being for males versus those for females. A statistical sample would be necessary to then measure how these ideas about food are distributed in the population.

Figure 108.1. A comparison of the portion of variation (*shaded area*) in a group's food behavior that will be detected from research using a probability sample (*top*) and an ethnographic sample (*bottom*). (Based on information in Werner O, Bernard HR. *Cult Anthropol Methods* 1994;(June):7–9; and Arcury TA, Quandt SA. *Arthritis Care Res* 1998;11:66–73.

Group interviews are an increasingly popular alternative to key-informant interviewing for qualitative research. Group interviews about food consumption can be conducted with natural groups (e.g., neighbors or members of a class or club), expert groups (e.g., home economics extension agents for a group of counties), or focus groups (56). Focus

groups are unacquainted persons who are brought together to participate in a facilitated discussion of a particular issue (57, 58). For example, the Best Start breast-feeding promotion intervention used focus groups of women to identify barriers to breast-feeding among low-income and minority group mothers (59, 60). Focus groups were also used to critique possible media messages for breast-feeding promotion. Group interviews, unlike key-informant interviews, have the potential for reactive effects as participants listen to others and shape their responses to topics introduced by the facilitator. For example, it may be more difficult for a participant to state a socially unacceptable opinion in a group than when alone. For this reason, it is important to conduct multiple group interviews with groups defined on theoretically relevant characteristics. In Best Start, separate groups were conducted with members of different ethnic groups, and mothers were interviewed separately from pregnant women because ethnicity and parity were expected to be linked to contrasting ideas about infant feeding. This made it possible to link different sets of ideas or beliefs with different groups, as well as ensuring that participants were not suppressing their opinions because of contrasting ideas from persons different from themselves.

Participant observation is a research method in which the researcher tries to fit into the group under study, to systematically interpret the interviews conducted and observations made in such a role (61, 62). In several of the studies described above (16, 42), researchers lived in homes of research subjects to observe and participate in meals.

Qualitative methods appear deceptively simple to those not trained in their use (63). However, they are extremely time-consuming and subject to established conventions of scientific rigor for their use within the social sciences that are analogous to the standards used in laboratory-based nutrition methods (64). These include such aspects of research design as sampling, measurement, and analysis. Despite the lack of familiarity with these methods, their use by nutritionists in studies of food and nutrition, either alone or in combination with other quantitative or nutritional methods (65, 66), can produce understanding of food consumption behaviors.

IMPACT OF SOCIAL FACTORS ON NUTRITIONAL STATUS

In addition to explaining the social and cultural patternings of food consumption, social science provides ways of examining the impact of social structures on nutritional status. Such an approach can help identify points for intervention for both under- and overnutrition.

Families and Food

The family is the basic social unit in which individuals are socialized into eating and which is organized to reflect larger societal patterns, such as age and gender roles. Some distinct patterns of nutritional status are attributable to variations in families (37). Several studies have examined the family environment's effect. Such indicators of family environment as levels of conflict and suppression of independence predict less-adequate dietary intake among adult family members (67). For children, poor parenting skills, family conflict, and marital instability predict failure to thrive (68), as

does a family environment with little physical contact and verbal interaction from mothers (69).

Other studies of families indicate that family size and birth order affect nutritional status. Their results support the “dilution model” of family resources (70). This model argues that greater numbers of children necessitate stretching resources (money, time, food) so that the quality of the family's end product is lower. This end product can range from educational attainment of children to nutritional status. In general, children from large families are more likely to be stunted (short for age) than those from smaller families (71). The risk is particularly high for last-born children in large families (72). Such children have lower intakes of individual nutrients, and their diets are nutritionally inadequate overall compared with a standard such as the recommended dietary allowances (73). This pattern of poorer nutritional status of children in large families (74, 75 and 76) or of high birth order (77, 78, 79, 80 and 81), particularly in the context of poverty, has been documented in many populations, both Western and non-Western.

The effects of birth order sometimes differ when specific groups are examined, so that it is the oldest child who is most at risk. Cecily Williams was the first to describe acute protein energy malnutrition (82). She proposed the term “kwashiorkor,” the name for the disease used by the Ga people of Ghana among whom she worked (83). Translated, kwashiorkor is literally the disease of the first born. Even without understanding the specific nutritional effects of abrupt weaning and transition to low-nutrient-density gruels, the Ga recognized the adverse consequences for the weanling (82).

Because mothers and wives are responsible for feeding families in virtually all societies, it has been argued that women's participation in the labor force has a deleterious effect on the nutritional status of family members. However, there is little support for this argument. In the United States, a comparison of diets of children of mothers employed outside the home with those not employed (84) found no evidence of either inadequate intake of nutrients or excessive intakes of fats. This lack of difference may be explained by other research that shows that working outside the home simply makes production of family meals more difficult. Women simplify such meals (85), but they continue to produce them (29).

The evidence from research in the Third World linking maternal employment and nutritional status demonstrates that children's nutritional status frequently improves as a result of their mothers' income-generating activities (86), particularly when women control the income. Women are more likely than men to direct extra cash income to feeding children, and in many cases, it can smooth out the highs and lows of the agricultural cycles (87, 88). Hence, many developing country interventions aimed at improving child nutritional status take advantage of circumstances such as those in West Africa, where spousal incomes are customarily separated, by introducing income-generating activities for women. However, maternal employment can sometimes impair child nutrition by diverting time from food preparation and child care activities (89, 90), so assessments of its impact are situation dependent.

Social Stratification and Nutritional Status

Whether measured by income, education, ethnic group, occupation, or composites of these, social stratification has a pronounced effect on nutrition-related health. Persons of higher social rank live longer and enjoy lower morbidity than do those of lower social rank. Recent sociologic analysis showed that the effect of social rank on mortality is continuous, not just a difference between those of the highest and lowest ranks. Even within higher social classes, there are health and mortality differences that parallel wealth and other measures (91, 92). These associations of social rank and health reflect the differences between groups in life course experience and are manifest in lifestyle differences.

In general, high social classes have greater access to high-quality diets, education, health care, and employment in higher-paying occupations that are not physically hazardous. These are associated with a lifestyle of more health-promoting behaviors, including more healthful diets, less smoking and other substance abuse, and lower rates of both chronic and infectious disease (93).

Class effects on nutritional status and dietary practices are evident in both historic and contemporary populations (94, 95). Persons of higher social class are taller. The secular trend in increasing stature correlates with social class, as stature increased earlier in upper than lower classes. Today, diminished nutritional status can be linked to poverty.

The social class distribution of obesity, another measure of nutritional status, is marked in women in the United States and other developed countries. Women in lower-income groups, those with lower educational attainment, and those of minority status are on average the most obese (96). This is reinforced by preference for fatter body shape (97) or greater acceptance of various body shapes (98) among lower class and minority women.

There are conflicting explanations for the social stratification of nutritional status. Economic and social explanations point to the greater cost of a high-quality diet and the limits on opportunities for physical activity in poor neighborhoods (98, 99). In contrast, cultural explanations suggest that obesity has historically symbolized wealth and plenty. This may continue among lower social classes, just as it predominates in many developing countries to the present (96, 99, 100, 101 and 102).

There is recent evidence that class differences in dietary intake among adults may be decreasing. In a comparison of national food consumption surveys in the United States from 1965 to 1991, socioeconomic and racial differences in dietary quality decreased over time (103). However, this leveling of dietary quality may not be occurring in children, the most vulnerable age group, or it may not suffice to offset factors such as disease and stress that depress nutritional status (104).

International Perspectives on Malnutrition

Moving from national or population contexts to a worldwide perspective, social scientists have attempted to explain and to help alleviate overwhelming inequalities in nutritional

status (105, 106). One approach is to note the association of numerous nutrition indicators (e.g., nutritional deficiency diseases, stunting, starvation, dietary quality) with a country's gross national product (GNP). The association of better nutritional status with higher GNP and greater evidence of malnutrition with lower GNP is clear (107, 108). Two contrasting perspectives have been taken to interpret this association. The first has predicted that increasing GNP will improve nutrition; the second has taken a historical approach to explore the interconnections of national economies and to predict the likelihood of ameliorating worldwide nutrition problems.

The idea that increasing GNP will lead to improvements in nutrition has produced a massive international economic development effort to raise the economic productivity of lower-GNP countries (109, 110). Some early nutritional research challenged the utility of this approach. In a classic study of the transition from subsistence agricultural production to cash cropping, the latter was found to result in a decline in nutritional status as workers expended larger amounts of energy for lower nutrient intake (111). Likewise, a study in Mexico exemplifies those that demonstrated that dietary shifts to a poor-quality diet accompanied participation in commercial agriculture (112). More recent studies suggest a more positive effect on nutrition, caused by the increased income being applied to family food purchases (113), resulting in improved nutritional status (114).

To explain these contradictory findings, other social scientists have been critical of the economic development approach to improving worldwide nutrition. They contend that such an approach may improve the GNP of countries, but with similar gains for developed countries, thus maintaining the same power relations and flow of resources from poor to rich countries. They present a much less hopeful outlook for improving nutrition worldwide. This approach is referred to as a world systems perspective (115). Adherents argue that current inequalities between nations that lead to high levels of malnutrition in some countries with overnutrition in others reflect centuries old patterns in which western Europe represented a core that economically exploited other peripheral countries with resources necessary for European lifestyles.

In recent years, countries at the periphery (those with the lowest GNPs) have become dependent on imported foods from core countries (often surplus grain production) as they either exported their food or turned to industrial production of goods to be sold to core countries. Dependence on fluctuating supplies and prices, as well as the necessity of having cash to purchase food has reduced food security and increased the likelihood of hunger (116).

World systems theory suggests that nations at the periphery will have lower standards of living and greater nutrition problems. Data compiled from international sources (117, 118) bear this out. Ranking countries on the basis of GNP and other aspects of development from periphery (e.g., Tanzania, Bangladesh, El Salvador) to semiperiphery (e.g., Egypt, Philippines, Mexico) to semicore (e.g., Brazil, Korea) to core (e.g., United States, Japan) results in a gradient in such measures as wasting, stunting, and prevalence of anemia in pregnant women (37). Both the economic development and world systems perspectives link nutritional status to such measures of national economic well-being as GNP. The latter, however, stress the interdependence of

economies and suggest that alleviating hunger and malnutrition around the world is far from simple.

Many of the concepts and findings presented in this chapter may seem, at first glance, self-evident. This is because all persons (including nutritionists) are members of families, communities, and societies, giving them ample opportunity to make observations related to the social and cultural aspects of food and nutrition. The value of social and behavioral sciences to modern nutrition lies in the rigorous methodology that they can employ. This methodology, usually based on commonplace behaviors of observation and conversation, can be used to examine ideas about food and their distribution, as well as the relationship of nutritional status to social and cultural variation.

Food faddism can be defined as an unusual pattern of food behavior enthusiastically adopted by its adherents (1). It is commonly expressed by (a) beliefs that particular foods or food substances can cure diseases, (b) elimination of certain foods from the diet without adequate reason, and/or (c) emphasis on “natural” foods. Many aspects of food faddism become social movements that represent symbolic rebellions against authority, society-at-large, or some imagined enemy.

Quackery can be defined as the promotion for profit of a medical scheme or remedy that is unproven or known to be false. This definition seeks to distinguish folk practices and neighborly advice from practices for financial gain. “Health fraud” has been defined in a similar way. However, since most people regard *fraud* as a deliberate attempt to deceive, the term *health fraud* is most appropriate when deliberate deception is involved.

Quack methods are sometimes referred to as “alternatives.” Since ineffective methods are not true alternatives to effective ones, the terms *unscientific* or *dubious* are preferable. “Alternative” methods related to nutrition are discussed in [Chapter 110](#).

Faddists and quacks urge everyone to distrust large food companies, government regulators, and scientific health professionals (2). This negative philosophy is essential because without it, there would be no reason to buy health-food-industry products or consult “alternative” practitioners.

VULNERABILITY TO QUACKERY

Victims of quackery usually have one or more of the following characteristics:

1. *They are unsuspecting.* Many people believe that if something appears in print or

in a broadcast, it must be true or somehow it wouldn't be allowed. People also tend to believe what others tell them about personal experience.

2. *They believe in magic.* Some people are easily taken in by the promise of an easy solution to their problem. Those who buy one fad diet book after another fall into this category.
3. *They are desperate.* Many people faced with a serious health problem that doctors cannot solve become desperate enough to try almost anything that arouses hope. Many victims of cancer, arthritis, multiple sclerosis, and AIDS are vulnerable in this regard.
4. *They are alienated.* Some people feel deeply antagonistic toward scientific medicine but are attracted to methods that are “natural” or otherwise unorthodox. They may also harbor extreme distrust of the medical profession, the food industry, drug companies, and government agencies.

MISLEADING CLAIMS

Nutritional faddism and quackery are promoted with five basic fallacies:

1. *Our food supply is nutritionally inadequate because our soils are depleted and important nutrients are removed by food processing.* These claims encourage purchase of “organic,” “natural,” and “health” foods. A typical example is this passage from a book by Earl Mindell (3), cofounder of the Great Earth chain of health-food stores: “Much of our soil our food is grown in has been depleted of many vitamins and minerals, thanks to the overuse of fertilizers and chemicals. Then the food takes a long time to get to the supermarket ... The longer these foods are stored the more vitamins they lose. Many of the foods we eat have been heavily processed, meaning they have been crushed, heated, bleached, extracted, chemicalized and preserved ... Then we cook the food, destroying valuable enzymes and what's left of many vitamins. It's a wonder there's any nutrition at all left in our food by the time it gets to our tables (3)!”
2. *Vitamin and mineral deficiencies are common.* This claim is used to persuade people that everyone should take supplements. A typical example is this passage from *Prescription for Nutritional Healing* (4), a book that recommends supplements and/or herbs for more than 250 health problems: “The problem with most of us is that we do not get what we need from our modern diet. Even if you are not sick, you may not necessarily be healthy. By understanding the principles of wholistic nutrition and knowing what nutrients we need, we can improve the state of our health, stave off disease, and maintain a harmonious balance in the way nature intended.”
3. *Most health problems are due to faulty diet and can be treated by nutritional methods.* These types of claims are used to market “food supplements,” “health foods,” and quack dietary methods.
4. *Americans are in danger of being poisoned by food additives and pesticide residues.* This claim, along with accusations that the food industry and government regulators are untrustworthy, is used to promote the sale of “organic” and “natural” foods.
5. *Personal experience is the best way to tell whether a health-related action is effective.* This claim encourages people to rely on testimonial evidence rather than

scientific studies and prevailing medical beliefs.

[Table 109.1](#) lists ways to help spot food quacks.

1. When talking about nutrients, they tell only part of the relevant story.	15. They claim that sugar is a deadly poison.
2. They claim that most Americans are poorly nourished.	16. They oppose pasteurization of milk and fluoridation of water.
3. They recommend "nutrition insurance" for everyone.	17. They recommend a wide variety of substances similar to those found in your body.
4. They say that if you eat badly, you'll be in as long as you take supplements.	18. They claim that "natural" vitamins are better than "synthetic" ones.
5. They say that most diseases are due to faulty diet and can be treated with "nutritional" methods.	19. They suggest that a questionnaire can be used to indicate whether you need dietary supplements.
6. They allege that modern processing methods and storage remove all nutrients value from our food.	20. They promise quick, dramatic, miraculous results.
7. They claim that diet is a major factor in leukemia.	21. They routinely sell vitamins and other "dietary supplements" as part of their practice.
8. They claim that foundation is dangerous.	22. They use disclaimers couched in pseudomedical jargon.
9. They claim that soil depletion and the use of pesticides and "chemical" fertilizers result in food that is less safe and less nourishing.	23. They use anecdotes and testimonials to support their claims.
10. They claim you are in danger of being "poisoned" by artificial food additives and preservatives.	24. They offer glory "vitamins."
11. They charge that the recommended dietary allowance (RDA) has become all too low.	25. They display credentials not recognized by responsible scientists or educators.
12. They claim that under stress, and in certain diseases, your need for nutrients is increased.	26. They offer to determine your body's nutritional state with a single laboratory test.
13. They recommend "supplements" and "health foods" for everyone.	27. They claim they are being persecuted by orthodox medicine and that their work is being suppressed (because it's controversial).
14. They say it is easy to lose weight.	28. They urge you not to trust your doctor.
	29. They use to recommend their own.
	30. They encourage patients to find political support to their truest methods.

From Barrett, L. (1997). The vitamin pushers: how the "health-food" industry is making Americans ill. New York, NY: Prometheus Books, 1997.

Table 109.1 Thirty Tips to Help Spot Vitamin Pushers and Food Quacks

Misleading Claims for Foods

Many foods are promoted with slogans suggesting that they are safer, more nutritious, or have special therapeutic value. “Organically grown” foods are said to be grown without use of “artificial” fertilizers or pesticides. The foods themselves are usually indistinguishable from “ordinary” foods but cost significantly more. Studies comparing organically grown and conventionally grown foods have found that their pesticide content is similar (5). U.S. Food and Drug Administration (FDA) market-basket studies indicate that pesticide residues are insignificant in the overall diet (6). Nutrients are absorbed by the plant in their inorganic chemical state regardless of whether the soil has been prepared with manure, compost, or manufactured fertilizer. Plants grow only if they receive enough nutrients, and their vitamin content is determined by their genes. Fertilizers can influence the mineral composition of plants, but these variations are rarely significant in the overall diet. A recent study encompassing 460 assessments of nine different fruits and vegetables found no significant difference in taste quality between “organic” and conventionally grown samples (7). Despite such facts, a federal law passed in 1990 requires the U.S. Department of Agriculture to establish standards for organic food “certification.”

The word *natural* is said by its proponents to designate foods that are minimally processed and contain no artificial additives or preservatives, implying that these substances pose a health risk. Actually, they help make our food supply safe, abundant, and palatable. Although one is occasionally found to pose a health hazard (e.g., sulfites), the vast majority appear safe, and the overall level in our food supply should not cause concern—or be a reason to buy “natural” foods. The health-food industry also circulates unfounded criticisms of food irradiation, milk pasteurization, and genetically

engineered foods (8).

Although the term *health food* cannot actually be defined, it is used to suggest that certain foods have special health-giving properties not found in “ordinary” foods. Some “health” foods are rich in various nutrients and can be a valuable part of a balanced diet. But no food has any special health-promoting property beyond those of its components. FDA regulations permit food labels and packages to contain truthful and nonmisleading claims related to (a) calcium and osteoporosis, (b) sodium and high blood pressure, (c) dietary fats and heart disease, (d) dietary fats and cancer, (e) dietary fiber and cancer, (f) fiber and cardiovascular diseases, and (g) oatmeal or oat bran and heart disease. The claims must be limited to the relationship between these conditions and a particular food component, rather than the specific product. The recommendation must also be consistent with sound total diet (9, 10). Food advertising is primarily regulated by the Federal Trade Commission (FTC), which plans to apply similar criteria (11).

Promotion of Supplements

Americans waste several billion dollars a year on worthless or unnecessary “dietary supplements.” These products are promoted with scare tactics and false promises. The most common sales pitch is “nutrition insurance,” the idea that everyone needs vitamin and mineral supplements to be sure of getting enough. Some promoters falsely suggest that it is difficult to balance one's diet, while others insist that our food supply is inadequate.

Another common ploy is the suggestion that supplementation is advisable to help deal with “stress.” This idea was commercialized by distorting a 1952 National Academy of Sciences report (12). The report merely stated that people who are seriously ill or injured (some of whom have impaired appetite) might benefit from supplementation to prevent depletion of water-soluble vitamins, which have limited storage. However, in 1976, a major vitamin manufacturer began falsely advertising that “stress robs the body of vitamins” and that water-soluble vitamins must be replaced *daily* because the body cannot store them. Other manufacturers embellished further, suggesting that extra vitamins are needed to cope with emotional stress, the stress of a busy lifestyle, or life's other stressful events. Some manufacturers made no claims for their “stress” products but assumed that consumers would understand the implications. Several manufacturers falsely suggest that being active and elderly creates special needs that their products supposedly meet.

In the mid-1980s, the New York State attorney general secured consent agreements with two major “stress supplement” manufacturers to stop misrepresenting the need for their products. Since that time, the amount of direct advertising of “stress supplements” has greatly decreased. However, the Council for Responsible Nutrition (CRN), a trade organization that represents major supplement manufacturers and suppliers, has advertised that a busy lifestyle places Americans at nutritional risk. The ad included a narrowly worded “Vitamin Gap Test” suggesting that virtually everyone may have one or more “gaps.” CRN representatives maintain that virtually everyone needs supplements (13). In 1990, the FTC secured a consent agreement barring another large manufacturer from making unsubstantiated claims that any vitamin product is needed to

replace nutrients lost as a result of athletic activities or “the stress of daily living.” Such “stress” is not a true hypercatabolic state in which increased amounts of calories and nutrients are needed (see [Chapter 96](#)).

During the past few years, many health-food manufacturers have developed “ergogenic aids”—amino acid supplements falsely claimed to increase stamina, endurance, and muscle development. Some of these products are claimed to be “natural steroids” that release growth hormone ([14](#)). There is no scientific evidence that these products actually release growth hormone—which is fortunate, because if they did, acromegaly might result. David Lightsey, who coordinates the National Council Against Health Fraud's Task Force on Ergogenic Aids, has requested documentation from more than 80 companies that market “ergogenic aids.” Fewer than half sent anything, and the rest submitted studies that were poorly designed or did not actually support product claims. Lightsey also checked statements that various teams were using certain products and found that management had neither endorsed the products nor encouraged their use ([15](#)).

The Federation of American Societies for Experimental Biology (FASEB) has criticized the widespread use of amino acids in supplements. Following extensive review, FASEB experts concluded that (a) single- or multiple-ingredient capsules, tablets, and liquid products are used primarily for pharmacologic purposes or enhancement of physiologic functions rather than for nutritional purposes, (b) little scientific literature exists on most amino acids ingested for these purposes, (c) no scientific rationale has been presented to justify use of amino acid supplements by healthy individuals, (d) safety levels for amino acid supplement use have not been established, and (e) a systematic approach to safety testing is needed ([16](#)).

Vitamin C, vitamin E, and b-carotene are being vigorously promoted with claims that their antioxidant properties can help prevent various diseases by blocking the harmful action of free radicals. Epidemiologic evidence indicates that diets containing significant amounts of fruits, vegetables, and grains are associated with a lower incidence of heart disease and certain cancers ([17](#)). But it is not known which, if any, specific substances in the diet are responsible or whether taking above-RDA doses of supplements will do more good than harm. Evidence exists, for example, that vitamin E can help prevent atherosclerosis by interfering with oxidation of low-density lipoproteins (LDL). However, this vitamin can also exert an anticoagulant effect. The issue can be settled scientifically by conducting long-term double-blind clinical studies that compare vitamin users and nonusers and measure death rates from all causes.

So far, four large clinical trials have been reported. The first compared the effects of vitamin E, b-carotene, and a placebo among heavy smokers. The researchers found no benefit from vitamin E and 18% *more* lung cancer among those who received b-carotene. In addition, the overall death rate of b-carotene recipients was 8% higher, and those who took vitamin E had a higher frequency of hemorrhagic stroke ([18](#)). The second study found no evidence that supplementing with vitamin C, vitamin E, or b-carotene prevented colorectal cancer ([19](#)). The third study, which followed 22,000 physicians for 12 years, found no difference in cancer or cardiovascular disease rates between users and nonusers of b-carotene ([20](#)). The fourth trial, which tested a

combination of b-carotene and vitamin A, was terminated after 4 years because it appeared that the supplement-takers who smoked had a 28% higher incidence of lung cancer and a 17% higher death rate (21).

In addition to marketing antioxidants, many companies are marketing products said to be concentrates of fruits and/or vegetables. Critics note, however, that it is not possible to condense large amounts of produce into a pill without losing fiber, nutrients, and many other phytochemicals (22). Although some products contain significant amounts of nutrients, these nutrients are readily obtainable at lower cost from foods.

Advice from Retailers

Health Foods Business estimates that in 1996 there were 9789 “health food” stores in America with total gross sales of \$7.6 billion, including \$3 billion for vitamins and other supplements, up from 1992 figures of 7500, \$3.8 billion, and \$1.5 billion, respectively (23). No special knowledge or training is required to become a salesperson at a health-food store. Personnel in these stores typically obtain information by reading books and magazines that promote supplements and herbs for treatment of virtually all health problems. Retailers also get information from manufacturers and can attend seminars at trade shows sponsored by industry groups and trade magazines (13). Several large studies have demonstrated that their proprietors often give advice that is irrational, unsafe, and illegal:

- In 1983, investigators from the American Council on Science and Health (ACSH) made 105 inquiries at stores in New York, New Jersey, and Connecticut. Asked about eye symptoms characteristic of glaucoma, 17 of 24 suggested a wide variety of products for a person not seen; none recognized that urgent medical care was needed. Asked over the telephone about sudden, unexplained 15-pound weight loss in 1 month's time, 9 of 17 recommended products sold in their store; only 7 suggested medical evaluation. Seven of 10 stores carried “starch blockers” despite an FDA ban. Nine stores contacted made false claims of effectiveness for bee pollen, and 10 stores did so for RNA (24).
- In 1987, a registered dietitian posed five similar questions to 10 health-food-store proprietors in eastern Pennsylvania and concluded that only 23 of 50 responses (46%) were correct (25).
- In 1989, volunteers of the Consumer Health Education Council telephoned 41 Houston-area health-food stores and asked to speak with the person who provided nutritional advice. The callers explained that they had a brother with AIDS who was seeking an effective alternative against the HIV virus. The caller also explained that the brother's wife was still having sex with her husband and wanted to reduce or eliminate her risk of being infected. All 41 retailers offered products they said could benefit the brother's immune system, improve the woman's immunity, and protect her against harm from the HIV virus. Thirty said they sold products that would cure AIDS. None recommended abstinence or using a condom (26).

In 1993, posing as prospective customers, FDA agents visited local health-food stores throughout the United States. The investigators asked, “What do you sell to help high

blood pressure?” “Do you have anything to help fight infection or help my immune system?” and/or “Do you have anything that works on cancer?” Of 129 requests for information, 120 resulted in recommendations of specific dietary supplements (27). Retailers who recommend products when customers describe symptoms violate state laws against the unlicensed practice of medicine or pharmacy, but they are rarely prosecuted.

Several dozen companies market supplements through person-to-person (multilevel) sales. Virtually anyone can become a distributor by filling out a one-page application and buying a distributor kit for less than \$50. Most multilevel companies claim their products can prevent or cure a wide range of diseases. A few companies merely suggest that people will feel better, look better, or have more energy if they use supplements.

Although pharmacists receive scientific training in nutrition, a study by *Consumer Reports* has cast considerable doubt on the ability of community pharmacists to give appropriate advice about supplements. When 30 pharmacists were asked by undercover reporters whether vitamins could relieve their nervousness or fatigue, 17 recommended vitamins, one recommended L-tryptophan, and only 9 mentioned seeing a doctor (28).

A large percentage of supplement products are irrationally formulated. Several years ago, two dietitians examined the labels of vitamin products at five pharmacies, three groceries, and three health-food stores in New Haven. Products were judged appropriate if they contained between 50 and 200% of the U.S. RDA and no more than 100% of others for which “Estimated Safe and Adequate Daily Dietary Intakes” exist. Only 16 of 105 (15%) multivitamin/mineral products met these criteria (29).

Few supplement products have any usefulness against disease, and most that do (e.g., niacin for cholesterol or triglyceride control and folic acid for lowering abnormal blood levels of homocysteine) should not be taken without competent medical supervision.

DUBIOUS CREDENTIALS

Since the early 1980s, many individuals and groups have developed credentials intended to resemble those of established medical and nutritional organizations (13, 30). During this period, unaccredited correspondence schools and other organizations have issued a steady stream of “degrees” and other certificates intended to suggest that the recipient is a qualified expert in nutrition. The schools typically issue B.S., M.S., and/or Ph.D. “degrees” based on study of unscientific writings plus open-book tests that are scored quite liberally. The professional organizations typically grant immediate “professional memberships” and a fancy certificate for a modest fee. Household pets and nonexistent individuals have achieved membership in several of these groups. Some organizations offer “certification” based on correspondence courses that invariably include unscientific teachings. The most significant of these is the C.N. (Certified Nutritionist) issued by the nonaccredited National Institute for Nutrition Education (NINE). Such credentials have no legal or scientific standing but can be advertised or displayed in most states that do not regulate nutritionists. The American

Dietetic Association is striving for increased regulation of nutritional practice and by 1996 had gained passage of laws in 38 states.

In 1993, a 32-state survey sponsored by the National Council Against Health Fraud found that 286 (46%) of 618 “Yellow Pages” listings under the heading “Nutritionists” were spurious, and 72 (12%) were suspicious. Listings were considered “spurious” if the advertiser used an invalid method of diagnosis, treatment, or nutritional assessment. Listings were rated “suspicious” if the practitioner did not comply with a request for information on credentials or methods used. Dubious nutrition practitioners were also found under the headings “Acupuncture,” “Health & Diet Products,” “Health, Fitness & Nutrition Consultants,” “Herbs,” “Holistic Practitioners,” “Weight Control Services,” and “Wellness Programs.” Many such listings were for chiropractors, homeopaths, naturopaths, “holistic” physicians, health-food stores, and multilevel distributors for such companies as Herbalife International, Nu Skin International, Shaklee Corporation, and Sunrider International. The credentials used included CCN (certified clinical nutritionist), CN (certified nutritionist), CCT (certified colon therapist), CMT (certified massage therapist), CNC (certified nutrition consultant), HMD (homeopathic medical doctor), L.Ac. (licensed acupuncturist), MLD (manual lymph drainage), NC (nutrition counselor), ND (doctor of naturopathy), NMD (doctor of nutriment), and OMD (oriental medical doctor). Of 24 individuals identified as “Ph.D.” in their ad, 17 had spurious credentials. Of 231 listings under the heading “Dietitians,” 21 (9%) were spurious, including several from GNC stores (31).

The best strategy to avoid entanglement with an unqualified nutritionist is to avoid *all* practitioners who sell supplements in their offices or espouse the statements listed in [Table 109.1](#).

DUBIOUS DIAGNOSTIC TESTS

Unscientific practitioners use a variety of tests as a basis for prescribing supplements and/or making dietary recommendations. The most common such test is hair analysis, which is purported to detect “mineral imbalances” or the presence of “toxic minerals.” The test is usually obtained by sending a small amount of hair from the nape of the neck to a commercial laboratory for analysis. The laboratory then issues a computerized report suggesting what supplements might be prescribed. When 52 hair samples from two healthy teenagers were sent under assumed names to 13 commercial hair-analysis laboratories, the reported levels of minerals varied considerably between identical samples sent to the same laboratory and from laboratory to laboratory. The laboratories also disagreed about what was “normal” or “usual” for many of the minerals. Literature from most of the laboratories suggested falsely that their reports were useful against a wide variety of diseases and supposed nutrient imbalances (32). Properly performed, hair analysis has limited value as a research tool but little if any clinical application (33).

Supplement purveyors sometimes use “nutrient deficiency tests” to help them decide what their customers need. One type involves completion of a dietary history; another involves completion of a questionnaire about common symptoms that supposedly are signs of deficiency. The answers are then fed into a computer program to recommend supplements for everyone. Some manufacturers issue a self-administered questionnaire

that invariably recommends supplements.

Functional intracellular analysis (FIA), formerly called essential metabolics analysis, is performed by a laboratory that claims that most Americans have nutrient deficiencies and that “intracellular nutrient deficiencies” even occur in over 40% of Americans who take multivitamins as “insurance.” The test is performed by placing isolated lymphocytes from the patient's blood into petri dishes containing various concentrations of nutrients. Properly performed lymphocyte cultures have a legitimate role in testing for concentrations of certain nutrients, but they are not appropriate for general screening or for diagnosing nutrient deficiencies (13).

Some practitioners use data from legitimate laboratory tests but misrepresent their meaning. Chemistry profiles, which measure many different chemical characteristics of the blood, are a valuable screening test in scientific medical practice. But dubious practitioners misuse the test by narrowing the normal ranges so that healthy individuals appear to have abnormalities, which are then used to recommend expensive supplements or special diets (13).

Some practitioners claim that food allergies may be responsible for virtually any symptom and can be treated with vitamin supplementation plus dietary restriction. To detect the alleged offenders, they assess the levels of various immune responses to foods. These levels, however, are not necessarily related to allergy and have nothing whatsoever to do with a person's need for supplements (13).

Although thousands of practitioners (mostly chiropractors) use the above procedures, government regulatory agencies rarely attempt to stop them. [Chapter 110](#) addresses this problem further.

OBESITY QUACKERY

Many weight-reduction schemes are promoted to the public as a solution to obesity. Fad diet books typically have several things in common. They claim to offer a revolutionary new idea based on the author's personal experience. They suggest that certain nutrients, foods, or food combinations are either the key to weight reduction or villains that prevent it. And, they contain inaccurate biochemical information. Many fad diets are unbalanced and lack important nutrients. During the past two decades, many best-selling diet plans have emphasized proteins, some recommending “unlimited” amounts and others using small amounts. “Food-combining” schemes also have been popular. *Fit for Life*, which sold over 3 million copies, claims that obesity caused accumulation of “toxic waste” from incomplete assimilation of foods eaten in the wrong combinations.

Mail-order diet pills are typically “guaranteed” to produce effortless, rapid, and permanent weight loss. Dozens of such pills are offered each year through direct mail solicitations and newspaper advertising. Some of these, as well as others sold over the counter, contain phenylpropanolamine (PPA), a nasal decongestant that can have a temporary effect on appetite. However, there is no evidence that PPA offers any long-term benefit for weight control, many users have experienced severe anxiety

reactions, and several cases have been reported of young adults who suffered a stroke after using products containing PPA (34).

Other mail-order pills have been falsely claimed to block absorption of starch, fat, or calories; to flush fat out of the body; or to step up the body's "fat-burning system." Some contain a fiber (e.g., glucomannan or guar gum) that is claimed to curb appetite by absorbing water and swelling to fill the stomach. However, the amount of fiber is too small to actually fill the stomach, and even if it could, that would not necessarily curb a person's appetite. In 1990, guar gum was banned as a diet aid after the FDA received 17 reports of individuals whose esophagus became blocked as a result of using tablets of Cal-Ban 3000, a widely promoted guar gum product (35).

Spirulina, a dark-green powder or pill derived from algae, is said by its promoters to suppress appetite. However, there is no scientific evidence to support this claim.

Products containing *Gymnema sylvestre* are being touted as weight-control aids with claims that they block absorption of sugar. The leaves of this plant, when chewed, can prevent the taste sensation of sweetness. But there is no evidence that *Gymnema sylvestre* blocks absorption of sugar into the body.

Supplements containing chromium picolinate are promoted with unsubstantiated claims that it promotes fat loss and increases lean muscle mass. The FTC has stopped two companies from making such claims, but others have continued to do so.

Products containing ma huang are marketed as weight-loss aids even though they have not been proven safe or effective for this purpose. Ma huang is an herb that contains ephedrine, a nasal decongestant and nervous-system stimulant. Ephedrine can raise blood pressure and therefore is hazardous to individuals with high blood pressure. Deaths have been reported among users of stimulants containing ephedrine and caffeine.

DANGERS OF QUACKERY

Quackery's harm can be classified as economic, indirect, direct, psychologic, and societal (36). Individual economic damage can range from a few dollars a year for "nutrition insurance" to many thousands of dollars wasted on quack remedies for serious disease. Since everyone must eat, the potential market for nutritional quackery is immense. Indirect harm occurs when the use of an ineffective approach diverts someone from effective care. Direct harm occurs when a dubious method causes death (Fig. 109.1), serious injury, or unnecessary suffering. Psychologic harm arises when individuals blame themselves for the failure of an ineffective remedy or when they mistakenly conclude they have been helped and become more vulnerable to future deception. Quackery can also harm our democratic society when large numbers of people hold erroneous beliefs about the nature of disease and the best way to deal with it. Limited resources can be wasted if funds are used to follow leads based on inadequate or faked data. Between 1986 and 1990, the American Dietetic Association documented more than 500 cases of people harmed by inappropriate nutritional advice from bogus "nutritionists," health-food-store operators, and others. Privacy

considerations, however, have prevented the association from publishing a detailed analysis.

In a study of 653 sick babies, every infant with colic had low blood potassium. "Improvement was dramatic," and the colic disappeared immediately, when physicians gave 500 to 1,000 milligrams of potassium chloride intravenously or 1,000 to 2,000 milligrams by mouth. These doctors found that most babies needed 3,000 milligrams of potassium chloride (½ teaspoon) before colic was corrected. They suggested that potassium be given to prevent colic, especially during diarrhea, when much of this nutrient is lost in the feces. Potassium is also lost when too much salt (sodium) is allowed a baby, and/or when pantothenic acid is so deficient that the adrenals become exhausted.

Figure 109.1. Fatal advice. In 1979, this passage from Adelle Davis's *Let's Have Healthy Children* persuaded the mother of 2-month-old Ryan Pitzer to administer potassium drops when he developed colic and became dehydrated. The potassium caused Ryan's heart to stop beating. Davis's advice was based on misrepresentation of a scientific study of infants hospitalized for severe gastroenteritis. The article had nothing do with colic and even warned that giving potassium to dehydrated infants could produce cardiac arrest. Ryan's parents sued Adelle Davis's estate, the book's publisher, and the manufacturer of the potassium drops and won out-of-court settlements totaling \$160,000.

The recent tryptophan tragedy illustrates how inappropriate use of supplements can lead to disaster. In 1989, a form of L-tryptophan was implicated in an outbreak of eosinophilia-myalgia syndrome, a previously rare disorder characterized by severe muscle and joint pain, weakness, swelling of the arms and legs, fever, and rash. This amino acid had been promoted by the health-food industry to treat insomnia, depression, premenstrual syndrome, and overweight, although it had not been proven safe and effective for these purposes. Within a year, more than 1500 cases were reported, with 27 deaths and many hospitalizations (37). When the outbreak's cause was identified, the FDA banned the sale of L-tryptophan products. The outbreak was traced to a Japanese bulk wholesaler that had used a new bacterial strain to produce the L-tryptophan sold to American manufacturers. Attorneys handling the resultant lawsuits state that more than 5000 users were injured and total damages paid by the errant producer have exceeded \$1 billion (38).

CONSUMER PROTECTION

Three federal agencies have responsibility for fighting quackery. The Postal Service has jurisdiction over products sold through the mail with false claims. When a scheme is detected, the Postal Service can use an administrative procedure to block transfer of

money and orders through the mail. The Postal Service has a vigorous enforcement program but is hampered by loopholes in its law.

The FTC has jurisdiction over the advertising of nonprescription products and services. It files complaints and negotiates settlements, going to court when necessary. It has a very powerful law but insufficient manpower to act against most violations it encounters. The FTC's most notable recent action was a 1994 consent agreement under which General Nutrition, Inc., paid \$2.4 million dollars to settle charges that it had falsely advertised 41 products, most of which had been packaged by other manufacturers. The products included 15 alleged weight-control products, 18 alleged "ergogenic aids," 5 bogus hair-loss preventers, 2 alleged antifatigue products, and 2 purported disease-related products ([13](#)).

The FDA has jurisdiction over the labeling of foods and drugs. Under federal law, any product "intended for use in the cure, mitigation, treatment or prevention of disease" is a drug. If a product is marketed with drug claims that lack FDA approval, the agency can issue a warning letter, initiate a seizure, obtain an injunction, and/or seek criminal penalties. The claim does not have to be on the product label itself. Any claim traceable to the manufacturer is considered part of the label. The FDA's enforcement ability has been weakened by passage of the Dietary Supplement Health Education Act of 1994 (see [Chapter 115](#)), which defines the term *dietary supplement* to include not only vitamins and minerals but also herbs, amino acids, and other substances intended "for use to supplement the diet by increasing total dietary intake." The law also shifted the burden of proof of product safety from manufacturers to the FDA and permits sellers to use third-party literature as sales aids.

Several state attorneys general have been active in combating quackery. But their actions may not stop promoters from continuing their schemes out of state. State and federal laws pertaining to quackery need strengthening ([39](#)).

The primary antiquackery force in the United States is the National Council Against Health Fraud (NCAHF), Inc., P.O. Box 1276, Loma Linda, CA 92354. NCAHF is a nonprofit organization of about 1300 health and nutrition professionals, educators, researchers, attorneys, and other concerned citizens wishing to actively oppose misinformation, fraud, and quackery in the health marketplace. Financed primarily by membership dues, it conducts research, publishes a newsletter and task force reports, serves as a clearinghouse, and helps victims of quackery file lawsuits. [Table 109.2](#) advises where to complain about nutrition-related wrongdoing.

Problem	Agencies to Contact*
False advertising	FTC, Bureau of Consumer Protection or regional office National Advertising Division, Council of Better Business Bureaus Editor or manager of trade outlet where ad appeared
Product mislabeled (weight, name or ingredients)	Federal or regional FDA office State attorney general State Health Department Local Health Department State or local consumer advocate
Biogenetic modification	U.S. Food and Drug Administration (FDA) State attorney general
Unlabeled food	FDA, Bureau of Consumer Protection or regional office
Unlabeled food	Federal Food Inspection Control Institute State or local inspector of trade outlet where ad appeared
Unlabeled food	Local or state professional society of practitioners U.S. Food and Drug Administration (FDA) Local professional association Federal Consumer Product Safety Fraud Task Force U.S. Customs Service
Unlabeled food	Local or state professional society of practitioners U.S. Food and Drug Administration (FDA) Local professional association Federal Consumer Product Safety Fraud Task Force U.S. Customs Service

*Some state and local regulatory agencies decline to have jurisdiction; contact each of them to determine if you should contact them. For more information, contact each of the following:

Chapter References

Selected Readings

The dictionary definition of the noun *alternative* is a choice between mutually exclusive possibilities. Until the late 1980s, in standard medical usage, it referred to choices among effective treatments. In some cases, they were equally effective (e.g., the use of radiation or surgery for certain cancers); in others, the expected outcome differed, but there were reasonable tradeoffs between risks and benefits. During recent years, however, the word *alternative* has been applied to a multitude of unsubstantiated approaches that differ from standard medical ones.

To avoid confusion, alternative methods should be classified as genuine, experimental, or questionable. *Genuine* alternatives are comparable methods that have met science-based criteria for safety and effectiveness. Under the rules of science (and federal law), proponents who make health claims bear the burden of proof. It is their responsibility to conduct suitable studies and report them in sufficient detail to permit

evaluation and confirmation by others. Methods can be evaluated by addressing four questions: (a) Has the method shown potential for benefit that clearly exceeds the potential for harm? (b) Have safety and efficacy been demonstrated by objective studies using adequate controls? (c) Have the methodology and results been published in peer-reviewed scientific journals? and (d) Have the results been replicated by others? Peer review is a process in which work is reviewed by others, usually with equivalent or superior knowledge. The best scientific journals use experts for this purpose. Detailed standards for reporting and evaluating studies have been published (1).

Experimental alternatives are unproven but have a plausible rationale and are undergoing responsible investigation. The most noteworthy is the use of a 10%-fat diet for treating coronary heart disease. *Questionable* alternatives are groundless because they lack a scientifically plausible rationale or have been disproved. The archetype is homeopathy, which claims that “remedies” so dilute that they contain no active ingredient can exert powerful therapeutic effects. When the three types of alternatives are lumped together, promoters of questionable methods can argue that because some have merit, the rest deserve equal consideration and respect. This chapter uses the word *alternative* in its “questionable” sense.

When someone feels better after using a product or procedure, it is natural to credit whatever was done. This can mislead, however, because most ailments resolve spontaneously, and those that persist can have symptoms that wax and wane. Even serious conditions can have sufficient month-to-month variation to enable spurious methods to gain large followings. In addition, taking action often temporarily relieves symptoms via the placebo effect. This effect is a beneficial change in a person's condition that occurs in response to a treatment but is not due to the pharmacologic or physical aspects of the treatment. Belief in the treatment is not essential, but the placebo effect may be enhanced by such factors as faith, sympathetic attention, sensational claims, testimonials, and the use of scientific-looking charts, devices, and terminology. Another drawback of individual success stories is that they don't indicate how many failures might occur for each success. (In other words, no score is kept.) People unaware of these facts often give undeserved credit to “alternative” methods.

“Complementary medicine” is described by its proponents as a synthesis of standard and “alternative” methods that uses the best of both. However, no published data indicate the extent to which “complementary” practitioners actually use proven therapies or the extent to which they burden patients with medically useless methods. These practitioners typically claim credit for any improvement experienced by the patient and blame standard treatments for any negative effects. The result may be to undermine the patient's confidence in standard care, reducing compliance or causing the patient to abandon it altogether (2).

“Alternative” nutrition therapies appeal to people who would like to take an active role in their treatment. The products used are claimed to be safer and more effective than medically prescribed drugs. Government regulation of these products and the practitioners who prescribe them is minimal.

UNSUBSTANTIATED CLAIMS

When challenged about the lack of scientific evidence supporting what they espouse, “alternative” promoters may claim that (a) scientific reports (whose meaning they distort) back them up, (b) research isn't necessary because they have seen with their own eyes that their methods are effective, (c) funds are not available for them to perform research, (d) the scientific establishment is unwilling to test their methods or look at their data, and (e) scientific journals are unwilling to consider their research because it poses a threat to the establishment. Each of these claims is incorrect. Preliminary research does not require funding or even take much effort. The principal ingredients are careful clinical observations, detailed record keeping, and long-term follow-up to “keep score.” Proponents of “alternative” methods almost never do any of these things. Some even claim their concepts cannot be tested by scientific methods.

A study involving vitamin C illustrates why anecdotal evidence is not an appropriate substitute for carefully designed clinical trials. The study compared the effect of administering vitamin C supplements and placebo before and during colds. Although the experiment was supposed to be double blind, half the subjects were able to guess which pill they were getting. When the results were tabulated with all subjects lumped together, the vitamin group reported fewer colds per person over a 9-month period. But among the half who hadn't guessed which pill they had been taking, no difference in the incidence or severity was found (3). This demonstrates how people who think they are doing something effective can report a favorable result even when none exists.

Each of the approaches described in this chapter has one or more of the following characteristics: (a) its rationale or underlying theory has no scientific basis, (b) it has not been demonstrated safe and/or effective by well-designed studies, (c) it is deceptively promoted, or (d) its practitioners are not qualified to make appropriate medical diagnoses.

“ALTERNATIVE” SYSTEMS

Many “alternative” approaches involve nutrition-related methods. Proponents of these methods typically claim that (a) certain foods or nutrients have special ability to cure specific diseases; (b) certain foods are harmful and should be eliminated from the diet; and (c) “natural foods” are best. Most systems described in this section are also rooted in *vitalism*, the concept that bodily functions are due to a “vital force” that cannot be explained by the laws of physics and chemistry. Vitalistic proponents maintain that diseases should be treated by stimulating the body to heal itself rather than by “treating symptoms.” Naturopaths, for example, claim that illness is due to a disturbance of the body's natural healing force, which they can augment by “detoxification.” Some vitalists assert that food can be “dead” or “living” and that “live” foods contain a dormant or primitive “life force” that humans can assimilate. None of these “energies” can be measured by scientific methods.

Chinese Medicine

Traditional Chinese medicine (TCM), also called Oriental medicine, is based on beliefs that the body's vital energy (*Chi* or *Qi*) circulates through 14 hypothetical channels called meridians, which have branches connected to bodily organs and functions (4). Illness and disease are attributed to imbalance or interruption of *Chi*. Acupuncture, herbs, and various other modalities are claimed to restore balance. After extensive study of published reports, a National Council Against Health Fraud task force concluded that (a) acupuncture has not been proven effective for the treatment of any disease; (b) the greater the benefit claimed in a research report, the worse the experimental design, and (c) the best-designed experiments—those with the highest number of controls on variables—found no difference between acupuncture and control groups (5).

Many TCM practitioners are licensed acupuncturists. They are not permitted to prescribe drugs, but they are free to recommend dietary supplements and herbs. The diagnostic process they use may include questioning (medical history, lifestyle), observations (skin, tongue, color), listening (breath sounds), and pulse taking. Medical science recognizes only one pulse, corresponding to the heartbeat, which can be felt in the wrist, neck, feet, and various other places throughout the body. TCM practitioners check six alleged pulse aspects at each wrist and identify more than 25 alleged pulse qualities such as “sinking,” “slippery,” “soggy,” “tight,” and “wiry.” TCM's “pulses” supposedly reflect the type of imbalance, the condition of each organ system, and the status of the patient's *Chi*. The herbs they prescribe are not regulated for safety, potency, or effectiveness. Although some cases of adverse effects from herbs have been reported (6), no systematic assessment of this problem has been published.

Maharishi Ayur-Ved

Proponents state that ayurvedic medicine originated in ancient times but was reconstituted in the early 1980s by the Maharishi Mahesh Yogi, who also popularized transcendental meditation (TM). Its origin is traced to four Sanskrit books called the *Vedas*—the oldest and most important scriptures of India, shaped sometime before 200 BCE. These books attributed most disease and bad luck to demons, devils, and the influence of stars and planets. Ayurveda's basic theory states that the body's functions are regulated by three “irreducible physiologic principles” called *doshas*, whose Sanskrit names are *vata*, *pitta*, and *kapha*. Like the “sun signs” of astrology, these terms are used to designate body types as well as the traits that typify them. Like astrologic writings, ayurvedic writings contain long lists of supposed physical and mental characteristics of each constitutional type. Through various combinations of *vata*, *pitta*, and *kapha*, 10 body types are possible. However, one's *doshas* (and therefore one's body type) can vary from hour to hour and season to season.

Ayurvedic proponents state that the symptoms of disease are always related to balance of the *doshas*, which can be determined by feeling the patient's wrist pulse or completing a questionnaire (7). Balance is supposedly achieved through “pacifying” diets, “purification” (to remove “impurities due to faulty diet and behavioral patterns”),

TM, and a long list of procedures and ayurvedic products, many of which are said to be formulated for specific body types. Most of these cost several hundred dollars, but some cost thousands and require the services of an ayurvedic practitioner. Although many ayurvedic herbal products have been marketed with illegal claims, FDA regulatory action has been minimal.

Macrobiotics

Macrobiotics is a quasireligious system that advocates a semivegetarian diet. Macrobiotic diets have been promoted for maintaining general health and for preventing and treating cancer, AIDS, and other diseases. The optimal diet is said to balance “yin” and “yang” foods. It is composed of whole grains (50–60% of each meal), vegetables (25–30% of each meal), whole beans or soybean-based products (5–10% of daily food), nuts and seeds (small amounts as snacks), miso soup, herbal teas, and small amounts of white meat or seafood once or twice weekly (8). The yin/yang classification is not related to nutrient content but is based on the food's color, pH, shape, size, taste, temperature, texture, water content, and weight; the region and season in which the food was grown; and how it is prepared and eaten. Some macrobiotic diets contain inadequate amounts of certain nutrients. Infants on macrobiotic diets have developed rickets and had deficiencies of vitamin B₁₂ and iron (9, 10).

Macrobiotics is promoted through books, local organizations, health-food stores, unlicensed practitioners, and a few physicians. Practitioners typically base their recommendations on “pulse” diagnosis and other unscientific procedures related to Chinese medicine. These include “ancestral diagnosis,” “astrologic diagnosis,” “aura and vibrational diagnosis,” “environmental diagnosis” (including consideration of “celestial influences” and tidal motions), and “spiritual diagnosis” (an evaluation of “atmospheric vibrational conditions” to identify spiritual influences, including “visions of the future”) (11).

Today's leading proponent is Michio Kushi, founder and president of the Kushi Institute in Becket, Massachusetts. Institute publications state that the macrobiotic way of life should include chewing food at least 50 times per mouthful (or until it becomes liquid), not wearing synthetic or woolen clothing next to the skin, avoiding long hot baths or showers, having large green plants in your house to enrich the oxygen content of the air, and singing a happy song every day (12). Kushi claims that cancer is largely due to improper diet, thinking, and way of life, and can be influenced by changing these factors. He recommends yin foods (such as tropical fruits) for cancers due to excess yang, and yang foods (such as eggs and meat) for tumors that are predominantly yin (13). His books contain case histories of people whose cancers have supposedly disappeared after they adopted macrobiotic eating. However, the only reports of efficacy are testimonials by patients, many of whom also received standard medical treatment (14). The high-fiber diet can cause cancer patients to undergo serious weight loss (15).

Naturopathy

Naturopaths claim to remove the underlying cause(s) of disease and to stimulate the body's natural healing processes (16). They maintain that diseases are the body's effort

to purify itself and that cures result from increasing the patient's "vital force" by ridding the body of waste products and "toxins." However, they do not specify the chemical names of the "toxins," indicate how to measure them, or demonstrate that "detoxification" reduces the quantity in the body.

Although naturopaths say they emphasize prevention, they tend to oppose immunization. The doctor of naturopathy (N.D.) degree is available from three full-time naturopathy schools and a few correspondence schools. Naturopaths are licensed as independent practitioners in 11 states and may legally practice in a few others.

Most naturopaths believe that virtually all diseases are within the scope of their practice. Their methods include fasting, "natural food" diets, vitamins, herbs, tissue minerals, cell salts, manipulation, massage, exercise, colonic irrigation (see below), acupuncture, natural childbirth, minor surgery, and applications of water, heat, cold, air, sunlight, and electricity. They may use radiation for diagnosis but not for treatment. "Detoxification" plays a prominent role. The most comprehensive naturopathic textbook recommends special diets, vitamins, minerals, and/or herbs for more than 70 health problems ranging from acne to AIDS (17). For many of these conditions, daily administration of 10 or more products is recommended, some in dosages high enough to be toxic.

Natural Hygiene

Natural Hygiene, an offshoot of naturopathy, is a "philosophy" of health and "natural living" that advocates a "raw food" diet of vegetables, fruits, and nuts. It also advocates periodic fasting and "food combining" (avoiding food combinations it considers detrimental) (18). Natural Hygienists oppose immunization, fluoridation, and food irradiation and eschew most forms of medical treatment.

Orthomolecular Therapy

During the early 1950s, a few psychiatrists began adding massive doses of nutrients to the treatment of severe mental problems. The original substance used was niacin, and the therapy was termed *megavitamin therapy*. Since that time, the treatment regimen has been expanded to include other vitamins, minerals, hormones, and diets, any of which may be combined with mainstream drug therapy or electroconvulsive therapy.

Current proponents now call this system *orthomolecular psychiatry*, a term meaning "the treatment of mental disease by providing an optimum molecular environment for the mind, especially substances normally present in the human body." Proponents claim that abnormal conditions are caused by molecular imbalances that can be corrected by administration of the "right" nutrient molecules at the right time. (*Ortho* is Greek for "right.") They also claim that their treatment is effective against many diseases. Their evaluations usually include laboratory tests that most physicians would consider questionable.

In 1973, an American Psychiatric Association task force report noted that megavitamin proponents used unconventional methods not only in treatment, but also in diagnosis.

The report concluded that “the credibility of the megavitamin proponents is low” and “is further diminished by a consistent refusal over the past decade to perform controlled experiments and to report their new results in a scientifically acceptable fashion” (19). In 1979, the Research Advisory Committee of the National Institute of Mental Health concluded that megavitamin therapy was ineffective and could be harmful. Additional claims that megavitamins and megaminerals are effective against psychosis, learning disorders, and mental retardation in children were debunked in reports by the nutrition committees of the American Academy of Pediatrics in 1976 and 1981 and by the Canadian Academy of Pediatrics in 1990 (20). Both groups warned that there was no proven benefit in any of these conditions and that megadoses can have serious toxic effects. The 1976 report concluded that a cult had developed among followers of megavitamin therapy (21).

Iridology

Iridology is based on the notion that each area of the body is represented by a corresponding area in the iris of the eye (the colored area surrounding the pupil). Many of its practitioners are chiropractors or naturopaths, but it is also used by bogus nutritionists and by laypersons involved in multilevel marketing (22). Iridologists claim that states of health and disease can be diagnosed from the color, texture, and location of various pigment flecks in the eye. Iridology practitioners purport to diagnose “imbalances” and treat them with vitamins, minerals, herbs, and similar products. They may also claim that the eye markings can reveal a complete history of past illnesses as well as previous treatment. Two large objective trials involving prominent iridologists found that they could not distinguish between patients who had a disease (kidney or gallbladder disease) and those who were healthy. Nor did they agree with each other about who was ill (23 and 24).

Metabolic Therapy

Proponents of “metabolic therapy” claim to diagnose abnormalities at the cellular level and correct them by normalizing the patient's metabolism. They regard cancer, arthritis, multiple sclerosis, and other “degenerative” diseases as the result of metabolic imbalance caused by a buildup of “toxic” substances in the body. They claim that scientific practitioners merely treat the symptoms of the disease while they treat the cause by removing “toxins” and strengthening the immune system so the body can heal itself. The “toxins” are neither defined nor objectively measurable. “Metabolic” treatment regimens vary from practitioner to practitioner and may include a “natural food” diet, coffee enemas, vitamins, minerals, “glandulars,” enzymes, laetrile, and various other nostrums that are not legally marketable in the United States. The components of metabolic therapy vary from practitioner to practitioner. No controlled study has shown that any of its components has any value against cancer or any other chronic disease. However, many people find its concepts appealing because they do not seem far removed from scientific medicine's concerns with diet, lifestyle, and the relationship between emotions and bodily responses.

The most visible proponent of metabolic therapy was Harold Manner, Ph.D., a biology professor who announced in 1977 that he had cured cancer in mice with injections of

laetrile, enzymes, and vitamin A. In fact, he had digested the tumors by injecting them with digestive enzymes, which cannot cure cancers that have metastasized. During the early 1980s, Manner left his teaching position and became affiliated with a clinic in Tijuana, Mexico. Although he claimed a high success rate in treating cancers, there is no evidence that he kept track of patients after they left his clinic (25). He died in 1988, but the clinic is still operating.

“Chiropractic Nutrition”

Chiropractic nutrition is based on beliefs that most ailments are the result of spinal problems (26). Chiropractors can be divided into two main types: “straights” and “mixers.” Straights tend to cling to the doctrine that most illness is caused by misaligned vertebrae (“subluxations”) that can be corrected by “spinal adjustment.” Mixers acknowledge that germs, hormones, and other factors play a role in disease, but they tend to regard mechanical disturbances of the nervous system as the underlying cause (through “lowered resistance”). In addition to spinal manipulation, mixers may use nutritional methods and various types of physiotherapy (heat, cold, traction, exercise, massage, and ultrasound). Chiropractors are licensed in all 50 states. They are not permitted to prescribe drugs or perform surgery, but most states permit them to prescribe dietary supplements, herbs, and homeopathic products.

Chiropractors who give nutritional advice typically recommend supplements that are unnecessary or are inappropriate for treating health problems. One such product is Spine Align, which, according to its manufacturer, can help repair, regenerate, correct, and normalize the spine. Its ingredients include “whole spinal column” (from cows), bone meal, silica, boron aminoate, copper gluconate, aromatic root beer, and potassium iodide. Many chiropractors espouse nutrition-related systems of diagnosis and treatment that lack scientific validity. The most noteworthy are applied kinesiology (AK), bioenergetic synchronization technique (B.E.S.T.), and contact reflex analysis (CRA).

AK is a pseudoscientific system of muscle testing and therapy based on assertions that specific muscle weaknesses are signs of disease in body organs. AK practitioners—most of whom are chiropractors—claim that nutritional deficiencies, allergies, and other adverse reactions to food substances can be detected by placing substances in the mouth or hand and testing muscle strength. “Good” substances supposedly make specific muscles stronger, whereas “bad” substances cause specific weaknesses. “Treatment” typically includes dietary modification, food supplements, acupressure, and spinal manipulation. Controlled studies of AK muscle-testing procedures have found no difference between results with test substances and those with placebos (27). Differences from one test to another may be due to suggestibility, variations in the amount of force or leverage involved, and/or muscle fatigue.

B.E.S.T. practitioners claim that an imbalance in the patient's electromagnetic field causes unequal leg length, which the chiropractor can instantly correct by applying his or her own electromagnetic energy to proper points on the body. According to this notion, two fingers on each of the chiropractor's hands are “North poles,” two are “South poles,” and the thumbs are electromagnetically neutral. When imbalance is detected, the hands are held for a few seconds at “contact points” on the patient's body until

“pulsation” is felt and the patient's legs test equally long. Proponents recommend that such testing be started early in infancy and continued at least monthly throughout life.

B.E.S.T.'s “nutritional” component is based on the notion that “patients can maintain life and vitality by consuming four times as much alkaline-forming as acid-forming foods.” Proponents claim that saliva pH can reveal whether a person's symptoms are nutritionally or emotionally based and indicates whether the most effective method of care is nutritional supplementation and/or adjustive. The recommended supplements include a barley juice concentrate, a weight-reduction formula, an alleged digestive aid, and various herbs. For babies, a mixture of raw goat milk, carrot juice, and distilled water is said to be “an excellent replacement for infant formulas.”

CRA resembles aspects of applied kinesiology and B.E.S.T. To diagnose a patient, the practitioner pulls on the patient's outstretched arm while placing a finger or hand on one of about 75 “reflex” points on the patient's body. If the patient's arm can be pulled downward, the disease corresponding to the reflex is said to be present. Large numbers of pills containing vitamins, minerals, dehydrated vegetables, and/or freeze-dried animal organs are then prescribed to correct the alleged problems.

Many companies market supplements exclusively or primarily through chiropractic offices, where they are sold for at least twice their wholesale cost. Thousands of these products are intended for the treatment of disease, even though they are questionable and lack FDA approval for this use.

The percentage of chiropractors engaging in unscientific nutritional practices is unknown but appears to be substantial. A 1991 survey by the National Board of Chiropractic Examiners found that 83.5% of 4835 full-time practitioners who responded said they had used “nutritional counseling, therapy or supplements,” and 37.2% said they had used AK within the previous 2 years. Chiropractors who prescribe supplements usually sell them to their patients for two to three times their wholesale cost. A typical regimen costs the patient several dollars per day. Chiropractic licensing authorities have not attempted to curtail inappropriate “chiropractic nutrition.”

Colonic Irrigation

Some chiropractors and naturopaths advocate colonic irrigation as part of their treatment system. In this procedure, a rubber tube is passed into the rectum for a distance of up to 20 or 30 inches, and warm water is pumped in and out, a few pints at a time, typically using 20 or more gallons. Some practitioners add herbs, coffee, or other substances to the water. The procedure is said to “detoxify” the body. Its advocates claim that as a result of intestinal stasis, intestinal contents putrefy, and toxins are formed and absorbed, which causes chronic poisoning of the body.

This “autointoxication” theory was popular around the turn of the century but was abandoned by the scientific community during the 1930s. No such “toxins” have ever been identified, and careful observations have shown that individuals in good health can vary greatly in bowel habits. Proponents may also suggest that fecal material collects on the lining of the intestine and causes trouble unless removed by laxatives, colonic

irrigation, special diets, and/or various herbs or food supplements that “cleanse” the body. The falsity of this notion is obvious to doctors who perform intestinal surgery or peer within the large intestine with a diagnostic instrument. Fecal material does not adhere to the intestinal lining.

Colonic irrigation is not only therapeutically worthless but can cause fatal electrolyte imbalance. Cases of death due to intestinal perforation and infection (from contaminated equipment) have also been reported ([28](#)).

“Electrodiagnosis”

Hundreds of “alternative” practitioners use devices purported to detect and treat “energy imbalances” said to signify organ dysfunctions, allergies, and other problems. This approach, called electrodiagnosis or Electroacupuncture according to Voll (EAV), was initiated during the 1970s by a German physician who developed the first model of the device ([29](#)). Subsequent models include the Vega, Dermatron, Accupath 1000, and Interro. Proponents claim these devices measure disturbances in the body's flow of “electro-magnetic energy” along “acupuncture meridians.” Actually, they measure electrical resistance of the patient's skin when touched by a probe. One wire from the device goes to a brass cylinder covered by moist gauze, which the patient holds in one hand. A second wire is connected to a probe, which the operator touches to “acupuncture points” on the patient's other hand or foot. This completes a low-voltage circuit, and the device registers the flow of current. The information is then relayed to a gauge that provides a numerical readout. The size of the number actually depends on how hard the probe is pressed against the patient's skin. The “treatment” selected depends on the scope of the practitioner's practice and may include acupuncture, dietary change (to avoid supposed allergens), vitamin supplements, and/or homeopathic remedies.

FAD DIAGNOSES

Some practitioners misdiagnose large numbers of their patients with one or more conditions considered rare or even nonexistent by scientific practitioners. Some of these diagnoses are based on the patient's history (typically including fatigue and other common emotionally related symptoms), while others are based on inappropriate or misinterpreted laboratory tests.

Hypoglycemia

Many “alternative” practitioners diagnose “hypoglycemia” in large numbers of patients who report symptoms of nervousness or fatigue. It is actually quite rare, however. The diagnosis of functional hypoglycemia should not be made unless a person on a balanced diet gets symptoms 2 to 4 hours after eating, has a blood glucose level below 45 mg/100 mL whenever symptoms occur, and is immediately relieved of symptoms when the blood glucose level is raised. The glucose tolerance test is not reliable for evaluating most cases of suspected hypoglycemia ([30](#)). Low blood sugar levels without symptoms occur commonly in normal individuals fed large amounts of sugar and are of

no diagnostic significance.

“Environmental Illness”

“Clinical ecologists” claim that hypersensitivity to common foods and chemicals triggers dozens of symptoms that they label “environmental illness,” or “multiple chemical sensitivity.” They speculate that (a) although various substances alone may not cause trouble, low doses of different substances can add to or multiply each other's effects; (b) hypersensitivity develops when the total load of physical and psychologic stresses exceeds a person's tolerance; (c) hypersensitivities may be related to “immune system dysregulation” that can be difficult to diagnose and treat; (d) potential stressors include practically everything that modern humans encounter; and (e) the resultant symptoms can mimic almost any other condition (31). They base their diagnoses primarily on the results of “provocation” and “neutralization” tests, which are performed by having the patient report symptoms that occur within a specified period of time after suspected harmful substances are placed under the tongue or injected into the skin. If any symptoms occur, the test is considered positive, and lower concentrations are given until a dose is found that “neutralizes” the symptoms. Double-blind testing conducted by researchers at the University of California demonstrated that these procedures are not valid (32).

The American Academy of Allergy and Immunology (AAAI), the nation's largest professional organization of allergists, has warned that “although the idea that the environment is responsible for a multitude of health problems is very appealing, to present such ideas as facts, conclusions, or even likely mechanisms without adequate support, is poor medical practice” (33). [Chapter 92](#) describes the appropriate diagnosis of food allergies.

“Yeast Infections”

“Candidiasis hypersensitivity” is an alleged condition with multiple symptoms similar to those of “environmental illness.” The AAAI regards this diagnosis as “speculative and unproven.” Nevertheless, proponents claim that if a careful checkup does not reveal a cause for such symptoms and a medical history includes antibiotic usage, a “yeast” problem is likely (34). The proposed treatment program includes food supplements, special diets, and treatment with antifungal drugs. In 1990, a double-blind trial found the antifungal drug nystatin was no better than a placebo for relieving systemic or psychologic symptoms attributed to “candidiasis hypersensitivity syndrome” (35).

“Mercury-Amalgam Toxicity”

The alleged condition “mercury-amalgam toxicity” is diagnosed by a few hundred dentists and physicians who claim that the mercury in silver-mercury fillings is toxic and causes a wide range of illnesses. They recommend replacing these fillings with other materials, which can cost thousands of dollars. Some recommend an elaborate program of supplements to minimize negative effects said to occur when the mercury-containing fillings are removed. The ADA Council on Ethics, Bylaws, and Judicial Affairs considers the unnecessary removal of silver-amalgam fillings improper and unethical (36). The

leading anti-amalgamist, a dentist, had his license revoked in 1996.

Many physicians accustomed to rendering the above “fad diagnoses” have added chronic fatigue syndrome, Lyme disease, food allergies, and “parasites” to their list of overdiagnosed conditions.

QUESTIONABLE CANCER THERAPIES

The American Cancer Society (ACS) defines questionable methods as lifestyle practices, clinical tests, or therapeutic modalities that are promoted for *general* use for the prevention, diagnosis, or treatment of cancer and which are, on the basis of careful review by scientists and/or clinicians, deemed to have no real evidence of value (37). These methods include corrosive agents, plant products, special diets and “dietary supplements,” drugs, correction of “imbalances,” biologic methods, devices, miscellaneous concoctions, psychologic approaches, and worthless diagnostic tests. Many promoters combine methods to make themselves more marketable. A 1987 ACS investigation found that 452 (9%) of 5047 cancer patients identified through a telephone survey had used questionable treatments. Of these, 49% had used “mind therapies” (mental imagery, hypnosis, or psychic therapy), and 38% had used diets (38).

Promoters of questionable cancer treatment typically explain their approach in commonsense terms that appear to offer patients an active role: (a) cancer is a symptom, not a disease; (b) symptoms are caused by diet, stress, or environment; and (c) proper fitness, nutrition, and mental attitude allow biologic and mental defense against cancer. Nutrition-related methods are compatible with each of these “selling points” and therefore are highly marketable. They include fasting, megadoses of nutrients, consumption of raw foods, “detoxification,” organ extracts, and various dietary regimens. The ACS advises that although dietary measures (e.g., eating more vegetables) may help prevent certain cancers, there is no scientific evidence that any dietary regimen is appropriate as a primary *treatment* for cancer (39).

Laetrile

Laetrile, which achieved great notoriety during the 1970s and early 1980s, is the trade name for a synthetic relative of amygdalin, a chemical in the kernels of apricot pits, apple seeds, bitter almonds, and some other stone fruits and nuts. Some promoters have called it “vitamin B₁₇” and falsely claimed that cancer is a vitamin deficiency disease that laetrile can cure. When subjected to enzymatic breakdown in the body, amygdalin forms glucose, benzaldehyde, and hydrogen cyanide. Some cancer patients treated with laetrile have suffered nausea, vomiting, headache, and dizziness, and a few have died from cyanide poisoning (40). Laetrile has been tested in at least 20 animal tumor models and found to have no benefit either alone or together with other substances. Studies of case reports of humans have also been uniformly negative, as has a clinical trial sponsored by the National Cancer Institute (NCI) (41, 42 and 43).

In 1975 a patient sued in federal court to try to stop the FDA from interfering with the sale and distribution of laetrile. Early in the case, a sympathetic judge issued orders

allowing cancer patients to import a 6-month supply of laetrile for personal use if they could obtain a physician's affidavit that they were "terminal." A higher court partially upheld this ruling, but in 1979, the U.S. Supreme Court ruled that it is not possible to be certain who is terminal and that even if it were possible, both terminally ill patients and the general public deserve protection from fraudulent cures. In 1987, after further appeals were denied, the judge who set up the affidavit system finally yielded to the higher courts and terminated it (44). Today few sources of laetrile are available within the United States, but it still is used at Mexican clinics (45).

Gerson Method

Proponents of the Gerson diet claim that cancer can be cured only if toxins are eliminated from the body. They recommend "detoxification" with frequent coffee enemas and a low-sodium diet that includes more than a gallon a day of juices made from fruits, vegetables, and raw calf's liver. This method was developed by Max Gerson, a German-born physician who emigrated to the United States in 1936 and practiced in New York City until his death in 1959. Still available at a Mexican clinic, Gerson therapy is actively promoted by his daughter, Charlotte Gerson, through lectures, talk show appearances, and publications. Gerson protocols have included liver extract injections, ozone and coffee enemas, "live cell therapy," thyroid tablets, royal jelly capsules, linseed oil, castor oil enemas, clay packs, laetrile, and vaccines made from influenza virus and killed *Staphylococcus aureus* bacteria.

Charlotte Gerson claims that treatment at the clinic has produced high cure rates for many cancers. In 1986, however, a Gerson publicist admitted that patients were not monitored after they left the facility (46). Three naturopaths who visited the Gerson Clinic in 1983 were able to track 18 patients over a 5-year period (or until death) through annual letters or phone calls. At the 5-year mark, only one was still alive (but not cancer free); the rest had succumbed to their cancer (47).

A review of the Gerson rationale has concluded that (a) the "poisons" Gerson claimed were present in processed foods have never been identified, (b) frequent coffee enemas have never been shown to mobilize and remove poisons from the liver and intestines of cancer patients, (c) there is no evidence that any such poisons are related to the onset of cancer, (d) there is no evidence that a "healing" inflammatory reaction exists that can seek out and kill cancer cells (48).

Kelley Metabolic Therapy

In the 1960s, William Donald Kelley, D.D.S., developed a program for cancer patients that involved dietary measures, vitamin and enzyme supplements, and computerized "metabolic typing." Kelley classified people as "sympathetic dominant," "parasympathetic dominant," or "metabolically balanced" and made dietary recommendations for each type. He claimed that his "Protein Metabolism Evaluation Index" could diagnose cancer before it was clinically apparent and that his "Kelley Malignancy Index" could detect "the presence or absence of cancer, the growth rate of the tumor, the location of the tumor mass, prognosis of the treatment, age of the tumor

and the regulation of medication for treatment” (49).

In 1970, Kelley was convicted of practicing medicine without a license after witnesses testified that he had diagnosed lung cancer on the basis of blood from a patient's finger and prescribed dietary supplements, enzymes, and a diet as treatment. In 1976, following court appeals, his dental license was suspended for 5 years. However, he continued to promote his methods until the mid-1980s through his Dallas-based International Health Institute. Under the institute's umbrella, licensed professionals and “certified metabolic technicians” throughout the United States would administer a 3200-item questionnaire and send the answers to Dallas. The resultant computer printout provided a lengthy report on “metabolic status” plus detailed instructions covering foods, supplements (typically 100–200 pills per day), “detoxification” techniques, and lifestyle changes.

Treatment said to be similar is still provided today by Nicholas Gonzales, M.D., of New York City, who claims to have analyzed Kelley's records and drafted a book about his findings. The manuscript was never published, but experts who evaluated its chapter on 50 cases found no evidence of benefit (50). Gonzales says that he offers “10 basic diets with 90 variations” and typically prescribes coffee enemas and up to “150 pills a day in 10 to 12 divided doses.”

In 1997, a jury awarded \$2.65 million in damages to a former Gonzales patient. The woman had consulted Gonzales after having surgery for early uterine cancer. She testified that he encouraged her to rely on his treatment instead of medically recommended follow-up radiation and chemotherapy. The cancer progressed, damaging her spine and leaving her blind (49a).

Livingston-Wheeler Regimen

Virginia C. Livingston, M.D., who died in 1990, postulated that cancer is caused by a bacterium she called *Progenitor cryptocides*, which invades the body when “immunity is stressed or weakened.” She claimed to combat this by strengthening the body's immune system with vaccines (including one made from the patient's urine); “detoxification” with enemas; digestive enzymes; a vegetarian diet that avoided chicken, eggs, and sugar; vitamin and mineral supplements; visualization; and stress reduction. She claimed to have a very high recovery rate but published no clinical data to support this (51).

Scientists who attempted to isolate the organism she postulated found that it was a common skin bacterium. Researchers compared 78 patients treated at the University of Pennsylvania Cancer Center with similar patients treated at the Livingston-Wheeler Clinic. All had advanced cancers for which no proven treatment was known. As expected, the study found no difference in average survival time of the two groups. However, Livingston-Wheeler patients reported more appetite difficulties and pain (52).

Shark Cartilage

Powdered shark cartilage is purported to contain a protein that inhibits the growth of new blood vessels needed for the spread of cancer. Although a modest effect has been observed in laboratory experiments, it has not been demonstrated that feeding shark

cartilage to humans significantly inhibits blood-vessel formation in patients with cancer. Even if direct applications were effective, oral administration would not work because the protein would be digested rather than absorbed intact into the body. Nevertheless, in 1993 CBS-TV's "60 Minutes" aired a program promoting the claims of biochemist/entrepreneur I. William Lane, Ph.D., coauthor of *Sharks Don't Get Cancer*. The program highlighted a Cuban study of 29 "terminal" cancer patients who received shark-cartilage preparations. Narrator Mike Wallace filmed several of the patients doing exercises and reported that most of them felt better several weeks after the treatment had begun. The fact that "feeling better" does not indicate whether a cancer treatment is effective was not mentioned. Nor was the fact that sharks do get cancer, even of their cartilage (53). NCI officials who reviewed the Cuban data called them "incomplete and unimpressive" (54). Proponents claim to be doing additional research, but none of it has been published in a significant scientific journal.

Vitamin C

The claim that vitamin C is useful for treating cancer is largely attributable to Linus Pauling, Ph.D. During the mid-1970s, Pauling began claiming that high doses of vitamin C are effective in preventing and curing cancer. In 1976 and 1978, he and a Scottish physician, Ewan Cameron, reported that a group of 100 terminal cancer patients treated with 10,000 mg of vitamin C daily had survived three to four times longer than historically matched patients who did not receive vitamin C supplements. However, Dr. William DeWys, chief of clinical investigations at the NCI, found that the patient groups were not comparable (55). The vitamin C patients were Cameron's, while the other patients were managed by other physicians. Cameron's patients were started on vitamin C when he labeled them "untreatable" by other methods, and their subsequent survival was compared with the survival of the "control" patients after they were labeled "untreatable" by their doctors. DeWys found that Cameron's patients were labeled untreatable much earlier in the course of their disease, which meant that they entered the hospital before they were as sick as the other doctors' patients and would naturally be expected to live longer. Nevertheless, to test whether Pauling might be correct, the Mayo Clinic conducted three double-blind studies involving a total of 367 patients with advanced cancer. All three studies found that patients given 10 g of vitamin C daily did no better than those given a placebo (56, 57 and 58).

POLITICAL CONSIDERATIONS

The "alternative movement" is part of a general societal trend toward rejection of science as a method of determining truth. This movement embraces the postmodernist doctrine that science is not necessarily more valid than pseudoscience (59). In line with this philosophy, "alternative" proponents assert that scientific medicine (which they mislabel as allopathic, conventional, or traditional medicine) is but one of a vast array of healthcare options. Instead of subjecting their work to scientific standards, they would like to change the rules by which they are judged and regulated.

Research proposals normally get funded by competing on the basis of merit. A federal law passed in 1991 ordered the National Institutes of Health (NIH) to foster research into unconventional practices. The law was passed after proponents of questionable

cancer treatments convinced several congressmen that they deserved more study than they had been getting. To carry out the law's intent, NIH established what is now called the Office of Alternative Medicine (OAM). It also appointed an advisory committee that included the former congressman and advocates of acupuncture, "energy medicine," homeopathy, ayurvedic medicine, and questionable cancer therapies. A few qualified researchers have served on the panel but have had little influence on its output. Some advisory committee members have used their NIH affiliation for promotional purposes.

In 1992, about 200 "alternative" proponents attended a workshop to help develop a research agenda for OAM. The outcome was a 420-page report, published in 1995, that promotes a large number of questionable methods plus a few that have scientific support (60). The report states that NIH has not endorsed the practices it describes and warns that "many of the therapies described have not been subjected to rigorous scientific investigation to prove safety or efficacy."

The OAM has distributed 42 grants of about \$30,000 each for research projects, two \$840,000 grants to set up research centers at Bastyr University (a naturopathic institution) and at a mental health facility that treats drug abusers with acupuncture, and eight grants averaging about \$1 million to set up research centers affiliated with medical schools (61). Many academic scientists have criticized these awards and doubt that they will generate significant research results (62). The OAM's first director resigned in 1994, charging that a prominent senator and others had interfered with his ability to carry out the OAM's mission in a scientific manner (63).

"Alternative" proponents trumpet the OAM's existence as evidence that whatever they espouse is valid. Most press reports—even in medical publications—have contained little criticism and featured the views of proponents and their satisfied clients. Few reporters make any effort to determine whether the "alternative" methods they mention are useful, promising, or nonsensical. Even if the OAM generates some useful research, the benefit is unlikely to outweigh the publicity bonanza already given to worthless methods (64).

Additional publicity has been generated by a *New England Journal of Medicine* report of a telephone survey concerning 16 types of "unconventional therapy." The authors concluded that 34% of the respondents had used at least one unconventional therapy during the previous year and that Americans had made an estimated 425 million visits to providers of such therapy during 1990 (65). However, the methods they selected included some that are medically appropriate (e.g., self-help groups) and some that are appropriate under proper circumstances (e.g., relaxation therapy, biofeedback, hypnosis, massage, and commercial weight-loss clinics). Although the numbers of those using "alternative" methods were thus inflated, most commentators now accept as gospel the idea that "One out of three Americans uses alternative therapies."

"Alternative" promoters would like to weaken or overturn the laws that protect against methods that are ineffective or are promoted with misinformation. During the height of the laetrile controversy, 27 states legalized the manufacture and sale of laetrile within their borders. Within the past few years, 6 states have passed "Medical Freedom of Choice" bills. These prevent or make it difficult for their licensing boards to discipline

practitioners who use an inappropriate treatment, as long as it does not directly threaten the life or health of the patient. A federal "Access to Medical Treatment" Act has been introduced to prevent the FDA from protecting the public against the sale and distribution of questionable drugs and devices. The 1976 Proxmire Amendment to the Food, Drug, and Cosmetic Act and the 1994 Dietary Supplement Health Education Act prevent the FDA from regulating the dosage of vitamin, mineral, amino acid, and herbal products unless it can prove in court that a product is inherently unsafe (see also [Chapter 115](#)).

Proponents claim that such laws increase individual freedom without increasing consumer risk. This is untrue. The basic principle of health-related consumer-protection law is that products cannot be marketed until demonstrated safe and effective by appropriate testing. Physicians and pharmaceutical companies who wish to test a new product can obtain FDA permission by showing reasonable preliminary evidence of safety and potential usefulness. This policy is not oppressive; it simply requires that studies be carried out as outlined in the front section of this chapter. "Medical freedom" laws facilitate the sale of worthless treatments and make it difficult to prevent unscientific practitioners from exploiting patients.

Mankind's attempts to preserve food go back for centuries. One of the earliest examples is the curing of meat, which involves drying, salting, and smoking. This practice dates from 1500 BC. A more recent advancement in food preservation came in the late 18th century in France. Napoleon's armies were hindered by inadequate supplies of food, and prizes were offered as an incentive to develop useful methods for preserving food for soldiers. In this competition, Nicholas Appert showed that food sufficiently heated in a sealed container and stored unopened could be preserved. For this, he was awarded 12,000 francs in 1809, and canning was born. The work of Louis Pasteur 50 years later helped explain the effectiveness of Appert's canning by showing that growth of microorganisms was the major cause of food spoilage (1).

Today's society has evolved from a largely rural way of life to modern urban living. Relatively few people live on farms, because of improvements in farm production and development of the food-processing industry. Processing, storage, and transportation systems are critical to provide food for urban populations. Additionally, the number of dual-income families has grown, leaving less time for home food preparation and creating increased demand for convenience foods.

Consumers are health conscious and insist that even convenience foods be nutritious. Although foods are processed to increase the storage time for which a food is safe with minimal nutrient and quality losses, some losses are inevitable. There will always be a

need to reevaluate processing techniques and to look for ways to improve nutrient retention and food quality. As technology continues to advance, it will be possible to produce processed foods with even greater nutritive value.

OVERVIEW OF FOOD PROCESSING

Foods are processed for several beneficial reasons: to preserve and extend shelf life, to increase digestibility, to increase bioavailability of some nutrients, to improve palatability and texture, to prepare foods for serving, to eliminate microorganisms, to destroy toxins, to remove inedible parts, to destroy antinutritional factors, and to create new types of foods. Food processing can also increase consumer convenience and availability of a variety of foods year-round. Of these reasons, perhaps the most important is safety. Although processing may decrease the overall nutrient content of a food, it is a small price to pay for increased safety.

There are three major causes of food spoilage: microbial growth, chemical changes, and enzymatic changes. Raw foods are living systems containing enzymes that may contribute to rapid spoilage. Additionally, microorganisms are ubiquitous and can multiply under certain conditions. Inactivation of these enzymes or microorganisms by a thermal process can greatly extend the shelf life and quality of a food. This is especially important for foods with a high moisture content, because they deteriorate more rapidly than those with a low moisture content or low water activity.

Food-borne illnesses can occur because of (a) microorganisms, including bacteria, molds, viruses, and parasites; (b) chemicals or additives added to food intentionally or unintentionally as the result of their use in the processing or distribution; or (c) poisonous plants or animals. It has been reported that the public is most concerned about (b), although microorganisms are a larger safety issue. Effective food processing can reduce the risk of food-borne illnesses.

Environmental conditions such as pH, temperature, light, and oxygen can affect the shelf life and nutrient retention of a stored food. Manipulation of these environmental conditions can minimize spoilage and nutrient damage. For example, riboflavin is greatly affected by environmental conditions. It is very sensitive to light, and its rate of destruction increases as the temperature and pH increase. Milk is sold in cardboard or opaque plastic containers to minimize riboflavin degradation.

Food processing can have both positive and negative effects on nutrient retention. An example of a positive effect is the lime- $[\text{Ca}(\text{OH})_2]$ treatment of corn during tortilla or corn chip production. Unfortunately, the added calcium is not highly bioavailable (2), but the process increases the bioavailability of niacin. Niacin is tightly bound to corn proteins as niacytin but can be liberated under alkaline conditions (3). Alkaline treatment of corn helps eliminate pellagra in populations where corn is the mainstay of the diet (4). Unfortunately, the alkaline conditions associated with lime treatment are damaging to another B vitamin, thiamin.

An example of a negative effect of food processing is nutrient destruction during

extrusion of food materials. Heat-labile nutrients such as thiamin and ascorbic acid can be destroyed in the extrusion process. Significant losses of the amino acids lysine and methionine can occur as well. Appropriate processing of foods is always a question of balance. Some nutrient loss is inevitable, especially with certain vitamins. In a breakfast cereal, one wants sufficient heat treatment to maximize digestibility of the cereal and destruction of heat-labile antinutrients, while minimizing the loss of heat-labile vitamins and amino acids.

Are nutrient losses in food processing significant or a cause for concern? This depends on whether the nutrient in question is abundant or scarce in the total average diet and whether the food is generally relied on as a major source of that nutrient. About 15% of the vitamin C in milk is destroyed in pasteurization, but milk is not an important source of this vitamin, compared with citrus fruits and juices. Conversely, milk is an important source of riboflavin; thus, its destruction due to light or heat would be a concern to populations consuming low levels of riboflavin.

A common misconception is that commercially processed foods are always nutritionally inferior to freshly prepared foods. In fact, nutrient losses in commercially processed products are often comparable to those in preparation of "fresh produce" in the home (5). Unprotected raw food can rapidly lose nutritional value after harvest if not preserved. The procedures used during harvesting and the ensuing handling and storage period can dramatically affect both nutritional value and sensory properties of fruits and vegetables. Ascorbic acid, thiamin, and folic acid are especially susceptible to both enzymatic and nonenzymatic oxidation during this period. Enzymatic destruction of ascorbic acid can begin as soon as a crop is harvested. Storage under both cool and humid conditions reduces wilting and improves retention of ascorbic acid during storage. Other preprocessing conditions that influence nutrient content of the final prepared food are genetic variation, soil composition, fertilizer use, type of feed, and degree of maturity when picked or killed (6).

Vitamin C and thiamin are readily lost in the processing of foods because they are thermally labile and water soluble (susceptible to leaching during processing). It is generally assumed that if these two vitamins are well retained during processing and storage, other nutrients also are well retained (7). Vitamin stability during processing is largely related to heat, pH, oxygen, and light. The presence of trace elements can also accelerate the loss of some vitamins. Factors that affect vitamin loss are presented in [Table 111.1](#).

Nutrient	Main Causes of Loss
Ascorbic acid ¹	Water leaching, oxidation-accelerated by heat, light, copper, iron
Biotin	Alkaline conditions
Carotenoids	Oxidation, isomerization, accelerated by heat, light
Cobalamin (B ₁₂)	Alkaline and acid conditions, oxidation
Folic acid	Light and heat
Niacin	Water leaching
Pantothenic acid	Alkaline and acidic conditions, accelerated by heat
Pyridoxine (B ₆)	Light, accelerated by alkaline conditions
Riboflavin (B ₂) ²	Light and heat, accelerated by alkaline conditions
Thiamin (B ₁) ²	Alkaline conditions, water leaching, oxidation; accelerated by heat and light
Vitamin E	Oxidation
Vitamin A	Oxidation and isomerization, accelerated by heat and light
Vitamin D	Alkaline conditions; accelerated by light and oxygen
Vitamin K	Light and alkaline conditions

¹Considered one of the more heat-labile vitamins.

Table 111.1 Factors Affecting Vitamin Loss

Minerals are relatively heat stable, but many of them are easily leached from food exposed to excess water. During processing, their bioavailability may be altered both positively and negatively by interactions with other components of the food.

Of the amino acids, lysine is the most labile, but all amino acids are sensitive to dry heat. Thus, in roasting and toasting legumes, cereals, and prepared dry mixtures of foodstuffs, the biologic value of proteins may be significantly reduced (8).

Essential fatty acids can isomerize when heated in alkali and are sensitive to oxygen and light, especially at high temperatures. When oxidized, they become biologically inactive and can produce off flavors and free radicals.

THERMAL PROCESSING

Heat processing is one of the most important methods of food preservation. The sections below detail some of the advantages and disadvantages of blanching, pasteurization, canning, extrusion, microwaving, and baking. In general, for any thermal process, exposure to high temperature for a short time is less damaging to nutrients than a moderate temperature for a longer time. Heat increases the digestibility of protein, carbohydrates, and other nutrients in many foods, thereby enhancing their nutritive value. Heat treatment can also inactivate some naturally occurring spoilage enzymes, such as pectinase and lipoxxygenase, in fruits and vegetables, thereby protecting against off flavors, color loss, and poor texture. The bioavailability of vitamins B₆, niacin, folacin, and certain carotenoids can be enhanced by thermal processing, because heat can release these nutrients from poorly digested complexes. Another advantage of thermal processing is inactivation of antinutritional factors in certain foods. In these foods, nutritional value is greatly enhanced by processing (Table 111.2) (9). On the other hand, thermal processing does have several adverse effects. During thermal processing and subsequent storage, thiamin and ascorbic acid are especially susceptible to leaching and thermal degradation. Carotenoids and folacin are also heat

labile. Lipids, minerals, vitamin K, biotin, and niacin are normally stable during heating.

Antinutritional Factor	Common Food Sources	Effect of Antinutritional Factor
Avidin	Egg whites	Binds biotin, making it biologically unavailable
Hexaglutinins	Red kidney beans, yellow wax beans	Interferes w/ blood cell clumping
Lectins	Chick peas	Disrupts collagen structure
Galectins	Sweet potatoes, beans, cabbage, turnips	Causes gut pain by binding colic absorption
α -Amylase inhibitors	Cereal grains, peas, beans	Slows starch digestion
Trypsin inhibitor	Legumes, egg whites, potatoes	Inhibits activity of trypsin
Thermolases	Fish, shellfish, brussels sprouts, red cabbage	Destroys thiamin

Table 111.2 Heat-Labile Antinutritional Factors Inactivated by Thermal Processing

Maillard browning (nonenzymatic browning) is commonly accelerated during thermal processing conditions. It can occur in foods containing reducing sugars (glucose, fructose, lactose) and protein. Foods that undergo Maillard browning include bread and other baked items, dried fruits, gravy mixes, maple syrup, dried milk, cocoa, and extruded products (e.g., cereals). During heat processing, the free aldehyde or ketone groups of sugars can react with amino groups of certain amino acids to create poorly digested complexes. Maillard browning can destroy many of the amino acids, in particular the basic amino acids. Lysine is one of the most labile of the amino acids because of its ϵ -amino group. Loss of arginine and methionine also occur. Thus, Maillard browning reduces the protein quality of plant foods (10). Overall, the Maillard reaction can decrease caloric content, increase color and flavor, and reduce essential amino acids and total nitrogen digestibility. For foods such as breads, cocoa, and maple syrup, a certain amount of Maillard browning is desirable to improve appearance and flavor. On the other hand, for a food such as milk, Maillard browning is undesirable because it produces a “cooked” flavor and undesirable color. The Maillard reaction can be minimized by decreasing the concentration of reducing sugars, increasing the moisture content, reducing heat, and lowering pH.

In addition to the Maillard reaction, thermal processing at high temperatures for extended periods can also cause other undesirable reactions with protein. Such reactions include oxidation of amino acids (particularly sulfur amino acids), altered peptide linkages between amino acids that delay or impair amino acid release during digestion, and formation of new amino acid structures or dipeptides that are not subject to normal digestion and absorption processes.

Blanching

Blanching is the heat treatment typically applied to fruits and vegetables prior to

canning, freezing, or drying. Before canning, blanching can activate desirable enzymes such as pectin methyl esterase or can inactivate such undesirable enzymes as catalase and peroxidase, but it is mainly used to wilt food tissue prior to can closure and to remove tissue gases. Further enzymatic and microbial inactivation occurs during commercial sterilization. The primary purpose of blanching before freezing or drying is to inactivate enzymes that cause undesirable changes in color (browning), texture, flavor, aroma, or nutritive value during storage. Microbial destruction is not a primary objective of blanching.

The nutritive value of fruits and vegetables can vary, depending on the plant variety, maturity, and time of harvest. Harvest, transport, and storage conditions prior to processing can also influence the vitamin content. Blanching helps maintain the harvest quality of a product until it is prepared at home.

Blanching typically uses temperatures around 75 to 95°C for 1 to 10 minutes, depending on the product, and involves water, steam, microwaves, or hot gas. Water blanching is most common because the initial capital investment and running costs are lower. It also allows addition of processing aids. For example, acidification of blanching water improves vegetable color and retention of vitamin C (ascorbic acid). Trace minerals found in processing water also enhance the nutritional quality of the product. However, some processing aids can be detrimental to the nutritional quality. Sulfite in blanching water can destroy thiamin (11).

Overall, the effects of blanching are predictable. Loss of water-soluble vitamins increases with contact time in water blanching, because of increased leaching, while fat-soluble vitamins are relatively stable. Vitamin C loss ranges from about 10 to 50%, and about 9 to 60% of thiamin is lost (7). Steam blanching retains more of the water-soluble vitamins, but not enough to make the process cost-effective (12). The three vitamins most affected by blanching are thiamin (vitamin B₁), vitamin C, and folate. The extent of loss depends on the vegetable and the location of the vitamin within it. For example, more vitamin C is lost from broccoli than from green beans in blanching because vitamin C is stored in the green bean seed and is protected by the pod. In blanching, thermal destruction and enzymatic oxidation can explain a small portion of the disappearance of vitamin C, thiamin, and folate; however, most is lost by leaching (11). Finally, microwave blanching results in even smaller losses of nutrients than steam blanching (7); however, this method is relatively expensive (12).

Generally, blanching is a pretreatment for freezing, drying, or canning. With the exception of freezing, these further processing methods can also affect the nutritive value of the food as described below.

Pasteurization

The main objectives of pasteurization are to reduce the populations of spoilage microorganisms and enzymes and to inactivate pathogenic microorganisms. The food is not rendered sterile, so pasteurization must be used in conjunction with another preservation method like refrigeration (e.g., milk). It may be used alone if the food is highly acidic (e.g., jams, jellies, or wine) and packaging is adequate. Nutrient losses

during pasteurization of acidic products are minor, because most heat-labile nutrients are relatively stable under acidic conditions (13).

Milk is pasteurized by one of three methods: (a) Low temperature–long time (LTLT), 63°C (145°F) for 30 minutes; (b) high temperature–short time (HTST), 72°C (161°F) for 15 seconds; and (c) ultra-high temperature (UHT, sterilization), 135°C (275°F) for less than 10 seconds, an aseptic process. UHT milk is commercially sterile and does not require refrigeration. As can be seen above, a higher processing temperature requires a dramatically shorter processing time. This results in a product with greater nutrient retention because, as Lund noted, “an increase in process temperature (with an appropriate decrease in process time) will have a greater effect in increasing the rate of microbial destruction than it will on the rate of nutrient destruction” (13). For example, the Institute of Food Technologists' Expert Panel on Food Safety and Nutrition stated, “An 18°F rise in processing temperature usually produces a tenfold increase in bacterial destruction, while only doubling the chemical reactions which lead to the destruction of certain nutrients and flavors” (12). So theoretically, a higher processing temperature results in better quality and nutrient retention. However, in the United States, where most families have refrigerators, UHT milk has not become popular. HTST milk is comparable to UHT milk in nutritional quality and is considerably less expensive. Therefore, in the U.S., milk is most frequently processed by HTST (12).

Pasteurization of milk is geared toward elimination of the most heat-resistant pathogen, *Coxiella burnetii*, the rickettsial organism responsible for Q fever. Both HTST and UHT processes destroy harmful microorganisms without adversely affecting most nutrients to a great extent. All the fat-soluble vitamins and certain water-soluble vitamins such as riboflavin, pantothenic acid, biotin, and nicotinic acid are stable during pasteurization. On the other hand, folic acid, thiamin, and vitamins B₆, B₁₂, and C are susceptible to heat and oxidative degradation. Methods that exclude oxygen during processing and storage protect folic acid and vitamins C and B₁₂ (14).

UHT is also used for juices and other low-viscosity products such as pudding. The products are heated in thin layers by heat exchangers or direct steam injection, cooled, and packaged into sterile containers (15). Aseptic processing provides products that are superior to retorted versions in flavor, texture, and nutrition. In particular, retention of vitamin B₆ and thiamin is significantly improved (12).

Canning

Canning, also known as commercial sterilization or retorting, produces shelf-stable foods with longer shelf lives than pasteurized products. The thermal heat treatment varies with the type of food but usually exceeds 80°C (176°F). Canning destroys most pathogenic and toxin-forming organisms, with a maximum allowable level of $1 \times 10_{-12}$ organisms per can. Because some nonpathogenic microorganisms and spores are extremely heat resistant, it is impossible to render a food completely sterile without unacceptably altering its sensory qualities and nutritive value (13). On the other hand, foods are not always processed solely on the bases of safety and optimal nutrient retention. In terms of food quality, UHT milk can be commercially sterile and still contain

active enzymes that cause “lipase taint.” Additionally, beans can be sterilized without being fully cooked. A balance between safety, nutrition, and quality must be achieved (15).

Retorting is an in-package thermal process in which the package can be a metal can, glass jar, or flat retortable pouch. The rate and mechanism of heat transfer determine the processing time. For example, a solid food such as pumpkin heats by conduction. To heat the center of the can adequately, the outer layer receives a more severe heat treatment, and fewer nutrients are retained. Similarly, uneven heat transfer occurs when still retorts are used.

A product processed in an agitating retort or by flame sterilization heats more quickly, because of convection currents within the can. Flame sterilization, an HTST process in which cans rotate over gas burners, is used for particulate canned food such as mushrooms (15). Nutrient retention is better in agitating systems than in still retorts.

Retort pouches are flexible, heat-sealable, flat containers made of polymeric laminates capable of withstanding the high temperatures of thermal processing. Polymeric laminates are thinly layered materials such as plastics, paper, or aluminum that are tightly joined together (10). The thin slablike retort pouch has a higher surface:volume ratio than glass containers or metal cans. Because of the pouch geometry, the product temperature increases more rapidly than it does in a traditional container, typically decreasing process time by one-third to one-half. As in HTST processing, retention of heat-labile vitamins is significantly enhanced because of the shorter processing time. For example, one study showed that retorted sweet potato puree had a thiamin retention of 77%, whereas heated cans with equal volume retained only 60% of the thiamin (10).

Canning is widely used for many fruits, vegetables, and juices. Unpeeled fruit retains more nutrients during canning. In canned vegetables, water-soluble vitamins and minerals are distributed between the solids and liquids. The liquid, usually discarded by the consumer, contains significant quantities of nutrients. For example, approximately 30% of the available thiamin is found in the liquid portion of canned vegetables (16). Also, more than 50% of the manganese, cobalt, and zinc may end up in the liquid portion of canned spinach, beans, and tomatoes (12). The consumer can avoid these losses by incorporating the liquid into soups, sauces, and gravies

Baking

Baking is a common heat-processing technique used by the food industry and in the home. It results in some destruction of nutrients, especially water-soluble vitamins (particularly thiamin) and basic amino acids because of Maillard browning. Thermal destruction is most pronounced in the crust portion of baked foods, where temperature exposure is highest. As one would predict, baking time, pH, trace metals, enzymes, and moisture content also affect the degree of destruction. Added milk solids or milk protein concentrates containing lactose intensify the Maillard reaction.

On the other hand, yeast fermentation followed by baking can improve the absorption

and use of nutrients by inactivating or destroying antinutrients and mineral complexes. Proteins become more digestible as the heat of baking denatures them. During fermentation of a yeast dough, microbial enzymes cause chemical changes. The loss of nutrients due to this fermentation is small. In fact, the nutrient level may even increase through vitamin and protein synthesis by the yeast and liberation of nutrients bound in indigestible plant materials (17).

Conversely, chemical leavening can have a negative impact on at least one nutrient. Thiamin is relatively stable during fermentation of a yeast dough because the pH is mildly acidic. However, in chemically leavened goods (such as some cookies and crackers), the pH can rise above 6, destroying nearly all the thiamin (18, 19). One study on high-protein cookies revealed thiamin losses of more than 90%, whereas losses of riboflavin and niacin were only modest. Lower baking temperatures may improve thiamin retention in baked goods.

Much of the niacin in grain products, especially those from unrefined flours, is present as bound niacin, which is essentially unutilizable by humans. Baking appears to release bound niacin; the proportion of free niacin was found to be higher in bread, cakes, and crackers than from the flours from which they were made (18, 19). As stated above, alkali treatment of corn in the making of tortillas improves niacin availability, probably through release of bound niacin during baking. In the United States, many breads are made with flour to which thiamin, riboflavin, niacin, iron, and possibly calcium are added. No significant losses of these added vitamins occur during bread making (18).

Baking is unlikely to have an adverse effect on the mineral content of foods (19). The enzymes present during fermentation of bread dough and the heat of baking may increase mineral bioavailability by breaking up organic complexes of minerals, such as phytate (18). Phytic acid, a much-studied organic chemical, is a chief storage form of phosphate and inositol in such whole-grain cereals as corn and wheat. It is a strong chelating agent that binds monovalent and divalent metal ions to form complex phytates. Unfortunately, phytate is not degraded when chemical leaveners are used.

Extrusion

Extrusion cooking is a modern HTST processing method applied primarily to grain. Raw materials can be converted to finished products in as little as 30 seconds. Extruded foods include breakfast cereals, snack foods, flat breads, textured vegetable proteins (TVPs), infant food formulas, modified starches and flours, and pet foods. Extrusion has both desirable and undesirable effects on nutritional quality. Benefits include increased digestibility, increased mineral availability, and destruction of heat-labile antinutritional factors such as trypsin inhibitors. Undesirable effects include reduced protein quality due to Maillard browning, destruction of polyunsaturated fatty acids (PUFAs), inactivation of amylase and phytase, and loss of heat-labile vitamins. The effects of extrusion on thiamin (vitamin B₁), riboflavin (vitamin B₂), vitamin C, and vitamin A have been investigated, but few or no data are available for extrusional effects on other B vitamins or vitamins E, D, or K (20).

Extruders can be classified into single-screw or twin-screw systems. Solids are fed into

the hopper and conveyed forward by rotation of the screw(s) at temperatures between 115 and 200°C for 10 to 90 seconds. Liquid or steam is added to create a continuous dough. During this process, starch granules are disrupted, and protein is denatured. At the barrel exit, water vaporization because of the pressure drop leads to product expansion. A spinning blade can be used to cut the product to appropriate lengths (10).

Vitamin retention can be negatively affected by higher process temperatures, increased screw speed, decreased moisture, decreased throughput, smaller die diameter, and higher specific energy input. Vitamin stability decreases with higher barrel temperatures or longer residence time in the extruder. Increasing the initial moisture content of the product improves retention of thiamin, vitamin B₆, vitamin B₁₂, and folate, potentially because higher moisture lowers the dough viscosity, resulting in less shear (20).

The effects of extrusion cooking and the processing parameters on vitamins have been investigated since the late 1960s. Pertinent references are available from the Killeit review (20). These studies showed that degradation of thiamin and b-carotene, a provitamin A carotenoid, follows first-order kinetics. Retention of nutrients could be improved with less-stringent processing conditions; however, products with high sensory appeal, such as some breakfast cereals and snacks, are unlikely to be changed. Instead, the industry has chosen to supplement the premixes with more thermally stable forms of the vitamins or to apply nutrients after extrusion.

In model systems for extrusion processing, extensive loss of lysine occurs before product browning is seen (21). Loss of lysine was comparable to or worse than losses that occur during baking. Lysine losses usually increase with increased extrusion temperature or decreased moisture content (10). For example, retention of available lysine was 93% at a processing temperature of 170°C, but only 63% at 210°C (10). Arginine and tryptophan retention also decreases as processing conditions become more severe.

Microwave Cooking

In conventional cooking, heat is applied to the exterior of the food and is conducted toward the interior. During microwave processing, heat is generated within the food product by microwave-induced molecular vibrations. The oscillation creates intermolecular friction that generates heat (22). Microwave cooking can be used for pasteurization, sterilization, precooking, dehydration, baking, blanching, and tempering (used to raise temperature in frozen foods to just below the freezing point of water). Combining traditional heating methods with microwave exposure can offer both sensory and nutritional benefits. In conventional ovens, microwaves are used to achieve internal heating, while conventional heating methods are used to produce the desired surface browning and crispness. The most highly developed commercial applications include tempering frozen foods (frozen meat and fish blocks), precooking meat products (bacon, poultry, and beef patties), and dehydrating low-moisture solids (pasta) (23).

Generally, microwave cooking can be as good as the best conventional processes for a food product. However, “drip” loss during microwave cooking of meats can result in higher losses of minerals, protein, water-soluble vitamins, and some fats than with

conventional methods (10).

Generally, less ascorbic acid is lost in microwave cooking than in conventional methods (24). In 1987, the Institute of Food Technologists' Expert Panel on Food Safety and Nutrition reported that vitamin retention in microwave foods is improved because cooking time is shorter than with conventional methods (23). Similarly, the use of microwaves for reheating minimizes the need for “warmholding,” which is a nutritional advantage (22). However, retention varies with cooking time, internal temperature, product type, oven size, oven design, power input, and cooking method. A cooking method that uses water will typically retain lower levels of water-soluble nutrients than one that does not.

FREEZING

Freezing is considered the best method of food preservation with regard to sensory qualities and retention of nutrients. Nutrient losses from fruits and vegetables can be minimized if blanching procedures are adequate, proper packaging is provided, and storage temperatures are low and constant. Any nutrient loss that occurs usually takes place during blanching or frozen storage, not during the actual freezing process. In general, low stable storage temperatures result in greater nutrient retention and product quality. Loss of vitamins during frozen storage varies, depending on the product and packaging. For example, ascorbic acid loss is influenced by the oxygen permeability of the packaging material. Vitamin C retention is greater when the oxygen permeability of the package is lower.

Storage temperature significantly affects nutrient retention. In one study, vegetables stored at -7°C lost more vitamin C, b-carotene, folic acid, and pantothenic acid than those stored at -18°C . No significant effect on niacin, riboflavin, thiamin, vitamin B₆, nor minerals was observed (7). For excellent nutrient retention, storage temperatures should remain below -18°C .

As discussed above, blanching is responsible for most water-soluble nutrient loss in vegetables prior to freezing (7). This loss could be significantly reduced if vegetables were blanched and cooled without water, by processes like microwaving or steaming. For fruits and meats, the biggest losses of vitamins occur during prolonged storage and thawing.

MOISTURE REMOVAL

Methods of moisture removal include both dehydration and concentration processes. Multiple factors prior to drying or concentration will influence ultimate nutrient retention. For example, the presence of sulfur dioxide adversely affects thiamin but protects ascorbic acid. However, the presence of copper, iron, light, or dissolved oxygen can decrease ascorbic acid concentration. Also, metals can catalyze oxidation of carotenes (25). Temperatures during moisture removal vary, depending on the process and the product, and can range from -30°C to above 100°C . Generally, low-temperature processing such as freeze-drying produces the least chemical deterioration. However,

low-temperature processing is usually more expensive because of the longer processing times (25).

Dehydration

Methods for dehydration include sun drying, tunnel drying, spray drying, drum drying, and freeze drying. Microbial metabolism and growth require free (not bound) water. Removing available water prevents microbial growth and reduces the rates of enzymatic activity and chemical reactions if the product is stored under proper conditions.

For most types of drying, heat is supplied to the food and vaporized moisture is removed. Dehydrated foods are susceptible to loss of vitamin A and provitamin A activity during storage when oxygen is present. Vitamin C may also be lost during drying.

Sun Drying

Sun drying is one of the least expensive methods of drying. It is used to dry grapes, prunes, apricots, dates, figs, spices, grain, and other foods. This is a time-consuming method that usually takes 3 to 4 days, and it is often accompanied by large vitamin losses. Additional problems such as mold growth can occur if rain or high humidity is present. An increase in mold toxins such as aflatoxin can be an issue. For best results, a warm, dry climate is necessary.

Tunnel Drying

Tunnel driers are an important class of driers used for pasta, fruits, and vegetables. The food is placed on trays or conveyors and passed through a stream of high-velocity air.

Spray Drying

Spray drying is an HTST process used for nonfat dry milk, eggs, tea, and coffee. It is more expensive than tunnel drying, but product quality is better. Little or no vitamin A or D is lost during the spray drying of milk. Additionally, spray-dried milk powder has negligible loss of available lysine. Most dried milk available to the consumer is further processed by rewetting and drying to produce an instant powder that dissolves well in water. During this rewetting and drying process, amino acid losses are minimal (25).

Drum Drying

A fairly inexpensive process, drum drying is generally used for foods that are relatively heat insensitive, such as potatoes. Mashed potatoes are processed by drum drying to produce "instant" potatoes. Most of the vitamin C in potatoes is lost during drum drying and subsequent storage of the product (5). Milk can also be processed by drum drying, which results in lysine losses of 3 to 16% (25). Little or no loss of vitamin A or D occurs during the drum drying of milk (25). Deterioration of heat-sensitive nutrients is greater in

spray drying or tunnel drying because of the high temperature and the direct contact between the food and the hot drum.

Freeze Drying

Freeze drying is the most expensive drying process, but it results in foods of very high quality. The food is frozen in sheets and placed in chambers with low atmospheric pressure. Water evaporates directly from the ice phase (sublimation) in about 6 to 8 hours. The effect of temperature on product quality and nutrient retention is minimal. Even vitamin C is retained in this process, because the process is carried out in the absence of oxygen (25).

Concentration

Evaporation, freeze concentration, and membrane processes are commonly used by the food industry to concentrate foods and juices.

Evaporation

Evaporation is the most common method of concentrating food products and the least expensive. Basically, this process consists of boiling off water at temperatures that depend on the product and process. Foods processed by this method include condensed milk, fruit juice, candy, jam, and jelly. The processing times should be short to minimize nutrient destruction. Some lysine is lost due to nonenzymatic browning. One study showed a 20% reduction in lysine when evaporated milk was retorted at 113°C for 15 minutes. However, when sweetened condensed milk was evaporated at 50 to 55°C, only 3% of the lysine was destroyed (25). Evaporation under partial vacuum can improve nutrient retention because of the lower boiling temperatures and lower concentration of atmospheric oxygen.

Freeze Concentration

Freeze concentration is a low-temperature moisture-removal method used commercially for the manufacture of orange juice concentrate. This process involves freezing water to produce large ice crystals, which are then separated from the orange concentrate. Excellent nutrient retention is expected because it is a low-temperature process. Only adhering solutes that are removed with the ice are lost (25).

Membrane Processes

Ultrafiltration and reverse osmosis are nonthermal food processing methods that use membranes. Reverse osmosis is a concentration process designed to remove only water, whereas ultrafiltration is a less-specific concentration and purification process. With both processes, the liquid solution to be concentrated is passed through equipment holding a membrane. The membrane allows selective passage of water, with or without other compounds of low molecular weight (25). Ultrafiltration results in a substantial loss of water-soluble vitamins and minerals along with the water. Reverse osmosis uses a

much smaller pore size, so fewer nutrients are lost.

Of the concentration methods discussed, ultrafiltration shows the highest nutrient losses (particularly of water-soluble vitamins and minerals). Drying processes generally offer good nutrient retention, with the exception of b-carotene and ascorbic acid. Losses of water-soluble vitamins, other than ascorbic acid, during drying average approximately 5%. Fat-soluble vitamins are not lost to any significant degree during spray drying, drum drying, or evaporation of milk. Loss of ascorbic acid during concentration is minimal. Freeze concentration offers excellent nutrient retention (25).

OTHER PROCESSES

Irradiation

Food irradiation is used to destroy microorganisms, to eliminate insect infestations, and to inhibit ripening and sprouting in a number of food products. The process uses high-energy ionizing radiation to create free radicals that can react with the DNA of insects or microorganisms to kill them (26).

The ionizing radiation used for food products comes from one of two sources. Most commonly, g-radiation or x-rays are used, which are generated from cobalt-60 (^{60}Co). The ^{60}Co is encapsulated in several layers of stainless steel and raised into an irradiation chamber with the food. g-Rays are effective because of their high penetration power; the g-ray source never contacts the food directly. This makes g-rays suitable for irradiation of bulk items such as chickens or drums of food. Ionizing radiation can also be generated by machines. The electron beams produced can only penetrate about 8 cm into food, which limits their use to low-density foods such as spices or grains. However, this system is more suited to in-line processing because it can be used with conveyors and can be switched on and off (26).

Irradiation doses are measured in kilograys (kGy), with a maximum dose of 10 kGy recommended by the World Health Organization and legalized in Europe. Doses below 1 kGy are effective in inhibiting potato sprouting or in preventing insect breeding in grains and citrus fruits. A slightly higher dose, 1 to 3 kGy, reduces both spoilage and food poisoning microorganisms in soft fruit, meat, and fish. It has been reported that the O157:H57 *Escherichia coli* bacterium is highly sensitive to irradiation and can be eliminated from ground meat with a dose of only 0.16 to 0.44 kGy (27). Decontamination of dry spices requires the highest irradiation dose, 10 kGy (26).

The changes in food caused by irradiation are small. As with the other thermal processes, thiamin and vitamin C are the most sensitive nutrients. However, beef sterilized by irradiation is reported to retain more thiamin than that canned and thermally processed. Additionally, reported vitamin C losses in irradiated fruits and vegetables are small relative to the natural variance in vitamin C content. The effect of ionizing irradiation on the nutrient content of food is comparable to that of conventional heat processing (12). Irradiating food at low temperatures without oxygen further improves

retention of nutritional quality.

Even though irradiation of food has been shown to be safe, approval for its use in foods has been limited. Consumer mistrust of the process and difficulties in gaining Food and Drug Administration (FDA) clearances have prevented substantial commercial use in the United States (29). However, because irradiation is a promising replacement for hazardous chemical fumigants such as methyl bromide and can effectively prevent food-borne illnesses, it will gradually become a more widespread food processing tool.

Milling

Milling is a process by which bran and germ are removed from cereal grains. It is commonly used to refine wheat to make white flour. In the United States, milling wheat to produce white flour results in a 40 to 60% loss of vitamins and minerals. Most wheat flour and breads are enriched with thiamin, niacin, riboflavin, and iron (addition of calcium and other nutrients is optional) in accordance with a standard defined by the FDA (12, 30). Degermination of grains also results in loss of vitamin E.

Milling is used to remove bran and germ from rice. The outer husk is broken and separated from the grain by winnowing, although some of the germ and pericarp are removed at the same time. Traditionally, rice was extracted from the husk by pounding it in a stone or wooden mortar. Today, machine milling can produce an even more refined product with an even greater loss of bran. Brown rice may contain about 15.0 nmol/g (4 µg/g) thiamin, whereas highly polished rice may contain as little as 2.6 nmol/g (0.7 µg/g). Other B vitamins are also lost. The Asian practice of washing the rice before cooking results in additional loss of water-soluble thiamin. Thiamin losses are of most concern in areas of the world where polished rice is the staple food. Thiamin deficiency can result in beriberi, which at one time was a major cause of death in many countries (5). Now, white rice is usually enriched with niacin, thiamin, and iron.

Home Cooking

A discussion of nutrient loss during processing would not be complete without mentioning the losses that occur in the home or food service establishment. The greatest nutrient losses are due to excess heat, leaching into cooking water, and “cook-drip.” Thus, the cooking methods ultimately determine nutrient retention. Substantial vitamin and mineral losses often occur in the final preparation steps.

The final vitamin content of home-cooked foods may be similar to that of commercially processed foods, because vitamin losses are inevitable with cooking. Vitamin retention can be improved by using less cooking water, minimally trimming fruits and vegetables, chopping coarsely, covering pans to lessen cooking time, cooking vegetables only until tender, and using cooking water for soups. For example, baked or unpeeled boiled potatoes were reported to have almost total vitamin retention, whereas boiled peeled potatoes retained as little as 63% of the initial nutrients (20). In general, steaming or stir-frying result in greater nutrient retention than boiling or typical pan frying (12, 31).

Overall, there are a few things that both the industrial food processor and home cook must remember. Steaming retains more nutrients than boiling. Boiling with minimal water is better than boiling with larger amounts of water. Finally, vitamin losses increase with surface contact area. In more practical terms, this means that more nutrients are lost from leafy vegetables than from root vegetables (20).

In conclusion, the most common food-processing methods generally do not cause major loss of nutrients. Some loss of nutrients will accompany the process used to ensure product safety and quality. Major nutrient losses are incurred with excessive use of heat and water during cooking. Extreme or prolonged conditions of food storage, distribution, and food preparation can also influence nutrient retention. As more sophisticated food-processing methods are perfected, even greater nutrient retention during commercial processing will be possible.

Throughout evolution, each species, whether single cell or multicellular, has sought sustenance to provide nutrients for survival, growth, and reproduction. Humans have selected a broader variety of foods of animal and vegetable origin than most other species to provide the nutrients needed for their existence (1). As a complex mixture of chemicals, food provides essential nutrients, requisite calories, and other physiologically active constituents needed for life and health. Yet, very little is known about most substances found in foods.

The amount and composition of food consumed at various stages of life may affect the expression of certain diseases. During the past 25 years, epidemiologic studies have consistently implicated diet with the five leading causes of death in the United States: coronary heart disease (CHD), certain types of cancer, stroke, non-insulin-dependent diabetes mellitus (NIDDM), and atherosclerosis (2). In this century alone, nutrition and food sciences have enhanced development of an abundant, nutritious, safe food supply that has contributed to better health for people around the world.

A new paradigm for “optimal nutrition” may be evolving that would emphasize the positive aspects of diet, identifying physiologically active components that contribute to disease prevention. Understanding how individual nutrients and nonnutrient constituents function physiologically should allow food scientists actually to design food products for a healthy diet. Thus, even though genetic predisposition increases susceptible persons' risk for some of these chronic diseases (especially with advancing age), optimal nutrition should enable persons to achieve their maximum genetic potential and decrease their susceptibility to disease.

From the beginnings of recorded history, plant components (leaves, flowers, roots, and bark) have been used to treat specific diseases. Hippocrates, the father of medicine,

included food as a basic part of treatment to cure disease. Taken from many cultures, herbs and plants commonly used for treatment of specific disorders have been carefully identified. Modern analytic methods have identified numerous physiologically active constituents, many of which have been developed into pharmaceutical agents.

Epidemiologic evidence continues to correlate positive effects of fruits, vegetables, and grains with a lower incidence of cancer, CHD, and other diseases (3, 4), although the correlations do not always agree solely with nutrient content. Nonnutrient constituents have been identified with beneficial physiologic effects that may retard or prevent disease (5). Foods that combine these properties have been called “designer foods,” “functional foods,” “nutraceuticals,” and other related names.

The new diet-health paradigm acknowledges the nutritious and healthful aspects of food but goes beyond the role of food constituents as dietary essentials for sustaining life and growth to one of preventing or delaying the premature onset of chronic disease later in life. The promise of functional foods has emerged at a time when consumer interest in diet and health are at an all-time high (6).

FUNCTIONAL FOODS

The functional foods concept has unified the medical, nutritional, and food sciences. Over the past decade, new technologies, such as biotechnology, genetic engineering, food processing, product innovations, and mass production have enabled food scientists to design new healthful products. Initially, the term *designer foods* was developed by the National Cancer Institute to describe foods that naturally contained, or were enriched with, nonnutritive, biologically active chemical components of plants (phytochemicals) that were potentially effective in reducing cancer risk (7). The Institute of Medicine of the U.S. National Academy of Sciences defined functional foods as those that encompass potentially healthful products, including any modified food or food ingredients that may provide a health benefit beyond the traditional nutrients it contains.

Nutraceutical was the term first described by the Foundation for Innovation in Medicine (8, 9) to identify “any substance considered a food or part of a food that provides medical or health benefits, including the prevention and treatment of disease.” Nutraceuticals may range from isolated nutrients, dietary supplements, and diets to genetically engineered “designer” foods, herbal products, and processed products such as cereals, soups, and beverages.

The term *functional food* may prove to be the best name for the category of physiologically active foods. The response of consumers to the different names suggests that “ceutical” reminds people of medicine, while “designer” suggests artificial or synthetic.

In 1988, the orphan drugs amendment to the federal Food, Drug, and Cosmetic Act provided the term *medical foods* with a legal definition: “A food which is formulated to be consumed or administered enterally under the supervision of a physician and which is intended for the specific dietary management of a disease or condition for which distinctive nutritional requirements, based on recognized scientific principles, are

established by medical evaluation.” Thus, medical foods are complex, formulated products designed to provide complete or supplemental nutritional support to individuals who cannot ingest adequate amounts of food in a conventional form or to provide specialized nutritional support to patients who have special physiologic and nutritional needs associated with their conditions (10).

Medical foods differ from the general food supply, since these foods frequently serve as the sole source of nutrition. Generally, medical foods require sophisticated and exacting science and technology in their design and manufacture, comparable to that used in the manufacture of infant formulas and drugs. Yet, medical foods are subject to much less scrutiny by the Food and Drug Administration (FDA) than virtually all other foods categories. The 1990 National Labeling Education Act (NLEA) specifically exempted medical foods from the NLEA labeling provisions (11). There are no specific requirements for label information or substantiation of claims, formulations, and compositional characteristics; manufacturing quality controls; or notification to the FDA of intent to market medical foods.

Each of these terms, *functional foods*, *nutraceuticals*, *designer foods*, and *medical foods*, should be carefully defined so that consumers and health practitioners do not become confused. The significance and relevance of any definition of functional foods depend totally on an adequate description of these foods and substantiation of their health benefits (12).

REGULATORY ISSUES

The United States has established two new labeling laws in an effort to regulate functional foods, medical foods, and designer foods: the 1990 National Labeling Education Act (NLEA) and the 1994 Dietary Supplement Health and Education Act (DSHEA). These changes will affect the development of functional food products (13).

A major dilemma in considering functional foods, is that they exist at the interface between foods and drugs (14). Compounds exerting this type of physiologic effect have been classified by the federal Food, Drug, and Cosmetic Act of 1938 (15) as drugs, that is “articles intended for the diagnosis, cure, mitigation, treatment or prevention of disease.” Thus, the legal display on a label referring to disease prevention or risk reduction associated with consuming a particular functional food is extremely limited at this time. Currently four categories exist (16):

1. Ordinary foods and nutrients. Health claims can be made on labels only when they are supported by the totality of publicly available scientific evidence, and then only after receiving regulatory approval from the FDA.
2. Dietary supplements. Health claims are based only on “evidence that the statement is truthful and not misleading.” The FDA must be notified of the statement, and the label must include a disclaimer stating that the agency has not evaluated the claim and that the product is not intended to diagnose, treat, cure, or prevent any disease.
3. Medical foods. Health claims must be based on a somewhat higher standard than that for dietary supplements; namely, being backed by “sound scientific evidence.”

Medical foods do not require FDA approval for claims, though their packages must include disclaimers similar to those of dietary supplements.

4. Drugs. Drug claims have the strictest standards. Drugs must be proven safe and effective in FDA-approved and reviewed clinical trials.

NLEA

The NLEA (17) allows health or disease prevention claims on a food label. A health claim is a statement that asserts or implies a relationship of a substance to a disease or health-related condition within the context of a total daily diet (18). The NLEA requires a prominent panel of nutrition facts, daily reference values, ingredients, nutrient content, and health claims. The Institute of Medicine provided a working definition for functional foods, indicating that they were “foods in which the concentrations of one or more ingredients have been manipulated to enhance contributions to a healthful diet.” Eight health claims for foods are currently approved by the FDA (19) (Table 112.1).

-
- Fiber-containing grain products, fruits, and vegetables and cancer
 - Fruit, vegetables, and grain products containing fiber, particularly soluble fiber, and risk of cardiovascular disease
 - Fruits and vegetables and cancer
 - Calcium and osteoporosis
 - Dietary saturated fat and cholesterol and risk of cardiovascular disease
 - Dietary fat and cancer
 - Sodium and hypertension
 - Sugar alcohols and dental caries
-

From Department of Health and Human Services, Food and Drug Administration, 1993. Food labeling: general requirements for health claims for food. Fed. Reg. 58:2478-536

Table 112.1 Eight Health Claims for Foods Currently Approved by the FDA

New regulations might be needed to ensure some kind of limited patent or copyright on a health claim for companies willing to make the research commitment. Otherwise, because of the time delay and costs involved in achieving approval, companies may well not bother with clinical trials and simply avoid label claims. Although a strong claim for health or longevity would be very marketable in the long term, functional foods may be promoted in other ways first. If handled through advertising with satisfied customer statements, only the Federal Trade Commission (FTC) would be involved, and they only require that the advertising not be misleading.

DSHEA

The DSHEA (20) broadly defined a dietary supplement as a product “intended to supplement the diet that bears or contains a vitamin, a mineral, an herb or other

botanical, an amino acid, a dietary substance for use by man to supplement the diet by increasing the total dietary intake, or a concentrate, metabolite, constituent, extract or combination [of any ingredient described above].” Under the DSHEA, dietary supplements are exempt from regulation as drugs and, for the most part, as food additives. Unfortunately, the DSHEA puts the burden of proof for safety of dietary supplements directly on the FDA and limits the agency's authority over labeling. With regard to functional foods, DSHEA allows the use of structure/function claims and dissemination of third-party literature.

The description of a dietary supplement in the DSHEA specifically includes (a) a product intended for ingestion in tablet, capsule, liquid, powder, soft gel, or gelcap or (if not in such form) not represented as a conventional food or sole item of a meal or of the diet, and labeled as a dietary supplement; (b) a drug, antibiotic, or biologic marketed as a dietary supplement prior to such approval; (c) a food, but one not considered a food additive; (d) a preparation other than tobacco, intended to supplement the diet by increasing total intake, which bears or contains one or more of the following dietary ingredients: a vitamin, a mineral, an herb or botanical, an amino acid, a dietary substance for use by man to supplement the diet by increasing the total dietary intake, or a concentrate, metabolite, constituent, extract, or any combination of these ingredients (21). A definition of dietary supplement as broad as this allows the addition of many ingredients with functional effects that span the food-drug spectrum.

The DSHEA provides for statements of nutritional support, which can be applied to a wide variety of dietary ingredients. Specifically, one is permitted (20, 21):

- to claim a benefit related to a classical nutrient deficiency disease and disclose the prevalence of such a disease in the United States
- to describe the role of a nutrient or dietary ingredient intended to affect structure or function in humans
- to characterize the mechanism by which a nutrient or dietary ingredient acts to maintain such structure or function
- to describe the general well-being derived from the consumption of a nutrient or dietary ingredient.

Structure/function claims do not require prior approval. The FDA must be notified that such a statement is being made, and the product label must include the following: “This statement has not been evaluated by the FDA. This product is not intended to diagnose, treat, cure, or prevent any disease.” The tone of this message will deter consumer acceptance and thus diminish industry use.

Dietary supplements have been drastically redefined by the DSHEA in terms of what they are and may contain. They are permitted to contain ingredients based on a lesser safety standard than that which applies to those in conventional foods. The use of such components in different food products and their suitability for claims in labeling depend on the application of appropriate standards for safety of use and for labeling criteria of a particular product category. In the general food supply, an inherent constituent of the food can be marketed unless it has been found to be “ordinarily injurious to health.” As an intentional additive, a functional food component can be used to fortify a processed

food, but it requires a stricter condition of “reasonable certainty of no harm” within the context of the total estimated exposure of the “additive.” According to the DSHEA, a dietary supplement is considered an unapproved food additive in terms of conventional food use, since the supplement might be considered adulterated. A functional food component used in a supplement could be less safe than one that occurred naturally or that was intentionally added to a conventional food.

Additional regulations may be needed to clarify the product and label descriptions. There has not been a systematic approach to categorization and documentation for a role in health promotion or disease prevention. Some potential categories suggested by Glinsmann (21) are listed in [Table 112.2](#). Although further modification may be necessary, these categories can serve as an excellent starting point.

-
- Antioxidants, modifiers of oxidative damage, and defense mechanisms related to oxidative stress
 - Antimutagens, anticarcinogens, and inducers of enzymes of xenobiotic metabolism
 - Antimicrobial and antiviral substances
 - Enhancers of GI function, including dietary fibers, probiotics, prebiotics, and colonic microflora
 - Immunomodulators and antiinflammatory agents
 - Neuroregulatory substances
 - Phytoestrogens
 - Antihypertensives
 - Hypocholesterolemic agents
 - Food components with diminished allergenicity
-

Modified from Glinsmann WH. *Nutr Rev* 1996;54:533-7.

Table 112.2 Potential Categorization of Functional Dietary Supplements

The changes described in the DSHEA appear to favor development of functional food products in the form of dietary supplements. In the long term, this legislation may do little to stimulate scientific investigation into the potential role of functional food products in health promotion and disease prevention.

OPPORTUNITY FOR DEVELOPMENT

The key change in the new health paradigm is prevention rather than treatment. With the recent economic history of nutritional supplements, natural products, sports drinks, and health foods, all food companies have contemplated, or have already entered into, the functional foods arena.

Consumers are making more healthcare decisions for themselves than ever before, including lower-cost alternative healthcare and use of unconventional medical therapies. These consumers also select healthy foods that are low in fat, vitamin fortified, and high in fiber. Sales of vitamin supplements, “health” foods, and “natural” foods continue to

grow. Functional foods, food products, and supplements that deliver a possible physiologic benefit in the management or prevention of disease represent an opportunity for future new product growth in the food and beverage industries.

Market in the United States

By 1988, the health product market was growing at an annual rate of 18 to 20%, with annual sales of \$2.5 billion. The functional food market should remain a high-growth business and reach \$7.5 to 9.0 billion within a few years ([22](#), [23](#) and [24](#)). If the market value were expanded to include all health-benefit products, including natural and organic foods, the market might exceed \$71 billion ([24](#)). The inability of state and federal agencies to work with industry to develop equitable regulations hampers the development of functional foods.

If market interest in new products was stimulated by a health proclamation like that which accompanied oat bran, perhaps for a presumed anticancer component of phytochemicals, the market could easily increase at an annual rate of 30%. The specialty market may mature as the worldwide functional food market grows.

International Perspective

Japan. Functional food markets highlight cultural differences between regions in the global marketplace. For example, products that appeal to the Japanese consumer (e.g., lactic acid-containing beverages) may not appeal to the Western consumer. The Japanese can be credited with advancing the functional food market from its infant stage as functional isotonic beverages to the more advanced stages of functional sweeteners and natural sources of edible fiber. Beyond the organoleptic qualities, the potential therapeutic benefits offered by functional products will vary with the consumer desires within that market. Japanese functional food products are aimed at every market segment and include every age group. These products claim to improve intestinal health through inclusion of oligosaccharides or active bacterial cultures, whereas the functional food market in the United States has emphasized products related to reducing the incidence of CHD or cancer. Thus, the functional food market is influenced by both health interests and consumer acceptability within each culture.

To date, the Ministry of Health and Welfare (MHW) of Japan has viewed the functional food industry as benefiting the general well-being of the Japanese populace. A wide variety of products exist, including chewing gums with oligosaccharides, drinks containing high levels of soluble fiber, and infant formulas developed to be analogous to mother's milk. Until recently, these products were developed and sold with little concern, but the Japanese regulatory agencies are considering standards for these products and the claims that are made ([25](#)).

The functional food market in Japan is mature, but the annual growth rate has slowed to 8%, totaling about \$4.5 billion in 1995. Product development and market growth continues because of a favorable government regulatory attitude and significant investment in ingredient and product development. Although the MHW has increased efforts to monitor and regulate the functional food industry, it has not inhibited innovation

and commercialization.

China. Currently, more than 10,000 varieties of functional food products identified as “health” foods exist in China, and annual sales of such foods totals about U.S. \$2.5 billion. Twenty different categories of these “new source foods” were approved in 1987, with the following characteristics: (a) most are based on compound formulas (mix of herb extracts); (b) all are claimed to have multiple health effects on various body systems; (c) in most cases, experimental evidence of their safety and efficacy is weak; (d) the active compounds of most of these mixtures derived from animals and plants are unknown; and (e) the mechanisms of their health effects are basically unknown (26). The Chinese populace differentiates little between foods used for traditional Chinese medicine and functional foods (27). Both are assumed to promote health.

Recently, the Chinese government has announced its intention to improve the standards for these products, including restricting the use of “curative” claims. The immediate result would be a major reduction in health food products in the market place (13).

Europe and the United Kingdom. The European diet, already high in fiber, is considered to be of natural origin. Many products already exist, but the functional food categories are limited to fiber-based products, yogurt and cultured milk products, and products that enhance intestinal function (28).

A large number of functional foods exist in the United Kingdom as well. Product claims are aimed at preventing heart disease, reducing blood cholesterol, promoting a healthy nervous system, and maintaining a healthy cardiovascular system. Food labeling regulations prohibit express or implied claims that a food can prevent, treat, or cure a disease unless the product has a medical license. No prior approval system exists, however; thus enforcement is difficult.

Regulatory Issues

The major concerns within the industry are (a) the inconsistency of regulatory guidelines for functional food products and (b) the lack of direction in promoting development of products and ingredients that actually can have a positive impact on the health of the consumer. The major regulatory agencies of the world may eventually adopt a more positive position in regard to certain classes of these products. However, the health goals of these agencies are (a) to protect the consumer from harm, including suppression of misleading health claims; (b) to ensure product safety, particularly in regard to high concentrations of specific constituents; and (c) to minimize the potential negative impact of such products on the maintenance of a nutritious diet. The consumer should be able to trust the safety and efficacy controls placed on these health products, which in turn will promote the quality of the food industry's products.

Market Overview

The functional foods market began with the introduction of isotonic sports beverages in

the United States and Japan that offered a benefit beyond the nutritional content of traditional products. These products were not classed as functional foods, and they received little regulatory attention. The advent of functional food products occurred in the United States and Japan with promotion of high-fiber products. These products received international attention through their claim to provide a physiologic and therapeutic activity. Fiber-based products set the stage for development of other types of functional products—low fat, low cholesterol, or low sodium—based on consumer demand for healthier products.

Functional foods are focused to meet the needs of different market segments; for example, new infant formulas, women's health, increased mental alertness and well-being, and maintenance of the physical condition of elderly persons. Functional foods represent an interesting challenge for the food industry, which must constantly adjust its products to meet the needs and demands of our ever-changing society.

PHYSIOLOGICALLY ACTIVE COMPOUNDS

There has been no evolutionary pressure on plants to cause development of food components that protect man from diseases and cancer; yet, diets rich in fruits and vegetables appear to do just that. Most likely, these compounds developed as part of the plants' own defense mechanisms against environmental insult and only fortuitously benefit man. Similar positive effects are being identified for a few specific proteins isolated from animal sources.

The number of physiologically active food chemicals has increased dramatically in the last decade. A few of the studied compounds are listed in [Table 112.3](#) ([29](#), [30](#), [31](#), [32](#), [33](#), [34](#), [35](#), [36](#), [37](#), [38](#), [39](#), [40](#), [41](#), [42](#), [43](#), [44](#), [45](#), [46](#), [47](#), [48](#), [49](#), [50](#), [51](#), [52](#), [53](#), [54](#), [55](#), [56](#), [57](#), [58](#), [59](#), [60](#), [61](#) and [62](#)). Most were identified by epidemiologic surveys that correlated a positive health benefit with specific food groups; then the focus narrowed to determining the dietary intake of individual foods. Researchers have examined the compositions of these foods, isolating and identifying chemical structures and suggesting possible functions for these agents. In many cases, animal experiments have tested the hypotheses of health benefits and mechanisms of action, while in others, some human testing has been initiated. Experiments needed to identify and characterize the physiologically active phytochemicals are described in [Table 112.4](#). Very few phytochemicals have been examined as thoroughly as necessary.

Chemical	Food Source	Biological Activity	Reference
Anthocyanins	Berries	Antioxidant, anti-inflammatory, anti-cancer	1
Carotenoids	Carrots, spinach	Antioxidant, anti-inflammatory, anti-cancer	2
Flavonoids	Tea, cocoa	Antioxidant, anti-inflammatory, anti-cancer	3
Isoprenoids	Garlic, onion	Antioxidant, anti-inflammatory, anti-cancer	4
Monoamines	Bananas, avocados	Antioxidant, anti-inflammatory, anti-cancer	5
Phenols	Apples, grapes	Antioxidant, anti-inflammatory, anti-cancer	6
Saponins	Lentils, chickpeas	Antioxidant, anti-inflammatory, anti-cancer	7
Tannins	Tea, coffee	Antioxidant, anti-inflammatory, anti-cancer	8
Terpenoids	Citrus fruits	Antioxidant, anti-inflammatory, anti-cancer	9
Vitamins	Various fruits and vegetables	Antioxidant, anti-inflammatory, anti-cancer	10

Table 112.3 Physiologically Active Food Chemicals That May Prevent Disease

Research Area	Objective	Methodology	Expected Outcome
1. Mechanism of Action	Identify the specific biochemical pathways through which phytochemicals exert their health benefits.	In vitro and in vivo studies, including molecular biology and animal models.	Clarification of the underlying mechanisms of action for various phytochemicals.
2. Dose-Response Relationship	Determine the optimal dose of phytochemicals for health benefits, and identify any potential adverse effects at higher doses.	Controlled human trials and animal studies.	Establishment of safe and effective dosing guidelines.
3. Bioavailability and Metabolism	Investigate how phytochemicals are absorbed, transported, and metabolized in the human body.	Pharmacokinetic studies and metabolic pathway analysis.	Understanding of the factors that influence the effectiveness of phytochemicals.
4. Synergistic and Antagonistic Effects	Explore how different phytochemicals interact with each other, either enhancing or inhibiting their effects.	Co-treatment studies and mechanistic investigations.	Identification of synergistic combinations for improved health outcomes.
5. Clinical Applications	Develop evidence-based dietary recommendations and functional food products based on phytochemical research.	Large-scale clinical trials and product development.	Integration of phytochemicals into mainstream medicine and nutrition.

Table 112.4 Research Needed to Clarify Possible Roles of Phytochemicals in Health

It will be many years before we clearly understand whether these agents offer significant health benefits as either natural ingredients, food additives, or dietary supplements. In many cases, benefits may result from additive or synergistic effects. In all cases, safety must be ensured. Only a few examples of research are presented here to represent the exciting potential of some of these agents as future physiologically active agents that might be incorporated into functional foods. A decision on efficacy must consider the lowest doses that produce their effects, since higher doses increase the risk for toxicity. In addition, it is important to determine whether the dose of agent in the food has the same efficacy as the isolated compound. Each of the following examples has physiologic effects at levels found naturally in foods.

Catechins. Jasmine green tea is an excellent source of natural polyphenol antioxidants, specifically including (–)-epicatechin (EC), (–)-epicatechin-3-gallate (ECG), (–)-epigallocatechin (EGC), and (–)-epigallocatechin-3-gallate (EGCG). The purified

catechins exhibited strong protection against red blood cell (RBC) hemolysis induced chemically by an azo free-radical initiator. The effective dose for antioxidant activity was between 2.5 and 40 μ M. EGCG and ECG were most effective. Only EGC and EC were found in the circulation after a gavage dose of jasmine tea, suggesting selective absorption. However, the tea also reduced RBC hemolysis (33).

The effects of green tea as a chemopreventive agent in multiple animal models is of great interest. Either green tea infusion or isolated tea catechins express a broad spectrum of anticarcinogenic activity. EGCG inhibits proliferation of leukemic blast cells from patients with acute myeloblastic leukemia. EGCG did not inhibit granulocyte-macrophage colony-stimulating factor (GM-CSF) but did block stimulation of GM-CSF release by tumor necrosis factor (TNF)- α or tetradecanoylphorbol acetate (TPA) and blocked modulation of c-kit, a receptor for stem cell factor on leukemic cells (34).

Catechins can inhibit every stage of the carcinogenic process, including development of tumors at different sites and in different organs, a wide array of enzymes involved in cell proliferation (such as protein kinase C, DNA polymerase, RNA polymerase, lipoxygenase, ornithine decarboxylase, cytochrome P450, and the induction of phase II enzymes), and a variety of indirect and direct chemical carcinogens and tumor promoters. The results of animal experiments consistently indicate that the effective concentrations of these phenolic compounds equal the levels found naturally in brewed tea (63).

Phytoestrogens. Phytoestrogens are present in the human diet in substantial amounts, especially in soybeans and soy foods (43, 44 and 45). They have been shown to have many biologic effects in cell culture and in animals and humans. Most of these effects are considered positive, although a few harmful effects have been reported.

Phytoestrogens, estrogenic compounds found in plants, exert estrogenic effects on the central nervous system, induce estrus, and stimulate growth of the female genital tract in animals (43). Three main classes of phytoestrogens exist: isoflavones, coumestans, and lignans. All are diphenolic compounds with structural similarities to natural estrogens and antiestrogens.

Although the amount of phytoestrogen absorbed may be low, the level circulating in the blood may be 100 to 500 times that of naturally occurring b-estradiol. Absorption is facilitated by hydrolysis of the sugar moiety by intestinal bacterial b-glucosidases, gastric hydrochloric acid, and b-glucosidases in foods. When the diet is supplemented with soy products, the level of phytoestrogens can reach 1000 times the level of b-estradiol. Soy food processing appears to affect isoflavone bioavailability (e.g., fermented tempeh appears to enhance their absorption).

After absorption, isoflavones and lignans are conjugated with glucuronic acid and sulfate by hepatic phase II enzymes (UDP-glucuronosyltransferases and sulfotransferases). These metabolic changes make the lipophilic compounds more water soluble and enhance their excretion. Glucuronic acid derivatives are the primary

excretory products in urine.

Phytoestrogens can affect the menstrual cycle and the concentration of reproductive hormones in the blood of premenopausal women but less so in postmenopausal women. Natural flavones, such as daidzein or coumestrol, inhibit the (placental) aromatase enzyme in vitro. Aromatase catalyzes the rate-limiting step in estrogen synthesis in humans.

Genistein, the most abundant phytoestrogen, and coumestrol enhance bone calcium retention in rats. They inhibit bone resorption and stimulate bone mineralization. Similar effects are noted after consuming soy protein, which still contains the phytoestrogens. The protective effects are also observed in osteoporotic patients. Soy foods also contain a good source of dietary calcium, which enhances the effect.

Isoflavones (e.g., genistein) inhibit protein tyrosine kinase (PTK), an oncogene product that catalyzes tyrosine phosphorylation involved in tumor cell signal transduction and proliferation. Genistein inhibits growth of various human cancer cells, including melanoma cells and leukemic cells. Similarly, phytoestrogens inhibit endothelial cell proliferation in capillaries.

Genistein also increases the activities of such antioxidant enzymes as superoxide dismutase, glutathione peroxidase, glutathione reductase, and liver cumene hydroperoxidase. Thus, genistein might work together with other phytochemicals with antioxidant activities to provide a broader cellular defense against free-radical attack and oxidative damage.

Thus, studies in humans, animals, and cell culture all indicate a positive role for phytoestrogens in prevention of menopausal symptoms, osteoporosis, cancer, and heart disease, and dietary supplementation with soy foods produces a response similar to that of the isolated phytoestrogen.

Lactoferrin. Lactoferrin (LF) represents a physiologically active animal product (LF) ([37](#), [38](#), [39](#) and [40](#)). Similar to transferrin, it has been assumed to be an iron transport protein that delivers iron to the infant gut. Lactoferrin binding sites have been identified on a variety of cells and tissues, but a high pI makes it difficult to determine whether these “receptors” are specific or nonspecific. Several functions have been hypothesized LF: enhancing bioavailability of breast milk iron, antimicrobial activity, and enhancing immune responses, including antibody production, complement activation, and natural killer cell function ([64](#)). The broad-spectrum antimicrobial properties of LF highlight the potential application of this protein as an enteral and parenteral antimicrobial factor, as well as a potential food additive.

The bacteriostatic effect of orally administered bovine LF (bLF) was evaluated on intestinal bacteria in the gut of mice fed bovine milk. Bovine milk feeding increased proliferation of Enterobacteriaceae, but added bLF suppressed this proliferation. Similar effects were noted when the gut was seeded with *Clostridium ramosum* and other *Clostridium* spp. Compared with other proteins, only bLF demonstrated this effect. Partial hydrolysis of bLF with pepsin—similar to digestive hydrolysis—did not alter the

bacteriostatic effect; bLF still protected infant animals from gastrointestinal infections (64).

Recombinant human LF (rhLF) has been produced and characterized. Addition of rhLF to infant formula awaits further research to ensure stability during processing and to further evaluate biologic activity through studies on intestinal microflora from large numbers of infants. Before implementing a new product with increased cost, the biologic effect must be confirmed and shown of clear benefit to the infant. Mature human milk contains 2 to 3 mg/mL of hLF, although most infant formulas currently contain no LF. At this level, benefits can be seen after 3 months of feeding, although not all studies indicate a need for LF supplementation.

The potential exists for use of LF as a food additive. As a natural antimicrobial agent, many uses can be identified, such as decreasing microbial contamination and decreasing risk for toxicity from ground meat used in fast food restaurants.

Carotenoids. Understanding the use and function of phytochemicals requires understanding the bioavailability, absorption, metabolism, transport, and distribution of carotenoids, as well as determining their mechanism of action (65) (see also [Chapter 33](#) on carotenoids).

The term *carotenoids* encompasses both carotene, which identifies the hydrocarbon forms, and the xanthophylls, which include carotenoid derivatives with one or more oxygen-containing functional groups (66). With more than 600 distinct carotenoids and their glycosides identified, it is curious that most research has focused on b-carotene. Other carotenoids may better support health in certain instances than b-carotene. Use of b-carotene as a model carotenoid because of its availability and relative safety, however, provides an opportunity to establish methods for studying other carotenoids and phytochemicals in general.

Important factors affecting carotenoid availability include the release of carotenoids from the physical food matrix in which they are ingested. Heating food improves bioavailability by disassociating the protein-carotenoid complexes and enhancing dispersion of the crystalline carotenoid to form multilamellar lipid vesicles with the lipid droplets resulting from bile salt and pancreatic lipase action. Nondigested lipids such as sucrose polyesters and some dietary fibers interfere with carotenoid absorption.

Movement of the carotenoid micelle into the mucosal cells of the duodenum appears to occur via passive diffusion but may be species specific (67). An intracellular binding protein was recently identified for b-carotene (68), as was previously reported for a-tocopherol, retinol, and cholecalciferol.

Transport of the carotenoids in plasma occurs exclusively by lipoproteins. b-Carotene, a-carotene, and lycopene are primarily found in low-density lipoproteins (LDLs), as is cholesterol. Some 40 to 50% of the dihydroxy carotenoids (lutein and zeaxanthin) are distributed in HDLs, which is more similar to the distribution pattern of a-tocopherol (35, 67). Differential uptake and retention of different carotenoid species has been confirmed for several tissues. The specificity of tissue distribution may contribute to further

understanding of the physiologic role of carotenoids in biologic processes.

The source of dietary carotenoid affects transport from the intestine to the circulation. In one study, carotenoids were fed to 30 men over a 6-week period; either of two supplementary doses of b-carotene (30 and 12 mg) was compared with dietary intake of carrots, broccoli, or tomato juice. Purified b-carotene produced greater plasma response than did similar quantities of carotenoids provided from the food sources, suggesting a difference in bioavailability or interference by other dietary components (69).

Intestinal absorption, serum clearance, and interactions between b-carotene and lutein have been evaluated in human subjects (70). Individual variance included 9-fold differences for lutein and 6-fold differences for b-carotene. Comparison of individual and combined doses indicated that b-carotene significantly reduced lutein absorption by 40 to 45%, while lutein had mixed results on b-carotene levels in the same patients (half were increased, half decreased).

The role of b-carotene, and other carotenoids, in relation to other antioxidants has been examined. Tocopherols, tocotrienols, ascorbic acid, and carotenoids react with free radicals (specifically, peroxy radicals) and with singlet oxygen (71). *RRR*- α -Tocopherol is the primary peroxy radical scavenger in biologic lipid phases, such as membranes or LDL. Ascorbic acid is present in aqueous compartments, such as cytosol or plasma and other body fluids, and can reduce the tocopheroxy radical. These biologic agents are regenerated via coupling to nonradical reducing systems such as glutathione peroxidase. Carotenoids such as b-carotene, lycopene, and some oxycarotenoids (e.g. zeaxanthin and lutein) can exert antioxidant actions as well as quench singlet oxygen and interact with free radicals.

Carotenoids may also interact with α -tocopherol and ascorbic acid. Using peroxidation of a microsomal membrane suspension as a model, b-carotene was an effective antioxidant at low oxygen tension (150 mm Hg pO₂); however, at higher oxygen tension (760 mm pO₂), b-carotene became a prooxidant (72). Oxygen binds to the carotene radical to form peroxy radicals, which then become part of the propagation reaction stimulating lipid peroxidation. α -Tocopherol prevents the prooxidant effect of b-carotene in a dose-dependent manner.

Recent studies involving b-carotene supplementation of smokers has indicated that there is no "magic bullet." In reviewing these human experiments, Mayne (73) indicated that most carotenoids had either no effect on cancer expression or actually enhanced it in lung and possibly enhanced cardiovascular disease as well. These studies suggest that other carotenoids and other substances in fruits and vegetables may be more protective than b-carotene. However, the enhanced lung cancer in males who smoke heavily may also be related to the high dose of b-carotene provided as a supplement (see [Chapter 33](#) on carotenoids).

To date, dietary levels of the carotenoids have not been shown to cause adverse effects. However, the other dietary phytochemicals cannot be ignored. Since diets rich in fruits and vegetables correlate highly with health benefits, any one phytochemical may not be protective alone but may enhance protection in concert with other dietary

components.

DESIGNING FUNCTIONAL FOODS

The new generation of functional foods represents an opportunity to apply food technology to production of specific functional ingredients by using gene transfer, genetic engineering, bioengineering, cell culture, and specialized breeding programs. Many of these processes have been used over the last decade in an effort to enhance the nutritional quality of the food supply. Examples are breeding meat animals for lower body fat content, altering plant fatty acid content to achieve desired ratios of beneficial fatty acids in the extracted oil, and improving the nutritional quality of plant proteins. These efforts continue as a means of improving the diet without labeling them as functional foods.

The examples of functional food products provided here only represent a larger effort to provide a healthy and safe diet. Some are in existence; others are being developed.

- Soyfoods are food sources containing naturally occurring phytochemicals such as isoflavones that may provide health benefits. In addition, tofu and other products are prepared by calcium coagulation of the protein, thus providing the food products with a ready source of calcium. Potential functional food areas include postmenopausal treatment to prevent osteoporosis, heart disease, or cancer.
- Milk and dairy products provide high-quality protein with a good source of calcium. Partial hydrolysis of casein has yielded phosphorylated peptides that enhance calcium absorption and may also enhance other physiologic responses. These peptides have been added to beverages as natural products that enhance calcium absorption.
- A nutraceutical milk has been developed, replacing fat with β -glucan + Oatrim (USDA) to lower cholesterol. A similar fiber-based drink has been popular in Japan.
- Yogurt and bifidobacteria cultures are promoted as beneficial for intestinal function. One aspect of this claim is the use of live cultures to compete with pathogenic or unfavorable microbial growth in the intestine.
- Lactoferrin, a milk protein, has several unique properties including antimicrobial functions. It has excellent potential of serving as a natural food additive, replacing other chemically derived agents. Use in sausages or canned meats would not only protect the food supply but also provide a biologically active protein that could also diminish gastrointestinal pathogens. Expansion into enteral and parenteral medical products is possible.
- The dairy cow can be used as a bioincubator. If the cow is challenged with specific microorganisms, production of specific gamma globulins is induced. These natural antimicrobial agents can then be isolated from the milk and used in therapeutic situations.
- Modified cheese starter cultures are being created in an effort to find a strain that will diminish cholesterol, reduce fat, and reduce sodium. Using the natural culture to change the cheese composition might well provide a health benefit and produce a product that could be used in a variety of new functional food products.
- Recovery of blood from slaughterhouses has provided an opportunity to isolate

several blood proteins for food use. For example, albumin can be used as an egg white substitute. The crude gamma globulin fraction fed to newborn animals can serve as a natural antimicrobial agent to maintain their growth. Other blood components might also be isolated, purified, and developed into usable products.

- Calcium fortification of beverages, such as orange juice and snack foods, can contribute to prevention of osteoporosis.
- Chewing gum has been used to deliver specific functional ingredients. Inclusion of zinc allows coating of the throat and supposedly decreases colds significantly (42%).
- Chewing gum has been used to deliver oligosaccharides (in Japan) to promote maintenance of beneficial bacteria in the gastrointestinal tract.
- Ready-to-eat breakfast cereals are one of the early functional foods. Whole grains were processed to deliver fiber and nutrient value in a palatable form. Milk and fruit are consumed with the product as well. Today the cereal is coated with vitamins and some minerals, thereby acting as a convenient nutrient delivery system. This medium will most likely provide an early delivery system for other functional food ingredients. "Breakfast" bars might subsequently develop.
- w-3 Fatty acids have been promoted for numerous properties primarily in prevention of CHD. Originally, the products were sold as supplements; namely, oil that had been extracted from fish livers. The same positive effects were provided by eating modest portions of fish two to three times weekly. The primary source of the fish w-3 fatty acids is algae consumed by the fish. A better delivery system is sought to provide general access to this functional food ingredient; for example, an w-3 fatty acid-containing margarine might be developed.
- Growth incubators have been designed for continuous growth of the algae, which are actively recovered for isolation of the w-3 fatty acids.
- Plant species are also being developed through breeding and biotechnology programs that will contain w-3 fatty acids for use in an ever-increasing product category.
- "Designer" oils containing eicosapentanoic acid and docosahexanoic acid can be created. These oils could be mixed with other oils as ingredients to create specialty products.
- Adding cholestyramine to the diet of poultry reduces the cholesterol content of eggs. Eggs with a lower cholesterol level might further enhance the use of these inexpensive, nutritionally rich foods.
- If chickens are fed higher levels of dietary carotenoids, the dietary carotenoids are incorporated into egg yolks. Incorporating phytochemicals in this way essentially transforms eggs into a functional food.

To date, the average consumer has seemed willing to pay a higher price for health foods and supplement products. How much the consumer will consistently pay for these and future "value-added" products remains unknown.

CONCLUSIONS

In view of the consumers' preference for more convenient and healthful foods, the U.S. food industry, armed with improved knowledge of human nutritional and physiologic needs and more sophisticated technology, has developed a wider variety of products.

These include fortified foods, low-fat and low-calorie foods, functional foods (in which the concentrations of one or more food constituents have been manipulated to enhance their contributions to a healthful diet), and, most recently, foods produced by the emerging techniques of biotechnology (cereal grains with greater nutritional value). Taking a raw commodity, such as wheat or soybeans, and making it more nutritious, safer, more convenient, more acceptable, easier to prepare, or more appropriate for the needs of special population groups adds immense value to the commodity.

Techniques of adding value to foods in the future also include improved methods of manufacture, preservation, and packaging. Our ability to prepare high-quality, value-added foods will increase as we learn more about the physical properties of food, develop better technologies to prepare food ingredients, and make greater use of computers and biosensors in food-processing systems. As a result, product quality and safety and process efficiency will improve, while minimizing waste. Beneficial effects on health will depend on integration of a well-balanced diet, good lifestyle habits, environmental factors, and heredity. This context must be stressed; otherwise, the designer-functional foods concept might be misinterpreted as a kind of “magic bullet.”

Better health through improved diet and nutrition, together with the factors just mentioned, can improve the quality of life, enhance productivity, and maximize learning potential. Functional foods can help reduce healthcare costs by preventing or delaying the onset of chronic disease. The food industry should be recognized for its contribution to a healthier, safer diet that benefits everyone.

Human foods contain a wide variety of chemicals with the potential for adverse effects if consumed in excess. These substances may occur naturally in foods, may be added directly or indirectly during food processing, or may contaminate foods as a result of their use in agricultural or livestock production (1). Direct food additives are intentionally added to foods to perform a variety of technical functions. Other chemicals (indirect food additives) are present in foods as a result of their use in some phase of food production, processing, storage, etc. Contaminants such as mercury, lead, arsenic, selenium, and cadmium enter foods or forages via the soil or the marine environment in which they occur naturally or to which they have been added as a result of human agricultural or industrial activities. Proteinase inhibitors, goitrogens, alkaloids, allergens, oxalates,

phytates, and other such substances are natural innate components of particular foods, whereas other compounds (e.g., aflatoxins, paralytic shellfish toxins) are products of the metabolism of fungi, molds, or marine dinoflagellates. Some of these toxicants or contaminants are found in foods that are common in the human diet, whereas others are found only in unusual food sources. As might be expected, the potential hazard to human health posed by such varied compounds ranges from virtually nil to substantial.

FOOD ADDITIVES

Categories

The broadest use of the term *food additive* would include all natural or synthetic, nutritive or nonnutritive, physiologically active or inert chemicals added directly or indirectly to foods. Such a definition is far more inclusive than the legal definition of food additive used in the Food Additive Amendment to the Federal Food, Drug, and Cosmetic Act (FDCA). For regulatory purposes, distinctions are made between *direct* and *indirect* food additives and between food additives and *generally recognized as safe (GRAS) substances* (1). *Direct* food additives include chemicals added to foods during processing to perform a specific function. From a functional viewpoint, examples of direct additives include antioxidants, antispoilage agents, vitamins, minerals, flavoring agents, coloring agents, emulsifiers, stabilizers, bleaching agents, acidulants, nutritive and nonnutritive sweeteners, fat substitutes, and leavening agents; some of these food additives are GRAS substances and others are not. Indirect additives include chemicals that become components of foods indirectly or unintentionally via, for example, contact of food with processing equipment or packaging containers. Food contaminants include substances such as products of molds (e.g., aflatoxins), agricultural chemicals (e.g., pesticide residues), and environmental chemicals (e.g., dioxin and lead).

Safety considerations for food chemicals begin with the axiom that any substance can be toxic if consumed in sufficiently high quantity. The intake necessary to generate a toxic response, however, varies greatly from one substance to another. Some substances, such as sucrose, have such low toxic potential and such a long history of widespread use as direct food additives that they are known as GRAS substances for defined uses, with the amount limited only by good manufacturing practice. Contaminants such as aflatoxins and dioxin have such high toxicity that they are stringently regulated in foods.

Certain categories of food chemicals have generated much interest and debate because of their widespread use, their relatively common occurrence in foods, or the uncertain degree of health risk associated with them. Selected categories that meet these criteria are discussed in detail below.

Nutrients

Interest is growing in the value of treating specific diseases with vitamins and minerals in larger than nutritionally required quantities. Clinical uses of iron, iodine, and fluoride have long been recognized and are well described (2). The safety of vitamins and

minerals, whether used as food ingredients, dietary supplements, or, in some cases, drugs depends on (a) the inherent toxicodynamic potency of the specific compound, (b) its chemical form, (c) total daily intake, (d) the duration and regularity of consumption, and (e) the biologic characteristics of the person consuming the compound ([2](#), [3](#)).

Fat-soluble vitamins are usually considered more toxic than those that are water soluble. This generality is not valid: vitamin E (tocopherols and tocotrienols) is fat soluble but quite nontoxic, and niacin and pyridoxine are water soluble but have demonstrated toxicities. There are large differences in inherent toxic potency within each category.

Vitamin A

Among the vitamins, vitamin A is one of few for which substantial numbers of human cases of intoxication have been reported ([4](#), [5](#) and [6](#)). To assess toxic potential, the total intake of preformed vitamin A from all sources must be considered; these include foods with naturally high levels (e.g., eggs and liver), foods fortified with vitamin A (milk and many ready-to-eat cereals), and nutrient supplements. Although vitamin A toxicity from excessive consumption of liver has been reported, most reports have associated vitamin A toxicity with prolonged consumption of very high potency single-nutrient supplements. The toxicity of vitamin A is discussed in [Chapter 17](#).

Vitamin E

Vitamin E is added to food as a nutrient and as an antioxidant. Vitamin E is considered relatively innocuous, with no side effects at intakes up to 300 IU (201 mg *RRR*- α -tocopherol or its equivalent) per day (20 times the adult male recommended dietary allowance, or RDA) ([7](#), [7a](#)) and with few side effects at intakes of 3200 IU (2148 mg *RRR*- α -tocopherol or its equivalent) per day ([8](#)). Food additive uses of vitamin E are not known to generate intakes near the possibly adverse range. The potential toxicity of vitamin E is discussed in [Chapter 19](#).

Pyridoxine

Water-soluble vitamins usually have been considered virtually nontoxic because of their solubility and rapid excretion. Reports of toxic effects of pyridoxine have proven such assumptions to be unjustified ([6](#)). No toxicity has been reported from food-ingredient uses of pyridoxine. The toxicity of pyridoxine is discussed in [Chapter 24](#).

Vitamin C

Vitamin C is used in foods as a nutrient and as an antioxidant. Intakes resulting from such uses of vitamin C are modest compared with those that can cause adverse effects ([2](#), [7](#), [8](#), [9](#), [10](#), [11](#), [12](#), [13](#), [14](#), [15](#) and [16](#)). Most high intakes result from supplement use ([8](#)). Apparently, vitamin C has low toxicity, or intoxications would be common because of the widespread use of supplements. Although large intakes may cause adverse effects in some individuals, some of the widely reported and often-cited adverse effects

have little apparent basis. High intakes of vitamin C can make a small contribution to oxalate excretion but such intakes are not known to increase the risk of oxalate renal stones. The toxicity of vitamin C is discussed in [Chapter 29](#).

Niacin

Niacin (nicotinic acid or nicotinamide) is nutritionally essential. At high dosages, it is an effective drug for lowering blood cholesterol levels ([17](#), [18](#)), and this use of niacin has led to nearly all cases of niacin toxicity. An error in preparation of niacin-containing bagel dough resulted in accidental overfortification, with undesirable reactions (skin flushing) in consumers ([19](#)). Niacin toxicity is discussed in [Chapter 23](#).

Copper

Copper in single massive doses is among the most inherently toxic of the essential trace elements. At the low levels found naturally in foods or added by food-additive (GRAS substance) uses, dietary copper causes no known toxicity, except in persons with Wilson's disease ([15](#)). In general, humans are less sensitive to copper intoxication than are some animals, such as sheep. The toxicity of specific levels of copper is affected by dietary iron and zinc as well as protein. Copper toxicity is discussed in [Chapter 12](#).

Iron

Iron oxides are used as food-coloring agents. Ferric phosphate and pyrophosphate, ferrous gluconate, lactate, sulfate, and reduced iron are classified as GRAS substances for use as food ingredients in the United States. Absorption of nonheme iron is closely regulated by the intestinal mucosa. Diets high in heme iron or high in promoters of nonheme iron absorption may occasionally lead to iron overload and resulting disease ([20](#), [21](#) and [22](#)). The contribution of dietary iron to iron overload in some individuals is uncertain. Accidental, massive, acute ingestion of multiple units of high-potency iron supplements for adults can result in severe injury or death in young children. To help prevent this problem, the Food and Drug Administration (FDA) has recently required warnings on iron-containing dietary supplement and drug products and on individual unit-dose ("blister") packaging for products with more than 30 mg of iron per dosage unit. The toxicity of iron is discussed in [Chapter 10](#).

Zinc

Several zinc compounds are used as food additives. Prophylactic supplementation of poultry and livestock feeds with zinc is common. Individual tolerances for zinc sulfate vary widely ([3](#)). Chronic ingestion of large doses of supplements may have adverse effects, but no toxicity seems to have resulted from ingestion of the moderate levels from food-additive uses ([3](#), [23](#), [24](#)). Zinc toxicity is discussed in [Chapter 11](#).

Selenium

Selenium is one of the most toxic of the essential elements. Intoxications have been

caused by incorrectly formulated supplements and may be caused by high dietary intakes in some geographic areas ([15](#), [24](#), [25](#) and [26](#)). There are currently no approved selenium compounds for use as food additives in human foods in the United States, although the FDA has set a reference daily intake as a standard for food labeling ([27](#)). The toxicity of selenium is discussed in detail in [Chapter 14](#).

Artificial Sweeteners

Much of the use of nonnutritive sweeteners is prompted by the accompanying reductions in calorie intake. Also, some consumers may be motivated by the absence of a procariogenic effect. Safety concerns center around possible carcinogenicity of some artificial sweeteners and neurologic effects of others.

Saccharin

Saccharin is 300 to 500 times sweeter than sucrose. There is no apparent tissue accumulation or metabolism, and ingested saccharin is excreted unchanged in the feces or urine. Mutagenicity studies have been all negative. Carcinogenicity studies in animals have produced positive results in certain experimental designs ([28](#), [29](#)). Saccharin produced bladder cancer in two-generation studies in which exposure began in utero by dietary treatment of the pregnant rat and continued through the diet for 2 years following birth. The doses used ranged up to 7.5% of the diet. No adverse effects have been observed with less than 1% dietary saccharin. Epidemiologic studies have given relative risk ratios close to unity (no significant risk).

Cyclamate

The metabolism of cyclamate depends on the intestinal microflora. It is excreted largely unaltered in test animals treated for the first time. Pretreatment with cyclamate, however, may alter the microflora by selection of microbes capable of converting cyclamate to cyclohexylamine, dicyclohexylamine, and cyclohexanone. These metabolites have been found in rats, dogs, guinea pigs, monkeys, and humans. The results of toxicity studies with cyclamate have been largely negative ([27](#), [29](#)). In the rat, bladder tumors have occurred when cyclamate and saccharin were fed in a 10:1 ratio in conjunction with cyclohexylamine. Also, dietary cyclamate appears to promote bladder cancer initiated by intravenous doses of methylnitrosourea (MNU) in the rat. The results of carcinogenicity studies in mice, dogs, hamsters, and primates have been negative. The FDA banned food use of cyclamate in 1969.

Aspartame

Considering its structure and constituent parts, there are many hypothetical possibilities for adverse effects by aspartame. Extensive investigation has not shown side effects from aspartame ([28](#), [29](#)), but research and further interpretation of possible adverse effects continues. Aspartame is metabolized to several products, including phenylalanine and aspartic acid. Thus, aspartame is a very low calorie sweetener, not a zero-calorie sweetener. Diketopiperazine occurs as a contaminant in aspartame, at

about 1%. Since aspartame is metabolized to phenylalanine, it carries a risk for persons with phenylketonuria (PKU) proportional to consumption of equivalent amounts of phenylalanine. Claims of risk for other consumers, however, have not been substantiated. Such claims relate mainly to purported adverse neurologic effects of phenylalanine or aspartame. Phenylalanine is a precursor of the neuroactive substances norepinephrine and epinephrine. Adverse neurologic effects might logically be related to overproduction of either or both of these compounds. Concrete evidence for such effects, however, has not been found.

Fat Substitutes

Fat substitutes are substances that have one or more of the technical effects of fat in foods but are not metabolized as fats and thus may be used in low-fat foods and diets. At present, two types of fat substitutes have been approved for use in human food: (a) microparticulated proteins that have the functional properties of fat (viscosity and organoleptic properties) only at low temperatures and (b) heat-stable sucrose polyesters that are not hydrolyzed by digestive enzymes and thus make no contribution to dietary (digestible) fat.

Microparticulated Proteins

A microparticulated protein product (*Simplese*) has been affirmed by FDA as a GRAS ingredient for use as a fat substitute in low temperature products such as ice cream (30). The proteins come from egg or milk or both and can be digested and metabolized as dietary protein. The microparticulation process does not provide heat stability; thus, this fat substitute may be used as a fat substitute in low-fat foods and diets but not in cooking and frying. Because this fat substitute is composed of microparticulated edible proteins, safety questions mainly relate to possible antigenicity and allergenicity. Individuals who consumed a microparticulated product with protein from both eggs and milk had normal clinical signs and chemistries (31) and no evidence of immunologic sensitivity to “novel” protein fractions (32).

Sucrose Polyesters

Olestra is the common name for a mixture of sucrose polyesters used as a food additive. The additive may have six, seven, or eight fatty acid molecules esterified to the hydroxy groups of sucrose. The fatty acids used are commonly found in foods (as triacylglycerols). The chain length and degree of unsaturation of the fatty acids affects the physical characteristics of the product. *Olestra* has organoleptic properties similar to those of ordinary lipids. It is heat-stable and is not hydrolyzed or otherwise metabolized. In food products it behaves as a dietary fat, but it is not digested and thus yields no fatty acids or energy. From the viewpoint of nutritional effects, it is not a dietary fat.

Toxicologic research has shown no systemic uptake, storage, or direct toxicologic effects of *olestra*. Sucrose polyesters present a different set of safety issues than most food additives. Since *olestra* is not digested or absorbed, it raises unique issues for a food additive. Because it becomes an ever-larger fraction of intestinal contents as it passes through the intestine, it raises safety issues related to effects on the intestine

and its functions, including possible interference with normal digestion and absorption.

After extensive review of a petition for food-additive approval of olestra, the FDA approved use of olestra as a replacement for fats and oils in certain types of foods (33). The data evaluated came from studies on absorption, distribution, metabolism, and elimination; genetic toxicity; animal toxicity; effects on absorption of fat-soluble drugs; effects on gastrointestinal health and function; and nutritional studies. The potentially adverse effects observed included antinutritive effects on the fat-soluble vitamins and carotenoids. To compensate for these effects, the FDA's approval required addition of the following vitamins to foods containing olestra (quantity per gram of olestra): 1.9 mg a-tocopherol, 51 µg retinol equivalents of vitamin A as retinyl acetate or retinyl palmitate, 12 IU vitamin D, and 8 µg vitamin K₁. The FDA determined that current scientific evidence does not justify or indicate a need for fortifying olestra-containing foods with any carotenoid. Although consumption of olestra lowered the serum concentration of b-carotene more than that of the fat-soluble vitamins, the decision not to require fortification of olestra-containing foods was based on the absence of recognized direct benefits from consumption of carotenoids.

Based on review by their own scientists and with the advice of outside experts, the FDA found that all potentially adverse effects of olestra could be ameliorated by the specified additions of fat-soluble vitamins to food that contain olestra and concluded that with these additions, the required "reasonable certainty of no harm" had been demonstrated.

Food-Color Additives

Food colorants include both natural substances and synthetic compounds (34). Natural substances that have been used as food colorants include carmine, paprika, saffron, and turmeric. When used to impart color, certain nutrients (e.g., b-carotene and riboflavin) are regarded as color additives, as are fruit or vegetable juices, carrot oil, and beet extract. Synthetic compounds permitted for food use under good manufacturing practices and subject to certification by the FDA include FD&C (Food, Drug & Cosmetic Act) Yellow No. 5 (tartrazine), Red No. 3 (erythrosine), Red No. 40, Blue No. 1, and Citrus Red No. 2. Provisionally listed colors include FD&C Blue No. 2, Yellow No. 6, and Green No. 3.

The safety evaluation and history of use and regulation for food colors are complex (34). For several food colors, such as FD&C Red No. 2 (amaranth) and FD&C Red No. 3, the crucial safety issue is possible carcinogenicity. Use of FD&C Red No. 2 was banned because concerns about carcinogenicity were not addressed by available data. For FD&C Red No. 3 (a synthetic compound with a high content of iodine), the possibility of indirect carcinogenicity has provoked much controversy about whether this should be sufficient reason to ban it from use in food. Erythrosine causes hypertrophy, hyperplasia, adenomas, and carcinomas of the thyroid glands. These changes may be associated with secondary (indirect) oncogenesis. Whether hypertrophy and hyperplasia from any cause in any organ would carry risk for increased tumors remains an unanswered question. The FDA concluded there were insufficient data to determine that erythrosine-induced carcinogenicity was caused by an indirect mechanism.

Synthetic food colors and some flavoring agents such as methyl salicylate (oil of wintergreen) have been alleged to cause hyperactivity in some children (35). This concept, promoted by Feingold in 1975, stimulated research in hyperactivity in both humans and animals. Various chemical insults to the central nervous system can result in hyperactivity in brain-damaged animals. Some dyes (e.g., FD&C Red No. 3) inhibit uptake of neurotransmitters in rat striatal synaptosomes, but this effect may be nonspecific and may not account for any selective behavioral effects. The ease with which hyperactivity can be induced in brain-damaged rats suggests that this model should not be used to evaluate the hyperactive child. Clinical trials of salicylates and other food additives in children have yielded little or no information concerning the cause of hyperactivity or therapy for it.

The viewpoint that the only function of food colors is to add aesthetic appeal overlooks the psychologic value of food color in diet therapy. Alteration of the average American diet to meet the dietary goals in the *Surgeon General's Report on Nutrition and Health* (35a) is a difficult objective. Food colors may have a positive role in di-etary management (35), but few argue that this role is essential.

Preservatives

Chemical preservatives include both antioxidants and antimicrobial agents. Antioxidants are used to inhibit changes in flavor, nutritive value, and appearance that result from oxidation of fatty acids, amino acids, and vitamins. Antimicrobial agents are used to prevent the growth of bacteria, yeasts, and molds that may generate food-borne intoxications or infections or cause undesirable alterations in flavor, appearance, or nutritive value. Although refrigeration obviates the need for some preservatives, it is comparatively expensive and is not available under many circumstances. Food irradiation as an alternative to chemical preservatives has received relatively little acceptance because of technical requirements and public controversy.

Antioxidants

Common antioxidant food additives include ascorbic acid, ascorbyl palmitate, tocopherols, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), ethoxyquin, propyl gallate, and *t*-butylhydroquinone (TBHQ). The common antimicrobial agents nitrite and sulfite have antioxidant activity as well as other properties.

BHA and BHT. Considerable controversy has existed about the safety of BHA and BHT. Both are lipid-soluble antioxidants capable of inducing increased concentrations and activities of several liver enzymes involved in detoxifying foreign compounds. Each of these roles, antioxidant and inducing agent, can provide protection against chemically induced carcinogenesis under certain experimental conditions.

Antioxidants can protect against the reactivity of electrophilic chemicals that may bind to DNA and cause mutations and initiate carcinogenesis. Many carcinogens are actually procarcinogens that are metabolized to electrophilic carcinogens. Some carcinogens

are electrophilic and do not require metabolic activation. Inducers of liver enzymes that metabolize foreign compounds may have either anticarcinogenic or procarcinogenic activities, depending on the dose and timing in relation to exposure to the initiating carcinogen. If treatment with the inducer precedes treatment with the carcinogen, the resulting induction usually results in more-rapid metabolism of the carcinogen to inactive forms and decreased net carcinogenicity. If exposure to the carcinogen precedes treatment with high doses of the inducing agent, the resulting hyperplasia and hypertrophy can promote the carcinogenesis caused by the carcinogen. With certain carcinogens, late treatment with high doses of inducing antioxidants may inhibit carcinogenesis.

BHA treatment alone in high doses (2% of the diet) has produced hyperplasia, papilloma, and squamous cell carcinoma in the forestomachs of rats and hamsters (36). No evidence of carcinogenicity was found when BHT was included in diets of male and female mice at a level of 0.5% in one study (36). Both BHA and BHT protect against the early neoplastic changes in the liver caused by diethylnitrosourea.

The importance of early administration of BHA or BHT in studies of their potential anticarcinogenic actions is well established (37, 38). It is widely thought that lung cancer requires two decades for development from the first initiation events to clinically obvious cancer. Indeed, with the most powerful known protective action against lung cancer, cessation of smoking, decreases in risk become significant only over a 10- to 15-year period (39).

The relationships between antioxidants and carcinogenesis are complex, and no generalization can be completely accurate. The effect of antioxidants on cancer depend on the carcinogen, organ and tumor types, and timing and dose of both antioxidant and carcinogen.

Nitrite

Sodium nitrite is used as an antimicrobial preservative, a flavoring agent, and a color-fixing agent (via its reactivity with myoglobin). Nitrite is effective in preventing growth of *Clostridium botulinum*, thereby decreasing the risk of botulism.

Nitrite reacts with secondary amines and amides to form the corresponding N-nitroso derivatives (40, 41). Many but not all N-nitroso compounds are carcinogenic. Ascorbic acid and other reducing agents inhibit the nitrosation reactions of nitrite; ascorbic acid is an especially effective inhibitor in the acid environment of the stomach where much nitrosation takes place. Some nitrosamines are formed in foods during processing, but the largest part of nitrosamine exposure occurs via the nitrosation reactions in the stomach. Food-additive sources of nitrite are significant, but a substantial portion of total nitrite exposure comes from bacterial reduction of nitrate to nitrite in the mouth. Food nitrate, principally from vegetables, is absorbed and then slowly released into saliva. This slow reconsumption of nitrate allows ample time for reduction to nitrite in the mouth and subsequent nitrosation reactions in the stomach. Safety evaluation of nitrite as a food additive must take into account this major additional endogenous source.

The question of possible direct carcinogenicity by nitrite has been addressed through studies of nitrite “alone.” Biologic systems, however, always contain a variety of amines, and any studies comparing the carcinogenicity of nitrite with that of nitrosamines must take this into account.

Nitrite is capable of causing some toxic reactions not related to carcinogenesis, but the dose required is relatively large. Persons chronically exposed to large amounts of nitrite may develop methemoglobinemia, but this problem is not common.

Sulfite and Sulfur Dioxide

Sulfur dioxide and its salts are commonly used as inhibitors of enzymatic and nonenzymatic browning, broad-spectrum antimicrobial agents, dough conditioners, bleaching agents for certain products, and antioxidants. Sulfites are very reactive, and consequently little free sulfite remains in foods. Sulfites have been used for centuries with little evidence of adverse reactions in consumers.

Asthma is the most common and severe adverse reaction attributed to sulfite ingestion (42, 43). An association has been recognized between sulfite ingestion and the onset of asthma in sensitive individuals. To date, more than 20 deaths have been attributed to this idiosyncratic reaction. Sensitive individuals are more likely to respond to acidified sulfited beverages than to sulfited foods, perhaps because sulfur dioxide is volatilized in the beverages. Challenge tests indicate that only 1 to 2% of asthmatics are sensitive to sulfite. In one large test, none of the mild asthmatics was sensitive to sulfite.

The pathogenesis of sulfite-induced asthma is not understood. The mechanisms may involve IgE-mediated reactions, hyperreactivity to inhaled sulfur dioxide, or sulfite oxidase deficiency. Sulfite-sensitive individuals are especially sensitive to sulfite-containing acidified beverages and sulfite-treated lettuce. Lettuce contains a preponderance of free sulfite. Regulations limiting sulfite concentrations and labeling requirements have been strengthened in recent years.

Toxicity studies in animals indicate rapid metabolism to sulfate by sulfite oxidase and excretion. At high concentrations in vitro, sulfite causes some mutations and sister chromatid exchanges in Chinese hamster ovary cells. At high doses (more than 600 mg/kg), there is no evidence of sulfite genotoxicity in Chinese hamsters.

GRAS Substances

The Food, Drug and Cosmetic Act has been much amended since its passage in 1938 (44). One of these amendments, the Food Additives Amendment of 1958, used the phrase “generally recognized as safe,” from which the term *GRAS* arose. The amendment required prior approval from the FDA for all substances intended to be added to foods. When this amendment was passed, several hundred substances that were previously sanctioned or that were already in common use as food additives were exempted from its requirements. A listing of “Substances Generally Recognized as

Safe” for their intended use was first published in the early 1960s. Among the several hundred substances on the diverse GRAS list were a variety of nutrients, general purpose food chemicals, emulsifying agents, anticaking agents, stabilizers, spices, and flavorings.

The Food Additives Amendment of 1958 exempted GRAS substances from the premarketing clearance required for food additives; thus GRAS substances are not officially food additives. In presuming GRAS substances to be safe when used in the amounts and manner intended and in accordance with good manufacturing practice, the Food Additives Amendment effectively negated the need for the FDA to require a demonstration of safety before these ingredients could be used in food. Consequently, the 1958 amendment required the FDA to demonstrate that a GRAS substance was no longer generally recognized as safe before its use in food could be prohibited. In 1972, a Select Committee on GRAS Substances, in coordination with the FDA and the Federation of American Societies for Experimental Biology (FASEB) reevaluated the safety data available on GRAS substances. The committee supported continued GRAS status for many substances, suggested further studies for some, and rescinded the GRAS status for others. Because the safety and toxic potential of any substance depends on intake, the GRAS reviews have prompted considerable study of the consumption levels for many substances in food.

CONTAMINANTS

Food contaminants may include minerals and heavy metals, mycotoxins, shellfish toxins, pesticide residues, and environmental organic chemicals.

Minerals and Heavy Metals

A number of minerals present in foods are of concern because of their potential toxicity. Because plant materials are the primary source of minerals for both animals and humans, the complex factors influencing the mineral content of plants are also important as major determinants of dietary intakes of certain elements. The literature relating to the metabolism of essential and nonessential minerals, the interrelationships among environmental factors and plant and seafood content of minerals, and the toxic and carcinogenic effects of excessive mineral intake is extensive ([45](#), [46](#) and [47](#)). Only a few examples of toxicities related to high levels of specific minerals in foods are described here.

Arsenic

Arsenic (As) is ubiquitous in the environment and occurs in inorganic and organic compounds in the trivalent or pentavalent form ([48](#), [49](#)). Levels of arsenic in most foods are low (normally below 0.25 mg/kg) ([50](#)). Meats, poultry, and fish contribute most of the arsenic consumed by humans. Analysis of a special diet excluding seafood gave a calculated average intake of 0.04 mg As/day whereas a more typical diet contributed 0.19 mg As/day ([51](#)). Arsenic uptake by plants is related to the type of plant, chemical composition of the soil, and concentration of soluble arsenic in the soil. Arsenic

concentrations in marine organisms and seaweed, in which arsenic occurs in a variety of organic methylated forms, are generally much higher than those in other foods. These methylated compounds are considerably less toxic than inorganic arsenic compounds. Symptoms from acute and chronic arsenic toxicity from various arsenic compounds have been reviewed by Anke (48) and Nielsen (49). Carcinogenic effects of arsenic were recognized more than 100 years ago through examination of workers in the smelting industry. It has been suggested that arsenic alone cannot produce malignant changes and should therefore be considered a cocarcinogen (52, 53).

Selenium

Selenium (Se) is among the most toxic of the essential trace elements. It is ubiquitous in the environment but is unevenly distributed over the earth's surface. Areas of both selenium deficiency (e.g., New Zealand and parts of China) and selenium excess (e.g., North Dakota and parts of China) are now recognized. "Accumulator" (or "converter") plants play major roles in determining the effects of soil conditions on selenium availability to livestock in selenium-rich areas. These plants absorb selenium from soils containing selenium in forms that are relatively unavailable to other plants. The absorbed selenium is converted to organic forms that are returned to the soil and then become available to other plants. Cereal grains may accumulate high levels of selenium in selenium-rich areas. Excess selenium intake due to consumption of seleniferous plants by animals produces a wide range of adverse effects (54). Well-defined symptoms and lesions following acute or chronic ingestion of high-selenium forages are now recognized. Chronic toxicity signs in livestock include cirrhosis, lameness, hoof malformations, hair loss, and emaciation. In laboratory animals, the signs most commonly include cirrhosis. The minimum dietary level of selenium recognized to produce adverse effects in farm animals is 4 to 5 µg/g dry weight of diet.

The discovery of selenium as the cause of the "blind stagger" syndrome and "alkali disease" in livestock led to concerns about possible deleterious effects of human dietary overexposure to selenium. Liver dysfunction resulting from excessive selenium intake was proposed as a possible cause of a high incidence of gastrointestinal disturbances and skin discolorations reported in a group of people living in a high-selenium area of North Dakota (55, 56).

Endemic human selenium intoxication has been reported in a high-selenium area of China (57). This syndrome involves adverse effects on nails, skin, the nervous system, and teeth. The adverse effects occurred in susceptible persons with intakes of 910 µg/day or more. No adverse effects have been associated with lower levels, but the ratio of plasma selenium to erythrocyte selenium increases with dietary intakes of 750 µg/day or more (58). Human surveys in seleniferous areas of the United States have failed to find any signs of selenium intoxication with intakes up to slightly more than 700 µg/day (59). Because the chemical forms of selenium in foods grown in seleniferous areas are not known, the human data on adverse effects from chronically high intakes apply only to total dietary selenium and not to any specific form. During the peak prevalence years of 1961 to 1964, morbidity approached 50% in the most severely affected Chinese villages. No adverse effects were observed, however, in the 8- to

10-year clinical trial at daily supplemental intakes of 200 µg selenium in yeast (60, 61).

Signs and symptoms similar to those in China have been reported among persons living in a seleniferous area of Venezuela (62).

Mercury

With the exception of fish, food products generally contain inorganic mercury (Hg) at levels below 50 ng/g. Fish can contain 10 to 1500 ng/g in the form of methyl mercury (63). Even higher levels can be found in fish following ingestion of methylmercury formed from mercury released into lakes from chloroalkali plants (64). The hazardous nature of residues of mercury in fish is well recognized. Recent episodes of serious poisonings include those of Minamata Bay (1953 to 1960) (65) and the Niigata area (1965) in Japan. In 1971 to 1972, ingestion of bread prepared from alkyl mercury-treated wheat seed caused widespread mercury intoxication in Iraq. These acute poisonings were widely publicized. However, chronic effects of low-level exposure are harder to identify and evaluate. "Late-onset" symptoms have been recognized in individuals not thought to have been affected in the original poisonings in the Niigata area in Japan, for example, which raises concern about injuries that are not detectable using current procedures and about determination of "lowest-effect" levels. Marketing limits of 0.4 to 1.0 mg/kg for mercury in fish have been established in several countries including the United States, Canada, Finland, Sweden, and Japan.

Lead

Lead is a toxic element but cannot be completely avoided because it occurs naturally in soil and foods. Exposure from lead in water, food, and insecticides has decreased since antiquity, but exposure from paints, automobile exhaust, and workplace environment increased in this century (66). In recent decades, concern about lead exposure and toxicity caused uses to decrease and blood levels to decline (67). Entry of lead into the food chain depends strongly on human activities. Significant and irreducible background amounts, however, originate from the lead in the earth's crust and soil.

The concentration of lead in a food depends on the type of food and the human activities in the geographic location of its origin. Bread, cereals, and beverages account for about 35% of the daily intake of lead, with the remainder coming from a wide variety of other foods; daily ingestions of lead are thought to range from 9 to 278 µg for children and 20 to 282 µg for adults (67). The concentration of lead in milk may vary as much as tenfold across geographic locations (68). The lead content of calcium dietary supplements also varies widely, with bone meal usually having higher concentrations than other sources (69).

Lead is poorly absorbed, but high blood levels can cause a variety of toxic effects including adverse neurologic, neurobehavioral, and developmental effects, decreased erythrocyte life span, inhibition of heme synthesis, renal tubular dysfunction, and increased blood pressure (67).

Because most dietary lead occurs as a divalent cation, this element strongly interacts with chemically similar nutrients such as calcium and iron (70, 71). Much of the absorbed lead deposits in bone, perhaps replacing calcium in the mineral matrix. Accordingly, increased dietary concentrations of calcium or iron inhibit intestinal absorption of lead, thereby limiting its toxic potential. Moreover, low calcium intake would be expected to cause mobilization of lead as well as calcium from the skeleton; thus, low dietary calcium levels may increase the risk of lead toxicity, and high calcium intakes may decrease the risk, even if the better calcium sources contain more lead than other foods in the diet.

Cadmium

Cadmium (Cd) is a highly toxic element that accumulates in biologic systems and has a long half-life. There is increasing concern regarding the potential for renal damage from long-term, low-level exposure to cadmium. The kidney is a critical target organ for cadmium accumulation, and the half-life of cadmium in this tissue is about 30 years (72). Food is one of the principal environmental sources of cadmium. Cadmium in soil can be increased by application of sewage sludge and phosphatidic fertilizers, all of which contain some cadmium. Wheat and the edible portions of fruits and vegetables grown on soil heavily fertilized with superphosphate have higher levels of cadmium than those grown on less heavily treated soil. Atmospheric cadmium contamination may also increase the cadmium content of foods. Daily intake of 25 to 60 µg of cadmium for a 70-kg individual has been estimated for typical diets in Europe and the United States (73). Cadmium accumulates primarily in the kidney, liver, lungs, and pancreas; the kidney is the organ most sensitive to long-term, low-level exposures.

Cadmium toxicity results in a variety of syndromes. Effects include kidney dysfunction, hypertension, hepatic injury, reproductive toxicity, lung damage after inhalation exposure, and bone effects (72, 74). Itai-itai (“ouch-ouch”) disease, first reported in Japan in 1955, resulted from industrial contamination of the food and water supply (75). The poisoning occurred primarily in postmenopausal, multiparous women who consumed diets poor in calcium and protein. Symptoms included bone pain, lumbago, and a ducklike gait. Pathologic changes associated with the progressive disease included osteomalacia, osteoporosis, and renal atrophy and degeneration. The disease appeared to be caused by a combination of low dietary calcium, mobilization of bone calcium during pregnancy, and a cadmium-induced calciuria. Cadmium-induced calciuria and radiologic signs of osteomalacia have been reported in occupationally exposed workers (76). The bone changes caused by ingestion of cadmium in rats are more severe when the animals are fed calcium-deficient diets low in protein (77).

Ikeda (1992) reported the results of cadmium analysis of more than 2000 blood samples and about 1000 24-hour total food duplicates collected in nonpolluted regions of Japan between 1977 and 1981 (78). The levels of cadmium in blood correlated significantly with levels of cadmium in foods when results were compared on a regional basis. Boiled rice was the major food source of cadmium. A preliminary follow-up in 1989 suggested a decrease of about 30% in blood cadmium levels among the Japanese population. The decrease may have been due to a reduction in the cadmium concentration in rice and a

decreased rice intake.

Louekari (1992) has reviewed the strengths and weaknesses of methods used to estimate dietary intake of cadmium, emphasizing the importance of representative sampling of foods, quality assurance of analytical methods, selection of adequate food consumption data, and combining food consumption data with concentrations of heavy metals in foods. He also emphasized the importance of intake estimations for possible risk groups such as children, those living in contaminated areas, lactating women, and smokers (79).

Information on background levels of elements in U.S. shellfish is of interest since shellfish may be collected from chemically contaminated waters and the contaminants may enter into the commercial food chain; shellfish can accumulate toxic elements from environments contaminated from natural or industrial sources (80). Background levels of elements can also be used as baselines for future comparisons. A recently reported FDA survey provided the agency with extensive baseline data on cadmium, lead, and 19 other elements in shellfish (80). The FDA continues to monitor shellfish and other types of seafood for elements to identify potential public health hazards.

Pesticides

The most common types of pesticides are fungicides, herbicides, insecticides, and rodenticides. Pesticides may also be classified by chemical type, such as organochlorine, organophosphorus, pyrethrins, and carbamates.

Pesticides are, by definition, toxic to living organisms, which raises the possibility that nontarget organisms, including humans, will also be harmed (80, 81, 82 and 83). Pesticides are deliberately introduced into the environment, in contrast to other types of environmental and food contaminants. Humans may be exposed through air, water, or direct contact, as well as through residues in foods.

Selective Exposure

Because it is not usually feasible to administer a pesticide directly to organisms of the pest species, the pesticide is applied to the particular part of the environment that a pest is likely to occupy. Most pesticides are quite unstable in the environment, thereby allowing application of the substance at higher concentrations when the pest is likely to be present and at much lower concentrations when the food is harvested (84). This strategy is highly effective for most pesticides in current use. In contrast, the organochlorine insecticides, such as dichlorodiphenyltrichloroethane (DDT) and lindane, are environmentally persistent pesticides for which this strategy is not very successful. For these substances, selective exposure is helpful but not sufficient to prevent harm to nontarget species.

Selective Toxicity

Selective toxicity may be based on species differences in either toxicokinetic or

toxicodynamic characteristics, or both. These changes influence the distribution of the substance into tissues, rate of elimination, type of toxic reactivity, and toxicodynamic potency of the molecule (81, 82).

When humans or other inadvertently exposed species have responsive systems or receptors essentially identical to those for the pesticide in the target species, the relationships of toxicity and potency to the effective exposure (tissue concentration) may be similar, even though responsiveness to the total exposure may differ. Toxicity in humans may also involve effects on structures and systems not found in the target species.

Most pesticides are active as the parent compound; metabolic changes generally result in detoxification. Phase I metabolism usually introduces functional groups into the pesticide molecule or exposes existing functional groups. Toxicity and potency may or may not be decreased, but responsiveness to phase II metabolism is dramatically increased. Phase II (i.e., conjugation with another substance) ordinarily causes markedly decreased reactivity and large increases in water solubility and rate of excretion.

The difference between pest species and humans or other nontarget species in rate of metabolism of the pesticide chemical is a common basis of selective toxicity. Rapid metabolism in most instances decreases toxic potency. If the rate of metabolism is high enough, the compound may never reach the threshold toxic concentration in the exposed organism. In general, organophosphorus insecticides are hydrolyzed much faster by mammals than by insects, causing mammals to be relatively resistant to these toxicants. Some compounds such as aldicarb are exceptions to this generalization.

Because of resistance to metabolic degradation and excretion some substances bioaccumulate. These substances may also be resistant to environmental breakdown, that is, resistant to light, heat, water, oxygen, and other factors. Also, highly bioaccumulative substances usually are lipid soluble and readily absorbed by organisms ingesting them. Bioaccumulation involves gradual increases in the concentration of a substance in an organism with continuing exposure. This is reflected in magnification of the concentration at succeeding steps in the food chain. The environmental behavior of DDT is an excellent example of bioaccumulation and food-chain magnification with resulting toxicity in the species at the top of the exposed food chain.

Acute Effects. Organophosphate and carbamate insecticides produce their lethal effects in insects by inhibiting acetylcholine esterase, an enzyme essential to the function of nerves that use the neurotransmitter acetylcholine (62, 63). Humans and other mammals also have essential nerve functions based on acetylcholine; thus, organophosphorus and carbamate pesticides are potent toxicants in these nontarget species. Toxicity in humans is limited by selective (lower) exposure and by more-rapid metabolism, not by any inherent resistance to these pesticides. Both types of cholinesterase-inhibiting pesticides can be powerful acute toxicants in vertebrate species. The most important difference between organophosphorus and carbamate pesticides is the rate at which the phosphoryl and carbamoyl groups are released from the active site of acetylcholine esterase. The release step, which occurs rapidly

(milliseconds) with the natural substrate acetylcholine, proceeds at a moderate rate (seconds or minutes) for carbamates, but very slowly (hours or days) for organophosphorus compounds. Thus, carbamate poisoning is a reversible inhibition, whereas organophosphorus poisoning is essentially irreversible, even though both result from competitive inhibition of the active center of the enzyme. Although a crisis phase in poisoning may be reached rapidly following exposure to a high level of either type of insecticide, the more-rapid recovery of acetylcholine esterase from carbamate inhibition makes this type of poisoning more survivable.

Pyrethroid compounds, notably the natural pyrethrum extracted from certain chrysanthemums, have multiple toxic actions (81). The effect on neuron Na^+ channels is similar to that of DDT, and ATPases and Cl^- uptake are inhibited in much the same way as they are by the organochlorine insecticides.

A wide variety of other compounds have been used as pesticides, and they produce numerous types of toxicity. In general, the herbicides, being designed for toxicity to plants, are relatively nontoxic to humans. Notable exceptions are paraquat and diquat, which have high toxic potency in mammals (LD_{50} values of 100 to 250 mg/kg).

The practical importance of food-borne pesticides as a cause of acute toxicity seems to be limited to occasional heavy contamination related to a spill, not to the usual residue levels in foods.

Neurotoxicity. Chronic neurotoxicity of gradually increasing severity may be caused by continued exposure to pesticides. Also, many pesticides causing chronic toxicity are bioaccumulative and can be accumulated in nerve and adipose tissues. If dietary energy intake is suddenly reduced to a level substantially below expenditures, mobilization of energy stores from body fat may increase blood levels of stored fat-soluble pesticides enough to cause toxicity (85).

Gradual accumulation of alkylmercury compounds in nerve tissue may cause gradual-onset central nervous system toxicity with symptoms of tremors, incoordination, paralysis, and behavioral/emotional changes. For example, ingestion of wheat treated with a methylmercury fungicide resulted in an outbreak of methylmercury poisoning among Iraqi farmers (81).

Certain organophosphorus compounds cause a delayed toxic response (82). In experimental animals, the toxic symptoms are irreversible and may start 10 days or more after a single dose of certain phenylphosphonothioates. The mechanism of this delayed neurotoxicity is uncertain but may involve inhibition of the synthesis of microtubules in neurons. Thus, neurotoxicity is delayed until deficits in microtubule replacement impair function.

The significance of pesticide residues in foods as a cause of neurotoxicity is intensely debated, but the preponderance of available scientific evidence indicates that they are not a problem for most individuals. Some individuals are claimed to be extremely

sensitive to such effects, but evidence of such susceptibility is lacking.

Mutagenicity. Many pesticides are mutagenic in various tests (81). Mechanisms of these changes in genetic information include DNA alkylation, base substitution, intercalation of the mutagen molecule into the DNA helix, chromosome breakage, and chromosome cross-linking. Some pesticides are directly mutagenic, whereas others require activation through formation of a derivative that reacts with nucleic acids. Although mutagenesis itself may be considered a toxic effect, a major concern is the possibility that carcinogenesis may result from exposure to a mutagen. The significance, if any, of mutagenesis caused by pesticide residues in food and the clinical importance of such mutagenicity are not known.

Carcinogenicity. Some organochlorine pesticides cause malignant tumors in mammals (81, 82, 86). Carcinogenic nitrosamine contaminants occur in nitroaniline herbicides. The potent carcinogen ethylene thiourea is a degradation product of the ethylene bisdithiocarbamate fungicides. The pesticides mirex, aminotriazole, and daminozide (Alar) produce positive results in multiple carcinogenesis test systems. The degree of threat to the public health generated by exposure to carcinogenic pesticides in foods is the subject of continuing debate over both exposure estimates and risk assessment methods.

Teratogenicity. Adverse effects on embryonic and fetal development caused by maternal exposure have been experimentally demonstrated for a wide variety of pesticides (81, 82). The chlorinated hydrocarbons mirex, Kepone, and DDT have teratogenic activity. Some organophosphorus pesticides, notably dimethoate and monocrotophos, have some teratogenic potency. The teratogenic effects of pesticides include impaired growth, neurologic defects, biochemical abnormalities, and deformed structures of the skeleton, skull, and viscera. Pesticide residues in foods are not known to cause such effects.

Reproductive Toxicity. Adverse reproductive effects, other than teratogenesis, can result from high exposure to some pesticides. The effects include fetotoxicity, decreased female fertility, lowered sperm count, and decreased male libido (81, 82). Some chlorinated hydrocarbons or related compounds, such as methoxychlor and *o,p'*-DDT, have estrogenic activity, thereby altering reproduction. The fumigant dibromochloropropane (DBCP) has caused spermatogenesis to fail in factory workers and experimental animals. A variety of other toxic reproductive effects may be caused by a few pesticides. Reproductive problems associated with pesticides relate to pesticide workers and have not been associated with the pesticide residues in foods.

Behavioral Toxicity. As might be expected for substances that are neurotoxic or concentrated in nerve tissue, many pesticides can cause behavioral alterations (81). Very low levels of exposure can cause decreased learning and memory functions, hyperactivity, altered aggressive and defensive behaviors, and other behavioral changes. Two main issues are of importance: (a) alterations in higher-order functions such as memory and learning and (b) the extremely low dose threshold for behavioral effects.

Impairments in physical behavioral tests such as swimming, walking, and balance seem directly attributable to neurotoxic effects. The importance of behavioral effects in evaluating the safety of pesticide residues at levels commonly found in foods is not established.

Enzyme Induction. Pesticides can induce increased enzyme activity in many species. Different types of enzymes are affected, but most commonly affected are those involved in detoxification processes, namely, the cytochrome P450-dependent mixed-function oxidases (monooxygenases) and the transferases (conjugating enzymes) (81, 82). The effects include increased cellular concentrations of the endoplasmic reticulum membrane, the most common location for cytochrome P450 and some of the transferases, and increased expression of the genes for these enzymes. Enzyme induction not only increases rates of pesticide metabolism (and hence usually increases rates of pesticide detoxification) but also increases metabolism of essential substances such as hormones.

Enzyme induction cannot be categorically considered harmful because it is often protective, but it does indicate that exposure suffices to elicit a response. Whether any enzyme induction whatever should be considered evidence of excessive exposure is an unsettled issue, but the usual conclusion is that it should not.

Sources of Exposure

The total exposure to pesticides may occur through air, water, food, or direct contact. Determination of the risk associated with a specific level of exposure through food must take account of the additional contributions of the other routes of exposure. In some instances, the contribution of food to the total may be relatively small compared with exposure through the other routes, especially for pesticide workers (87).

There are few basic sources of pesticide residues in foods; these include approved applications in registered uses, unapproved applications (use of an approved pesticide in excessive amounts or at times too near harvest), and environmental contamination (accidental spillage, contamination from a source such as nearby application or a manufacturing facility in the vicinity, and persistence from previous use). In general, accidents cause massive and possibly highly toxic contamination in localized areas, inappropriate applications cause higher-than-normal and perhaps higher-than-permitted residue levels, and environmental persistence can result in low levels of residues of substances no longer in use.

Risk Assessment

The term *risk assessment*, although seemingly general, is most often used to mean quantitative assessment of cancer risk. The science of assessment of carcinogenic risk is well developed, compared with that of risk assessment for other types of toxicity such as reproductive effects and neurotoxicity. A recent National Research Council report titled "Regulating Pesticides in Food" focuses specifically on carcinogenic risk from

herbicides, insecticides, and fungicides that the Environmental Protection Agency (EPA) has found to be oncogenic.

The basic steps in risk assessment are (a) determination of carcinogenicity and the dose-response relationship in animal studies, (b) estimation of human exposure, and (c) calculation of the human risk from human exposure data and animal dose-response data (86, 88). After these steps are completed, a decision must be made as to whether the calculated risk is at an acceptable level. Although the basics of risk assessment may be conceptually defined in simple terms, the actual process is complex.

Carcinogenicity and Dose-Response Studies. The validity of extrapolation from animal data to humans is uncertain because of possible species differences in reactivity and the potency of the carcinogen. Calculation of equivalent dosages for different body sizes may be performed on several bases, including dose per weight and dose per surface area. Animal studies of practical size (tens to no more than hundreds of animals per treatment group) must use dosage levels that will give statistically significant results with the numbers of animals used. In practice, a treatment group of about 50 is needed to detect a tumor rate of about 10%; the specific number depends on the background tumor rate and the uniformity of response. Tumor induction rates far below 10% would, of course, be important in assessing the impact of the pesticide on human health. Thus, high doses far in excess of anticipated human exposure levels are necessary in animal studies.

Estimation of Risk to Humans. Many procedures have been proposed for extrapolation from the high-dose, high-response range in test animals to the low-dose, low-response range of interest in human health and pesticide regulation. Although the mathematical models and procedures used to estimate carcinogenic potency in humans assume that effects seen at higher doses in animals extend to lower doses in humans, the data do not exclude the possibility that a threshold exists. The assumption is usually made in risk assessment that there is no threshold or (if it is concluded that one logically must exist) that it cannot be identified with present data and methods (86, 89). This is one of several conservative assumptions used to preclude underestimating risk. Thus, a risk assessment usually does not attempt to assess actual risk, but maximum risk. Risk assessment may be used to estimate the risk that may be associated with a specific residue intake. Conversely, risk assessment may be used to calculate the dose associated with an agreed-to upper limit of acceptable risk, for example, 1×10^{-6} in a lifetime.

Elimination of the “Delaney Paradox” for Pesticides. The so-called Delaney Amendment to the food additive provisions of the Federal FDCA (sec. 409(c)(3)(A)), passed in 1958, stipulated that “no food additive shall be deemed to be safe if it is found to induce cancer when ingested by man or animals.” Although this provision seems to apply only to food additives, the EPA and FDA have applied it to pesticide residues in a processed food when those residues occurred in concentrations above those found in the raw (and unprocessed) food (88). In essence, the pesticide residue with increased concentration in a processed food was regulated as a food additive. This regulatory scheme sometimes produced an illogical and paradoxical outcome: Any measurable residue whatever of a carcinogenic pesticide with increased concentration in a

processed food was prohibited, even though a larger amount might be permissible, under carcinogenic risk assessment methods and regulatory standards, in another food product if the concentration were not increased in that product through processing of the raw agricultural commodity. This long-lasting focus on the possible carcinogenicity of synthetic pesticides may have had a perverse effect by diverting attention from other factors making substantial contributions to the population's cancer rate (90).

A recently passed law, the Food Quality Protection Act, amended the FDCA in relation to pesticides (91). Among other provisions, this amendment imposed the same standards for pesticide residues in processed foods as for raw agricultural commodities, thereby preventing the regulation of pesticides with increased concentration in processed foods as “food additives” and thus eliminating the “Delaney paradox” for processed foods. The new law made no change, however, in application of the “Delaney clause” to substances properly considered to be food additives and regulated as such.

Synthetic Environmental Organic Chemicals

Several types of synthetic organic chemicals in addition to pesticides are present in the environment at detectable concentrations and may become incorporated into food. Dioxin is a contaminant in certain chlorinated pesticides, combustion products, and bleached paper. Polyaromatic hydrocarbons occur in soot, diesel smoke, and many coal tar–derived chemicals. Polychlorinated biphenyls (PCBs) and polybrominated biphenyls (PBBs) are used in a wide variety of industrial applications, and spillage may result in their entry into the food chain (92).

Polychlorinated Biphenyls (PCBs)

PCBs caused food contamination problems after their use became widespread as heat-transfer liquids in applications such as electrical transformers. Because PCBs are environmentally stable, resistant to metabolism, lipid soluble, and readily absorbed, they bioaccumulate strongly. The environmental contamination and migration patterns of these substances caused the greatest exposure to persons who consumed fresh water fish. Few adverse health effects have been clearly related to PCB exposure. In the late 1960s in Japan, a heat exchanger leaked PCB into rice oil, resulting in massive contamination and heavy exposure of consumers (92). Many exposed persons, including newborn babies exposed in utero, developed a variety of symptoms, including chloracne, increased skin pigmentation, eye discharges, transient visual disturbances, lethargy, tactile sensory loss in extremities, and decreased liver function. The affected adults showed protracted effects and slow regression of symptoms.

A significant factor in estimating human intake of PCBs from fish consumption is determining the loss of PCBs that may occur during cooking. Although several studies have investigated the extent of such loss, perceived inconsistencies in the data precluded determining the extent to which cooking alters contaminant levels (93). Sherer and Price reviewed the available literature and concluded that expressing the degrees of PCB loss on a mass basis greatly reduced the apparent variability in the existing data and allowed concluding that PCBs are preferentially removed by cooking processes that involve higher temperatures, longer cooking times, and separation of fat

from the cooked fish (93).

Spontaneous fetal death has been observed in some mammalian species following exposure to PCBs. As a consequence, the relationship between consumption of PCB-contaminated Lake Ontario sport fish and spontaneous fetal death among more than 1820 women was examined in a recent exposure-based cohort study (94). The results of the study suggested that consumption of PCB-contaminated sport fish did not increase the risk of spontaneous fetal death.

Polybrominated Biphenyls (PBBs)

A major contamination of food occurred in Michigan in 1972 when a PBB-containing flame retardant sold under the trade name FireMaster was mistakenly used in place of a dairy-feed supplement containing magnesium oxide sold under the trade name NutriMaster (92). Both products contained the same level of magnesium, which may have contributed to the mixup. The contamination was first noticed when cows in several dairy herds refused to eat, produced less milk, lost body weight, and developed abnormal hoof growth and lameness. Affected cattle and swine aborted. No acute human intoxications occurred, but contamination of humans was confirmed by blood analysis. Long-term effects of exposure include some alterations in liver functions and a decrease in immune competence.

Toxicants Produced during Cooking of Foods

Poly(cyclic) aromatic hydrocarbons (PAHs) represent one of the most important classes of organic contaminants in food. Human exposure to these compounds occurs via air, water, and food. One pathway is contamination resulting from environmental pollution (e.g., air, water, soil), and a second is contamination resulting from food processing (e.g., smoking, roasting, grilling, broiling, and frying) due to the pyrolysis of lipids, proteins, carbohydrates, and other food components. Contamination of foods with PAHs may occur during processing and home cooking.

Smoking, charcoal-broiling, grilling, frying, and roasting are primarily responsible for PAH-contamination of meat, meat products, fish, coffee, tea, certain kinds of cheese, and cereal products. PAHs originating from the smoking of meats may be a particularly important source of secondary contamination. Smoke and smoke flavor contain various PAHs that are deposited on the surface of smoked products. The distribution of PAH in smoked meats is not homogeneous, with about 60 to 70% of benzo(a)pyrene formed in the surface layer (95). In addition to smoked meats, smoked cereal products may also be a source of PAHs. For example, foods prepared from smoked oats, barley, and peas, widely consumed in some Finnish and Russian localities, may add significantly to intake of PAHs (96).

Many cooking methods involve intense heat and limited availability of oxygen at the site of highest heat, conditions that cause pyrolytic decomposition of some food components. Major pyrolytic products are the PAHs (97) and the heterocyclic amines (HCAs) (98). PAHs are produced during cooking mainly by pyrolysis of fats, and HCAs are pyrolysis products of amino acids, especially tryptophan. PAHs also originate from

environmental sources such as wood-burning stoves, diesel exhaust, oil-burning heaters, and boilers.

A high rate of food component pyrolysis occurs during charbroiling of meats. In addition to direct pyrolysis of the fats or amino acids in the meat, melted fat and water drip into the flame or onto the hot charcoal where oxygen supplies probably are low, and the searing heat pyrolyses the fat and any amino acids in the water. Steam from the water steam-distills the pyrolysis products, which may then come in contact with the meat.

A large number of PAHs have been identified as pyrolysis products in foods; those most likely to pose problems are benzo[a]pyrene (BP) and 7,12-dimethylbenzanthrene (DMBA). These PAHs and many others are potent carcinogens that are active after metabolic conversion to electrophilic epoxide derivatives.

HCAs produced by food pyrolysis include several carbolines, quinolines, and quinoxalines. The carbolines Trp-P-2 and Trp-P-1 are tryptophan pyrolysis products, and they are considerably more potent in mutagenesis test systems than are BP and DMBA. The quinolines IQ and MeIQ and the quinoxalines MeIQx and two dimethyl MeIQx derivatives have mutagenic potencies similar to those of the Trp-P compounds.

These HCAs occur in very small quantities, but their mutagenic potencies raise concerns about their possible carcinogenicity (99). For several years after their discovery, the HCAs were not available in sufficient amounts to permit carcinogenesis bioassays. Carcinogenicity of several of the HCAs has been confirmed in animal test systems. An epidemiologic survey indicated a higher risk of stomach cancer in people who frequently ate broiled fish. Thus, HCAs may be related to some types of cancer in humans.

Polycyclic aromatic compounds (PACs) comprise the largest class of known environmental carcinogens. Some PACs and PAHs are constituents of some coals, asphaltic rocks, and petroleum and are obtained from these matrices by distillation or extraction. Incomplete combustion of organic matter yields complex mixtures of many types of PACs. Mixtures of PACs are also found in smoke from motors, heating units, and cigarettes and from industrial emissions (e.g., the iron, aluminum, and steel industries), coke ovens, and incinerating plants. Possible sources of PACs found in processed food include environmental contamination and possible accidental contamination during food processing (e.g., as a result of thermal processes used during food manufacture). Several reliable methods may be used for separation and quantitative determination of PACs from foods (100).

Contaminants from Natural Sources

Diseases associated with consumption of contaminated seafood include hepatitis A, Norwalk virus gastroenteritis, cholera (*Vibrio* species), *Campylobacter* gastroenteritis, botulism, and various parasitic infections. Additional diseases are caused by ingestion of seafood toxins. Seafood toxins are becoming increasingly important as causative agents of food-borne illnesses around the world. There is increasing awareness of potential problems with paralytic shellfish poisoning (PSP), neurotoxic shellfish

poisoning, diarrhetic shellfish poisoning, and more recently, a new type of shellfish poisoning called amnesic shellfish poisoning (101). Discussions of seafood-borne viral, bacterial, and parasitic illnesses are beyond the scope of this chapter.

Areas of particular concern and interest include development of standardized methods for detecting and quantifying seafood toxins, the importance of economic losses resulting from their presence, and the importance of establishing regular chemical monitoring for them.

Fishing industries dealing with affected fish species from endemic areas face major problems as they try to expand their market worldwide. To deal with the problems, it has become necessary to develop practical and sensitive detection methods for the wide range of seafood toxins (102).

In the past, assays have relied heavily on use of experimental animals such as mice for detection of toxins. The mouse bioassay involves injecting mice with fish or shellfish extracts and observing them for a set of defined symptoms against control mice over a given period of time. The bioassay requires large numbers of test animals, uses relatively large amounts of tissue extracts, relies on subjective interpretation of results, and lacks specificity (102). Because of these problems, the evolution of marine toxin detection assays have moved in the direction of analytical high-performance liquid chromatography (HPLC) and immunologic analysis. The ideal characteristics of toxin detection assays are within the capabilities of immunologic technology. Development of reliable and practical toxin detection will allow expansion of various fishing industries, increase the food supply, and prevent marine food poisonings on an individual level.

Mycotoxins

A wide variety of fungal toxins are now recognized as contaminants of human foods and animal forages. These include aflatoxins, patulin, ochratoxin, penicillic acid, trichothecene toxins, zearalenone, slaframine, and swainsonine (103, 104, 105, 106 and 107).

Aflatoxins. The first reports of aflatoxin contamination of plant products followed large-scale poisonings of turkeys in the early 1960s (108). The birds had consumed Brazilian ground nut meal contaminated with the mold *Aspergillus flavus*. The responsible fungal metabolites were identified and collectively termed *aflatoxins*. These highly substituted coumarins were further classified as B or G, depending on their fluorescence (blue or green, respectively) in ultraviolet light. Aflatoxin B₁ is the most potent hepatocarcinogen known, and the Fischer 344 rat is the most sensitive to aflatoxin-induced carcinogenesis among the wide variety of species tested.

Acute poisonings in man by foodstuffs contaminated with aflatoxin-producing *A. flavus* and *Aspergillus parasiticum* have been described, with primary effects relating to hepatotoxicity. One study showed that feeding contaminated ground nut meal to rats resulted in formation of liver tumors (109). A role for aflatoxin as a human liver carcinogen is based on epidemiologic data. Epidemiologic associations between the

level of staple food contamination by aflatoxin-producing molds and the incidence of primary liver cancer have been found in parts of Africa and Asia but not in the United States (110, 111). Because epidemiologic studies have also indicated a high correlation between primary hepatocellular carcinoma and exposure to hepatitis B virus, a combined role for aflatoxin and hepatitis B virus in hepatic carcinogenesis has also been suggested.

In the United States, the major commodities affected by aflatoxin contamination are corn, peanuts, and cottonseed meal. Given the potential significance of a role for aflatoxins in human hepatic carcinogenesis, it is important that measures be established and used to remove or reduce possible risks posed by the consumption of aflatoxin-contaminated products (112). Ammoniation processes can effectively reduce aflatoxin levels in corn (113). Under the conditions used, the inactivated aflatoxin does not revert to the parent compound following treatment. Studies are in progress to evaluate the potential uses of ammonia-treated aflatoxin-decontaminated corn in products for animal feed as well as for human consumption.

Studies of storage of products in controlled environments are important because they can help identify conditions that may be necessary to minimize growth of *Aspergillus*. Recent studies with sorghum seeds showed that each of the aflatoxin components B₁, B₂, G₁, and G₂ has a well-defined range of temperature and humidity for optimal production, and these in turn depend on the specific substrate and the fungal strain (114).

Hundreds of different metabolites are produced by *Penicillium* species (115). These include the nephrotoxins citrinin and ochratoxin A (produced by various species of *Aspergillus* and *Penicillium*) and patulin and penicillic acid (produced by *P. expansum* and *P. aurantiogriseum*, respectively).

Patulin. Patulin, a mycotoxin produced by species of *Penicillium*, *Aspergillus*, and *Byssoschlamys*, is found in apples and other fruits subject to soft rot (116). *Penicillium* spp. are the predominant sources of patulin, whose structure (4-hydroxy-4H-furo[3,2-c]pyran-2(6H)-one) is that of a highly reactive unsaturated lactone. Patulin was initially intended for use as an antibiotic because it was found to be bacteriostatic to *Staphylococcus*, *Streptococcus*, *Corynebacterium*, *Neisseria*, and *Haemophilus*. Its antibiotic activity was eliminated when patulin was treated with cysteine. Subsequent toxicologic studies concluded that the compound was too toxic for therapeutic use (117). Patulin was found to be carcinogenic in 100-g rats (118), but a later study apparently did not confirm this result (119).

Ochratoxins. Ochratoxins are produced by several *Penicillium* and *Aspergillus* spp. and may be found in grains and related foodstuffs. Ochratoxin A is the major causative factor in outbreaks of porcine nephropathy in Denmark, which occur in association with unusually wet climatic conditions. Histologic similarity between the nephropathy described in pigs and "Balkan nephropathy" in humans suggests a role for ochratoxin in the latter (120). Balkan nephropathy occurs endemically in Bulgaria, Romania, and Yugoslavia. Levels of ochratoxins in foodstuffs, like those of other mycotoxins, are affected by heavy rainfall, especially during harvest. A significant association between

the number of individuals dying of nephropathy over a 2-year period and excess rainfall during two previous harvest periods has been reported (121). Ochratoxin levels of 3 to 5 ng/g of serum were measured in 6.5% of blood samples obtained from individuals living in an endemic area (122). These data together with epidemiologic data linking rainfall and death rates from the nephropathy support a possible link between ochratoxin contamination and the disease. Ochratoxin produces a similar renal disease in animals (123). The nephrotoxicity of other metabolites of some *Penicillium* strains was recognized in the course of studies of endemic Balkan nephropathy (123, 124). The role of other mycotoxins (e.g., penicillic acid) in the disease remains to be determined.

In Tunisia, many cereals, olives, and mixed feed for fish are contaminated by ochratoxin A and other aflatoxins. Ochratoxin A has been detected in high concentrations in human blood samples collected in nephrology departments in Tunisia from nephrology patients undergoing dialysis, particularly those categorized as having a chronic interstitial nephropathy of unknown origin (125). To clarify the situation, food and blood samples were collected from nephropathy patients and controls (i.e., those with no familial cases of nephropathy). The disease appeared to be related to ochratoxin A blood levels and food contamination, since the control group had significantly lower levels of ochratoxin A contamination in both food and blood than did the nephropathy group. A correlation exists between ochratoxin A in human food, blood contamination, and chronic interstitial nephropathy. Because biologic, biochemical, clinical, and radiologic parameters in Tunisian patients seem very similar to those of Balkan nephropathy, it is likely that human nephropathy related to ochratoxins is occurring in Tunisia and possibly in other parts of northern Africa with the same climate and eating patterns.

Vomitoxins. Many *Fusarium* species produce trichothecene toxins, all of which have a tetracyclic 12,13- epoxytrichothec-9-ene skeleton. Moldy barley may contain the trichothecene “vomitoxin” (deoxynivalenol), which causes vomiting in pigs, deaths with hemorrhagic lesions in the gut in cattle, and necrosis of the mucosa of the esophagus and gizzard in ducks and geese.

Zearalenone. Zearalenone, a fungal metabolite found in feed grains, maize, and soybeans, is related to periodic infection of the plants by *Fusarium roseum*. Estrogenic syndromes in pigs fed moldy grains have been described for many years (126). Enlargement of the mammary glands and vulva are the primary signs of the disorder. Feeding studies in animals have confirmed these findings. There are at present no confirmed reports of effects in man.

Slaframine. “Slobbers” in ruminants is caused by consumption of forage that has been infected with *Rhizoctonia leguminicola*. Various clovers, soybean, kudzu, blue lupine, cow peas, and alfalfa may be infected. Conditions favoring the growth of *R. leguminicola* include wet weather and high humidity. Outbreaks of the disease have been reported in the northwestern, midwestern, and southeastern United States. Pathologic effects of ingestion of the fungus include excessive salivation, lacrimation, diarrhea, and frequent urination. The structure of the toxin is L-acetoxy-6-aminooctahydroindolizine, and total synthesis of the compound has been achieved (126). Slaframine is activated in the liver following ingestion; a ketoimine derivative is thought to be the active metabolite (127).

Swainsonine. Consumption of legumes of the genus *Swainsonia* by cattle, horses, and sheep produces a chronic disease characterized by neurologic disturbances, weight loss, and addiction to the plant (128). Mortality is high among young animals; older animals may survive for months in poor condition. Swainsonine, the active toxicant of the plant, is a strong inhibitor of mannosidase. Swainsonine has been identified in hays that are known to cause slobbers. Its role, if any, in sporadic outbreaks of the slobber syndrome is unknown.

Tremorgenic Mycotoxins. A number of potent neurotoxins, termed *tremorgenic* mycotoxins, have been identified as metabolites of *A. flavus*, *Penicillium crustosum*, and *Paspalum dilatatum* (103). These metabolites at low doses cause sustained, incapacitating whole-body trembling in susceptible animals. Higher doses can lead to convulsive seizures that may be fatal.

Fumonisin. Equine leukoencephalomalacia (ELEM) is a readily diagnosed toxicosis of horses, historically referred to as “moldy corn poisoning” because it was associated with consumption of corn infested with *Fusarium moniliforme*. The etiologic agent of ELEM was identified as fumonisin B₁ and characterized in 1988.

Numerous reports of a syndrome of pulmonary edema and hydrothorax in swine (PPE) and of ELEM in horses occurred following the 1989 U.S. corn harvest (129). Reports of outbreaks continued into the first half of 1990 as corn was moved from storage into animal feeds. Studies clearly implicated feed containing fumonisin-contaminated corn or corn screenings as the cause of the toxicosis. Investigations demonstrated fumonisins in almost all corn and corn-related products harvested in 1989. The significance of the outbreak has been difficult to determine because of a lack of toxicologic data and/or data on incidence and levels of the disease. Subsequent corn harvests have not been associated with widespread toxicoses (129), but survey data have shown fumonisins in corn each year.

Fumonisin is structurally similar to sphingosine, which forms the long-chain base backbone of sphingolipids, prompting speculation that they may be biosynthetically related. Fumonisin B₁ is a potent inhibitor of de novo sphingolipid biosynthesis in vitro, which led to the hypothesis that consumption of feed containing fumonisins should cause an increase in the free sphinganine:free sphingosine ratio in tissues and serum. Use of the free sphinganine:free sphingosine ratio has been suggested as a presumptive test for identifying animals consuming fumonisin-contaminated feed (130). Since their discovery and characterization in 1988, the fumonisins have been extensively studied because of their toxic effects in animals, their cancer-promoting potential, their occurrence in corn-based human food, and the worldwide occurrence of fumonisin-producing fungi (131).

Seafood Toxins

Several marine illnesses may result from consumption of toxic fish and shellfish. Such illnesses are being increasingly recognized and reported in the United States as

consumption of seafood increases. Almost one-fourth of the cases of food poisoning reported to the Centers for Disease Control from 1978 to 1982 resulted from ingestion of toxic fish or shellfish (132).

Ciguatera Toxins. Ciguatera poisoning is a serious human intoxication that can be caused by ingestion of any one of over 400 species of marine fishes, many of which are highly valued as food (133). The poisoning results from eating certain tropical and subtropical fish that consume marine bacteria and dinoflagellates associated with coral reefs and nearby coastal waters. Various species of dinoflagellates from the Caribbean have been grown in large-scale culture and assayed for toxicity (134). Five of nine species examined produced one or more toxin fractions that killed mice within 48 hours. Okadaic acid has been isolated and characterized from the Caribbean dinoflagellates *Pfiesteria concavum* and *P. lima* (135). Signs and symptoms observed in humans following ingestion of contaminated fish vary but generally include moderate-to-severe gastrointestinal disorders, moderate-to-severe neurologic problems and, in extreme cases, death due to respiratory failure. Gastrointestinal symptoms are of relatively short duration, but the neurologic problems may persist for weeks or months.

As a consequence of these toxins in the food chain, ciguatera poisoning is the most commonly reported fish-borne illness worldwide and the most common type of nonbacterial food poisoning reported in the U.S. The most commonly implicated human food species are large predatory reef fish such as barracuda, grouper, snapper, and sea bass (136). Important amounts of the toxin or toxins are produced by the dinoflagellate *Gambierdiscus toxicus* and transmitted up the food chain, although the toxin is harmless to the fish.

Significant differences in the stable carbon and nitrogen isotope contents of the meat tissues of identifiable fish have been found in the gut contents of ciguatoxic and nonciguatoxic barracuda caught along the coast of Puerto Rico (137). Stable isotopic ratios ($^{13}\text{C}:^{12}\text{C}$ and $^{15}\text{N}:^{14}\text{N}$) have been used successfully to trace trophic levels and pathways in terrestrial and aquatic organisms, and measurement of such ratios may be a potentially powerful tool for tracing ciguatoxins through the food chain and possibly for identifying ciguatoxic fish. Such studies provide a means to address the unresolved question of the origins of ciguatoxins and their relationship with toxins isolated from presumed benthic microalgal and/or bacterial vectors (137).

Paralytic Shellfish Toxins. Poisonings of shellfish have been recorded in Atlantic and Pacific coastal waters and in waters around South Africa, New Zealand, and a number of Western European countries for many years. The poisonings, which primarily affect mussels and clams, are associated with the growth of dinoflagellates in the waters. The dinoflagellates produce a toxin that is retained in the hepatopancreas of the shellfish. The toxic principle, "saxitoxin," has been isolated from Alaskan butter clams and from cultured dinoflagellates and appears to block nerve transmission in the motor axon. Hazardous levels of toxin accumulate in shellfish feeding in waters in which the dinoflagellates are undergoing rapid growth ("blooms"). The associated conditions are referred to as "red tides." Symptoms of toxicity, which develop within several hours of eating infected shellfish, include numbness of the lips and fingertips and an ascending paralysis. Death from respiratory paralysis may occur in as many as 8.5% of cases

([138](#), [139](#)).

Contamination of bivalves with paralytic shellfish poison (PSP) poses a serious problem to the shellfish-culture industry and to public health in various parts of the world. In late March to May of 1993, monitoring for toxins in commercial shellfish in Hiroshima Bay, one of the largest oyster-culture areas in Japan, showed that clams, mussels, and oysters were contaminated with paralytic toxins associated with appearance of the toxic dinoflagellate *Alexandrium tamarense*. Although no cases of food poisoning were associated with the infestation, the incident provided an opportunity to determine the PSP profiles of the causative dinoflagellate and the infested bivalves ([140](#)).

The alkaloid neurotoxins, or saxitoxins, are estimated to be 50 times more potent than curare ([141](#)). Until recently, outbreaks were thought to occur principally along cold temperate coastlines. In July to August 1987, however, a major outbreak of PSP occurred along the Pacific coast of Guatemala, in which 26 of 187 persons affected with the poisoning died. The case-fatality rate was 50% in children under 6 years of age. This poisoning represented the first large outbreak of PSP in Guatemala. The illness can occur with little or no warning and can have disastrous outcomes, particularly for children ([141](#)).

Four significant PSP incidents occurred in the Philippines between 1983 and 1991. Because there is no specific antidote to the poison, clinical management has largely remained symptomatic ([142](#)). Thus, the best approach to the problem of PSP is prevention, with strict adherence to public health quarantine guidelines regarding harvesting areas, conduct of intensive education campaigns, and provision of economic alternatives for affected fishermen and vendors.

In November, 1993, 188 people were hospitalized in Madagascar after eating the meat of a single shark. Clinical signs appeared 5 to 10 hours after ingestion of the shark flesh and liver and consisted almost exclusively of neurologic dysfunction (e.g., stinging or burning sensations in the mouth and lips, paraesthesia, ataxia with hypotonia and predominant involvement of the lower limbs, and severe gait impairment). The agent of this outbreak was remarkably toxic, and every individual whose consumption of the shark could be confirmed became ill. Case mortality was close to 30%. The extent and seriousness of this mass poisoning were uncommon for an incident of fish poisoning and differed in several significant aspects from ciguatera poisonings. Two potent heat-stable lipid-soluble toxins tentatively named “carchatoxin-A” and “carchatoxin-B” were isolated; differences observed in biologic and chromatographic properties between these two new toxins and ciguatoxin may explain the differences observed in clinical aspects and mortality ([143](#)).

Domoic Acid. Domoic acid intoxication in humans (also called amnesic shellfish poisoning) is a recently recognized entity. The first reported outbreak occurred in November 1987, when 145 individuals developed gastrointestinal and neurologic symptoms following consumption of cultured mussels from Prince Edward Island in Canada. Domoic acid, an excitatory neurotoxin, was subsequently detected in the mussels associated with this mass intoxication.

Toxic material isolated from mussels caused death with some highly characteristic and unusual neurotoxic symptoms, very different from those of paralytic shellfish toxin and other known toxins. Probably the most remarkable finding was that approximately 25% of those affected reported some memory loss ([144](#)). Subsequent studies determined that the toxin, a potent heat-stable neurotoxin, had been produced by a marine diatom *Nitzschia pungens* forma multiseriis ([145](#)).

NATURAL TOXINS INNATE IN CERTAIN FOODS

The literature on naturally occurring toxicants of the types mentioned above is extensive, and it was necessary to select specific topics to be covered. The toxicities of specific foods can arise from lipids, antivitamins, plant phenolics, estrogens, hallucinogens, and a variety of other components ([146](#), [147](#), [148](#), [149](#), [150](#), [151](#), [152](#) and [153](#)). Two National Research Council volumes review the available information on the carcinogenicity of a variety of naturally occurring toxicants ([146](#), [154](#)).

Proteinase Inhibitors

Legumes are the source of compounds that inhibit the proteolytic activity of enzymes such as trypsin and chymotrypsin. Proteinase inhibitors have been found in many varieties of beans, peas, and peanuts as well as potatoes and sweet potatoes. The trypsin inhibitor found in soybeans is perhaps the best studied of this type of compound ([155](#)). Soybeans contain two major types of trypsin inhibitors: the Kunitz inhibitor (molecular weight ~20,000) and the smaller, extensively disulfide cross-linked Bowman-Birk inhibitor (molecular weight ~8000). Enzyme activity assays for trypsin inhibitors do not distinguish between the two types of inhibitors. Progress is being made in development and application of an enzyme-linked immunosorbent assay that should permit rapid determination of the amounts of the two types of inhibitors in raw and processed soy products ([156](#)).

Chicks, rats, and mice fed raw soy meal experience reduced growth, decreased fat absorption, enlarged pancreas, and hypersecretion of pancreatic enzymes. Metabolizable energy from the diet is also reduced. The nutritive value of soy protein is enhanced by heat treatment, with increased nutritive value paralleling the loss of trypsin inhibitor activity ([155](#)). The observation that feeding raw soybeans or trypsin inhibitor concentrates led to hypertrophy and hyperplasia of the pancreas and increased output of proteolytic enzymes explained the effects of trypsin inhibitors on protein nutrition: fecal loss of nitrogen as digestive enzymes would be a substantial drain on protein supply. Although heat treatment improves the nutritional quality of soybean products through destruction of trypsin inhibitor activity, standard heat processing methods often leave 5 to 20% of the original trypsin inhibitor content ([157](#)).

The rat responds to treatment with trypsin inhibitor with increased secretion of trypsin and chymotrypsin. Continued treatment with trypsin inhibitor leads to hypertrophy and hyperplasia of the pancreas ([158](#), [159](#)). No overtly neoplastic changes are observed unless the animals are also treated with a pancreatic carcinogen such as azaserine

(158, 160). Both adenomas and adenocarcinomas have been observed in the pancreas after about a year of trypsin inhibitor treatment following azaserine initiation. In these studies, trypsin inhibitor appears to promote azaserine-initiated pancreatic cancer. Long-term feeding of trypsin inhibitor (1–2 years) without treatment with azaserine or other initiators may result in progression of hypertrophy and atypical acinar cell foci to adenoma and carcinoma (158).

The relationship between trypsin inhibitors and pancreatic carcinogenesis and the species differences in response to such inhibitors are not fully understood. Species that respond to trypsin inhibitor with increased pancreatic enzyme secretion, hypertrophy, and hyperplasia include rats, mice, and chickens; species reported to be unresponsive include the calf, pig, dog, rhesus monkey, cebus monkey, and marmoset (160). A recent study with humans indicated that a single dose of the soybean Bowman-Birk inhibitor elicited increased pancreatic secretion of trypsin and chymotrypsin (161). Present knowledge is insufficient for risk assessment of residual trypsin inhibitors in foods (162).

In a review of the biochemical properties, physiologic effects, mode of action, and nutritional significance for humans of soybean proteinase inhibitors, Liener noted that with increasing use of soybean products for human consumption, it is increasingly important to assess, if possible, the risk to human health that may be associated with consumption of soybean preparations in which trypsin inhibitors may not be fully inactivated (163). Because of the need to achieve a balance between the amount of heat necessary to destroy the trypsin inhibitors and that which may damage the nutritional or functional properties of the protein, commercially available edible-grade soybean products retain 5 to 20% of the trypsin inhibitors originally present in the raw soybeans from which they were prepared (164).

The question remains whether chronic ingestion of low levels of trypsin inhibitor remaining in some soybean products constitutes a risk to human health (163). In considering means of eliminating trypsin inhibitors from foods, Liener notes that some efforts have been directed at the search for varieties and cultivars of soybeans that are low in trypsin inhibitor (165). Two cell lines devoid of the Kunitz inhibitor were found, and although soybeans without the Kunitz inhibitor still retained about 50% of the trypsin inhibitor activity of most commercial varieties of soybeans (presumably because of the presence of the Bowman-Birk inhibitor), a milder heat treatment than that used with standard varieties of soybeans achieved near-zero levels of trypsin inhibitor (163).

Trypsin inhibitor activity is usually measured by inhibition of the hydrolytic activity of bovine trypsin on *N*-α-DL-arginine-*p*-nitroanilide, a synthetic substrate, or on casein. Specific quantification of the two inhibitors by an immunochemical approach has also been described (166, 167).

Differences in the responses of various species of animals to the physiologic effects of trypsin inhibitors have been mentioned above. Differences have also been observed in the *in vitro* inhibition of proteases by pancreatic juice of different species of animals as well as in the amount of activity that the protease inhibitors retain after exposure to gastric juice (163). Thus, caution must be observed in attempting to extrapolate the results of *in vitro* assays for protease inhibitor activity to their physiologic effects in a

specific animal species ([163](#)).

Hemagglutinins

The terms *phytohemagglutinins*, *phytagglutinins*, and *lectins* are used interchangeably to refer to plant proteins that can agglutinate red blood cells. Plant sources of hemagglutinins include castor beans (ricin), soybeans, peanuts, red kidney beans (phytohemagglutinin A), black beans (phaseolotoxin, phaseotoxin A), yellow wax beans (hemagglutinin), and jack beans (concanavalin A) ([148](#), [168](#)). Rats fed purified kidney bean agglutinin at 0.5% of the diet died within 2 weeks in one study ([169](#)). Differences in oral toxicity among various hemagglutinins may be related to susceptibility of some (but not others) to inactivation by pepsin or other proteolytic enzymes. Most purified plant hemagglutinins are carbohydrate-containing proteins. Concanavalin A from jack beans is free of sugars ([170](#)). The phytohemagglutinins have marked effects on cell division: lymphocytes respond with induction of mitosis. Some phytohemagglutinins have become useful tools in studies related to immunocompetence in which exposure to specific lectins causes increased DNA synthesis.

Although protease inhibitors are generally regarded as the primary antinutritional factor in soybeans, they may account for only about 40% of the growth inhibition observed in animals fed untreated raw soybeans. Research into other factors in soybeans responsible for growth inhibition led to identification of the class of proteins called lectins. Lectins are widely distributed in the plant kingdom and have high specificity in binding to carbohydrate-containing molecules. Lectins can agglutinate red blood cells and interact strongly with specific glycoconjugate receptors on other types of cell membranes.

Soybean lectin, or soybean agglutinin, accounts for about 25% of the growth inhibition produced by feeding raw soybeans. A significant portion of the lectin survives intestinal transit, becomes bound to the intestinal epithelium, and causes disruption of the brush border, atrophy of the microvilli, and reduced viability of epithelial cells. Although the mechanism(s) whereby soybean lectin causes its effects are not understood, they are related to the ability of the lectin to interact with specific glycoprotein receptors on the cell membranes of organs involved in metabolism ([163](#)).

Aminonitriles and Related Compounds

Seeds of various vetches (*Lathyrus sativus*, *L. cicera*, and *L. clymenum*) contain potent toxic compounds that cause neurologic diseases in humans, cattle, and horses, thereby limiting food use of these plants ([171](#)). Toxic compounds isolated from *Lathyrus* species include various diaminobutyric acids, diaminopropionic acid, oxalylaminoalanine, and b-cyanoalanine ([150](#)). Neurolathyrism, characterized by progressive muscle weakness and irreversible paralysis of the legs, may be fatal. Outbreaks of neurolathyrism are generally associated with periods of famine during which large quantities of *Lathyrus* meal are eaten for lack of other food ([172](#)).

The condition of osteolathyrism, as distinct from neurolathyrism, is observed in domestic fowl (chickens, turkeys) and experimental animals (rats) following ingestion of *L.*

odoratus and is characterized by significant disturbances in development of bones and connective tissue. The toxic component responsible for this disease has been isolated from seeds of *L. odoratus* and *L. pusillus* and identified as b-N-(L-glutamyl)-aminopropionitrile. The b-aminopropionitrile (BAPN) moiety is thought to be the active component of this toxicant (173).

Osteolathyrism results from inhibition by BAPN (which occurs naturally in several *Lathyrus* species) of lysyl oxidase. The enzyme is required for formation of lysine-derived cross-links in structural proteins, including those of eggshell membranes (174). Adverse effects of lathyrogens on egg quality (e.g., increase in misshapen eggs, soft or thin-shelled eggs) contribute to increased breakage and economic loss. This disorder has been induced experimentally in laboratory animals by feeding seeds of *L. odoratus* (sweet pea). The disorder involves defective collagen and elastin metabolism induced by BAPN and its g-glutamyl derivative. These compounds lack toxic effects on the nervous systems and have no known relationship to human neurolathyrism (175).

Levels of b-N-oxalyamino-L-alanine (BOAA), one of the neurotoxic amino acids formed from b-cyano-L-alanine, may be reduced by plant breeding, but a safe level has not been defined. While repeated cooking, draining, soaking, and steeping may reduce the BOAA content of seeds by up to 80%, this reduction may not suffice to prevent long-term toxic effects of ingestion (175).

Alkaloids

A wide variety of alkaloids, some very toxic, are found in plants that have considerable economic and food value. For example, glycoalkaloids occur in potato, tomato, and eggplant. Quinolizidine and/or piperidine alkaloids are found in lupine (*Lupinus albus*, *L. luteus*, *L. angustifolius*) seeds, a food crop in South America and a valuable oilseed crop in temperate climates. Purine alkaloids are found in coffee, tea, cola beverages, cocoa, and chocolate; and quinine and alkaloids in black and red peppers are important flavoring ingredients.

Solanum Glycoalkaloids. Glycoalkaloids are the naturally occurring toxicants of potato tubers, and consumption of potatoes high in glycoalkaloids has caused severe illness and death (176). The two major potato glycoalkaloids are a-solanine and a-chaconine. a-Solanine inhibits blood and brain cholinesterases and injures membranes in the gastrointestinal tract and elsewhere (177).

The current toxicologic status of the glycoalkaloids present in potatoes is poorly defined, a conclusion that can also be drawn for many natural dietary constituents (178). Although a no-observed-adverse-effect level (NOAEL) has not been established, the traditionally held view is that potatoes can contain up to 200 mg of glycoalkaloids per kg of whole raw unpeeled potato and still be fit for human consumption.

The potential toxic effects of consumption of potato leaves, which form part of the diets of certain ethnic communities, has been less well studied. Although potato leaves contain several highly toxic alkaloids, it is unlikely that moderate consumption of potato tops would result in intake of high enough concentrations of the alkaloids to cause injury

(179).

Ingestion of ripened nightshade berries, *Solanum dulcamara*, is one of the commonest poisonous plant exposures reported (180). Nightshade is in the same genus as the potato (*Solanum tuberosum*), which is known to contain a variety of toxic glycoalkaloids and alkalamines, collectively known as solanine (181).

Pyrrolizidine Alkaloids from *Senecio* Species

A large number of inedible plants may contaminate animal forages and human food grains. For example, a variety of *Senecio* spp. produce toxic alkaloids, and “Senecio disease” has been reported in human populations eating breads containing seeds from the poisonous plants (182). A major feature of pyrrolizidine alkaloid intoxication in man and animals is delayed liver damage (183). Venooclusive disease and cirrhosis have been reported in humans, and induction of liver cancer has been reported in animals (184, 185). The genera *Senecio* (ragworts), *Crotalaria* (rattleboxes), and *Heliotropium* (heliotropes) contain specific alkaloids in amounts ranging from traces to as much as 5% of the dry weight of the plant.

Consumption of teas prepared from plants of the *Senecio* genus has been associated with several forms of cancer, but data are not conclusive. Seneciphylline and senkirkine, two pyrrolizidine alkaloids that occur in animal forages and medicinal teas, respectively, appeared to act as indirect mutagens (186). Transfer of mutagenic activity via milk following treatment of lactating rats with seneciphylline was also reported (186). The hepatocarcinogenicity of the pyrrolizidine alkaloids may be due to promoting effects on initiated hepatocytes rather than to their weak initiating activity (187).

Little research has been directed toward elucidating the natural toxicants or their metabolites that may enter the food chain through milk, milk products, or meat. With the increasing concern for food safety, it is important to broaden research in these areas. Factors that need to be considered are consumption of milk by infants or young children who are more susceptible to plant toxicants, consumption of milk produced by lactating mothers who use natural product remedies with potential toxicity, and availability of toxic plants to lactating animals. Currently, few methods have been developed for monitoring natural toxicants (particularly those of plant origin) in milk, milk products, and meat products. Research is needed to identify toxins in poisonous plants ingested by livestock, to determine the ability of the products of such plants to pass into the food chain, and finally, to assess their potential danger to human health.

Determining the disposition of xenobiotics, including natural plant toxicants, in milk and other natural products, is important. It is generally believed that the human health risk from plant toxicants in milk is minimal because of current practices of bulk milk handling, which dilutes possible plant toxicants, and intense range-land management, which eliminates opportunities for dairy animals to graze on poisonous plants.

Milk is an emulsion of lipids in an aqueous solution of proteins. For this reason, it may contain a mixture of virtually any toxins or compounds that are in solution in the animal's body water (188). Many natural plant toxicants are known to be present in milk from

lactating animals grazing on plants that contain them. These include tremetol from *Eupatorium* and *Haplopappus*, pyrrolizidine alkaloids from *Senecio*, piperidine alkaloids, quinolizidine alkaloids, glucosinolates in *Brassica* and *Limnanthes*, indolizidine alkaloids in *Astragalus* and *Oxytropis*, and seleno compounds known to accumulate in grasses and some cereal grains. In the western United States, the pyrrolizidine alkaloid-containing plants of greatest concern to livestock are various *Senecio* species; in the southern U.S., various *Crotalaria* species are of major concern.

The principal effects of pyrrolizidine alkaloids on the liver are acute necrosis, venoocclusive disease, and megalocytosis. It has been postulated that effects on lungs and kidneys may occur from excess pyrrolic metabolites generated in the liver. The alkaloids themselves are not hepatotoxic, but after they are ingested, they undergo microsomal enzyme oxidation to the corresponding pyrrole and subsequent hydrolysis to the hepatotoxin. The pyrrolizidine alkaloids are carcinogens and mutagens. Carcinogenic effects in livestock are limited because most animals are slaughtered relatively early in their lives. Carcinogenicity becomes a greater issue in milk-transmitted pyrrolizidine alkaloids and presents a potential risk to the human population.

Some plants that produce pyrrolizidine alkaloids are consumed directly by humans. *Symphytum officinale* (comfrey) is commonly used as a salad vegetable and tea. Pyrrolizidine-containing herbs are also in use. The flower stalks of *Petasites japonicus*, a type of coltsfoot that has been shown to be carcinogenic in rats (189), are used as a vegetable in Japan.

Accidental consumption of pyrrolizidine alkaloids may occur when seeds from pyrrolizidine alkaloid-containing plants contaminate grain crops. This has been reported in underdeveloped countries when drought situations have caused weed species to flourish at the expense of cultivated crops or when famine has forced populations to consume poor-quality commodities.

Goitrogens

A number of food-borne compounds interfere with utilization of iodine or functioning of the thyroid gland (190). The type of goiter induced by goitrogens results from inhibition of iodine incorporation into thyroid hormones. Goiter induced by goitrogenic compounds is not prevented or alleviated by high iodine intake. Vegetables and fruits containing goitrogens were shown to reduce the rate of uptake of radioactive iodine by human thyroid glands (191). Seeds of various vetches (*Lathyrus sativus*, *L. cicera*, and *L. clymenum*) contain potent goitrogenic compounds. Goitrogens such as sinigrin (allylthioglucoside), glucobrassicin (3-indoylmethylthioglucoside), progoitrin (2-hydroxy-3-butenylthioglucoside), and gluconapin (3-butenylthioglucoside) are among the compounds isolated and characterized from various *Brassica* species (cabbage, kale, Brussels sprouts, cauliflower, broccoli, and kohlrabi).

Mimosine, a nonprotein free amino acid, and its ruminal degradation product 3,4-dihydroxypyridine (3,4-DHP) are the major toxic constituents of *Lucaena leucocephala* and closely related species with limited food and forage uses. Mimosine is an antimetabolic and depilatory agent, and 3,4-DHP is a potent goitrogen. Signs of *Lucaena*

toxicosis in ruminants, which can be acute or chronic, include alopecia, reduced weight gain or weight loss, enlarged thyroid, and low circulating concentrations of thyroid hormones (192). *Lucaena* toxicosis does not occur in all geographic areas where ruminants are fed the crop; the lack of toxicosis in such areas is due to the ability of rumen bacteria in unaffected ruminants to degrade and detoxify 3,4-DHP. Important steps are being taken to control *Lucaena* toxicosis in ruminants by inoculating ruminal contents from “adapted” ruminants into those susceptible to intoxication. The availability of viable approaches to controlling *Lucaena* toxicosis makes exploitation of *Lucaena*'s potential as a high-quality legume for tropical and subtropical areas possible (192).

The prevalence of goiter in rural areas of western Sudan, where the staple food is millet, is significantly higher than in urban areas, where less millet is consumed. Millet diets are rich in C-glycosylflavones, the three most abundant of which are glycosylvitexin, glycosylorientin, and vitexin. Vitexin has significant antithyroid activity when fed to rats (193), and like the potent antithyroid drug methimazole, vitexin inhibits thyroid peroxidase–catalyzed protein iodination. These results directly implicate the C-glycosylflavones as the goitrogens in millet (194).

Allergens

In some individuals, complex interactions among ingested food antigens, the digestive tract, tissue mast cells, circulating basophils, and food antigen–specific IgE lead to food hypersensitivity (195, 196 and 197). Foods such as peanuts, nuts, eggs, milk, soy, fish and other seafood, bananas, and chicken have been implicated in immediate hypersensitivity reactions in children. Symptoms may include atopic eczema, asthma, and rhinitis (198, 199 and 200). The numerous foods studied in attempts to characterize specific food allergens include codfish (201), peanuts (202), shrimp (203), and eggs (204).

Gluten, a protein found in wheat, rye, barley, and oats, elicits a severe enteropathy (“gluten-sensitive-enteropathy” or “nontropical sprue”) in sensitive individuals. The complex and heterogeneous nature of wheat proteins has hindered attempts to identify the component of gluten responsible for the intestinal damage that occurs in sensitive individuals. Gliadin, an alcohol-soluble component of gluten, appears to be the primary toxic component (205).

Oxalates

High levels of oxalates are found in a number of vegetables. Oxalates generally occur as soluble sodium or potassium salts or as insoluble calcium salts (206). Leafy portions of plants usually contain higher concentrations of oxalates than do stalks. Insoluble calcium oxalate crystals are readily visible on microscopic examination of leaves of high-oxalate plants (207). The percentage oxalate content of some plant foods is as follows (fresh-weight basis): beet tops and cocoa leaves, 0.3 to 0.9%; spinach and rhubarb, 0.2 to 1.3%; and tea leaves, 0.3 to 2.0%. Ingestion of oxalate-containing plants can cause acute poisoning; plants of the rhubarb and sorrel grass species are particularly harmful. Symptoms of mild oxalate poisoning (e.g., following ingestion of rhubarb) include abdominal pain and gastroenteritis. Symptoms of severe poisoning

include diarrhea, vomiting, convulsions, noncoagulability of the blood, and coma (207). Calcium oxalate kidney stones have been found in Thai children consuming native plants of high oxalate content (208).

Since urinary oxalate is considered an important determinant for formation of calcium oxalate kidney stones, it has been customary to recommend restricting oxalate-rich foods in persons with calcium oxalate nephrolithiasis. In considering the stone-forming potential of various oxalate-rich foods, the bioavailability of oxalate from foods may be calculated by expressing oxalate absorption as a percentage of the total oxalate contained in specific foods (209). The ability of different food items to increase urinary oxalate excretion varies significantly. Based on activity in increasing urinary oxalate, spinach was rated as a “high-risk” food item; peanuts, instant tea, almonds, chocolate, and pecans were rated as “moderate-risk” items; and turnip greens, brewed tea with milk, and okra were rated as “negligible-risk” items. The authors noted that these results were derived from studies with normal subjects and may not apply to certain patients with nephrolithiasis (209).

Phytates

Phytate (myoinositol hexaphosphate) is widely distributed in plants. Its location in specific plants varies; for example, the phytate of seed plants such as corn is contained primarily in the bran and germ. The primary adverse effects of dietary phytate are due to its activity in decreasing the bioavailability of such essential minerals as zinc, calcium, iron, and manganese (210). The bioavailability of zinc appears to be most severely affected. Extensive studies in the Middle East resulted in recognition of the seriousness of this effect in humans. Zinc deficiency with delayed sexual development and growth retardation observed in certain populations was attributable to the high amounts of phytate ingested in whole-grain bread that served as the main dietary staple.

Much of the phytate of plants goes into the byproducts of flour milling and may become concentrated in high-protein flours (211). The concentration of protein from seeds, particularly soybeans, and the use of plant protein to supplement or replace meat products is an important activity of the food industry. The processes used to obtain plant protein from seeds include adjustments in pH, aqueous washes, drying, and hot pressure extrusion to yield a wide range of products varying in protein, fiber, phytic acid, and essential mineral content. Other food processes result in hydrolysis of phytate to yield lower-inositol phosphates or inorganic phosphate and myoinositol. Processing seeds to prepare protein concentrates and isolates results in some mineral loss and sometimes decreased bioavailability of the remaining minerals. The decreased bioavailability of minerals resulting from food processing can be counterbalanced to some extent by the large amount of minerals occurring in most whole seeds. Areas of current interest in relation to phytates in foods include (a) methods of removing phytate, (b) beneficial and adverse effects of smaller inositol phosphates, (c) differences in sensitivity among varying age groups, and (d) adaptation to dietary phytates.

The deleterious effects of phytates on growth and mineral status have led to attempts to reduce the phytate content of soybeans. One of the most effective means of reducing phytate takes advantage of endogenous phytase (212). For example, autolysis of an

aqueous suspension of soy flour results in a low-phytate soybean protein isolate. Ultrafiltration, ion-exchange chromatography, and close control of such variables as pH, salt concentration, and temperature during extraction of the protein from the bean have also been used to remove phytate.

Cycad

High-incidence foci of amyotrophic lateral sclerosis (ALS) and parkinsonism dementia (PD) occur on Guam, the Kii peninsula of Japan, and southern West New Guinea in the western Pacific. The original incidence rates of ALS in the foci on Guam and in West New Guinea were 50 and 1300 per 100,000 population, respectively, versus a rate of 1 per 100,000 population in the United States (213). These foci have provided unique opportunities to study the cause and mechanisms of pathogenesis of fatal neurodegenerative disorders. Attempts to identify an infectious agent in ALS and PD have been unsuccessful. Several studies have attempted to identify a relationship between the high incidence of ALS and ingestion of cycad plant material. In tropical and subtropical regions, including the foci mentioned above, nuts of the palmlike cycad trees provide food for humans and livestock. Because ingestion of cycad fruits was known to produce motor neuron toxicity in foraging domestic animals, the cycad became a major candidate for a causative role in the human disorders. Rats fed diets containing 2% of a crude flour prepared from unwashed cycad nuts developed liver and kidney tumors (214, 215). A neurologic disease was not observed (216). Extensive efforts to implicate cycad in neurologic disease have been unsuccessful (213).

A toxic substance was extracted from cycad nuts and identified as methylazoxymethanol-b-glucoside (cycasin). Cycasin is one of the most potent carcinogens found in plants. Macrozamin, a related glucoside, is also found in cycad nuts. Because liver cancer also occurs at high rates in Guam and Okinawa, ingestion of cycasin in cycad nuts has been proposed as an etiologic factor in this disease. The available information does not allow a definitive conclusion (217). In contrast, studies with experimental animals support the hypothesis that a basic metabolic defect, provoked by a chronic nutritional deficiency of calcium, leads to increased absorption of toxic minerals and deposition of calcium, aluminum, and silicon in neurons of patients with ALS (147). Although deposition of toxic minerals in neurons of patients with ALS is now recognized, the process by which neuronal degeneration occurs is not understood.

Cycad flours from various geographic areas of Guam and Rota were found to contain the neurotoxins previously found in cycad seeds. Consumption of food products prepared from these flours would expose consumers to numerous cycad chemicals, including the known neurotoxins. The body burden of these chemicals may also be increased by percutaneous exposures to unprocessed cycad seed, since in some areas, crushed raw cycad seed kernel is used to poultice open wounds (218).

While washing cycad seed may potentially remove all traces of cycasin, the Chamorro methods of seed kernel detoxification are variable and incomplete in this regard. Differential processing of cycad seed in the islands of the western Pacific may be related to the respective presence and absence of western Pacific ALS/PD among different cycad-consuming populations (219). The findings provide evidence for

discontinuing cycad consumption on Guam. If the contaminated cycad flour is a major etiologic factor for ALS/PD on Guam, then cessation of cycad use should lead to the eventual disappearance of the disease.

Bracken Fern Toxins

Bracken fern is consumed by both humans and animals in several parts of the world. Damage to the bone marrow and intestinal mucosa of cattle has been associated with ingestion of this plant. In one study, a high risk of esophageal cancer was associated with daily intake of bracken fern (146). Rats fed fresh or powdered milk from cows that had consumed bracken fern daily (1 g/kg body weight) for about 2 years developed carcinomas of the intestine, urinary bladder, and kidney (220). In another study, however, dietary administration of quercetin, which occurs as a conjugate in the fern, did not lead to increased incidence of tumors in ACI rats (126). A highly mutagenic substance has been isolated from bracken fern and identified as aquilide-A (221).

Phytoalexins

Several plants, including the sweet potato, can produce “stress metabolites” (phytoalexins) in response to fungal infections, mechanical damage, and insect invasion. These compounds accumulate at fungitoxic levels at sites of infection and are thought to be part of the mechanisms by which potatoes resist disease. Some of these metabolites are toxic to animals consuming infected roots. Because sweet potatoes are a food staple for large numbers of people, the toxicities of these metabolites are of considerable importance (103, 148). One of the most abundant of these metabolites, ipomeamarone, produces liver necrosis in mice when fed or injected intraperitoneally. In large-scale outbreaks of moldy sweet potato poisoning, however, the predominant manifestation is lung edema, leading to death from asphyxiation rather than liver damage. The fatal pulmonary disease has been described as acute interstitial pneumonia, acute bovine pulmonary emphysema (ABPE), or pulmonary edema (222). Components of moldy sweet potatoes other than ipomeamarone, when fed to mice, reproduce certain features of the bovine disease and cause death of the animals from asphyxiation within 24 hours.

ABPE can be caused by other toxic plant components (223). Outbreaks of ABPE occur in animals grazing on pastures that contain a variety of plant species, but no single plant type or combination of plants has been consistently associated with the disease (224). The most common observation associated with outbreaks of the disease is a sudden change from relatively dry to lush forage. Ruminal microorganisms can convert L-tryptophan via indoleacetic acid to 3-methylindole, which can cause pulmonary lesions in cattle, goats, and sheep. Presumably, tryptophan contained in pasture plants can be converted to enough 3-methylindole to induce ABPE. Observations that ABPE is associated with changes from dry to wetter pastures may also support a role for mycotoxins or stress metabolites.

Vasoactive Amines

Certain foods, notably aged cheeses, contain vasoactive amines such as tyramine,

dopamine, norepinephrine, serotonin, and histamine. These compounds can cause large increases in blood pressure when administered intravenously to humans. Levels of tyramine may be as high as 2000 µg/g in Camembert cheese; somewhat lower levels have been reported in cheddar (120–1500 µg/g) and Emmentaler (225–1000 µg/g) cheeses. Pickled herring may contain as much as 3000 µg tyramine/g (225). The foregoing amines are normally metabolized rapidly in the human body by monamine oxidase (MAO). Tyramine has been found to produce serious effects in persons taking drugs that inhibit MAO, often prescribed for depressive illnesses. Episodes of hypertension, intense headaches, and intracerebral hemorrhage have been reported following ingestion of high-tyramine food by individuals taking MAO inhibitors. Hypertensive reactions are not limited to cheese or to ingestion of tyramine only and have been reported in persons taking MAO inhibitors following ingestion of pickled herring, chicken liver, stewed bananas, and beef liver. Other chemically effective antidepressants without the “cheese effect” have been described (226, 227).

Dr. Rader's contribution to this chapter was made in her private capacity. No official support or endorsement by the Food and Drug Administration is intended or should be inferred.

[Suggested Readings](#)

In the past three decades, the public has become increasingly aware of and concerned about health risks associated with the chemical products and byproducts of modern industrial society, as well as naturally occurring substances, that may be present as chemical contaminants in food. Potential health hazards from food may result from microbiologic contaminants, pesticide residues, excessive preservatives or additives, nutritional imbalances, overconsumption, and other chemicals (natural or synthetic) accumulated from the environment. The present discussion focuses on health issues associated with environmental chemicals found in, but not intentionally added to, food (pesticides and direct additives are excluded and are reviewed in [Chapter 113](#)), plus other current and emerging issues relating to dietary risk. Regulatory agencies use the risk assessment process for safety assessment and to establish regulatory limits in media such as air, water, soil, and food. For food, the process involves special considerations and complexities not found in other media.

REGULATORY AGENCIES AND SCIENTIFIC BODIES

In the United States, the U.S. Food and Drug Administration (FDA) is primarily responsible for assessment and management of chemical contaminants in food. The process and responsibilities involved (described in [\[1\]](#)) are summarized below. The Center for Food Safety and Applied Nutrition (CFSAN) within the FDA is charged with

protecting the public from chemical hazards in foods. Although the present discussion is focused on environmental contaminants, excluding substances intentionally added to foods, some indirect food additives may become contaminants in food. Thus, a brief description on additives as regulated by the FDA is in order. *Direct additives* are substances added deliberately in limited amounts (usually at very low concentrations) for a special technical purpose and consumed because they remain in the food. *Secondary direct additives* are substances added to food during manufacturing or processing that are removed before the final product is consumed, but low levels may still remain. *Indirect food additives* are substances that may unintentionally become components of food because they migrate from food contact surfaces during production, packaging, transporting, preparing, or storing (e.g., lead in ceramic ware and diethylhexylphthalate [DEHP] from plastic wraps).

The FDA uses a formal risk assessment process to estimate the hazard posed by food contaminants, color additives, and residues of animal drugs in animal food products (1). These procedures are also used under the general safety clause included in the FDA's impurities or constituents policy published in 1982 as an advanced notice of proposed rule making (ANPR). Under this clause, if a food or color additive itself is found to induce cancer, it is subject to the Delaney clause. However, if the additive itself is not a carcinogen, but a contaminant or constituent of the additive is found to be a carcinogen, then the risk assessment procedure is used, as appropriate, to determine the upper limit of risk to the consumer from a contaminant or chemical constituent of the food additive.

At CFSAN, the Cancer Assessment Committee (CAC) performs hazard identification with information from various scientific disciplines such as toxicology, pathology, and epidemiology. A Quantitative Risk Assessment Committee (QRAC) performs dose-response assessment, exposure assessment, and risk characterization—the steps in the traditional risk assessment process, further described below. The first two steps (hazard identification and dose-response assessment) are common to all risk assessment procedures for carcinogens and noncarcinogens, whether they are used to evaluate chemicals in food, water, air, or soil. The data most appropriate for the route of exposure under assessment are used (e.g., dietary data rather than inhalation data in experimental animals would be used to assess risk in humans from food). The third and fourth steps, exposure assessment and risk characterization, may differ more widely for different chemicals because the exposure pattern varies depending on the medium of primary exposure.

FDA evaluations of food are applicable nationwide, but food safety evaluations also occur at the state level. For example, regulatory actions related to commercial fish are addressed by the FDA, but state government agencies have taken the responsibility of evaluating and issuing health advisories concerning contamination of sport fish. The U.S. Environmental Protection Agency (EPA) also addresses sport fish contamination by providing general guidance on fish sampling, risk management, and risk communication. However, this guidance does not apply to commercial fish, nor does the EPA issue site-specific advisories. In addition to the FDA, the agency responsible for the safety of animal, poultry, and dairy products is the U.S. Department of Food and Agriculture (USDA).

Many states depend on the federal agencies for risk assessment support in food contamination situations. Other states have their own resources and capabilities. Since the food distribution system and interstate commerce often involve various states, food contamination situations often require coordination among the affected states and with the federal agencies.

At the international level, the International Program on Chemical Safety (IPCS) of the World Health Organization (WHO) evaluates the effects of chemicals on human health and the environment (2). Two other joint committees of the Food and Agriculture Organization (FAO) and the WHO are responsible for evaluation of food additives, contaminants, and pesticides. The Joint Expert Committee on Food Additives (JECFA) evaluates food additives and contaminants and the Joint Meeting on Pesticide Residues (JMPR) evaluates pesticide residues in food. These committees serve as scientific advisory bodies to the Codex Alimentarius Commission, a subsidiary body of FAO and WHO. The Codex primarily promotes harmony in international trade of food commodities by establishing standards with consensus views based upon safety evaluations conducted by JECFA and JMPR. The JECFA has evaluated more than 700 different substances, primarily food additives but also numerous chemical contaminants. JECFA sets provisional endpoints for food contaminants, subject to reevaluation if new data become available. Health benefits of limiting exposure to contaminants are balanced against the impact of limiting intake of a nutritious food supply.

PRINCIPLES AND APPROACHES IN RISK ASSESSMENT

Response to the increasing concern regarding health risks from environmental chemicals has led to new legislation and regulations aimed at reducing human exposure to these chemicals. Risk assessment is either specified or may be assumed as the methodology to be used to predict health risks and establish regulatory limits. In the 1960s, qualitative methods were developed to estimate risks from carcinogens, and these methods and the underlying science evolved during the 1970s and 1980s. In 1986, the EPA issued guidelines for assessing the risk of carcinogens, mutagens, developmental toxicants, and chemical mixtures. They include default options and various assumptions for assessing exposure and risk. Several of these guidelines and new guidelines for emerging issues are being revised. (For an update on the status and trend of risk assessment see Fan et al. [3].)

The principles of risk assessment were identified by the National Academy of Sciences and recently updated by Roberts and Abernathy (4). Risk assessment of a chemical estimates the possibility of a health-related event occurring in a population following exposure to that chemical. The basic elements include hazard identification, dose-response assessment, exposure assessment, and risk characterization. *Hazard identification* is the evaluation and determination of the toxic or hazardous properties of a chemical, based on all available human, animal, and in vitro data. Animal studies examine acute, subacute, or chronic toxicity (e.g., any target organ toxicity such as toxicity of the liver or lung, reproductive or development toxicity, neurotoxicity, genotoxicity, immunotoxicity, and carcinogenicity). The *dose-response assessment* determines the relationship between changes in exposure levels and specific effects

that result. *Exposure assessment* determines the extent of exposure to a chemical (in this case, the amount of food ingested and the concentration of chemical in or on that food). *Risk characterization* is the qualitative and quantitative description of risk, with the attendant limitations and uncertainties, after integration of all factors involved.

In practice, hazard identification may identify one or more toxic endpoints of concern from experimental animal studies or human studies. Human studies generally are preferred, if they are of adequate quality. The FDA publishes guidelines for experimental animal studies for food additives and contaminants (5). The use of human data is described by Ames (6), and extrapolation of animal data to humans, by Brown and Salmon (7). Extrapolation of animal experimental data to humans requires many assumptions to compensate for differences in size, life span, metabolic rate, and absorption and to relate the high doses used in animal studies to the expected low-dose exposures in humans. For the carcinogenic endpoint, a carcinogenic potency factor (CPF) is developed for a specific chemical based on suitable data sets using appropriate mathematical models, from the slope of the dose-response curve. The CPF can be used to estimate cancer risk, by incorporating information on exposure using the following formula:

$$\text{Cancer risk} = \text{CPF (mg/kg-day)}_{-1} \times \text{exposure (mg/kg-day)}$$

Overall assessment of carcinogenic risk and future trends in the field are described by Velazquez et al. (8). To assess the risk from ingestion of a specific environmental chemical from food, the known or estimated exposure (i.e., amount of chemical ingested) is used to calculate the risk level if the chemical is considered a carcinogen.

For noncarcinogens, the no-observed-adverse-effect level (NOAEL) and lowest-observed-adverse-effect level (LOAEL) for a toxicity endpoint specific to a chemical are determined. These are then divided by an uncertainty factor (UF) as shown below to account for one or more of the following: quality of data, intraspecies differences, and interspecies differences. The value obtained represents the total health protective reference exposure level (REL), with a reasonable safety margin, at which no appreciable adverse health effects are anticipated. A more detailed description of the method is provided by Cicmanec et al. (9). The REL may be referred to as the reference ingested level (RIL), the acceptable daily intake (ADI), or the the reference dose (RfD), depending upon the scientific body.

$$\frac{\text{NOAEL or LOAEL (mg/kg-day)}}{\text{UF}} = \text{RIL (mg/kg-day)}$$

The RIL obtained can also be used to establish an exposure limit for an environmental chemical in food, based on the same information on NOAEL/LOAEL and use of the UF. Setting such limits has been described for pesticides in food (10). The general formula can be expressed as

$$[\text{RIL (mg/kg-day)} \times \text{body weight (kg)}] / \text{Food consumption rate (kg/day)} = \text{level of chemical in food (mg/kg)}$$

One major difficulty in setting a limit for a chemical in food or in assessing total exposure for a chemical in foods, is that a specific chemical may be present in more than one type of food item, and one food item or category of food may be composed of different individual food items (e.g., egg and cheese in cake and pizza). A total assessment would require considering the consumption rate for each food item. Assessing ingestion of a chemical from the consumption of various food items and setting a limit for that chemical in each of those food items complicate the risk assessment process and are further described below.

SPECIAL CONSIDERATIONS

Diet Composition and Food Consumption Rate

A major component of risk assessment of chemicals in food is estimation of chemical exposure based on food consumption. This can be difficult, since an individual's diet contains a variety of items, and the food composition and dietary intake, or food consumption rate, can vary in relation to individual variability, age, seasonal differences, and geographic, cultural, and economical conditions.

Various studies have been conducted to collect food consumption information. Nationwide food consumption surveys include those conducted by the USDA ([11](#), [12](#)), which give consumption rates by age and sex for dietary items either for the United States as a whole, or for various populations based on regional differences (northern, southern, western, eastern regions). Special studies have been conducted that consider ethnic differences, income level, women, and infants. Each of these studies has certain limitations that require careful consideration before the information collected can be used for risk assessment.

The USDA has used the available food consumption data to estimate intake of various substances in food in the annual total diet study ([13](#)), based on information on the diet of the U.S. population, sampling and analysis of food purchased in supermarkets and consumed as prepared, and chemical residue levels in food sample analyses. The chemical intakes are then compared with the WHO's ADIs and the EPA's RfDs for the chemicals.

Chemical Intake Estimates

As described by Rees and Tennant ([14](#)), the accuracy of chemical intake estimates is important for optimal balance of the potential risk from an environmental chemical contaminant and the potential benefits to be achieved. Such dietary intake assessments can be done by estimating actual or potential intakes. Different systems have been used to assess risk to "average," "nonaverage," or "critical" groups of consumers, the latter being those who may be more susceptible to the specific toxic effects of a chemical, who consume greater quantities, or who regularly consume foods with higher concentrations of the specific contaminant. Estimates can be averaged for consumers (eaters) or noneaters or averaged over a study period as actual number of consuming

days. Chemical intake can also be expressed as a percentile of the range of intakes or by body weight. Methodologies used for food intake assessment include the following: per capita, total diet study, modeling scenarios, surveillance, duplicate diet, and postmarketing surveillance. One must know how the food intake data were generated to determine their appropriateness for use in risk assessment.

Toxicity versus Essentiality

Some trace metals that occur as environmental contaminants also play an important role in human nutrition, creating a delicate balance between chemical toxicity and nutritional essentiality. Usually, the nutritional role involves comparatively low levels of intake, and the potential for toxicity increases as the intake increases beyond the nutritional needs. For some metals (e.g., selenium), the margin between nutritional intake level and toxicity level is very narrow. For others (e.g., zinc), estimated ranges of nutritional and toxicity levels actually overlap. Therefore, risk assessment for these substances has to consider both the toxicity and nutritional aspects.

In environmental toxicology, risk assessment is used to establish a limit of exposure to prevent or protect from chemical toxicity, based on the RIL or RfD. For nutritional essentiality, a level of intake is established to meet the nutritional requirement based on the recommended dietary allowances (RDAs) ([15](#)). An estimated safe and adequate daily dietary intake (ESADDI) may be established for micronutrients when the scientific database is not adequate to establish a RDA, but available information suggests that a range of intakes will meet nutritional requirements and represent no threat of toxicity. Performing risk assessment requires understanding the concepts underlying these terms and the associated chemical intake values.

Chemical Forms and Effect of Food Processing, Food Preparation, or Metabolic Conversion

The chemical and physical properties are important determinants of a chemical's toxicity and bioavailability. For example, the inorganic form of arsenic is more toxic in humans, whereas in fish, the organic form of mercury is the toxic form. In addition, the toxicity of dioxins and polychlorinated biphenyls (PCBs) varies greatly among the different congeners. These examples are further discussed below under the specific chemicals.

Food processing may also affect the final concentration and form of chemicals found in food as consumed, but this information for environmental contaminants is limited. However, to better characterize the risk, it is important to know if the parent compound or a breakdown product is of concern and should be targeted for risk assessment. The issue of chemical mutagens (i.e., agents that cause genetic effects) resulting from cooking (such as charbroiling) has been extensively studied and discussed but this information has not been regularly used for risk assessment purposes.

Other examples in which a breakdown or conversion product should be the major chemical form used for risk assessment (rather than the parent chemical) include the 1,1-unsymmetrical dimethylhydrazine (1,1-UDMH) that is a hydrolysis product of daminozide, and nitrite, which is converted from nitrate by microorganisms in

contaminated water or in the body.

Bioaccumulation, Bioconcentration, and Biomagnification

Increased concentration of a chemical in various dietary items can result from bioaccumulation, bioconcentration, or biomagnification. Lipophilic chemicals such as PCBs, dioxins, and other chlorinated pesticides can accumulate in fatty tissues and breast milk. Chemicals in the aquatic environment (e.g., selenium) can bioconcentrate in fish; the degree of bioconcentration depends on the bioconcentration factor (the ratio of the concentration in tissue to concentration in water). Chemical concentration can also increase with biomagnification up the food chain, such that fish at higher trophic levels contain more of the chemical than fish at the lower trophic level (as with mercury in fish).

RISK ASSESSMENT OF SELECTED CHEMICALS

Inorganics

Lead (Pb)

The major concern regarding lead exposure is neurotoxicity, both in adults and children ([16](#), [17](#)). In children, lead toxicity can be seen as impaired neurobehavioral development and other effects on red blood cells and their stem cells, the central and peripheral nervous system, and the kidneys. In adults, the effects are peripheral nerve dysfunction, red blood cell protoporphyrin elevation, and elevated blood pressure. In male adults, hypertension occurs at about the same level of lead exposure that affects cognitive function, the most sensitive endpoint in children.

The index of lead exposure is the concentration of lead in blood. A 1991 report from the Centers for Disease Control (CDC) ([16](#)) suggests that as little as 10 µg lead/dL of blood may be of concern. Each incremental increase in lead intake is expected to result in an incremental increase in blood level. The relationship between lead ingestion and blood lead levels is estimated to be 0.16 and 0.04 µg lead/dL blood for each microgram of lead ingested daily by children and adults, respectively.

Humans are exposed to lead in air, water, soil, and food. Environmental exposure to lead in the United States has decreased significantly since the early 1970s, when the use of lead in gasoline and paint was restricted. Dietary exposure to lead in the United States has also declined since the reduction in the use of lead solder in cans. Human dietary intake in various age groups is estimated to be in the range of 1 to 5 µg of Pb daily ([17](#)).

Because safe levels of lead exposure have not been identified, the FDA has derived provisional and tolerable total intake (PTTI) levels ([17](#)) based on the relationship between lead ingestion and blood lead levels. The levels for children 0 to 6 years old, children 7+ years, pregnant and lactating women, and adults are 6, 15, 25, and 75 µg Pb/day, respectively. The PTTI level derived for adults was based on a blood lead level of 30 µg/dL associated with hypertension. On the basis of recent data reported by the

CDC (16), the authors indicated that it would be appropriate to adjust the PTTI level to 25 µg Pb/day for adults. Most of the U.S. population has a blood lead level below 10 µg/dL (18). The fetus, pregnant women, children (for neurotoxicity), and adult males (for hypertension) are identified as sensitive populations.

Zinc (Zn)

Zinc, an essential trace nutrient, is a cofactor for approximately 200 enzymes. On the other hand, gastrointestinal distress resulted from intake of high levels of zinc from improper storage of acidic foods in zinc-containing vessels, acute ingestion of 2000 mg of zinc sulfate (455 mg Zn), and zinc supplementation of 50 to 150 mg/day over a period of 6 weeks to 2 years (19). Consumption of zinc as a dietary supplement at moderate levels for several months to several years has also been reported to have adverse effects on immune function, serum lipoprotein levels, and copper and iron homeostasis. In the study of Yadrick et al. (20), nine healthy adult females received supplementation with 50 mg zinc as zinc gluconate and nine were given 50 mg Zn plus 50 mg Fe as ferrous sulfate monohydrate. After 10 weeks, erythrocyte copper-zinc superoxide dismutase (ESOD) decreased significantly in both groups. The LOAEL was 60 mg/day for effect on copper homeostasis. The EPA used this to develop an RfD, using an uncertainty factor of 3 for a minimally adverse effect in a moderate-duration study of the most sensitive humans and a substance that is an essential nutrient (19). Supplementation provided 50 mg of zinc and approximately 10 mg was from the diet. The reference female body weight was 60 kg.

Humans can be exposed to zinc through environmental sources or dietary supplements (19). Americans were reported to consume 4.5 to 7.0 mg of zinc per 1000 kcal. Approximately 70% of the zinc consumed by Americans is from animal products; thus, zinc intake is lower in the elderly, dieters, and vegetarians than in those who consume meat. A review of 12 studies published worldwide from 1969 to 1988 showed zinc intakes of 1.90 to 20.30 mg/kg for individuals aged 1 month to 85.5 years. Among these studies, six conducted in the U.S. (1969–1988) showed intakes of 5 to 96 mg/day for individuals aged 2 to 81.7 years. Pregnant women were reported to take in less than 20 mg/day. Intake from breast milk varied from 3 mg/day for week 2 of lactation to 0.36 mg/day for week 36. The 1989 RDA of the Food and Nutrition Board, National Academy of Sciences ranged from 5 mg/day for infants up to 19 mg/day for lactating women (15) (see Appendices [Table II A-2a-2.](#))

Selenium (Se)

Selenium toxicity can be described in terms of clinical manifestation of acute, subacute, and chronic selenosis (21). Acute selenosis in animals was associated with unsteady walking, cyanosis of the mucous membranes, labored breathing, and sometimes death. Pathologic findings revealed liver congestion, endocarditis and hypocarditis, degeneration of the smooth musculature of the gastrointestinal tract, gall bladder, and urinary bladder, and erosion of the long bones. Subacute selenosis resulted in neurologic dysfunction (impaired vision, ataxia, disorientation) and respiratory distress typically seen in grazing livestock feeding upon Se-accumulating plants. Chronic selenosis in animals resulted in skin lesions, alopecia, hoof necrosis and loss,

emaciation, and increased serum transaminase and alkaline phosphatase levels.

In humans, selenosis is characterized by chronic dermatitis, anorexia, gastroenteritis, increased concentrations of selenium in the hair and nails, hair changes, nail and hair loss, “garlic odor” in the breath, and central nervous system abnormalities (peripheral acute anesthesia, acroparesthesia, and pain in the extremities). These were reported in some of the case studies worldwide and in an epidemiologic study in China. In the U.S., selenosis (gastroenteritis, nail changes, hair loss) and sour-milk breath odor were found in individuals who had taken superpotent supplements that resulted from a manufacturing error.

Animal experiments showed reproductive toxicity in rats and mice following administration of selenium in a seleniferous diet or drinking water. Teratogenicity was not seen in experiments using rodents and nonhuman primates, but deformities were seen in avian species (waterfowl) following environmental and laboratory exposure. Selenium has both mutagenic and antimutagenic properties, depending on the concentration and chemical form used.

The EPA's oral reference dose is 0.005 mg/kg-day, or 350 µg/day, using an uncertainty factor of 3 (21), based on observation of clinical selenosis in a human epidemiologic study (22). In this study of 400 individuals from three separate geographic areas in China with low, medium, and high selenium levels in soil and food, persistent clinical signs of selenosis (changes in fingernail morphology) were seen at an intake of 1261 µg/day, and no signs of significant biochemical changes or selenosis were found at 853 µg/day. A regression equation relating selenium intake to blood selenium concentrations yielded an NOAEL of 853 µg/day or 16 µg/kg-day (for a 55-kg person). Supporting work included an epidemiologic study in the U.S. that showed no selenosis with intake of up to 724 µg/day, reported in 1990, earlier data on endemic selenosis in China reported in 1983, and data on human intoxication in the U.S. from selenium supplements, reported in the late 1980s.

Selenium occurs naturally in rock, shale, sandstone, limestone, coal, soil, surface water, and vegetation. The primary sources of human exposure to environmental levels of selenium are food and drinking water. Dietary selenium intake levels for various human populations range from 20 to 300 µg/day worldwide, or 60 to 240 for the U.S. (23). The common dietary sources are cereal grains and grain products, poultry, meat, vegetables, and seafood. The levels of selenium in plants (e.g., vegetables) are often directly correlated with the levels in soil. Selenium is also used as a dietary supplement for some farm animals and is taken as a nutritional supplement by humans. It has various industrial and commercial uses such as those in semiconductor research, glass manufacturing, photo-conductors, veterinary remedies, and biologic tracers. Occupational exposures may involve forms of selenium not present in the diet. The RDAs for selenium are 70 µg for men (79 kg) and 55 µg for women (63 kg) (or 0.87 µg Se/kg body weight/day) (15). No toxicity or deficiency has been reported in the U.S. from regular dietary intake of selenium, suggesting that intake has been adequate and not excessive.

Arsenic (As)

Organic arsenic is virtually nontoxic (24, 25). Arsenobetaine at 10 g/kg given to mice depressed mobility and respiration, but the symptoms disappeared within an hour. In contrast, the acute LD₅₀ for inorganic arsenic is in the range of 1 to 4 mg/kg for humans, 9 mg/kg for the guinea pig, and 40 mg/kg for the rat (for sodium arsenite). Short-term exposures affected the heart, liver, kidney, and nervous system. Subacute and chronic exposure of humans to high concentrations of inorganic arsenic produced signs of dermatosis, hematopoietic depression, liver damage, sensory disturbances, peripheral neuritis, anorexia, and weight loss. Animal studies showed developmental toxicity following arsenic exposures. In humans, inorganic arsenic can cause cancer of the skin, lung, and kidney. Peripheral vascular effects leading to gangrene of the extremities (blackfoot disease) have been reported in Taiwan following ingestion of well water containing arsenic.

The EPA evaluated various human studies on the effects of subchronic-to-chronic exposure of arsenic from drinking water (26) and determined that the work reported by Tseng and coworkers (27, 28), which surveyed over 40,000 residents on the southwest coast of Taiwan, was the best available study for deriving an RfD. Arsenic is unique in that animal experiments have not shown the carcinogenic potential seen in humans. Skin cancer has been reported in South America, India, and Taiwan from ingestion of arsenic from drinking water, but studies in the U.S. did not show similar responses.

The study population in Taiwan had various signs of arsenic exposure, including skin cancer, blackfoot disease, hypo- and hyperpigmentation, and keratosis. The critical noncancer effect used is blackfoot disease, a peripheral vascular disorder causing gangrene of the extremities. The critical effects for RfD derivation were limited to hyperpigmentation, keratosis, and possible vascular problems. The calculated NOAEL is 0.8 µg/kg-day and LOAEL is 14 µg/kg-day. An uncertainty factor of 3 is used to derive the RfD of 0.0003 mg/kg-day. However, any value from 0.0001 to 0.0008 mg/kg-day could be used for the RfD, depending on the scientific justification. For cancer, a unit risk estimate of $5.0 \times 10^{-5}/\mu\text{g/L}$ was developed by the EPA for ingestion of arsenic from drinking water.

In general, arsenic occurs in inorganic forms in water and organic forms in food. The average daily dietary intake of arsenic in humans ranges from 12 to 40 µg, with seafood, grains, and cereal products as the primary dietary sources (24). Studies in rats, hamsters, chicks, goats, and minipigs have supported the essentiality of arsenic. The requirement for growing rats and chicks eating a diet containing approximately 4000 kcal/kg is suggested to be 25 and 50 ng/g diet, respectively. The corresponding requirement for humans eating 2000 kcal is calculated to be 12 to 25 µg/day. However, presently there is no conclusive evidence of human arsenic essentiality. Given the lack of arsenic deficiency as a practical nutritional problem in humans and the derived requirement, it would seem that current dietary intakes satisfy the needs for arsenic. Thus, the ESADDI of arsenic by adults is suggested to be 12 to 40 µg/day for a 70-kg person. The ESADDI for infants 0 to 0.5 years of age (6 kg) is 1 to 4 µg; children 1 to 3 years (13 kg), 3 to 8 µg; children 4 to 6 years (20 kg), 4 to 12 µg; and children 7 to 10

years (28 kg), 5 to 16 µg. The FAO/WHO maximum acceptable daily load of arsenic for humans is 2 µg/kg, or 140 µg for a 70-kg person. The upper limit of the safe and adequate range probably could be higher than 140 µg/day, because in vivo reduction of As⁵⁺ to As³⁺ must also occur for toxicity. However, the closeness of the nutritional requirement and reported average intake may be of concern if the need for arsenic is enhanced by nutritional stressors that upset sulfur amino acid or labile methyl metabolism.

Although the carcinogenicity of inorganic arsenic from drinking water has been extensively studied, information on the carcinogenicity of arsenic in food is limited. Arsenic levels are generally high in seafood (0.39–42 ppm), and most of the dietary arsenic intake is organic and obtained from eating fish and shellfish (24). The health significance of the small fraction of inorganic arsenic in fish has not been clearly determined. Cancer risk estimated from drinking water at the current drinking water standard of 50 ppb is approximately 1/1000. More research has been proposed to reduce uncertainties in the database for risk assessment.

In vivo methylation of inorganic arsenic was considered a detoxification pathway because the acute toxicity of methyl and dimethyl arsenic acids is less than that of arsenite (As³⁺) or arsenate (As⁵⁺). More recently, a question has been raised as to whether some of the toxicity associated with inorganic arsenic exposure is due to the methylated metabolic product of inorganic arsenic or even the process by which these products are formed. Overall, the toxicity of arsenic appears to depend on the chemical form, and knowledge of the chemical form is important for risk assessment.

Organics

Methylmercury

Human exposure to methylmercury is primarily through fish consumption. Inorganic mercury is methylated by microorganisms in the aquatic environment and taken up by fish. The human health concerns from ingesting fish containing methylmercury are the potential neurologic and developmental/behavioral effects that characterize methylmercury toxicity. These can be seen as paresthesia, ataxia, impaired mental and motor development, coma, and even death.

The toxicity data for methylmercury are primarily derived from two poisoning episodes that occurred in Minamata, Japan, and Iraq (29, 30 and 31). The former involved eating fish contaminated with methylmercury as a result of industrial discharge of mercury, and the latter involved eating bread made from phenylmercury-treated grains. Various estimates of exposure to methylmercury have been based on measurements of mercury in hair and blood and modeling of dietary intake based on several studies of the poisoning outbreaks. The LOEL estimated by WHO corresponds to a blood mercury level of 200 to 500 µg/L (29). Extrapolation to average daily intakes was based on the biokinetics of methylmercury distribution among body compartments. The intake of methylmercury associated with the earliest effects in the most sensitive group in the adult population was estimated to be in the range of 3 to 7 µg/kg-day, based on the most conservative (linear) relationship of steady-state blood concentrations to daily

intake of methylmercury among data from numerous studies.

Several epidemiologic studies have attempted to determine a threshold for maternal exposure to methylmercury. The effects on offspring were the more sensitive endpoints. Since exposure estimates were made after the actual exposures had occurred, mercury concentrations were measured in hair and extrapolated to blood concentrations at the time of past exposures. Women with 10.0 to 19.9 $\mu\text{g/g}$ of mercury in hair were twice as likely to have offspring with neurologic abnormalities as those with less than 10.0 $\mu\text{g/g}$ (30). Based on all the studies combined, a maternal hair level of about 10 to 20 $\mu\text{g/g}$ was considered to be associated with subtle neurologic effects in offspring. This level is also the best estimate of an effective maternal threshold dose for a developmental neurologic endpoint.

In experimental studies, methylmercury affected spermatogenesis and was fetotoxic in mice. It was teratogenic in rats and adversely affected the behavior of offspring of monkeys administered the chemical before and during pregnancy. A number of the animal studies on the reproductive or developmental effects showed effects at 1 mg/kg-day or above, while some effects on development/behavior functions were observed at dose levels below 1 mg/kg-day. The lowest no-observed-effect level (NOEL) was 5 $\mu\text{g/kg/day}$ given prenatally to rats; 10 $\mu\text{g/kg-day}$ caused decrements in operant behavior performance (32). Pregnant rats were treated during days 6 to 9 after conception, and the offspring were tested at 4 months of age.

The FDA's ADI for methylmercury is 30 $\mu\text{g/day}$ (0.4 $\mu\text{g/kg-day}$ with a 10-fold uncertainty factor) (33). The EPA's reference dose is 0.3 $\mu\text{g/kg-day}$ (34). The FDA's ADI is based on a linear relationship between ingested methylmercury and blood mercury level that yielded a blood level of 200 $\mu\text{g/L}$ at steady state in a study of high fish consumers with an intake of 300 $\mu\text{g/day}$ in 70-kg persons. Both values are within the range calculated by the WHO.

Methylmercury is the only contaminant that has resulted in known human fatalities as a result of dramatic biomagnification in the aquatic food chain following industrial discharge. The WHO (30) concluded that the general population does not face a significant health risk from methylmercury. However, groups with high fish consumption may attain blood methylmercury levels that are associated with a low (5%) risk of neurologic damage in adults. Fetuses and children are the sensitive subpopulations.

Dioxins

Polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) (commonly known as dioxins) are ubiquitous environmental contaminants formed as byproducts in combustion of chlorine-containing compounds (ATSDR) (35). Of the possible 75 congeners of PCDDs and 135 congeners of PCDFs, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) is the most toxic and most extensively studied. Assessing the potential health implications of these individual compounds in various media including food is difficult because they are present as complex mixtures of PCDD and PCDF congeners with varying toxicity. Because of the presumed common mechanism of action and qualitative similarity of the toxic effects of various congeners,

exposure estimates are based on toxicity estimates of each congener in a mixture and are expressed as total toxicity equivalent (TEQs). The relative toxic potential of each congener is expressed as a toxicity equivalent factor (TEF). TEF is expressed as the ratio of toxic potency of a congener to the toxic potency of TCDD, which is assigned a TEF of 1. The total TEQ of a sample is calculated by multiplying the amount of each congener present in the sample by its TEF value and then adding the products for all congeners in the mixture. Depending on the availability of toxicity data, TEFs may be based on carcinogenic, reproductive, immunotoxic, subchronic or acute effects, Ah-receptor binding, or in vitro toxicity data.

Most of the toxic effects of dioxins are attributed to a mechanism involving cytosolic receptor (Ah receptor) binding and subsequent regulation of the transcription of specific genes. The most commonly known responses include P450 enzyme induction, weight loss, thymic atrophy, immunotoxicity, teratogenicity, reproductive effects, endocrine effects, and carcinogenicity. The toxicity of dioxins varies with the species, strain, age, and sex.

TCDD has been shown to be a multisite carcinogen in both sexes and in several species, including the rat, mouse, Syrian hamster, and fish (36). In a two-stage model for liver and skin cancer, TCDD was a promoter with limited initiating activity. The EPA has estimated an NOAEL of 1 ng/kg-day based on liver cancer in female rats; using the linearized multistage model, the cancer potency was calculated to be 1.56×10^{-5} /mg/kg-day. The EPA's safe dose estimate of 0.006 pg/kg-day is based on an upper-bound excess lifetime cancer risk of 1×10^{-6} (37). The TCDD regulations of European countries and Health Canada are based on determination of the tolerable daily intake (TDI), an absence of firm scientific evidence of human carcinogenicity, and equivocal evidence on genotoxicity. Using an NOAEL of 0.001 μ g/kg-day from a rat reproductive study and a safety factor of 100, Health Canada derived a TDI of 10 pg/kg-day (38).

There have been a number of human exposures to dioxins from accidental (Missouri, U.S.A., and Seveso, Italy; Yusho disease in Japan and Taiwan from contaminated rice oil) or occupational (use of Agent Orange in Vietnam by military personnel) exposure. To date, chloracne is the only proven consequence of human exposure to TCDD and related compounds. However, other toxic endpoints such as cancer, immunotoxicity, and reproductive and developmental toxicity have been suggested. A number of reports involving weight loss, digestive disorders, neurologic and psychiatric disturbances, and other nonspecific effects have also been reported. Due to the extreme toxicity of TCDD and some other congeners in various animal species, reported human exposure levels are close to Health Canada's TDI or exceed the EPA's safe dose estimate.

Most human exposure to dioxins is through contaminated food, primarily meat, dairy products, milk, eggs, and fish (35, 36). Exposure estimates from various European countries average about 120 pg/day, expressed as a TEQ. The estimated exposure of 119 pg/day in the United States is similar (36). Most daily intake (>90%) is from food (beef, 31%; dairy products, 20%; milk, 15%; fish 7%; eggs 3.4%). Small amounts are accounted for by inhalation (1.8%), soil ingestion (0.7%), and water ingestion (0.01%) (35). Children and certain subpopulations may receive a higher dose because of higher

intake of such foods as milk or fish.

Polychlorinated Biphenyls

PCBs are a group of 209 chemicals containing 1 to 10 chlorine atoms attached to a biphenyl backbone. PCBs (trade name, Aroclor) were widely used as lubricants and hydraulic and cooling fluids before being banned in the mid-1970s because of their toxicity and environmental persistence. The number of chlorine atoms and their positions in PCBs are the principal determinants of their physical (vapor pressure and stability in the environment) and biologic (metabolism, receptor binding, toxicity) properties. The different Aroclor preparations contained variable mixtures of congeners and isomers, which were commercially differentiated by the average number of chlorine atoms per molecule. Thus, Aroclor 1248 contains about 48% chlorine atoms and Aroclor 1260 contains about 60% chlorine atoms. Their large-scale use and long half-life resulted in widespread contamination of the environment.

A number of reviews on the health effects of PCBs have been published ([39](#), [40](#) and [41](#)). The main effects of PCBs are hepatic enzyme induction, potential carcinogenicity, immunotoxicity, neurodevelopmental toxicity, and possible reproductive effects in experimental animals and humans. Epidemiologic studies in occupationally exposed individuals have suggested that PCBs may cause dermal lesions, changes in cytochrome P450 metabolism, respiratory effects, reproductive effects, liver function changes, malignant melanoma, and low birth weight. People consuming fish from the Great Lakes containing high concentrations of PCBs have been evaluated for reproductive effects, neurologic effects on infants, child growth and cognitive functioning, breast cancer, and immune functions. Infants born to mothers who consumed a greater amount of fish from the Great Lakes had smaller head circumference and lower birth weight than those in a low-fish-consuming population. Because many confounding factors were not properly controlled for in data analysis in these epidemiologic studies, a recent critical review suggested that the association of effects with PCB consumption was generally either negative or inconclusive ([42](#)).

Studies conducted in experimental animals show more definite toxic effects of these chemicals. A number of rat studies with Aroclor 1260 suggest increased hepatocellular carcinoma and neoplastic nodules. Aroclor 1254 and related Kanechlor 500 promote cancer development in animals exposed to another carcinogenic initiator. PCBs decrease fertility and litter size in many laboratory animals. Developmental effects such as impaired learning, decreased activity, and delayed reflex development have been reported in monkeys. Immunotoxicity has been shown in various animal species. In monkeys, an increased antibody response of IgM and IgG to sheep red blood cells was observed after 23 months of exposure to 5 µg/kg-day of Aroclor 1254.

Certain planar PCB congeners have been reported to have toxicities similar to those of TCDD, such as immunotoxicity, reproductive effects, teratogenicity, endocrine effects, and carcinogenicity ([43](#)). The binding of these compounds to the Ah receptor suggests a mechanism of action similar to that of TCDD. Thus, to simplify risk assessment, TEQs are used for these “dioxin-like” PCBs. A recent EPA draft document on dioxins

recommends using international PCB TEF values (44) for risk assessment.

Because of the characteristic toxic effects of each Aroclor mixture, different toxic endpoints have been identified for PCB-induced toxicity. The EPA (45) has determined a cancer potency factor of 7.7 mg/kg-day for Aroclor 1260 based on an increased incidence of hepatocellular carcinoma. An RfD of 2×10^{-5} mg/kg-day for Aroclor 1254 is based on immunotoxicity, and a RfD of 7×10^{-5} mg/kg-day for Aroclor 1016 is based on reproductive toxicity.

Humans are exposed to PCBs from air, water, soil, and food. However, most exposure is thought to be from meat, dairy products, eggs, and fish, because of bioconcentration of PCBs in fat. Concentrations of PCBs in various media have been decreasing over the years because of restricted use since 1972. To decrease exposure to these compounds in food products, FDA set tolerances for various foods; for example, milk, 1.5 ppm; manufactured dairy products, 3 ppm; eggs, 0.3 ppm. Because of bioaccumulation of PCBs in aquatic organisms, fish consumption could be a major source of PCB exposure. Based on the FDA's total diet study survey, human exposures in 1989 were estimated to be 0.05 µg/day, compared with 6.9 µg/day in 1970 (40). Estimated human exposure from soil, air, and drinking water was 0.48 µg/day in the 1980s. Thus, the total exposure to PCBs was estimated to be 0.53 µg/day, or 0.008 µg/kg-day, based on a 70-kg human. Considering the overall human exposure to combined PCBs of 0.008 µg/kg-day and the lowest noncarcinogenic RfD of 0.02 µg/kg-day, exposure estimates are very close to the RfD.

Diethylhexylphthalate (DEHP)

Phthalate esters are added to plastics to make them flexible. Because phthalates are not part of the plastic polymer, they are easily released from the product. DEHP, one of the major phthalates, has been most studied, but usually a mixture of congeners is used. The chemicals enter the environment by vaporization from plastics in use, burning of plastic products, disposal of plastic waste in landfills, and groundwater leaching from landfills.

The oral LD₅₀ for DEHP in rats exceeds 25 g/kg, suggesting a low order of acute human toxicity (49, 50). The metabolite monethylhexyl phthalate (MEHP) has a lower LD₅₀, about 1.5 g/kg, suggesting a relatively higher acute toxicity. Hepatomegaly and increased relative kidney weights have been reported in long-term animal studies. DEHP produced reproductive and developmental effects in a variety of mammalian and nonmammalian species. Several studies have shown that DEHP and MEHP cause testicular atrophy. The suggested mechanism for testicular toxicity is a membrane alteration that leads to separation of germ cells (spermatocytes and spermatids) from the underlying Sertoli cells. Younger rats seem to be more susceptible than older ones, and susceptibility seems to differ among species. MEHP also has a toxic effect on Sertoli cells in vitro. Teratogenicity studies have reported malformations in mice at dietary levels of 0.5 to 2 g/kg. Embryotoxic effects were observed at dietary levels above 10 g/kg. DEHP was negative in most genotoxicity studies; however, it induces cell transformation and is carcinogenic in rats and mice. DEHP is a strong peroxisome proliferator and its liver carcinogenicity is associated with peroxisome proliferation. Very

limited information is available on the toxicity of DEHP to humans. Only gastric disturbances were reported in humans given 5 or 10 g of DEHP (49)

Morgenroth (51) determined a TDI of 1 mg/kg based on peroxisome proliferation, assuming a positive association with carcinogenicity. Based on teratogenicity, a TDI of 0.04 mg/kg was determined.

Humans may be exposed to DEHP from air, water, soil, and food (49, 50). The main source of DEHP and other phthalates in food products is from plastic used in food packaging. Persons who undergo repeated blood transfusion or dialysis may be exposed to a higher level of DEHP leached from polyvinyl chloride tubing. DEHP and other phthalate esters were reported in Canadian butter and margarine as migrating from laminated aluminum foil–paper. DEHP concentrations were estimated to be 11.9 µg/g of butter. A mean DEHP concentration below 50 µg/L in retail whole milk was observed in 1 German and 14 Danish dairy samples. A TDI of 25 µg/kg body weight is set by the EEC Scientific Committee for Food. This suggests that intake of whole milk does not constitute a health hazard for the Danish population. Migration of DEHP from plasticized tubing was found in a commercial milking operation. Concentration in the milking chamber for each individual cow averaged 30 µg/kg; this rose to 50 µg/kg in the central collecting tank. Two retail cream samples contained 1200 and 1400 µg/kg of DEHP, reflecting the association of plasticizer with the fat phase. Hand milking resulted in a DEHP concentration below 5 µg/kg. The WHO working group (49) estimated an average daily exposure to DEHP of about 300 µg/person in the U.S. in 1974 and 20 µg/person in the U.K. in 1986. Levels ranging from 13.4 to 91.5 mg/kg (dry weight) have been detected in lung tissues of patients receiving blood transfusions.

Naturally Occurring Substances

Aflatoxin and Mycrocystin

Mycotoxins are naturally occurring unintentional environmental contaminants in food. Among the mycotoxins are aflatoxins, which are fungal metabolites produced by *Aspergillus flavus* and *A. parasiticus*. Four major metabolites have been identified: aflatoxin B₁ (AFB₁), aflatoxin B₂ (AFB₂), aflatoxin G₁ (AFG₁), and aflatoxin G₂ (AFG₂). The predominant metabolite, AFB₁, is the most studied and of most public health concern. However, depending upon the environmental conditions, several metabolites may be present in different proportions in any contaminated food sample.

Aflatoxin is produced by these fungi in nut crops (peanuts, almonds, pecan, pistachios, walnuts), corn, cotton, sorghum, and millet, either in field conditions or during storage. Commercial peanuts and peanut butter are the major sources of aflatoxin exposure for consumers in the United States. FDA samples from 1984, 1985, and 1986 had average aflatoxin levels of 2.4, 1.6, and 8.3 ppb for shelled roasted peanuts and 2.1, 1.7, and 3.1 ppb for peanut butter, respectively. American Peanut Product Manufacturers Association (APPMI) samples in 1985, 1986, 1987, and 1988 had average aflatoxin levels of 1.1, 1.3, 1.3, and 1.1 ppb for roasted peanuts and 3.1, 4.0, 2.5, and 1.9 ppb, for peanut butter, respectively (46). In addition to aflatoxin exposure from contaminated

or moldy food, occupational exposure may occur from inhalation of contaminated dust from milling operations.

Aflatoxin is a well-understood hepatotoxicant and hepatocarcinogen, and there is considerable evidence of its carcinogenicity from both human and animal studies (46). Accordingly, the International Agency for Research on Cancer (IARC) classified aflatoxin as a human carcinogen. Many epidemiologic studies from Asia and Africa have shown a relationship between aflatoxin exposure and development of liver cancer. However, the role of such confounding factors as hepatitis B viral (HBV) infection and alcohol consumption, which are also known to cause liver cancer, were not addressed in these studies. A recent prospective study of about 8000 people in Guangxi, China, indicated a causal relationship between aflatoxin exposure and primary hepatocellular carcinoma. Aflatoxin exposure estimates were based on the aflatoxin content of staple foods sampled twice per year over several years. The HBV status was determined by testing for hepatitis B surface antigens (HbsAg) in sera of 25% of the cohort. From this study, a cancer potency factor of $46 \text{ (mg/kg-day)}^{-1}$ is estimated based on subjects who are negative for HbsAg (47). Using epidemiologic data obtained in various countries, Kuifer-Goodman (48) estimated the TDI for total aflatoxin B₁ to be 0.11 to 0.19 ng/kg-day for a risk level of 1×10^{-5} . The author suggested that in the absence of endemic HBV infection, the TDI would be about one order of magnitude higher. It was not possible to consider confounding factors in these studies.

In experimental studies, aflatoxin induced liver tumors in mice, rats, hamsters, and primates. The rat appears to be the most sensitive species tested. The cancer potency for humans, estimated from a study in which male Fisher rats were treated with AFB₁ for 109 weeks at concentrations ranging from 1 ppb to 100 ppb, would be 2700 (mg/kg-day) (46).

In addition to liver toxicity, aflatoxin affects the reproductive, renal, and gastrointestinal systems. Both cellular and humoral parameters of immune responses were altered by doses of aflatoxin that caused no overt toxicity. Aflatoxin was genotoxic and positive in gene mutation, chromosomal aberration, unscheduled DNA synthesis, and neoplastic transformation assays. Exogenous activation is required for in vitro studies.

Using the cancer potency value of $50 \text{ (mg/kg-day)}^{-1}$ derived from the human study in China, the cancer risk associated with consumption of peanut butter at 2.5 ppb (the APPMI average value, 1985–1988) is 6×10^{-6} , assuming a lifetime average dose in the range of 1.1×10^{-7} to 1.4×10^{-7} mg/kg-day.

Mycrocystin is an algal toxin, commonly found in ditch and pond water in China. In the laboratory, this toxin can cause severe liver damage and promote hepatocellular carcinoma. Epidemiologic studies in southern China found an association between liver cancer and drinking pond and ditch water (52).

GENERALLY RECOGNIZED AS SAFE (GRAS) COMPOUNDS

A good historical perspective on GRAS compounds is given by Kilgore and Li (53). The

amendment to the Food, Drug and Cosmetic (FD&C) Act in 1958 to regulate food additives recognized a category of additives presumed to be safe by the absence of toxic effects after long use. These chemicals were designated generally recognized as safe (GRAS). GRAS status can also be given to compounds determined safe by experts qualified by scientific training and experience to evaluate food safety. Additions to the GRAS list were proposed by the Flavor and Extract Manufacturers Association (FEMA) for flavoring ingredients, based on the approval of experts qualified by scientific training and experience.

Originally, GRAS status was not based on the relative toxicity or potency of the compounds, but on the assumed or apparent safety of the compounds under conditions of use. New toxicology data subsequently revealed that some GRAS compounds might have toxic potential in foods. For example, cyclamate, which had GRAS status, was later found to cause bladder cancer in rats and was banned from food. In 1970, the FDA started a review of GRAS compounds by a select committee. Based on the committee recommendations, GRAS compounds were either reaffirmed, allowed while additional data were sought, or changed to a food additive requiring toxicologic data for safety assessment. Thus, GRAS status is not permanent, and compounds can be added to or taken off the list on the basis of newly available toxicity data. Risk assessment of GRAS compounds follows the same principles and methodologies used for other chemicals.

EMERGING ISSUES

Biotechnology

Biotechnology has been practiced from ancient days to improve plants and animals, first by a simple process of selection and then by breeding and selection for desired qualities in plants or animals. Recombinant DNA techniques (genetic engineering) not only speed the process but also allow introduction of desired characteristics in plants or animals, which was not possible by traditional means. Thus, the process has a great potential to increase quality, yield, and disease resistance and to produce novel foods for specific needs. Current examples are the slow-rotting genetically engineered tomato and the administration of recombinant bovine somatotropin (r-BST) to increase milk production in cows.

However, along with desired characteristics, undesirable characteristics may also be introduced in this process. For example, introduction of an albumin from Brazil nuts into soybeans to improve the content of the sulfur-containing amino acids methionine and cysteine also transferred a main source of Brazil nut allergenic protein (54). Originally, the FDA statement of policy of 1992 dealt with such situations by requiring notification and premarket testing and labeling of foods when gene transfer is from commonly allergenic foods (54a). However, this fails to address the potential for rare protein allergies not previously known by requiring that consumers be informed of all cross-species protein transfer in the food they purchase. Gene expression depends upon the genetic makeup of the organism, and introduction of new genetic material may modify the characteristic of an existing gene and create a potential hazard for some consuming the product. Therefore, when genetic material is transferred to a product from a species not commonly used for food purposes, toxicity testing of the product

would help provide data for risk assessment.

Dietary Estrogens

There is growing concern about environmental toxicants that could alter endocrine regulation, called *endocrine disrupters*. Some environmental chemicals with estrogenic activity have been associated with sexual, behavioral, and reproductive problems and carcinogenesis (55). While most of the evidence comes from domestic and wildlife species, there are recent reports of reduced sperm count in human populations over the last 40 years and increases in breast cancer incidence and endometriosis. The potential for long-term effects of endocrine disruption in humans is well recognized in the classic example of daughters who developed cervical cancer because of prenatal exposure to diethylstilbestrol after their mothers took the drug to avoid miscarriage. Another example is eggshell thinning in birds exposed to high levels of DDE, a metabolite of DDT (56). Other epidemiologic reports appear to associate human cancer of the prostate and testicles with exposure to environmental estrogenic compounds (57).

Humans are exposed to a wide variety of synthetic and naturally occurring estrogenic and antiandrogenic compounds, and the results of such exposures are difficult to predict. The final outcome depends on the complex interactions among all the factors including genetic susceptibility, duration of exposure, and stage of development during exposure. For example, neonatal exposure of rat pups through milk of dams fed either a plant isoflavonoid, coumestrol, a control, or a soy-based diet for the initial 10 days had no effect on estrous cycle, but 21-day treatment resulted in a persistent estrous state by 132 days of age. In contrast, 10-day treatment in males produced a significant defect in sexual behavior suggesting variability in endpoints. Immature females treated with natural dietary concentrations of coumestrol demonstrated estrogenic effects in the reproductive tract, brain, and pituitary. Some low-potency estrogenic environmental chemicals may have little effect on biologic systems. However, a combination of such chemicals may have synergistic effects.

Low-level exposure to environmental toxicants such as dioxins, which showed no overt toxicity, altered mating behavior and induced structural abnormalities in the external genitalia of the female rat and altered sperm count and delayed puberty in male rats. Prenatal exposure to PCBs can also delay puberty. Some dioxin-like PCBs can cause endocrine effects similar to those of dioxin. Many of these estrogenic compounds are lipophilic and are stored in the body. They can be excreted with the milk during lactation, exposing infants to very high levels. Since their developmental and reproductive effects can be delayed for a long time, it may be difficult to associate exposure to the developmental effects. Thus, the greatest uncertainty in risk assessment of endocrine disrupters is in the unborn fetus, nursing infants, and the young, who would be at greatest risk (because of their immature development) of such adverse effects.

PUBLIC HEALTH PERSPECTIVE, CURRENT METHODOLOGY AND FUTURE DIRECTIONS

Risk assessment is an important tool used by regulatory agencies to control the use of

harmful substances and exposure to environmental hazards thought to be harmful to human health (59). More frequently, environmental substances or hazards are of concern in air, water, and soil rather than in food. However, many of these substances are also found in food, and thus they should be assessed in combination with all environmental exposures. Also, most essential trace elements are released into the environment in minute quantities so that no immediate effect is observed; yet they can accumulate in the environment and bioaccumulate up the food chain, and total exposure can involve multimedia exposure.

Different health agencies may have either separate or combined risk assessment and risk management practices. The overall public health perspective is gained only when agencies balance health hazards against health benefits, with a goal of providing a wholesome, nutritious, affordable food supply safe from environmental contaminants. Thus, the results of risk assessment are useful in providing information for the risk-benefit analysis that may follow.

There is an opinion that it is unrealistic to set exposure limits so low that they are unattainable in the diets of a large proportion of the population. The situation with methylmercury in fish is an example of a case in which the toxicity of a contaminant must be balanced against the health impact of severely restricting intake of the food that may contain it. At the 1988 JECFA reevaluation of methylmercury, the committee confirmed the provisional tolerable weekly intake (PTWI) of 3.3 µg/kg, noting that this weekly value could be exceeded easily, as some species of fish contain methylmercury at levels of up to several parts per million (2). However, JECFA did not strongly recommend limiting consumption of fish because of the nutritional value of fish, and efforts are under way in many countries to increase fish consumption as an integral part of a well-balanced diet. The adverse health impact of too-restrictive intake of fish may include undernutrition and lowered intake of essential nutrients. However, the committee did recommend that efforts be made to minimize industrial exposure to methylmercury. Others may hold that restricting industrial exposure is necessary to prevent methylmercury exposure. Under such circumstances, information on risk assessment of various dietary components or habits would be useful for the general public. With such information, people can make comparisons and informed decisions themselves and, at the same time, have confidence in the risk assessments performed by professionals who understand the associated health implications.

Risk communication is important to give the public confidence in risk assessment and associated decision-making processes. This activity reaches out to educate the public. To support this communication, risk analysis must describe the health risk, quality of the database, strength and weaknesses of the evidence compiled, assumptions, limitations, and uncertainties. In interpreting the results of risk assessment, one must note that the risks predicted by extrapolation from animal data are theoretical risks. In general, regulatory agencies adopt a conservative approach to ensure public health protection. Current awareness and evolving risk assessment techniques permit prediction of potential health risks to assist in developing and implementing such public health protection measures as issuing health advisories and setting exposure limits for environmental chemicals.

The current methodology in risk assessment has been considerably refined during the last 10 years, but the process still carries some limitations and uncertainties. Default assumptions are adopted to overcome data limitations in performing risk assessment. Some common uncertainties and limitations include inadequate toxicology data, extrapolation from high- to low-dose exposure, extrapolation from animal data to human situations, and the uncertainty of results produced by the theoretical modeling of exposures used in the absence of actual monitoring data. The following issues are being examined to improve the risk assessment process and the accuracy of the results: default options (e.g., conversion factors for extrapolating from animal data to humans) and the related principles for modifying and deviating from them, scientifically plausible exposure data considering human activity patterns, validation and update of methods and models for generating and analyzing data, consideration of uncertainties in methods and data obtained, variations among individuals based on sex, age, or ethnicity in their exposures to chemicals and the associated susceptibility to specific toxicity of chemicals, interactions among chemicals, and multipathway and multimedia exposures.

Although dietary exposure estimates for food contaminants should be based on the consideration of all routes of exposure, such estimates are limited by the availability of the database for food consumption rates, contaminant concentrations in various food items, and contributions from other sources of exposure, food preparation methods, bioavailability, bioactivity, monitoring data on chemical or reactive breakdown product, and chemical forms in food. With such limitations and uncertainties in mind, the question arises whether the present methodology produces relevant findings with regard to risk in foods. First, much of the limitation and uncertainty is associated with the database. As the database is strengthened, the findings will become more relevant. Second, the results of risk assessment may be applied to prevent adverse health outcomes, and an adverse health outcome will not be observed if it is prevented from occurring (e.g., risk assessment is used to set exposure limits.) Third, the results of a risk assessment may be used to predict an adverse outcome, but that outcome may take a long time to manifest itself (e.g., cancer), making it difficult to associate the outcome with exposure to a particular chemical in food ingested at a certain stage in life, unless other data and evidence exist. Fourth, an adverse effect that occurs later in life may also be masked by exposure to other possible etiologic agents. So a major question is whether data are being generated to build a database that will permit adequate assessment with current methodology. There are additional questions: What chemicals are present in our food supply and at what levels? How much of the food is monitored for chemical residues and how representative are the monitoring data of the overall food supply? What do we know of the toxicology of the chemicals and their breakdown products? As for the current methodology, guidelines provide a reasonable certainty that the conclusions drawn from risk assessment can be used to make health-protecting decisions. However, the current methodology conducts risk assessment for single chemicals, not for all chemicals that humans are simultaneously exposed to. It does permit consideration of multiple chemicals and thus allows additivity when dealing with the same health-effect endpoint. It does not usually consider synergism or antagonism between chemicals. The lack of information on other parameters of chemicals as noted above also poses a major limitation on consideration of multiple chemical exposure in risk assessment.

The FDA's total diet study (TDS) can be used to illustrate how risk assessment can help provide relevant information about risk in food. This major program provides systemic evaluation of chemicals in food in the United States. Although the TDS does not specifically conduct risk assessments, the dietary intake estimates derived for individual chemicals provide a database for comparison with health-protective values previously determined by risk assessment. No health risk is anticipated when an intake estimate is lower than a chemical's health-protective value (e.g., the WHO's ADI or the EPA's RfD).

In most cases, adults have been used for risk assessment, and thus infants and children, who may be more sensitive than adults to certain toxic properties of chemicals, may not have been adequately considered. In this regard, the recent Food Quality Protection Act of 1996 requires that the EPA address human variability and risk to infants and children and publish a specific safety finding before pesticide tolerances in food are established. It also provides for an additional safety factor (up to 10-fold) to ensure that pesticide tolerances are safe for infants and children. The EPA has been using a negligible-risk standard for chemicals that pose a carcinogenic risk, except in cases where the Delaney clause of the FFDCA applied. Prior to 1996 the FFDCA authorized pesticide residue tolerances for raw commodities under Section 408, based on risk-benefit standards, and for processed foods under Section 409, which contains the Delaney clause that prohibits carcinogens that concentrate in processed foods. This new law repeals the Delaney clause and provides for setting tolerances for pesticide residues in both raw and processed foods on the basis of a determination that the tolerances are safe. *Safe* is defined as "a reasonable certainty that no harm will result from aggregate exposure," including all dietary exposure and that from other nonoccupational sources including drinking water.

Future recognition of a health concern relating to environmental contaminants in food will rely on the availability of new toxicologic and exposure data and state-of-the-art techniques. Therefore, continued efforts in conducting food consumption surveys, total diet studies, and food residue monitoring, combined with development of our knowledge of the toxic properties of chemicals and refinement of risk assessment techniques, are necessary to provide early warning of any potential problem with chemicals in our food supply. Recent activities by the EPA, which include issuing the cancer-risk-assessment guidelines, issuing the risk-characterization guidelines, reevaluating the cancer potency of PCBs, the national forum on chemicals in fish and advisories issues, and developing a screening and testing program for endocrine disruptors, plus the passage by Congress of the Food Quality Protection Act of 1996 all point to current and future efforts in providing new developments to support risk assessment in ensuring a safe food supply. Increasing effort is also being expended to evaluate multiple chemical exposures or complex mixtures and human variability in response to chemical exposure. The variations in the kind, number, levels, intake, and combination of chemicals in any one medium, particularly food, make risk assessment of environmental chemicals in our food a very challenging task.

[Chapter References](#)

[Chapter 94](#) in the 8th edition of this textbook, entitled “National Nutrition Policy, Food Labeling and Health Claims,” discussed food labeling and health claims and reviewed three aspects of national nutrition policy: the key players, the system, and the policy (1). This chapter updates events related to food labeling and health claims from early 1993 to the spring of 1996 and reviews the Dietary Supplement Health and Education Act of 1996.

FOOD LABELING AND HEALTH CLAIMS: AN UPDATE

The Congress has become the leader in establishing national nutritional policy. On November 8, 1990, President Bush signed into law the Nutrition Labeling and Education Act of 1990, which in general became operational law as of November 8, 1992 (2). Much of the first part of this chapter pertains to implementation of the 1990 act. On October 25, 1994, President Clinton signed into law the Dietary Supplement Health and Education Act of 1994 (3); from a nutrition science point of view, this is one of the most unusual pieces of “health” legislation ever passed and certainly the most important nutritional event at the federal level over the past 4 years.

Despite the debates in the 104th Congress, little has changed on such matters as food stamps, school breakfast and lunch programs, other nutrition-related “entitlement” programs and nutritional research funding. The scientifically based nutrition infrastructure remains intact at the federal level at this time. This infrastructure provides the base for evolution of food labeling and health claims and implementation of the dietary supplement legislation.

Federal Agencies

National Institutes of Health (NIH)

In fiscal year (FY) 1988, support for nutritional research and training at the NIH was \$276 million (1), and in FY 1993, it had increased to \$373 million (4). This total represents the combined individual contribution of 17 NIH institutes and two centers. As in the past, NIH provides about three-quarters of support for nutritional research at the federal level, and the two biggest contributors continue to be the National Cancer Institute (NCI) and the National Heart, Lung and Blood Institute (NHLBI). Administration of the NIH Nutrition Coordinating Committee (NCC) has been moved from the Office of the Director of NIH to the Division of Nutrition Research Coordination, National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK). The functions of the NCC remain the same, and NIH continues to be a very active participant in governmentwide coordinating committees.

Department of Agriculture (USDA)

Since FY 1991, there has been a dramatic shift in USDA resources toward food and nutritional programs (5). In FY 1991, 47% of the total USDA budget went to support such programs. In FY 1996, this rose to 60%, specifically to \$39.8 billion, administered by the USDA Food and Consumer Service. As in the past, the lion's share of the total is now distributed as follows: (a) Food Stamp Program: \$27.6 billion; (b) School Lunch Program: \$4.4 billion; (c) School Breakfast Program: \$1.2 billion; and (d) Special Supplemental Nutrition Program for Women, Infants and Children (WIC): \$3.5 billion. There have been no fundamental policy changes at the USDA. Unfortunately, the Congress has only extended USDA's efforts in nutritional research, education, and economics for 2 years, so the fate of these programs remains unclear, and the matter will be a major policy issue for the next several years. In 1994, USDA established their internal Nutrition Education and Research Coordinating Council.

USDA plays a major role in the interdepartmental committees known as the Interagency Board on Nutrition Monitoring and Related Research and the Interagency Committee on Human Nutrition Research. The total USDA support for human nutritional research, monitoring, and education in FY 1993 was \$343.5 million, somewhat higher than that of NIH (6). The Agricultural Research Service (ARS) continues to support its five nutrition research centers, and has added a new one recently: the Arkansas Children's Hospital Research Institute in Little Rock. USDA's Continuing Survey of Food Intakes by Individuals (CSFII) remains ongoing under its 1994–96 plan. In 1995, USDA in collaboration with the Department of Health and Human Services (DHHS) published the 4th edition of *Nutrition and Your Health: Dietary Guidelines for Americans* (7). The seven basic guidelines remain much the same as in the 1st edition issued in 1980 (which one of us, ALF, coauthored). USDA's approach to food labeling is discussed further below.

Food and Drug Administration (FDA)

Most of this chapter is devoted to recent activities of the FDA; hence, comments here are limited. The food and nutritional activities of FDA continue to be administered by the FDA Center for Food Safety and Applied Nutrition (CFSAN). CFSAN has begun to go “outside” for advice and counsel, particularly by establishing the FDA Food Advisory Committee. This committee has already had a significant impact on nutrition policies, e.g., recommending approval of the nonabsorbable fat substitute olestra. This recommendation was accepted by CFSAN, and a final rule approving olestra as a food additive was issued on January 30, 1996 (8). The science base at CFSAN has been modified in the last several years as the focus has shifted from in-house nutritional research and development to purely regulatory issues. On April 15, 1996, FDA and the University of Maryland announced formation of a unique partnership program, the Joint Institute for Food Safety and Applied Nutrition (JIFSAN). FDA issues are discussed further below.

Centers for Disease Control (CDC)

In February 1996, the National Health and Nutrition Examination Survey (NHANES-IV) was nearly cancelled by Congress (9). It now appears that it has survived and will start in 1998. The NHANES surveys (including food labeling) are fundamental to our entire nutritional efforts at the national level, as operated by the National Center for Health Statistics (NCHS), which is part of CDC, located in Hyattsville, Maryland, and further supported by the Nutritional Biochemistry Branch at CDC in Atlanta.

Life Sciences Research Office (LSRO), Federation of American Societies for Experimental Biology (FASEB)

In December 1995, LSRO published a very extensive report entitled “Third Report on Nutrition Monitoring in the United States” (10). The report was prepared under a joint contract with USDA and DHHS and is required by Congress at least every 5 years under the provisions of the National Nutrition Monitoring and Related Research Act of 1990. The report is based on national data through June 1994. It provides the foundation for current nutritional status, covering nutrition-related health status (e.g., lipid status, obesity, hypertension, osteoporosis, maternal and child health), food consumption, nutrient intakes from food, dietary supplement use, household food expenditures, etc. The report provides information of major importance for the evolution of nutrition labeling. LSRO also has two major efforts under way currently under FDA contract that will affect food labeling: (a) criteria required to establish safety decisions about new food ingredients and (b) assessment of nutrient requirements for infant formulas.

Food and Nutrition Board (FNB), Institute of Medicine (IOM), National Academy of Sciences (NAS)

The FNB has one major current activity that will have a direct impact on food labeling.

The board is updating their classic series of texts on recommended dietary allowances. The first publication has been issued ([10a](#)), cosponsored by NIH, FDA, and USDA (see Appendix [Table II-A-2-b-1](#), [Table II-A-2-b-2](#), [Table II-A-2-b-3](#), [Table II-A-2-b-4](#), [Table II-A-2-b-5](#) and [Table II-A-2-b-6](#)).

Implementation of the Nutritional Labeling and Education Act of 1990 (NLEA)

A “Primer” on Terminology

Before getting into the specifics of implementation, a brief “primer” on terminology seems in order because of a general lack of understanding of certain terms that govern implementation of acts such as the NLEA. *Content claims* in labeling refer to such adjectival descriptors of food characteristics as “low fat,” “reduced calorie,” and “healthy.” No mention of diseases is involved. *Health claims* is a bit of a misnomer because it involves label claims referring to specific diseases or conditions such as “osteoporosis,” “cardiovascular disease,” and “hypertension.” Such claims are better categorized as *disease-specific claims*.

The Federal Register (FR) is distinct from the Code of Federal Regulations (CFR). The FR, published every working day of the year, provides an enormous array of notices by every segment of the federal government. Further, the FR provides details of why a specific regulation is being proposed or finalized, including the history of the idea, the science base, responses to comments received, cost analyses, and potential environmental impacts. All regulatory concepts must first be proposed in the FR for public comment before a final order is issued. The downside is that for practical purposes, these scholarly discussions are lost. Few libraries and fewer individuals can store and easily retrieve specific items in the FR because of its enormous size. (References to the FR are usually in a form such as 58 FR January 6, 1993, page 2066 where “58” refers to the volume, and the page listed is the first page for the notice.)

The CFR is exactly what it says it is—a compilation of actual finalized regulations, usually short, and without any of the justification for the regulations provided in the FR. All effective regulations governmentwide are published once a year in a massive collection of volumes, usually in April. All FDA regulations are in Title (or volume) 21; USDA nutrition-related regulations are in Title 9. (References to the CFR are usually in a form such as 21 CFR 101.12, where “21” refers to the title, and 101.12 refers to the specific section in the CFR.) The regulation is easy to find; how it got there is not.

Implementation of the NLEA

On January 6, 1993, FDA issued in the FR the core final rules to implement the NLEA. In that one issue, 897 pages were devoted to the task—obviously a massive effort by FDA ([11](#)). Since then, FDA has issued over 40 major regulations for NLEA and many more minor regulations to revise existing regulations for such things as standardized foods and food additive regulations. There are four consequences of all this: (a) nutrition labeling is now virtually universal on packaged foods; (b) new nomenclature for declaring nutrient contents has been implemented, specifically, reference daily intakes (RDIs) and daily reference values (DRVs) have replaced the former USRDAs, and are

combined as “Daily Values” (DVs) on labels; (c) the format of the nutrition label has been simplified, standardized, and made more flexible; and (d) a series of disease-specific claims are now authorized. Review of each regulatory proposal and final order would be information overload, so comment is limited to regulations of particular interest to the nutrition community.

The January 6, 1993 FR provided the general rules for implementation of the NLEA as a preamble (12). It then established the mandatory status of nutrition labeling (12) (now 21 CFR 101.9), revised the format (13) (now 21 CFR 101.9), and established effective dates for implementation by industry (February 14 and May 8, 1994) (13, 14).

This same issue of the FR contained the final rule to replace the USRDAs with the new RDIs and DRVs (15), now universally used. Also, an enormous final rule on serving sizes of foods was issued, covering hundreds of individual foods ([16], now 21 CFR 101.12). Simultaneously, a final order was issued on nutrient content claims (17), including general principles (now 21 CFR 101.13); definitions of terms such as *low*, *good source of*, *light*, *reduced*, and *fresh*; voluntary nutritional labeling of restaurant foods (now 21 CFR 101.10); and revision of a long series of new regulations governing label statements for foods for special dietary use (now 21 CFR part 105), e.g., weight reduction products.

Also, in the same issue of the FR, USDA published its final rules governing labeling of meat and poultry products (18) (now 9 CFR parts 317, 320, and 381), stating “FSIS’s (Food Safety and Inspection Service) nutrition labeling final regulations for meat and poultry products will parallel to the extent possible, as authorized by the Federal Meat Inspection Act and the Poultry Products Inspection Act, FDA’s nutrition labeling regulations promulgated under the Nutrition Labeling and Education Act.”

USDA did in fact do precisely that. Consequently, USDA labeling in the marketplace is almost identical to that of FDA-labeled products. USDA’s regulations provide for “voluntary nutrition labeling on single-ingredient, raw meat and poultry products, and by establishing mandatory nutrition labeling for all other meat and poultry products, with certain exceptions.” USDA accepted most of FDA’s nutrient-content claim definitions but had a problem with lipids, simply because meat and poultry by nature contribute significantly to lipid intake. USDA therefore emphasized additional adjectival descriptors such as “lean” and “extra lean.” For example, the regulation 9 CFR 317.362 states, “The term “lean” may be used on the label or in labeling of a meat product, provided that the product contains less than 10 grams fat, less than 4 grams saturated fat, and less than 95 milligrams cholesterol per 100 grams and Reference Amount Customarily Consumed (RACC) for individual foods, and per 100 grams and labeled serving size for meal-type products.”

FDA Rules for Disease-Specific Claims

Starting on January 6, 1993, FDA’s initial final rules for disease-specific claims were issued as required by Congress (briefly reviewed in [1]). Because they are fundamental parts of the current scheme for food labeling they deserve iteration. (The general requirements for disease-specific claims are now 21 CFR 101.14.) Specific claims and

their status are:

1. Fiber and cancer: *not authorized*, but a claim is authorized for diets low in fat and high in fiber and containing grain products, fruits, and vegetables. (Now 21 CFR 101.76.)
2. Fiber and cardiovascular disease: *not authorized*, but a claim is authorized for diets low in saturated fat and cholesterol and high in fruits, vegetables, and grain products. (Now 21 CFR 101.77.)
3. Folic acid and neural tube defects: *not authorized in 1993, but recently authorized*. In the March 5, 1996, issue of the FR, FDA finalized authorization of a health claim for folic acid and neural tube defects for both conventional foods and dietary supplements (now 21 CFR 101.79) ([19](#)). In addition, in this same FR issue (61 FR 8781), FDA mandated that standardized enriched grain products such as enriched bread, rolls, and buns add folate and amended a long series of standards of identity accordingly.
4. Antioxidant vitamins and cancer: *not authorized*, but a claim is authorized re substances in diets low in fat and high in fruits and vegetables. (Now 21 CFR 101.71.)
5. Zinc and immune function in the elderly; *not authorized*. (Now 21 CFR 101.71.)
6. Calcium and osteoporosis: *authorized*. (Now 21 CFR 101.72.)
7. w-3 Fatty acids and coronary heart disease: *not authorized*. (Now 21 CFR 101.71.)
8. Dietary saturated fat and cholesterol and coronary heart disease: *authorized*. (Now 21 CFR 101.75.)
9. Dietary fat and cancer: *authorized*. (Now 21 CFR 101.73.)
10. Sodium and hypertension: *authorized*. (Now 21 CFR 101.74.)

Currently, there are two new proposals by the FDA to add to the list of authorized disease-specific claims: (a) On July 20, 1995, FDA proposed authorizing a health claim on the association between sugar alcohols and nonpromotion of dental caries ([20](#)), referring particularly to xylitol, sorbitol, mannitol, maltitol, isomalt, lactitol, hydrogenated starch hydrolysates, and hydrogenated glucose syrups and (b) on January 4, 1996, FDA proposed authorizing a health claim on the association between oat products (i.e., oat bran and oatmeal) and reduced risk of coronary heart disease ([21](#)).

As pointed out above, FDA has issued a huge number of regulations to implement the NLEA. Many are technical corrections or additions, but one more deserves mention. On December 28, 1995, FDA issued a final order ([22](#)) establishing new RDIs for vitamin K, selenium, manganese, chromium, molybdenum, and chloride but not for fluoride. This action amends 21 CFR 101.9. The new regulation has one unfortunate drawback—on the label, it separates chloride from the other classic electrolytes, i.e., sodium and potassium. Appeals have been made in this regard.

As reported in *Food Labeling & Nutrition News* of May 2, 1996 ([23](#)), a number of consumer studies have been conducted recently by FDA and the private sector on the relative success of the new food labeling approach. Most consumers find the new labels easier to understand, but considerable concern about label accuracy remains, and in many cases, consumers are downright suspicious of health claims, particularly because

of the plethora of often-conflicting health claims they confront from the media. Many believe that the label information is at the discretion of the manufacturer, and that such information is not strictly regulated by FDA. At best, one can reasonably conclude that implementation of the NLEA has been only a modest success, in spite of the enormous efforts devoted to its implementation.

In some regards, FDA has been a bit overzealous in implementing labeling for disease-specific claims. For example, consider the regulation for calcium and osteoporosis. Most manufacturers would simply like to claim that “calcium helps prevent osteoporosis,” when their food product contains a reasonable amount of calcium. However, the FDA regulation (21 CFR 101.72) provides several model label statements that they anticipate being used. For example, one such model for foods exceptionally high in calcium and most calcium supplements states: “Regular exercise and a healthy diet with enough calcium helps teen and young adult white and Asian women maintain good bone health and may reduce their high rate of osteoporosis later in life. Adequate calcium intake is important, but daily intakes above about 2,000 mg are not likely to provide any additional benefit.” Given the limited space on food labels, that is too long. Thus, there are not a lot of disease-specific claims being made in the marketplace at present.

For the most part, the American public seems nutritionally illiterate, and they will remain so until our schools make nutritional education an integral part of health and science education. The food label does not substitute for such education.

DIETARY SUPPLEMENT HEALTH AND EDUCATION ACT OF 1994

Regulation of Dietary Supplements

During the period 1992–1994, there was extensive pressure on Congress to amend the Federal Food, Drug, and Cosmetic Act (FDCA) to reduce the regulatory burdens on dietary supplements. Many senators and representatives claimed to be receiving more mail, more phone calls, and generally more constituent pressure on this subject than on anything else—including healthcare reform, abortion, or the deficit.

Not surprisingly, given all of this pressure, Congress eventually passed the Dietary Supplement Health and Education Act of 1994 (DSHEA) ([24](#)). The House of Representatives approved the measure by unanimous consent on October 7, 1994, and the Senate approved it, also by unanimous consent, on October 8, 1994. The president signed it into law on October 25, 1994.

The new law, like virtually all legislation, is a compromise. It does not include all of the restraints on FDA regulation of dietary supplements that the sponsors had originally wanted. Furthermore, it imposes some significant new requirements for such products. Nevertheless, viewed as a whole, this legislation is a very favorable development for those who want to sell or consume a free range of dietary supplements of vitamins, minerals, herbs, other botanicals, amino acids, and other similar substances.

Expanded Definition of “Dietary Supplement”

For many years, there has been a substantial business in the selling of “dietary supplements” in the United States (25). These products, usually tablets or capsules, have provided not only vitamins or minerals viewed as “essential” by the mainstream community of nutritionists, such as vitamin A or iron, but also other substances that FDA personnel often have regarded as being of dubious usefulness—substances ranging from rutin and other bioflavonoids to herbs to shark cartilage.

Until the DSHEA was passed, agency personnel often maintained that it was “misleading” and improper to distribute as a “dietary supplement” a substance that the agency regarded as lacking in nutritional usefulness. Agency personnel sometimes also asserted that a substance that did not provide “taste, aroma, or nutritional value” in its dietary supplement (pill-type) form could not properly be sold as a food product (26).

The new DSHEA deals with this fundamental de-finitional matter by unequivocally providing a broad, expansive definition of *dietary supplement* that includes a “product ... intended to supplement the diet that bears or contains ... a vitamin; ... a mineral; ... an herb or other botanical; ... an amino acid; ... a dietary substance for use by man to supplement the diet by increasing the total dietary intake; or ... a concentrate, metabolite, constituent, extract, or combination [of any ingredient described above]” (27). The practical effect of this definition makes it clear that the new provisions of the DSHEA for dietary supplements apply broadly to a wide class of products, including products that FDA nutritionists might regard as having no nutritional value.

Exemption of Dietary Ingredients in Dietary Supplements from “Food Additive” Status

One of the most important provisions of the new law, from the perspective of manufacturers of dietary supplement products, is the explicit amendment of the FDCA to be clear that the term *food additive* does not apply to a dietary ingredient in, or intended for use in, a dietary supplement (28)

Previously, FDA had argued that substances added to dietary supplement products were much like substances added to any other food product, i.e., that if such a substance was not “generally recognized as safe” (not GRAS) by “experts,” based on published scientific literature, it would be subject to regulation as a “food additive” (29). Under the FDCA, if a substance is a food additive, it may not be added to food products unless a food additive regulation, issued by FDA, explicitly permits such addition (30). Typically, preparation of a food additive petition, including needed research (often involving extensive animal feeding studies) and participation in the ensuing administrative proceedings, can cost a petitioner \$1 million or more; and after receiving even a well-founded food additive petition, it often takes FDA 5 years or more to issue an approving food additive regulation (31).

The “bottom line” of all of this for dietary supplements had been that alleged “food

additive” status and the absence of a food additive regulation approving use as a dietary supplement meant alleged *illegality* and ended or curtailed marketing of many products. Based on allegations of “unapproved food additive” status, before the DSHEA, FDA had pursued regulatory actions against numbers of popular dietary supplement ingredients—including, for example, calcium acetate, orotate compounds such as magnesium orotate, evening primrose oil, black currant oil, borage seed oil, linseed/flaxseed oil, chlorella, lobelia, St. Johnswort, and coenzyme Q10.

The new law, thus, frees dietary supplement ingredients from the continuing risk that at any time, FDA might assert that its scientists did not believe that a particular dietary ingredient was GRAS for use in dietary supplements, and therefore, the ingredient was an unapproved food additive and illegal.

New Safety Standards

As a quid pro quo, however, the new law replaces the voided food additive provisions with some new safety standards. In general, the DSHEA provides that a dietary supplement will be deemed to be adulterated if it “presents a *significant or unreasonable risk of illness or injury*” [emphasis added] (“under ... conditions of use recommended or suggested in labeling, or ... if no conditions of use are suggested or recommended in the labeling, under ordinary conditions of use”) (32). The new law is also clear, however, that FDA shall bear the burden of proof in court if it asserts that a dietary supplement is adulterated under this standard (33).

There are additional requirements with respect to a *new* dietary ingredient, i.e., an ingredient that “was not marketed in the United States before October 15, 1994” (34). A dietary supplement that contains a *new* dietary ingredient is deemed to be adulterated unless either (a) the supplement “contains only dietary ingredients which have been present in the food supply as an article used for food in a form in which the food has not been chemically altered,” or (b) there is a “history of use or other evidence of safety establishing that the dietary ingredient when used under the conditions recommended or suggested in the labeling ... will reasonably be expected to be safe” (35). In the latter case, “at least 75 days before being introduced or delivered for introduction into interstate commerce,” the manufacturer or distributor of the dietary ingredient or dietary supplement must provide “the Secretary [of Health and Human Services] with information, including any citation to published articles, which is the basis on which the manufacturer or distributor has concluded that a dietary supplement containing such dietary ingredient will reasonably be expected to be safe” (36).

In addition, the new legislation provides that the secretary of health and human services may declare a dietary supplement “to pose an imminent hazard to public health or safety,” in which case it immediately becomes illegal to market the product, although the secretary must promptly hold a formal hearing to assemble data “to affirm or withdraw the declaration” (37). The new law gives the authority to declare a dietary supplement an “imminent hazard” only to the secretary, and it *may not be delegated to the FDA*.

In sum, under the new law, with respect to safety, the FDA-asserted “food additive” requirement for agency *preclearance* of dietary ingredients not believed by FDA to be

GRAS was deleted, but FDA and the secretary were granted substantial new *policing* authority to stop distribution of a dietary supplement if government personnel believe they can show that the product is not safe.

The amendment to the food additive definition that exempts ingredients in dietary supplement products only applies to “dietary ingredients,” that is, an ingredient that is a vitamin, a mineral, an herb or other botanical, an amino acid, a “dietary substance for use by man to supplement the diet by increasing the total dietary intake,” or a “concentrate, metabolite, constituent, extract, or combination” of any of these (38). This means that an ingredient added to a dietary supplement product as a binder, diluent, or preservative or for any other nondietary purpose remains subject to the food additive provisions of the FDCA and, if not “generally recognized as safe” for its intended use, may require approval of a food additive regulation prior to use (39). Furthermore, if an ingredient is added to a dietary supplement product for use as a color, it would be subject to the “color additive” approval requirements of the FDCA (40).

It may take some time for FDA to develop a consistent policy and practice concerning the nature and degree of risk to human health that will elicit regulatory action against an allegedly adulterated dietary supplement product under the new safety standards in the DSHEA. Nevertheless, it seems clear already that FDA has not abandoned safety-related enforcement actions against dietary supplement products that contain ingredients it believes present unreasonable risk to the public health. FDA has issued at least one warning letter and a related public warning asserting that a dietary supplement containing a particular combination of herbs was unsafe and adulterated within the meaning of the new standards of the DSHEA (41).

New Rights for Sellers to Convey Information about Usefulness of Dietary Supplements

Some of the most intriguing, and potentially important, changes brought about by the new legislation relate to new freedoms for sellers of dietary supplements to use published literature to convey information to potential customers about the usefulness of dietary ingredients. Prior to enactment of the new legislation, FDA routinely asserted that a book, article, or other publication used in connection with the sale of a dietary supplement to customers could be regulated as “labeling” for the product, and if the publication included information to the effect that an ingredient present in the product might be useful in the cure, mitigation, treatment, or prevention of any disease, the product itself was subject to regulation as a *drug*. For example, FDA would assert that someone selling a dietary supplement product could not promote that product to customers by showing them (in connection with selling the product) copies of books or articles that claimed disease prevention benefits for nutrients in the supplement (42).

The new law greatly restricts the FDA's ability to object to the use of books and other publications in connection with the sale of dietary supplement products. In a significant new provision, the law provides that a “publication,” including “an article, a chapter in a book, or an official abstract of a peer-reviewed scientific publication that appears in an article and was prepared by the author or the editors of the publication,” “shall not be defined as labeling” and may be “used in connection with the sale of a dietary

supplement to consumers” *if* the publication is “reprinted in its entirety” *and* meets certain specific criteria. Among these criteria: (a) the publication must not be “false or misleading,” (b) it must not “promote a particular manufacturer or brand of a dietary supplement,” (c) it must be “displayed or presented ... so as to present a balanced view of the available scientific information,” (d) *if* “displayed in an establishment,” it must be “physically separate from the dietary supplements,” and (e) it must *not* “have appended to it any information by sticker or any other method” (43).

So long as these criteria are met, the new law would appear to allow a salesperson to show a potential customer published nutritional or other scientific literature that describes the health benefits of a dietary supplement’s ingredients. Furthermore, an additional, explicit provision in the new legislation states that it shall *not* “restrict a retailer or wholesaler of dietary supplements in any way whatsoever in the sale of books or other publications as a part of the business of such retailer or wholesaler” (44). This is the first affirmative provision in the FDCA that protects the right of those selling dietary supplements to sell “books or other publications” as well—publications that would, of course, be expected to describe the health-related benefits of nutrients and to help sell dietary supplements as well as educate customers.

FDA Statements of Nutritional Support

FDA regulations published pursuant to the NLEA provide that *no* “health claim” may appear on the label or in other labeling (including brochures) for food products, *including dietary supplements*, unless FDA has first approved use of the claim in a final regulation (45). As a new exception to the general requirement for FDA approval of health claims in food labeling, under the DSHEA dietary supplements are *allowed* to have four types of “statements of nutritional support” on labels or in other labeling *without* obtaining FDA approval (46):

1. A statement that “claims a benefit related to a classical nutrient deficiency disease and discloses the prevalence of such disease in the United States”
2. A statement that “describes the role of a nutrient or dietary ingredient intended to affect the structure or function in humans”
3. A statement that “characterizes the documented mechanism by which a nutrient or dietary ingredient acts to maintain such structure or function”
4. A statement that “describes general well-being from consumption of a nutrient or dietary ingredient”

The legislation provides that such a statement may be made in labeling for a dietary supplement *if* (47)

1. The manufacturer “has substantiation that such statement is truthful and not misleading”
2. The labeling contains, prominently displayed, the following additional text: “This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease”
3. The manufacturer notifies FDA “no later than 30 days after the first marketing of

the dietary supplement with such statement that such a statement is being made”

Summary Effect of DSHEA

In summary, the new legislation will substantially change the way FDA regulates dietary supplements. As discussed above, in general, the legislation:

1. Creates a broad, new definition of “dietary supplement” products
2. Moderates the regulatory burdens for use of dietary ingredients in dietary supplements, both (a) changing the safety standards for use of an ingredient and (b) generally changing the regulating procedure from preclearance to policing
3. Permits additional use of information about the putative benefits of dietary supplements, both through the use of “statements of nutritional support” on labels or in other labeling and by enabling sellers to refer customers to books, articles, and other publications that provide health-related information

 25. FDA has long regarded dietary supplements as a type of *food* intended for “special dietary uses.” Section 403(j) of the FDCA, which has been part of the Act since its original passage in 1938, provides that a food shall be deemed to be “misbranded” (and therefore illegal) “[i]f it purports to be or is represented for special dietary uses, unless its label bears such information concerning its vitamin, mineral, and other dietary properties as the Secretary determines to be, and by regulations prescribes as, necessary in order fully to inform purchasers as to its value for such uses.” 21 USC 343(j). This section of the FDCA recognizes that a product that is intended “for special dietary uses” because of “its vitamin, mineral, and other dietary properties” is a type of *food*. Note that section 403(j) authorizes but does not require the issuance of regulations to prescribe mandatory label information. The authority of the secretary of DHHS to issue regulations under the FDCA has been delegated to the Commissioner of Food and Drugs, who directs the FDA. 21 CFR 5.10(a)(1). FDA regulations issued pursuant to section 403(j) of the Act state that the term “special dietary uses” includes “[u]ses for *supplementing* or fortifying the ordinary or usual *diet* with any vitamin, mineral, or other dietary property.” 21 CFR 105.3(a)(1)(iii) (hence “dietary supplement”). (Emphasis added.)
 26. Judicial rulings that FDA personnel have cited as supportive of this proposition include *Nutrilab, Inc. v. Schweiker*, 713 F.2d 335 (7th Cir. 1983) and *American Health Products Co. v. Hayes*, 574 F. Supp. 1498 (S.D.N.Y. 1983), *aff’d*, 744 F.2d 912 (2d Cir. 1984). However, perhaps inconsistently, FDA also has long accepted that, “Ingredients or products such as rutin, other bioflavonoids, para-amino-benzoic acid, inositol, and similar substances which have in the past been represented as having nutritional properties but which have not been shown to be essential in human nutrition...may be marketed as individual products or mixtures thereof: *Provided*, That the possibility of nutritional, dietary, or therapeutic value is not stated or implied...” 21 CFR 101.9(i)(5) (April 1, 1993 ed.). Tablets or capsules of such products might have no taste, aroma, or nutritional value, but nevertheless the agency acknowledged that they could properly be sold as foods (provided that no misleading nutritional or therapeutic claims were made). (This particular statement no longer appears in FDA’s revised regulations on nutrition labeling. 21 CFR 101.9 (April 1, 194 ed.). However, when the FDA revised its nutrition labeling regulations to delete this statement, it explicitly said that it was not intending to change its policy that permitted sale, as food, of a substance that offered no nutritional value (in FDA’s judgment). For example, *see generally* 58 FR 2166 (January 6, 1993).)
 27. New section 201(ff)(1) of the FDCA, 21 USC 321(ff)(1). There are additional criteria. The product must either be intended for ingestion in tablet, capsule, powder, softgel, gelcap, or liquid droplet form, or, if not intended for ingestion in such a form, not be “represented for use as a conventional food or as a sole item of a meal or the diet.” New section 201(ff)(2) of the FDCA, 21 USC 321(ff)(2). In addition, it must be labeled as a “dietary supplement.” New section 201(ff)(2)(C) of the FDCA, 21 USC 321(ff)(2)(C); new section 403(s)(2)(B) of the FDCA, 21 USC 343(s)(2)(B).

The new definition includes some highly technical provisions about the situation where an ingredient in a supplement is also approved by FDA for use as a drug. In general, if “an article” has been “marketed as a dietary supplement or as a food” *before* it is approved by FDA as a new drug, certified by FDA as an antibiotic, or licensed by FDA as a biologic, it may continue to be marketed as a dietary supplement unless FDA publishes a prohibitory regulation (which would be subject to

judicial review. New section 201(ff)(3)(A) of the FDCA, 21 USC 321(ff)(3)(A).

On the other hand, in general, if, *before* “an article” is “marketed as a dietary supplement or as a food,” *either* (1) FDA has approved the article as a new drug, certified the article as an antibiotic, or licensed the article as a biologic, *or* (2) FDA has authorized the article for investigation as a new drug, antibiotic, or biologic, *and* “substantial clinical investigations have been instituted,” *and* “the existence of such investigations has been made public,” under these circumstances the article may *not* be marketed as a dietary supplement unless FDA first issues an approving regulation. New section 201(ff)(3)(B) of the FDCA, 21 USC 321(ff)(3)(B).

28. New section 201(s)(6) of the FDCA, 21 USC 321(s)(6).
29. Section 201(s) of the FDCA, 21 USC 321(s). As an example of FDA's use of the food additive allegation for dietary ingredients in dietary supplement products prior to enactment of the DSHEA, see FDA Compliance Policy Guide No. 7117.04, “Botanical Products for Use as Food” (as issued on July 1, 1986). Even before enactment of the DSHEA, however, the courts had expressed the view that FDA had sometimes overreached in its attempts to regulate dietary ingredients in dietary supplement products as “food additives.” See, for example, *United States v. Two Plastic Drums...Black Currant Oil*, 984 F.2d 814 (7th Cir. 1993) (ruling that black currant oil in a gelatin capsule was not subject to regulation as a “food additive,” and that FDA's allegations of food additive status constituted an “Alice-in-Wonderland approach...to make an end-run around the statutory scheme and shift to the processors the burden of proving the safety of a substance in all circumstance,” 984 F.2d at 819) and *United States v. 29 Cartons...Oakmont Investment Co.*, 987 F.2d 33 (1st Cir. 1993) (“The [i.e., FDA's] proposition that placing a single-ingredient food product into an inert capsule as a convenient method of ingestion converts that food into a food additive perverts the statutory text, undermines legislative intent, and defenestrates common sense. We cannot accept such anfractuous reasoning.” 987 F.2d at 39.).
30. 21 USC 342(a)(2)(C), 348(a).
31. Kutak, Rock, Campbell. *Food Chem News* 1991;33:67.
32. New section 402(f)(1)(A) of the FDCA, 21 USC 342(f)(1)(A).
33. New section 402(f)(1) of the FDCA, 21 USC 342(f)(1).
34. New section 413(c) of the FDCA, 21 USC 350b(c).
35. New section 413(a) of the FDCA, 21 USC 350b(a).
36. *Id.*
37. New section 402(f)(1)(C) of the FDCA, 21 USC 342(f)(1)(C).
38. New section 201(s)(6) of the FDCA, 21 USC 321(s)(6), which cross-references the ingredients described in new section 201(ff) of the FDCA, 21 USC 321(ff).
39. 21 USC 321(s), 342(a)(2)(C), 348.
40. 21 USC 321(t), 342(c), 379e.
41. FDA. Warning letter no. 95-DAL-WL-04 (November 22, 1994) issued to Alliance U.S.A., Richardson, Texas (asserting that the company's “Nature's Nutrition Formula One” product was “in violation of Sections 402(a)(1) and 402(f)(1)(A) of the Federal Food, Drug, and Cosmetic Act,” i.e., 21 USC 342(a)(1) and (f)(1)(A), because the product allegedly “contain[ed] an added poisonous or deleterious substance, namely ephedrine and other alkaloids which may render it injurious to health”) and FDA news release dated February 28, 1995 entitled “FDA Warns Consumers Against Nature's Nutrition Formula One” (warning the public not to consume the “Formula One” product described in the warning letter). More recently, FDA has consulted with its national food advisory committee about how best to regulate dietary supplements of the herb ma huang.
42. For a judicial ruling upholding FDA assertions of this type, see *United States v. Articles of Drug...Honey*, 344 F.2d 288 (6th Cir. 1965) (ruling that a jar of honey became subject to regulation as a drug when a book that made drug claims for honey was used in “immediate connection...with the sale of the product” by the retailer). Cf. *United States v. Sterling Vinegar and Honey...Balanced Foods*, 338 F.2d 157 (2d Cir. 1964) (ruling that a book that made drug-type claims for a vinegar-honey combination did *not* create drug status for a vinegar-honey product, although the book was available for sale in the same store as the product, when there was “no evidence of any joint promotion” of the book and the product).
43. New section 403B(a) of the FDCA, 21 USC 343-2(a).
44. Section 403B(b) of the FDCA, 21 USC 343-2(b).
45. 21 CFR 101.14(e)(1).

46. New section 403(r)(6) of the FDCA, 21 USC 343(r)(6).
47. *Id.* It would appear that labeling claims that come within the four types of “statements of nutritional support” described in new section 403(r)(6) will *not* always come within FDA’s definition of a “health claim.” See 21 CFR 101.14(a)(1)–(6). For example, a label claim that “calcium helps build strong bones” is a claim that “describes the role” of calcium “to affect the structure or function in humans.” Yet, such a claim does *not* come within the FDA’s definition of a “health claim.” See 21 CFR 101.14(a)(6). In such circumstances, it would appear that *neither* the approval of a health claim regulation *nor* compliance with the DSHEA’s requirements for the new “statements of nutritional support” exception from health claim requirements would be applicable or needed.

SECTION I. CONVERSION FACTORS, WEIGHTS AND MEASURES, AND METABOLIC WATER FORMATION

The table contains conversion factors between traditional and SI units. Key sections include:

- Length:** Conversion factors for units like inches, feet, yards, miles, centimeters, meters, kilometers, etc.
- Area:** Conversion factors for units like square inches, square feet, square yards, square miles, square centimeters, square meters, etc.
- Volume:** Conversion factors for units like cubic inches, cubic feet, cubic yards, cubic miles, cubic centimeters, cubic meters, liters, etc.
- Mass:** Conversion factors for units like ounces, pounds, tons, grams, kilograms, etc.
- Force:** Conversion factors for units like pounds-force, newtons, etc.
- Energy:** Conversion factors for units like foot-pounds, joules, kilocalories, etc.
- Power:** Conversion factors for units like foot-pounds per minute, watts, etc.
- Temperature:** Conversion factors between Fahrenheit and Celsius scales.
- Time:** Conversion factors for units like minutes, hours, days, weeks, etc.

Table A-1-a Conversion Factors Between Traditional and SI Units

Table A-1-c-2 Atomic Weights (Order of Atomic Number)

The image shows a standard periodic table of elements. Each element's symbol and atomic weight are listed. The table is organized into groups and periods, with elements ordered by increasing atomic number from left to right and top to bottom.

Table A-1-d Weights and Measures

Source	Amount
Muscle	1 g yields 0.85 mL 0.1 mL from protein + 0.75 mL cellular water
Mixed tissue	100 kcal yields 10 mL
Fat	1 g yields 1.0 mL
Protein	1 g yields 0.4 mL
Glucose	1 g yields 0.64 mL
Glucose + H ₂ O	1 g yields 0.60 mL
Mixed diet	100 kcal yields 20 mL
Example: High-glucose TPN solution	
750 mL 10% amino acids	= 300 kcal yields 30 mL H ₂ O
1175 mL 50% glucose/water	= 2000 kcal yields 350 mL H ₂ O
143 mL 10% lipid	= 157 kcal yields 14 mL H ₂ O
Total: 2068 mL	= 2457 kcal yields 397 mL H₂O
Example: Glucose-lipid TPN solution	
750 mL 10% amino acids	= 300 kcal yields 30 mL H ₂ O
750 mL 50% glucose/water	= 1275 kcal yields 225 mL H ₂ O
500 mL 20% lipid	= 1000 kcal yields 100 mL H ₂ O
Total: 2000 mL	= 2575 kcal yields 355 mL H₂O

Table A-1-e Water Formed in the Metabolism of Tissue and Caloric Sources

SECTION II. NATIONAL AND INTERNATIONAL RECOMMENDED DIETARY REFERENCE VALUES

INTRODUCTION TO SECTION II

[Chapter 103](#) of the 9th edition of *Modern Nutrition in Health and Disease*, authored by George H. Beaton, Ph.D., is a comprehensive review of the historical development of

nutritional standards and current controversial issues. It provides pertinent comments and recommendations concerning key national and international standards.

Key tables from the various national and international reports are included in this section. The reader is referred to the original reports for background statements and ancillary tables. Because the United Kingdom report is unlikely to be easily available to readers in the United States, significant excerpts have been included in [Table II-A-4-a](#).

The tables from the first two volumes of the new Food and Nutrition Board—Institute of Medicine Dietary Reference Values are given in [Table A-2-b-1](#) to [Table A-2-b-2](#), [Table A-2-b-3](#), [Table A-2-b-4](#), [Table A-2-b-5](#) and [Table A-2-b-6](#) and [Table A-2-c-1](#), [Table A-2-c-2](#), [Table A-2-c-3](#), [Table A-2-c-4](#) and [Table A-2-c-5](#) following the excerpts from the reports preceding [Table A-2-b](#).

Life-Stage Group ^a	Criterion	AI (mg/day) ^b
0 to 6 months	Human milk content	210
6 to 12 months	Human milk + solid food	270
1 through 3 years	Extrapolation of maximal calcium retention from 4 through 6 years	540
4 through 6 years	Maximal calcium retention	800
6 through 12 years	Maximal calcium retention	1200
12 through 18 years	Maximal calcium retention	1300
18 through 30 years	Calcium balance	1000
31 through 50 years	Maximal calcium retention	1200
51 through 70 years	Extrapolation of maximal calcium retention from 51 through 70 years	1200
Pregnancy		
< 18 years	Bone mineral mass	1300
18 through 50 years	Bone mineral mass	1000
Lactation		
< 18 years	Bone mineral mass	1300
18 through 50 years	Bone mineral mass	1000

From Food and Nutrition Board, Institute of Medicine. Dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington, DC: National Academy Press, 1997 (republication copy). Table 5-1 in original.
^aAll groups except Pregnancy and Lactation are males and females.
^bAI = Adequate Intake. The observed average or experimentally determined intake for a defined population or subgroup that appears to sustain a defined nutritional state, such as growth rate, normal circulating nutrient values, or other functional indicators of health. AI is used if sufficient scientific evidence is not available to derive an RDA. For pregnancy breast-feeding infants, AI is the mean intake. General breastfeeding infants must receive only breast milk; infants who are not breastfed must receive iron-fortified formula and/or milk. AI is based on such nutrient intakes. **This AI is not equivalent to an RDA.**

Table A-2-b-1 Criteria and Dietary Reference Intake Values for Calcium by Life-Stage Group

Life-Stage Group ^a	Criterion	EAR (mg/day) ^b	RDA (mg/day) ^c	AI (mg/day) ^d
0 to 6 months	Human milk content	—	—	210
6 to 12 months	Human milk + solid food	—	—	270
1 through 3 years	Factorial approach	380	480	—
4 through 6 years	Factorial approach	425	520	—
6 through 12 years	Factorial approach	1050	1250	—
12 through 18 years	Factorial approach	1050	1250	—
18 through 30 years	Serum P ^e	800	700	—
31 through 50 years	Serum P ^e	800	700	—
51 through 70 years	Extrapolation of serum P ^e from 18 through 30 years	500	700	—
>70 years	Extrapolation of serum P ^e from 18 through 30 years	500	700	—
Pregnancy				
< 18 years	Factorial approach	1050	1250	—
18 through 50 years	Serum P ^e	800	700	—
Lactation				
< 18 years	Factorial approach	1050	1250	—
18 through 50 years	Serum P ^e	800	700	—

From Food and Nutrition Board, Institute of Medicine. Dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington, DC: National Academy Press, 1997 (republication copy). Table 5-2 in original.
^aAll groups except Pregnancy and Lactation are males and females.
^bEAR, estimated average requirement. The intake that meets the estimated nutrient needs of 50% of the individuals in a group.
^cRDA, recommended dietary allowance. The intake that meets the nutrient needs of almost all (97-98%) of individuals in a group.
^dAI, adequate intake. The observed average or experimentally determined intake for a defined population or subgroup that appears to sustain a defined nutritional state, such as growth rate, normal circulating nutrient values, or other functional indicators of health. AI is used if sufficient scientific evidence is not available to derive an EAR. For breast-feeding infants, AI is the mean intake. **This AI is not equivalent to an RDA.**
^eP^e Serum inorganic phosphate concentration.

Table A-2-b-2 Criteria and Dietary Reference Intake Values for Phosphorus by Life-Stage Group

Life-Stage Group	Criterion	EAR (mg/day) ^a		RDA (mg/day) ^a		AI (mg/day) ^a	
		Male	Female	Male	Female	Male	Female
0 to 6 months	Human milk content	—	—	—	—	30	30
6 to 12 months	Human milk + solid food	—	—	—	—	75	75
1 through 3 years	Extrapolation of balance from older children	65	65	90	90	—	—
4 through 8 years	Extrapolation of balance from older children	110	110	130	130	—	—
9 through 13 years	Balance studies	300	300	240	240	—	—
14 through 18 years	Balance studies	340	300	410	360	—	—
19 through 30 years	Balance studies	330	295	400	340	—	—
31 through 50 years	Balance studies	350	295	430	330	—	—
51 through 70 years	Balance studies	350	295	430	330	—	—
>70 years	Intervention studies, decreases in absorption	350	295	430	330	—	—
Pregnancy							
<10 years	Gain in lean mass	230	—	400	—	—	—
10 through 30 years	Gain in lean mass	290	—	350	—	—	—
31 through 50 years	Gain in lean mass	300	—	360	—	—	—
Lactation							
<10 years	Balance studies	300	—	360	—	—	—
10 through 30 years	Balance studies	295	—	340	—	—	—
31 through 50 years	Balance studies	295	—	330	—	—	—

From Food and Nutrition Board, Institute of Medicine. Dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington, DC: National Academy Press, 1980 (reproduction copyright 1993 by original author).

^aEAR = Estimated Average Requirement; the intake that meets the estimated nutrient needs of 50% of the individuals in a group.

^bAI = Recommended Dietary Allowance. The intake that meets the nutrient needs of almost all (97-98%) of individuals in a group. An adequate intake is the observed average or experimentally set intake by a defined population or subgroup that appears to sustain a defined nutritional status, such as growth rate, normal circulating nutrient levels, or other functional indicators of health. It is used if sufficient scientific evidence is not available to derive an EAR. For many nutrients, the EAR and AI are not established. The AI is not equivalent to an RDA.

Table A-2-b-3 Criteria and Dietary Reference Intake Values for Magnesium by Life-Stage Group

Life-Stage Group ^a	Criterion	AI (mg/day) ^{b,c}
0 to 6 months	Serum 25(OH)D	5
6 to 12 months	Serum 25(OH)D	5
1 through 3 years	Serum 25(OH)D	5

From Food and Nutrition Board, Institute of Medicine. Dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington, DC: National Academy Press, 1993 (reproduction copyright 1993 by original author).

^aAll groups except Pregnancy and Lactation are males and females.

^bAs cholecalciferol, 1 µg cholecalciferol = 40 IU vitamin D.

^cAI = Adequate Intake. The observed average or experimentally set intake by a defined population or subgroup that appears to sustain a defined nutritional status, such as growth rate, normal circulating nutrient levels, or other functional indicators of health. It is utilized if sufficient scientific evidence is not available to derive an EAR. For many nutrients, the EAR and AI are not established. The AI is not equivalent to an RDA.

Table A-2-b-4 Criteria and Dietary Reference Intake Values for Vitamin D by Life-Stage Group

Life-Stage Group	Criterion	AI mg/dL ^a	
		Male	Female
0 to 6 months	Human milk content	0.01	0.01
6 to 12 months	Caries prevention	0.5	0.5
1 through 3 years	Caries prevention	0.7	0.7
4 through 6 years	Caries prevention	1.1	1.1
6 through 13 years	Caries prevention	2.0	2.0
14 through 18 years	Caries prevention	3.2	3.9
19 through 30 years	Caries prevention	3.8	3.1
31 through 50 years	Caries prevention	3.8	3.1
51 through 70 years	Caries prevention	3.8	3.1
>70 years	Caries prevention	3.8	3.1
Pregnancy			
to 18 years	Caries prevention	—	2.9
19 through 50 years	Caries prevention	—	3.1
Lactation			
to 18 years	Caries prevention	—	2.9
19 through 50 years	Caries prevention	—	3.1

From Food and Nutrition Board, Institute of Medicine. Dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington, DC: National Academy Press, 1997 (republication except Table 5-6 in original).

^a AI is Adequate Intake. This represents average of experimental or observational data by a defined population or subgroup that appears to sustain a defined nutritional status, such as growth rate, caries-resistant teeth, normal circulating nutrient values, or other functional indicators of health. AI is used if sufficient scientific evidence is not available to derive an EAR. For fluoride, however, the criteria, AI is often used to indicate that defined life-stage groups should be covered at the AI value. **The AI is not equivalent to an RDA.**

Table A-2-b-5 Criteria and Dietary Reference Intake Values for Fluoride by Life-Stage Group

Life-Stage Group	Calcium (mg)	Phosphorus (mg)	Magnesium (mg)	Vitamin D (µg)	Fluoride (mg)
0 to 6 months	260 ^a	160	160	25	0.7
6 to 12 months	260	160	160	25	0.5
1 through 3 years	25	3	60	60	1.5

19 through 50 years	25	4	200	60	10

From Food and Nutrition Board, Institute of Medicine. Dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington, DC: National Academy Press, 1997 (republication except Table 5-6 in original).

^a AI, adequate intake value. The Recommended Dietary Allowance (RDA) is the daily intake level from food, water, and supplements that is sufficient to ensure an EAR. For fluoride, however, the criteria, AI is often used to indicate that defined life-stage groups should be covered at the AI value. **The AI is not equivalent to an RDA.**

For the complete data set, please refer to Appendix A-2, Table A-2-a-1, in the full report.
 *Median height/weight used by the NRC are those which are the median for the U.S. population of designated age or height in males.
 †Conversion based on (Kcal) equation derived from 1980 data (Page 3-4, 5-6), then rounded.
 ‡In the range of 100 to 1000 kcal/day, the coefficient of variation is < 20%.
 §None is recorded.

Table A-2-a-2 Recommended Dietary Allowances,^a Revised 1989 (Designed for the Maintenance of Good Nutrition of Practically All Healthy People in the United States)

Category	Age (years)	Vitamins		Trace Elements ^b				
		Retinol (µg)	Ascorbic Acid (mg)	Copper (mg)	Manganese (mg)	Fluoride (mg)	Chromium (µg)	Molybdenum (µg)
Infants	0-0.5	10	2					
	0.5-1	15	3					
Children and adolescents	1-3	30	3					
	4-6	35	3-4					
	7-10	50	4-5					
	11+	30-100	4-7					
Adults		30-100	4-7					

From Food and Nutrition Board, National Research Council, Recommended Dietary Allowances, 10th ed., Washington, DC: National Academy Press, 1989:30.
 *Because there is less information on which to base allowances, these figures are not given in the main table of RDA and are provided here in the form of ranges of recommended intakes.
 †Because the toxic levels for many trace elements may be only several times usual intakes, the upper limits for the trace elements given in this table should not be habitually exceeded.

Table A-2-a-3 Estimated Safe and Adequate Daily Dietary Intakes of Selected Vitamins and Minerals^a

A-2-b. DIETARY REFERENCE INTAKES FOR CALCIUM, PHOSPHORUS, MAGNESIUM, VITAMIN D, AND FLUORIDE BY LIFE-STAGE GROUP, 1997 (1). DIETARY REFERENCE INTAKES (DRIs) FOR THIAMIN, RIBOFLAVIN, NIACIN, VITAMIN B₆, FOLATE, VITAMIN B₁₂, PANTOTHENIC ACID, BIOTIN, AND CHOLINE (2). EXCERPTS FROM THE REPORTS

DRIs replace the Food and Nutrition Board's previous RDAs for healthy individuals (3). Four levels of intake values are documented.

The *Estimated Average Requirement (EAR)* is the nutrient intake value that is estimated to meet the requirement defined by a specified indicator of adequacy (e.g., balance studies) in 50 percent of the individuals in a life stage and gender group. Hence, it is a median rather than an average. At this level of intake, the remaining 50 percent of the specified group would not have its nutrient needs met. For some groups, data had to be extrapolated to estimate the value. In deriving the EARs, contemporary concepts of reduction of disease risk were among the factors considered, rather than basing reference values solely upon prevention of nutrient deficiencies. Because the EAR is a dietary in-take value, it includes an adjustment for an assumed bioavailability of the nutrient. The EAR is used in setting the RDA.

The *Recommended Dietary Allowance (RDA)* is the daily dietary intake level that is sufficient to meet the nutrient requirements of nearly all (97 to 98%) individuals in the life stage and gender group. The RDA applies to individuals, not to groups. The EAR serves as the foundation for setting the RDA. If the standard deviation (SD) of the EAR is known, the RDA is set at two SDs above the EAR. If the data are insufficient to calculate an SD, a coefficient of variation of 10% is assumed, and the $RDA = 1.2 \times EAR$.

The RDA for a nutrient is a value to be used as a goal for dietary intake by individuals and is not intended for use in assessing the diets of either individuals or groups or for planning for groups. [The 1989 RDAs are listed for comparison with the new RDA in Appendix [Table II-A-2-a-2](#).]

Adequate intake (AI). This is a value for a nutrient used when there is insufficient evidence to calculate an EAR. It is based on observed or experimentally determined approximations of the average intake of a defined population that appears to sustain a defined nutritional state such as normal circulating nutrient values or growth. AIs rather than EARs and RDAs are being proposed for all nutrients for infants to age 1 year (1, 2) and for calcium, vitamin D, and fluoride (1) and for pantothenic acid, biotin, and choline (2) for all life stages. The methods used in deriving the AIs are reviewed in the basic

document.

The *Tolerable Upper Intake Level (UL)* is the maximal level of nutrient intake that is unlikely to pose risks of adverse health effects to almost all individuals in the target group. The term was chosen to avoid implying a possible beneficial effect and is not intended to be a recommended intake level. For most nutrients, the UL refers to total intakes—from food, fortified food, and nutrient supplements. In some instances, it may refer only to intakes from pharmacologic agents. The UL applies to chronic daily use.

The relations of these four dietary reference intakes is depicted in the following figure.

Dietary reference intakes. This figure shows that the Estimated Average Requirement (*EAR*) is the intake at which the risk of inadequacy is 0.5 (50%). The Recommended Dietary Allowance (*RDA*) is the intake at which the risk of inadequacy is very small—only 0.02 to 0.03 (2 to 3%). The Adequate Intake (*AI*) does not bear a consistent relationship to the *EAR* or the *RDA* because it is set without being able to estimate the requirement. At intakes between the *RDA* and the Tolerable Upper Intake Level (*UL*), the risks of inadequacy and of adverse effects are both close to 0. The *UL* is the highest level of daily nutrient intake that is likely to pose no risks of adverse health effects to almost all individuals in the general population. At intakes above the *UL*, the risk of adverse effects increases. A *dashed line* is used because the actual shape of the curve has not been determined experimentally. The distances between points *A* and *B*, *B* and *C*, and *C* and *D* may differ much more than is depicted in this figure. (This is Figure S-1 in reference [2](#) below.)

Table A-3-b Summary of Examples of Recommended Nutrient Intake Based on Age and Body Weight Expressed as Daily Rates, Canada

A-4. DIETARY REFERENCE VALUES FOR FOOD ENERGY AND NUTRIENTS FOR THE UNITED KINGDOM (1)

Comments: To assist the reader in understanding the following tables taken from this Dietary Reference Values report, excerpts from its Introduction are given here. We make special note of the following:

1. The abbreviation RDA for nutrients differs from the RDA of the 10th RDA (1989)

([Table II-A-2-a](#)) and the recent Dietary Reference Intakes of the United States Food and Nutrition Board of the Institute of Medicine ([Table II-A-2-b](#)). The UK RDA refers to a group mean (see their paragraph 1.3 below).

2. The UK report defines three different sets of reference values as indicated in 1.3.8.
3. The figures in the various tables for individuals and groups are designated Dietary Reference Values (DRVs) rather than recommendations.
4. The values for protein, vitamins, and minerals given in the following tables are at the RNI level as defined in 1.3.8 below. These are statistically equivalent in derivation to the U.S. 1989 10th RDA and new U.S. dietary reference intakes. With the exception of the figures for energy (given as EAR), only the RNI values are included in these tables.

—The Appendix Editors

A-4-a. Excerpts from the Report's Introduction (1)

1.3 Interpretation of the Terms of Reference

- 1.3.1 The definition of the Recommended Daily Amount (RDA) for a nutrient which was used in the previous Report of the Committee on Medical Aspects of Food Policy is “the average amount of the nutrient which should be provided per head in a group of people if the needs of practically all members of the group are to be met.” This was framed in an attempt to make it clear that the amounts referred to are averages for a group of people and not amounts which individuals must consume ...
- 1.3.7 The Panel found no single criterion to define requirements for all nutrients. Some nutrients may have a variety of physiological effects at different levels of intake. Which of these effects should form the parameter of adequacy is therefore to some extent arbitrary. For each nutrient the particular parameter or parameters which were used to define adequacy are given in the text ...
- 1.3.8. *Definition of Dietary Reference Values* Although information is usually inadequate to calculate the precise distribution of requirements in a group of individuals for a nutrient, it has been assumed to be normally distributed ... This gives a notional mean requirement or Estimated Average Requirement (EAR) ... The Panel has defined the Reference Nutrient Intake (RNI) as a point in the distribution, that is two notional standard deviations above the (EAR) ... Intakes above this amount will almost certainly be adequate. At a point, two notional standard deviations (2 SD) below the mean, the Lower Reference Nutrient Intake (LNRI), represents the lowest intakes which will meet the needs of some individuals in the group. Intakes below this level are almost certainly inadequate for most individuals. For some nutrients the derivation of DRVs was not possible from these principles, and this is stated in the text. In particular, for those nutrients where no requirement could be defined (starches, sugars, fat and fatty acids), the DRVs are not derived on these principles, although analogous figures based on pragmatic judgements have been proposed (see original report).

- 1.3.9. At higher levels of consumption there may be evidence of undesirable effects. Guidance on such high levels of consumption is given in the text. The RNI ... is the amount sufficient or more than sufficient to meet the nutritional needs of practically all healthy persons in a population, and therefore exceeds the requirements of most.
- 1.3.11 *Interpretation of Dietary Reference Values* For most nutrients the Panel found insufficient data to establish any of the DRVs with great confidence. There are inherent errors in some of the data, for instance in individuals' reports of their food intake, and the day-to-day variation in nutrient intakes also complicates interpretation. Even given complete accuracy of a dietary record, its relation to habitual intake remains uncertain, however long the recording period. The food composition tables normally used to determine nutrient intake from dietary records contain a number of assumptions and imperfections. Furthermore, there is uncertainty about the relevance of many biological markers, such as serum concentrations of a nutrient, as evidence of an individual's 'status' for that nutrient ...
- 1.3.14 *Weights and standard age ranges* As requirements for most nutrients vary with both age and sex, the Panel has attempted to set DRVs for all such groups of the population. The Panel has sought new weight data for use in calculating DRVs for people of all ages in the UK ... These weights are given in the table below for each of the standard age groups.
- 1.3.18 *Safe intakes* For some nutrients, which are known to have important functions in humans, the Panel found insufficient reliable data on human requirements and were unable to set any DRVs for these. However, they decided on grounds of prudence to set a safe intake, particularly for infants and children, and these are given in [Report] Table 1.6 [Appendix [Table II-A-4-f](#)]. The safe intake was judged to be a level or range of intake at which there is no risk of deficiency, and below a level where there is a risk of undesirable effects.

Nutrient	Safe Intake ^a
Alcohol	
Ethanol	0-2 g/day
Alcohol	0-2 g/day
Calcium	
Infants 0-1 years	250-500 mg/day
Infants 1-3 years	250-500 mg/day
Children 3-10 years	500-1000 mg/day
Children 10-17 years	1000-1500 mg/day
Adults	1000 mg/day
Cholesterol	
Adults	300 mg/day
Copper	
Adults	1 mg/day
Iron	
Infants 0-1 years	10 mg/day
Infants 1-3 years	10 mg/day
Children 3-10 years	10 mg/day
Children 10-17 years	10 mg/day
Adults	10 mg/day
Zinc	
Infants 0-1 years	5 mg/day
Infants 1-3 years	5 mg/day
Children 3-10 years	5 mg/day
Children 10-17 years	5 mg/day
Adults	5 mg/day

Table A-4-f Safe Intakes, United Kingdom^a

1.4 *Uses of Dietary Reference Values* These DRVs apply to groups of healthy people and are not necessarily appropriate for those with different needs arising from disease, such as infections, disorders of the gastro-intestinal tract or metabolic abnormalities. **The DRVs for any one nutrient presuppose that requirements for energy and all other nutrients are met ...**

1.4.1 *For assessing diets of individuals*

1.4.1.1 The impression of most estimates both of individuals' nutrient intakes and of nutritional status, and thus of the estimation of the DRVs themselves, means that utmost caution should be used in applying the figures to the interpretation (or assessment) of individual diets. Even with a perfect measure of an individual's habitual intake of a nutrient (a difficult goal), the DRVs can give no more than a guide to the adequacy of diet for that individual.

1.4.1.2 If the habitual intake is below the LRNI it is likely that the individual will not be consuming sufficient of the nutrient to maintain the function selected by the Panel as an appropriate parameter of nutritional status for that nutrient, and further investigation, including biological measures, may be appropriate.

1.4.1.3 If the habitual intake is above the RNI, then it is extremely unlikely that the individual will not be consuming sufficient.

1.4.1.4 If the intake lies between the two, then the chances of the diet being inadequate (in respect of the chosen function parameter for any nutrient) fall as the intake approaches the RNI ... It is impossible to say with any certainty whether an individual's nutrient intake, if it lies between the LRNI and the RNI, is or is not adequate, without some biological measure in that individual.

1.4.2 *For assessing diets of groups of individuals*

1.4.2.1 When measures of individual diets are aggregated, one of the sources of imprecision is attenuated—that is intraindividual day to day variability. Assuming that the interindividual variability is random, then in a sufficiently large group, this source of imprecision is also diminished. Thus the group mean intake will more precisely represent the habitual group mean intake than any of the individual measures will represent individual intakes.

1.5 DRV for energy

1.5.1 RNIs for all nutrients, but not energy, can be set at the upper end of the range of requirements because an intake moderately in excess of requirements has no adverse effects, but reduces the risk of deficiency. For energy, however, this is not the case. Recommendations for energy have therefore always been set as the average of energy requirements for any population group. The Panel has therefore calculated EARs for energy, but not LRNIs or RNIs.

1.7 DRVs for protein ... The approach derived from estimates of basic nitrogen requirements with additions for specific situations such as growth and pregnancy, which was adopted by joint FAO/WHO/UNU Expert Consultation in 1985, has formed the basis of the Panel's deliberations and enabled calculations of DRVs including EARs shown in [Report] Table 1-3 [Appendix [Table II-A-4-c](#)].

Age	Reference Nutrient Intake* (g/day)
0-3 months	12.5 ^a
4-6 months	12.7
7-9 months	13.7
10-12 months	14.0
1-3 years	14.5
4-6 years	19.7
7-10 years	28.3

Table A-6 Recommended Daily Dietary Allowances, Korea^a

A-7. NOTES ACCOMPANYING AUSTRALIAN RDIs (1)

1. Amounts of nutrients which should be available per head of a population group if the needs of practically all members of the population group are to be met.
2. Recommendations for all nutrients were revised between 1982 and 1988, energy revised 1989.
3. All RDIs are based upon estimates of requirements with a generous “safety factor” added.
4. Recommendations for dietary intakes of vitamin D were not considered necessary unless people are house bound, since the vitamin D status of Australians is determined by exposure to UV light from the sun.
5. RDIs for thiamin, riboflavin, niacin, and vitamin B₆ are based on energy requirements in existence when these B vitamin recommendations were revised (NHMRC 1986).
6. The following factors were used:
Thiamin, 0.1 mg/1000 kJ
Riboflavin, 0.15 mg/1000 kJ
Niacin, 1.6 mg/1000 kJ
Vitamin B₆, 0.02 mg/g protein (based on protein as 10–15% of recommended energy uptake).
7. Niacin values are presented as a single figure, the midpoint of the range adopted in 1984.
8. Iron is expressed as a range to allow for differences in bioavailability of iron from different Australian foods. The RDIs for pregnancy are for the 2nd and 3rd trimesters.
9. Selenium intake should not exceed 600 µg/day.
10. Background documents to these recommendations are included in the bibliography to this report.

	Infants			Young Children

Source: Health and Medical Research Council. Recommended Dietary Intakes for use in Australia. Canberra: Australian Government Publishing Service, 1989.
 100 µg retinol equivalent for vitamin A is given for convenience only for the age 0-6 months. When calculating total vitamin A intake from foods, vitamin A (retinol) and vitamin A (retinol) equivalents should be used as a substitute for the first 6 months. It is important to calculate the protein requirements as well as the values of the minerals given at all times.

Table A-7-a Recommended Dietary Intakes for Children Under 7 Years (Expressed as Mean Daily Intake)

	Boys			Girls		
	6-11 years	12-15 years	16-18 years	6-11 years	12-15 years	16-18 years

Table A-7-c Recommended Dietary Intakes for Adults (Expressed as Mean Daily Intake)

A-7-d. METHODS FOR ESTIMATING ENERGY REQUIREMENTS (1)

A method for estimating energy requirements for individual adults and older children is given below.

Infants and Children Less Than 10 Years Old

The 1981 FAO/WHO/UNU Consultation estimated energy requirements from birth to 10 years by extrapolating from intakes of healthy children growing normally. Doubly-labeled

water studies by Prentice et al. in children up to 3 years of age suggest that these estimates may be too high for this age group.

The FAO/WHO/UNU Consultation took the NCHS charts to represent “normal growth” with 2 standard deviations from the median as the “normal range.”

Summary of Method to Estimate Food Energy Requirements from Estimates of Energy Expenditure in Adults and Children Aged 10–18 Years

The method summarized below may be applied to both groups and individuals. However, estimates of food energy requirements obtained by this method are only approximate, especially for individuals in whom variations in energy requirements can be very large, even in individuals of the same age, sex and body weight, and apparently similar levels of activity.

Method

1. Determine the basal metabolic rate (BMR) of the group or individual. BMR may be measured using indirect calorimetry, or predicted from the equations in Table 2. (See Appendix [Table II-A-7-d-1.](#))

	Age (years)	Equation
Males	10-18	$0.074wt + 2.754$
	18-30	$0.063wt + 2.896$
	30-60	$0.048wt + 3.653$
	over 60	$0.049wt + 2.459$
Females	10-18	$0.056wt + 2.898$
	18-30	$0.062wt + 2.036$
	30-60	$0.034wt + 3.538$
	over 60	$0.038wt + 2.755$

Equations are taken from Schofield WN, Schofield C, James WPT Basal metabolic rate—review and prediction, together with an annotated bibliography of source material. Hum Nutr Clin Nutr 1985;39C(Suppl 1):1-96.

*Wt is body weight in kg; BMR value is in MJ/day.

Table A-7-d-1 Equations for Estimating Basal Metabolic Rate (BMR)^a in MJ/Day from Body Weight (kg) of Adults and Children over the Age of 10 Years

2. Determine the approximate level of activity (expressed as a multiple of BMR) of the group or the individual, from estimates of the amount of time spent in different activities, or from the values listed in Table 3. (See Appendix [Table II-A-7-d-2.](#))

Activity Level	Daily Energy Expenditure as Multiples of BMR			
	Males		Females	
	Average	(Range)	Average	(Range)
Bed rest	1.2	(1.1–1.3)	1.2	(1.1–1.3)
Very sedentary	1.3	(1.2–1.4)	1.3	(1.2–1.4)
Sedentary/maintenance	1.4	(1.3–1.5)	1.4	(1.3–1.5)
Light	1.5	(1.4–1.6)	1.5	(1.4–1.6)
Light-moderate	1.7	(1.6–1.8)	1.6	(1.5–1.7)
Moderate	1.8	(1.7–1.9)	1.7	(1.6–1.8)
Heavy	2.1	(1.9–2.3)	1.8	(1.7–1.9)
Very heavy	2.3	(2.0–2.6)	2.0	(1.8–2.2)

Table A-7-d-2 Average Daily Energy Expenditure of Adults and Children over the Age of 10 at Different Levels of Activity Expressed as Multiples of Basal Metabolic Rate (BMR)

3. Determine daily energy expenditure by multiplying the BMR by the level of activity (expressed as a multiple of BMR).
4. Add to the estimate of energy expenditure any extra energy requirements for growth, pregnancy, or lactation, as appropriate.
 - a. The energy cost of growth may be taken as 8 kJ/kg body weight for children aged 10 to 14 years, 4 kJ/kg at 15 years, and 2 kJ/kg at age 16 to 18 years.
 - b. The average additional energy requirement in pregnancy may be taken as 0.85 to 1.1 MJ/day, assuming a weight gain of 10 to 12 kg and no change in level of activity.
 - c. The average additional energy requirement in lactation may be taken as 2.0 to 2.4 MJ/day in the first 6 months, assuming no change in level of activity and a maternal fat loss of 2 kg over 6 months.
5. Correct the estimate of energy requirement obtained from #4 above for the metabolizable energy content of the diet to be eaten, if appropriate. For the “typical” Australian diet that contains about 20 g/day of dietary fiber, no correction is necessary. For high-fiber diets, the estimate of energy requirement should be increased by about 5%.

Example

Prediction of the food energy required to maintain energy balance in a group of nonpregnant, nonlactating women aged 45 years, with a mean body weight of 60 kg and a light activity level.

- a. Predicted BMR (from Table 2 in original or Appendix [Table II-A-7-d-1](#)) is 5.6 MJ/day.
- b. Energy expenditure in light activity is $1.5 \times$ BMR (Table 3; Appendix [Table II-A-7-d-2](#)).

c. Daily energy expenditure

$$\begin{aligned} &= \text{BMR} \times \text{activity level} \\ &= 5.6 \times 1.5 \\ &= 8.4 \text{ MJ/day} \end{aligned}$$

d. No adjustments are necessary for growth, pregnancy, or lactation in this case.

e. No correction is needed to the energy requirement obtained if the women are consuming a “typical” Australian diet containing approximately 20 g/day of dietary fibre. If these women are consuming a high-fibre diet, the food energy requirement obtained in (d) above should be increased by 5% (i.e., from 8.4 MJ/day to 8.8 MJ/day).

[Table A-7-d-1](#) and [Table A-7-d-2](#) may be used as a guide to energy expenditure for use with groups of people.

A-8-b. European Community Nutrient and Energy Intakes

A-8-b-1. Recommendations and Nomenclature: Excerpts from the Report (1)

... This Committee is attempting to give, as far as possible, three values to indicate the spread of needs.

... This Committee will call the intake that is enough for virtually all healthy people in a group the Population Reference Intake (PRI). [This corresponds with the traditional RDA of the United States and includes the nutritional needs 2 standard deviation's above the mean requirement of the group—The Appendix Editors]

The Average Requirement (AR), the mean nutrient requirement of the group, according to the criterion chosen.

The Lowest Threshold Intake (LTI) is that which is 2 standard deviations below the mean. This is the intake below which, on the basis of our current knowledge, almost all individuals will be unlikely to maintain metabolic integrity according to the criterion chosen for each nutrient.

... In this report LTIs are often set on the prudent side, being not those intakes below which frank deficiency is almost certain, but rather those intakes below which there may be cause for concern for a substantial section of the population. Consequently, the PRI and LTI values are not always the means plus and minus two standard deviations.

For nutrients where the requirements are given in terms of energy intake, ... the convention adopted in this report [gives] the PRIs and LTIs for average energy intakes.

The Committee has given only one value for increases during pregnancy or lactation; it considers it has inadequate information to give more with any confidence.

Table A-9-c Dietary Recommendations to Reduce Cancer Risk in Industrialized Countries

A-9-d. NATIONAL NUTRITION OBJECTIVES (USA)

Table A-9-d-1 Objectives for the Year 2000

This table lists various health objectives for the year 2000, categorized by priority and target year. The objectives cover areas such as cardiovascular disease, cancer, diabetes, and general health status. Each objective includes a brief description and a target year (e.g., 2000, 2005, 2010).

Table A-9-d-1 Objectives for the Year 2000

A-9-d-2. Midcourse Review in 1995

A midcourse review and revisions in 1995 indicated that many challenges remain in preventing premature death and in improving health as the next century approaches ([Table A-9-d-2-a](#)) (1).

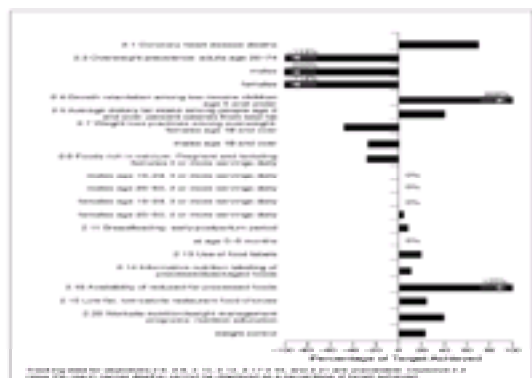

Table A-9-d-2-a. Status of nutrition objectives for the year 2000 at the time of midcourse review (1) in terms of the percentage of target achieved.

Summary of progress indicated that of the 27 objectives in this area (nutrition), 5 objectives (2.2, 2.4, 2.15, 2.23, and 2.25) have met the target. Progress toward the targets has been made on 11 objectives (2.1, 2.5, 2.6, 2.11, 2.13, 2.14, 2.16, 2.19, 2.22, 2.26, and 2.27). Five objectives moved away from the target (2.3, 2.7–2.9, and 2.24). Objectives 2.10 (for anemia prevalence) and 2.20 (for worksite nutrition or weight management programs) show mixed results. Four objectives have no new data beyond

the baseline with which to measure progress (2.12, 2.17, 2.18, and 2.21)(2).

A-9-d-3. Objectives for Healthy People for the Year 2010. Excerpts from The Report (3)

A-9-d-3-a Nutrition–Health Status Objectives

- 2.1 Reduce coronary heart disease deaths to no more than 100 per 100,000 people. (Age-adjusted baseline: 135 per 100,000 in 1987.)
- 2.2. Reverse the rise in cancer deaths to achieve a rate of no more than 130 per 100,000 people. (Age-adjusted baseline: 134 per 100,000 in 1987.)
- 2.3 Reduce overweight to a prevalence of no more than 20% among people aged 20 and older and no more than 15% among adolescents aged 12–19. (Baseline: 26% for people aged 20–74 in 1976–80, 24% for men and 27% for women; 15% for adolescents aged 12–19 in 1976–80.)
- 2.4 Reduce growth retardation among low-income children aged 5 and younger to less than 10 percent. ...

A-9-d-3-b Risk Reduction Objectives

- 2.5 Reduce dietary fat intake to an average of 30% of calories or less and average saturated fat intake to less than 10% of calories among people aged 2 and older. ... Increase to at least 50% the proportion of people aged 2 and older who meet the *Dietary Guidelines*' average daily goal of no more than 30% of calories from fat, and increase to at least 50% the proportion of people aged 2 and older who meet the average daily goal of less than 10% of calories from saturated fat. ...
- 2.6 Increase complex carbohydrate and fiber-containing foods in the diets of people aged 2 and older to an average of 5 or more daily servings for vegetables (including legumes) and fruits, and to an average of 6 or more daily servings for grain products. ... Increase to at least 50% the proportion of people aged 2 and older who meet the *Dietary Guidelines*' average daily goal of 5 or more servings of vegetables/fruits, and increase to at least 50% the proportion who meet the goal of 6 or more servings of grain products. ...
- 2.7 Increase to at least 50% the proportion of overweight people aged 12 and older who have adopted sound dietary practices, combined with regular physical activity, to attain an appropriate body weight. ...
- 2.8 Increase calcium intake so at least 50% of people aged 11–24 and 50% of pregnant and lactating women consume an average of 3 or more daily servings of foods rich in calcium, and at least 75% of children aged 2–10 and 50% of people aged 25 and older consume an average of 2 or more servings daily. ...

- 2.9 Decrease salt and sodium intake so at least 65% of home meal planners prepare foods without adding salt, at least 80% of people avoid using salt at the table, and at least 40% of adults regularly purchase foods modified or lower in sodium. ...
- 2.10 Reduce iron deficiency to less than 3% among children aged 1–4 and among women of childbearing age. ...
- 2.11 Increase to at least 75% the proportion of mothers who breastfeed their babies in the early postpartum period and to at least 50% the proportion who continue breastfeeding until their babies are 5–6 months old. ...
- 2.12 Increase to at least 75% the proportion of parents and caregivers who use feeding practices that prevent baby bottle tooth decay. ...
- 2.13 Increase to at least 85% the proportion of people aged 18 and older who use food labels to make nutritious food selections. ...

A-9-d-3-c Services and Protection Objectives

- 2.14 Achieve useful and informative nutrition labeling for virtually all processed foods and at least 40% of ready-to-eat carry-away foods. Achieve compliance by at least 90% of retailers with the voluntary labeling of fresh meats, poultry, seafood, fruits, and vegetables. ...
- 2.15 Increase to at least 5000 brand items the availability of processed food products that are reduced in fat and saturated fat. ...
- 2.16 Increase to at least 90% the proportion of restaurants and institutional food service operations that offer identifiable low-fat, low-calorie food choices, consistent with the *Dietary Guidelines for Americans*. ...
- 2.17 Increase to at least 90% the proportion of school lunch and breakfast services and child care food services with menus that are consistent with the nutrition principles in the *Dietary Guidelines for Americans*. ...
- 2.18 Increase to at least 80% the receipt of home food services by people aged 65 and older who have difficulty in preparing their own meals or are otherwise in need of home-delivered meals. ...
- 2.19 Increase to at least 75% the proportion of the Nation's schools that provide nutrition education from preschool–12th grade, preferably as part of comprehensive school health education. ...
- 2.20 Increase to at least 50% the proportion of worksites with 50 or more employees that offer nutrition education and/or weight management programs for employees. ...

- 2.21 Increase to at least 75% the proportion of primary care providers who provide nutrition assessment and counseling and/or referral to qualified nutritionists or dietitians. ...

A-9-d-3-d 1995 Additions

In the 1995 midcourse review, additional health status objectives were introduced as follows (3).

A-9-d-3-d-1 Health Status Objectives

- 2.22 Reduce stroke deaths to no more than 20 per 100,000 people. ...
- 2.23 Reduce colorectal cancer deaths to no more than 13.2 per 100,000 people. ...
- 2.24 Reduce diabetes to an incidence of no more than 2.5 per 1000 people and a prevalence of no more than 25 per 1000 people. ...

A-9-d-3-d-2 Risk Reduction Objectives

- 2.25 Reduce the prevalence of blood cholesterol levels of 240 mg/dL or greater to no more than 20% among adults. ...
- 2.26 Increase to at least 50% the proportion of people with high blood pressure whose blood pressure is under control. ...
- 2.27 Reduce the mean serum cholesterol level among adults to no more than 200 mg/dL ...

A-9-e. Approaches to Management of High Blood Cholesterol Levels

A-9-e-1. Excerpts from the NCEP Report (1 *)

General and Specific Approaches

The underlying theme of this report is specific therapy for high blood cholesterol, particularly elevated LDL-cholesterol, and dietary therapy is the cornerstone of cholesterol lowering. Three major dietary factors contribute to high levels of blood cholesterol: a high intake of saturated fat, a high intake of dietary cholesterol, and an imbalance between calorie intake and energy expenditure leading to obesity.

The first goal of dietary therapy is to reduce LDL-cholesterol levels, but dietary modification and increased physical activity may decrease risk for CHD in other ways as well. For example, weight reduction and increased physical activity will reduce VLDL and raise HDL levels, both of which may decrease CHD risk. Weight reduction (combined with decreased salt and alcohol intake) will often lower blood pressure and improve glucose tolerance, also decreasing CHD risk. Beyond these well-known effects, some epidemiologic and experimental data indicate that low intakes of saturated fats and cholesterol lessen risks for CHD beyond LDL-cholesterol lowering. ...

Diet modification is presented in two steps ([Table II-A-9-e-1-b](#)). The Step I Diet is similar in nutrient composition to the eating pattern recommended by the NCEP for the population at large. For patients who have not adopted this eating pattern prior to treatment, the Step I Diet is the initial therapy. For those already on the Step I Diet, further reductions in saturated fat and dietary cholesterol—the Step II Diet—should achieve more LDL-cholesterol lowering. Step I and Step II diets are given in [Table V-A-30](#).

Nutrient*	Recommended range	
	Step I Diet†	Step II Diet†
Total fat		30% or less of total calories
Saturated fatty acids	6-12% of Total calories	Less than 7% of total calories
Monounsaturated fatty acids		Up to 10% of total calories
Polyunsaturated fatty acids		Up to 15% of total calories
Carbohydrates		55% or more of total calories
Protein		Approximately 15% of total calories
Cholesterol	Less than 300 mg/day	Less than 200 mg/day
Total calories	To achieve and maintain desirable weight

Table A-9-e-1-b Dietary Therapy of High Blood Cholesterol: General Recommendations

Table A-30-b Examples of Foods to Choose or Decrease for the Step I and Step II Diets^a

These changes in diet composition should be carried out simultaneously with regular physical activity in all patients and weight reduction in the overweight.

The first task in dietary therapy is to assess current eating habits. This assessment determines whether to start with the Step I Diet or to move directly to Step II. The Step I Diet calls for 8 to 10% of calories from saturated fat, 30% or less of calories from total fat, and less than 300 mg/day of cholesterol. The serum cholesterol response to this diet should be determined at 4–6 weeks and at 3 months. Failure to obtain expected serum cholesterol lowering frequently indicates inadequate dietary compliance; therefore, reassessment of dietary adherence is needed at follow-up visits.

If the goals of therapy are not achieved after 3 months on a Step I Diet, it is important to reassess adoption of an adherence to this diet. If the goals are not achieved in spite of adherence, the patient should advance to the more intensive Step II Diet. This diet reduces saturated fat to *less than* 7% of calories and cholesterol to *less than* 200 mg/day. The decision to adopt a Step II Diet should be reinforced and encouraged through discussion of its feasibility between physician and patient and in consultation with other health professionals involved in the patient's management.

A-9-e-2. Primary Prevention

A-9-e-2-a High-Risk LDL-Cholesterol (³160 mg/dL) and Fewer than Two Other CHD Risk Factors ([Table A-9-e-2-a](#))

	Initiation Level	Goal of Therapy	Monitoring Goal
	LDL-Cholesterol		Total Cholesterol
Without CHD and with fewer than 2 risk factors	≥160 mg/dL	<160 mg/dL	<240 mg/dL
Without CHD and with 2 or more risk factors	≤130 mg/dL	<130mg/dL	<200 mg/dL
With CHD	>100 mg/dL	≤100 mg/dL	≤160 mg/dL

Table A-9-e-2-a Initial Cholesterol Levels and Therapeutic Goals

The goal of therapy for this category of patients is an LDL-cholesterol below 160 mg/dL; and, in the absence of severe hypercholesterolemia, dietary change combined with exercise is the mainstay of therapy. As indicated before, the initial step of dietary therapy depends on the patient's prior eating habits. If the Step I Diet is adopted and does not reduce the LDL-cholesterol level to <160 md/dL after 3 months, the Step II Diet should be initiated. If the LDL-cholesterol level still exceeds 190 mg/dL after 6 months of dietary therapy, drug treatment can be considered according to the general guidelines developed in this report. Patients with LDL-cholesterol levels well above 220 mg/dL can proceed to drug treatment once dietary therapy is underway, but they should progress to the Step II Diet and remain on this diet while on drug therapy.

A-9-e-2-b LDL-Cholesterol <130 mg/dL and Two (or More) CHD Risk Factors
([Table A-9-e-2-a](#))

The goal for LDL-cholesterol lowering in patients with two (or more) CHD risk factors is a level below 130 mg/dL. When LDL-cholesterol is 130 to 159 mg/dL, dietary therapy and exercise should achieve the goal of therapy in most patients. Even if an LDL-cholesterol level of <130 mg/dL is not reached, drug therapy rarely is necessary unless a patient is at very high risk from other risk factors that cannot be controlled.

When LDL-cholesterol is greater than 160 mg/dL and multiple other risk factors are present, diet and exercise should be instituted first, but drug therapy may be required to reach the target of <130 mg/dL. Drug therapy can be considered if the other risk factors are difficult to modify or if the LDL-choelsterol level is especially high. On the other hand, if obesity underlies high LDL-cholesterol and other risk factors (e.g., low HDL-cholesterol, hypertension, and diabetes mellitus), weight reduction alone may eliminate all these factors.

A-9-e-3. Secondary Prevention: CHD (or Other Atherosclerotic Disease) and

LDL-Cholesterol >100 mg/dL ([Table A-9-e-2-a](#))

The goal here is to reduce LDL-cholesterol to 100 mg/dL or below. In most patients dietary therapy should begin with the Step II Diet, combined appropriately with weight reduction and exercise. If the goal of therapy is not reached in 6 to 12 weeks, drug therapy can be considered. When LDL-cholesterol falls to 100 to 129 mg/dL on dietary therapy alone, the decision to proceed to drug therapy requires weighing the benefits of further LDL-cholesterol lowering versus the costs and potential side effects of drugs.

The degree of reduction of LDL-cholesterol levels achieved by dietary therapy depends on dietary habits before starting the diet, the degree of compliance, and inherent biological responsiveness. ... It is not possible to determine the inherent responsiveness of an individual short of a trial of dietary therapy. The response of many patients to a change in diet composition, however, may be considerably enhanced by weight reduction.

Table A-11-f Estimates of Energy Cost of Weight Gain^a

A-12-a. HEIGHT-WEIGHT TABLES: THEIR SOURCES AND DEVELOPMENT (SIDNEY ABRAHAM)

The Metropolitan Life Insurance Company presented their height and weight tables derived from data of the Build Study, 1979 (1). Metropolitan Life had previously utilized data from life insurance mortality studies compiled in the early 1900s and late 1950s to develop desirable weight tables in 1942 (2), 1943 (3) and 1959 (4). These studies reported the prevalence of mortality among insured persons according to variations in body build (height and weight) and also presented the average weight for height of persons by age. Such studies were designed to determine which groups (those underweight or overweight) showed a proportionately higher prevalence of mortality to yield information for underwriting purposes and for warranting changes in insurance policy premiums.

Average Weight By Height Tables and Age-Group

Mortality Studies

In the American life insurance industry, interest in build (height and weight) as factors that influence mortality dates back to 1885. In that year, the Union Mutual Life Insurance Company published a pamphlet containing the results of a study of the company's records on mortality in relation to build (5). The first indepth study on the subject was presented in 1901 by a representative of the New York Life Insurance Company at the twelfth annual meeting of the Association of Life Insurance Medical Directors of America (6). In this presentation it was pointed out that a certain amount of overweight had previously been looked on favorably. Nonetheless, the summary of this report noted that: "First among life insurance risks [is that] the [health] hazard increases in proportion to the degree of over- or underweight, second, whereas among overweights the mortality to be expected increases with [the] increased age of [the] applicant, among

underweights the mortality decreases with advancing years.”

Height-Weight Tables

The first height-weight table based on a considerable volume of statistics and taking age into account was the “Shepherd Table.” This table was prepared in 1897 and was based on 74,162 male applicants accepted for life insurance in the United States and Canada (7).

The basic study of height and weight based on life insurance statistics, however, was made as part of the study and the tables derived therefrom were the bases of the height-weight tables prepared for the general population. In addition to the study of the prevalence of mortality of certain groups of the insured population, the 1912 investigation included a study of the height and weight of a sample of persons insured from 1885 to 1900 (8). The height and weight were recorded with the subjects wearing shoes and street clothes. A total of 221,819 men residing in the United States and Canada were included in this sample. At least 40% of the weights were estimated by the medical examiners. The data as tabulated were then smoothed to provide the figures for the height-weight age tables, and the adjusted tables became the basis for height-weight tables for males in the United States at this time.

Substantially the same procedure was employed to develop height-weight tables for women, but to secure enough cases for the preparation of tables it was necessary to add 126,504 policies issued after 1900 to the 10,000 included in the 1885 to 1900 sample.

In the Medical Impairment Study of 1929 (9), height-weight data were again collected on 667,000 men and 85,000 women. The average weights of both men and women in the 1929 study were not significantly different from those observed in the Medico-Actuarial Mortality Investigation (8). In fact, differences were so small that it was decided not to revise the standard height-weight tables except for those individuals younger than age 15.

Tables of “Ideal” or “Desirable” Weights

An article presented in 1920, “Is the ‘Average’ the Same as the “Normal” for Weight and Blood Pressure?” (10) illustrates an important development in the preparation of height-weight tables. In this paper the “normal” weight group is defined as that having the lowest mortality rates. The article presented a table of “normal” weights, so defined, for medium-sized men averaging 68 inches in height, and several discussants added their tables of similarly defined normal weights for men of small, medium, and tall height. In 1922, complete height-weight tables were presented that showed this normal weight for each inch of height and for each age group (11). In general, all such tables of normal weight indicated that the ideal weight in terms of mortality was the average weight for height at age 30.

Metropolitan Life Develops “Ideal” Height-Weight Tables

Desirable Weight Tables, 1942 and 1943

The concept of a “normal” weight, represented by the average weight of men at age 30, plus an awareness of the shortcomings of height and weight alone as complete indications of obesity, led to the development of “ideal” weight tables by the Metropolitan Life Insurance Company (2, 3). Although employed for many purposes, these tables were originally intended for use in health education. The basic data were derived from the standard height-weight tables of the Medico-Actuarial Study of 1912, using the average weight for each inch of height at age 30 for men and at age 25 for women. Arbitrary ranges were then developed, using the base figures as reference points. These ranges are approximately the standard deviation of average weights for a given height and include the lightest weight for persons with small frames to the heaviest weight for persons with large frames. The total was then arbitrarily divided into three overlapping ranges, and the resulting figures represented ideal weights for individuals of small, medium, and large frames. However, no definition of frame size was presented.

These tables were intended to aid people in achieving a weight below the average for their height. Before these tables were developed, only average weights for each inch of height by age and sex were available. The new approach represented a change in concept between average weight (assuming that the average value is optimal for health) and desirable weight (weight based on the criterion of longevity). The concept underlying these tables deemphasized the use of a single average at each height and refuted the popular notion that weight increments attendant with advancing age were normal and therefore not harmful.

Desirable Weight Tables, 1959

The next study of build in relation to mortality was made in conjunction with the Build and Blood Pressure Study of 1959 (4). This investigation was based on the combined experience of 26 life insurance companies in the United States and Canada from 1935 to 1954 and involved observation of nearly 5 million insured persons for periods up to 20 years. Only those insured persons ages 15 through 69 were included. The height and weight data were recorded with the subjects wearing street shoes and indoor clothing. More than 90% of the insured persons were reported to have been actually weighed and measured at the time of examination for life insurance. The study presented average weights for men and women for each inch of height, ranging from 62 to 76 inches for men and from 58 to 72 inches for women. To provide some indication of the sole effect of weight on mortality, persons with heart disease, cancer, or diabetes were excluded.

When the Build and Blood Pressure Study was completed, the “ideal weight” table, originally developed by the Metropolitan Life Insurance Company in 1942 and 1943, was revised to conform to the latest data. The new table, called the “desirable weight” table (Table A-12-a-1) was derived directly from weights associated with lowest mortality. Ranges of “desirable weight” for individuals 25 years and older with small,

medium, and large frames were given, but again, no definition of frame size was included.

Men (in shoes, 1-inch heels)					Women (in shoes, 1-inch heels)

Table A-12-a-1 Desirable Weights for Men and Women Aged 25 and Over (in Pounds by Height and Frame, in Indoor Clothing), 1959

Metropolitan Height-Weight Tables

Data published by the Society of Actuaries and the Association of Life Insurance Medical Directors of American in the Build Study, 1979 (1), are the source for the 1983 Metropolitan Life Insurance Height-Weight Tables (Table A-12-a-2). The data are from 25 life insurance companies in the United States and Canada and show the prevalence of mortality from 1954 to 1972 of approximately 4.2 million insured men and women. Almost 90% of the recorded weights submitted for the study was obtained by actually weighing the applicants. As in the 1959 Build and Blood Pressure Study, applicants with major disease conditions at the time of policy issuance were excluded from the study. The terms “ideal body weight” and “desirable body weight,” used in the earlier tables were not applied to the new height and weight tables because of the various misinterpretations of their meaning.

Table A-12-a-2 Height-Weight Tables, 1983^a

The findings from the Build Study, 1979, showed that the gap between the weights based on lowest mortality and average weights had narrowed considerably since the 1959 Build and Blood Pressure Study. Metropolitan Life considered this factor in developing the 1983 height-weight tables. Weight for height has increased in contrast to the 1959 tables, but the increased weights are still less than the average weights ([Table A-12-a-5](#)). Additionally, the increases in weight are not uniformly distributed throughout the 1983 height-weight tables. For each frame size, the weight increases for tall men or women were not as large as those for short men or women or for those of medium height.

Table A-12-a-5 Average Weights by Height and Age Group: 1959 and 1979 Build and Blood Pressure Studies^a

In conjunction with investigations based on the life insurance data previously enumerated, long-term studies such as the Framingham Heart Study ([12](#)) and the Manitoba Study ([13](#)) all indicate that the weight associated with the greatest longevity tends to be below the average weight of the population under consideration and that “slimmer is better,” provided that the underweight is not associated with a medical history of significant impairment.

Frame Size

The 1983 Metropolitan height-weight tables related weight to body frame size. A distinction is made among persons with small, medium, and large frames. The previous Metropolitan height-weight tables also related weight to body frame size, but although

the body frame sizes were statistically defined, no generally accepted method of measuring frame size was provided. Body frame size is an integral factor in considering variation in weight, assuming that persons with larger frames have larger lean body mass and therefore weigh more. In the 1983 tables, elbow breadth is now used to determine frame size in men and women ([Table A-12-a-3](#)). The frame sizes were developed from elbow breadth measurements taken from the first National Health and Nutrition Examination Survey, 1971 to 1975 ([14](#)), and were distributed so that 50% of the population falls within the medium frame and 25% each falls within the small and large frames.

Height in 1-inch Heels	Elbow Breadth ^a

^aSee our Table A-12-b for other data on frame size by elbow breadth from NHANES I and II.
^bProcedure: Extend your arm and bend the forearm upward at a 90° angle. Keep fingers straight and turn the inside of your wrist toward your body. If you have a caliper, use it to measure the space between the two prominent bones on either side of your elbow. Without a caliper, place thumb and index finger of your other hand on these two bones. Measure the space between your fingers against a ruler or tape measure. Compare it with these tables that list elbow measurements for medium frame men and women. Measurements lower than those listed indicate you have a small frame. Higher measurements indicate a larger frame.

Table A-12-a-3 Height and Elbow Breadth for Men and Women^a

Summary

Major insurance mortality studies on insured populations in the United States and Canada conducted in 1912 by the Actuarial Society of America ([8](#)) and in 1959 and 1979 by the Society of Actuaries and the Association of Life Insurance Medical Directors of America ([1](#), [4](#)) analyzed the mortality experience among insured persons according to variations of weight by height. The studies also presented data on the distribution of weight and height. The earliest study showed that the lowest mortality by build (weight for height) was found for those somewhat overweight at younger ages and among those underweight at older ages. In later mortality studies, it was generally found that insured persons whose weight was below average lived longer than those whose weights were above average.

Since 1942, the Metropolitan Life Insurance Company has developed weight tables from data derived from each of the three major studies. The weights in each of the tables at given heights for men and women are classified according to frame size and refer to the weights associated with lowest mortality of policyholders. The weights were those obtained when the individual was originally insured. Because it is recognized that height and weight alone are incomplete indicators of excess weight, the weight tables also considered measurements of body build. In the tables issued in the 1940s ([2](#), [3](#)), 1959

(4), and 1983, three groups of frame size were identified. In each frame size, weight was given as a range rather than as a single value. However, no objective method was presented to estimate frame size in the earlier two tables. In the 1983 Metropolitan Height-Weight Tables, elbow breadth, unaffected by degree of adiposity and closely representative of bony dimension, was suggested to estimate frame size in the three categories of body build.

The 1983 Metropolitan Height-Weight Tables are based on the 1979 Build Study. The tables are statistical computations from individual weight gain from the 1979 Build Study. The 1979 Build Study is a study of 10,000 men and women, aged 18 to 74, who were measured for height and body frame at which normally has been found to be lowest or highest. Metropolitan Life does not advocate the use of the term "ideal" which has 0% weight change in various individuals. Because the term has been misapplied in the 1960's and 1970's, it is now being used in the sense that it was used in terms of fitness, morbidity, and use of "appropriate" in Reference. These tables do not provide weights related to morbidity, fitness, swimming job performance, or creating the best appearance.

^aGerontology Research Center data from Studies II, III, and IV, and others, is available for age-specific height-weight tables in Principles of Geriatric Medicine, Studer R, Ed., Humana Press, Inc., New York, NY, 1993, pp. 219-220.
^bValues in this table are for height without shoes and weight without clothes. To convert inches to centimeters, multiply by 2.54. To convert pounds to kilograms, multiply by 0.45.
^cThese weight ranges are the range of weights for normal frame and the upper range for large frame.

Table A-12-b Comparison of the Weight-for-Height Tables from Actuarial Data (Build Study): Non-Age-Corrected Metropolitan Life Insurance Company and Age-Specific Gerontology Research Center Recommendations^a

A-12-c, FRAME SIZE AND ELBOW BREADTH

A-12-c-1. ... three frame size categories, age- and sex-specific percentiles of Frame Index 2 were determined. Three categories of frame size were established—small, medium, and large—corresponding respectively to values below the 25th, from the 25th to the 75th, and above the 75th sex- and age-specific percentiles of Frame Index 2 [see original [Table II.5](#) in Frisancho]. With these percentile cutoffs, 25%, 50%, and 75% of the sample of both males and females were classified as either small, medium, or large frame, respectively.

We decided to base the frame size classification on Frame Index 2 rather than on elbow breadth alone [because] weight increases until about the fifth decade in males and the sixth decade in females, while height starts declining by the fourth decade (see [Table A-12-e](#)) (1).

^aRelationship of height and weight to age among adults. Male (left) weight increases until about the fifth decade in males and then declines in females, while height begins to decrease after age of 40 years in both sexes and females. From Frisancho, J. Anthropometric standards for the assessment of growth and nutritional status. University of Michigan Press, Ann Arbor, 1962 (Figure 11).

Table A-12-e Changes in Weight and Height With Age

Weight not only varies with height and age but it is also influenced by factors such as body width, bone thickness, muscularity, and length of trunk relative to total height ... An appropriate evaluation of frame size requires a reliable measurement of elbow breadth ... it should be measured accurately, not by simple manual touch as suggested by the Metropolitan Life Insurance Co., but with a broad faced calipers or other appropriate measuring devices. Otherwise estimations of desirable weight based on inappropriate frame size estimation may be unrealistic and subject to large errors.

Categories of Frame Size: Excerpts from Comments of A. R. Frisancho (1)

The present classification is based upon a new index hereafter referred to as *Frame Index 2*, which is derived from measurements of *elbow breadth*, *height*, and *age*. The formula for calculating Frame Index 2 is:

$$\text{Frame Index 2} = [\text{elbow breadth (mm)}/\text{stature (cm)}] \times 100$$

Table A-13-a Means, Standard Deviations, and Percentiles of Body Mass Index (w/s_2) by Age for Males and Females 1 to 74 Years

*This table of percentiles of BMI values from other distributions is used as the most generally useful index of relative body mass in adults. The nomogram represents 50% of the population in various percentiles, which deviates the weight in various percentiles in the population based on the normal distribution of BMI values. This method of calculation of BMI values is based on the relationship between weight and height and is not a measure of BMI values in absolute terms. From H. G. Ross, 1988.

 *Data from 118 men and 100 women. The subjects were all ambulatory.
 †From data compiled by Pissacchi from NHANES I and II data.

Table A-15-e Provisional Age- and Sex-Specific Reference Values for Weight in Kilograms (pounds) in Elderly Subjects^{a,b}

A-16. ANTHROPOMETRIC DATA

Anthropometric data are multiple and changing. Included here is basic material derived from Dr. Frisancho's publication *Anthropometric Standards for the Assessment of Growth and Nutritional Status*, Ann Arbor: University of Michigan Press, 1990. The interested reader is referred to this comprehensive publication for numerous other tables, graphs, and detailed text.

Table A-16-g Means, Standard Deviations of Percent Fat Weight (%) in Percentiles by Age for Males and Females, 18 to 74 Years

A-17. BODY FAT ESTIMATIONS FROM SKINFOLD DATA

Various investigators have developed equations for predicting the proportions of body fat by anthropometric measures of specific regions. Durnin and Womersley used four different skinfolds ([Table A-17-a](#)). Pollock, Schmidt, and Jackson have prepared tables based on three sites, including thigh skinfolds ([Table A-17-b](#) and [Table A-17-c](#)). Because some technicians have difficulty obtaining consistent results with thigh skinfold measurements, data also are available based on equations that do not use this skinfold. These data are included in the following sources:

Sex	Age	Durnin and Womersley				Pollock, Schmidt, and Jackson

Underweight	<18.5		--	--
Normal	18.5-24.9		--	--
Overweight	25.0-29.9		Increased	High
Obesity	30.0-34.9	I	High	Very High
	35.0-39.9	II	Very High	Very High
Extreme Obesity	≥ 40	III	Extremely High	Extremely High

From U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung, and Blood Institute. Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults. The evidence report. Bethesda, MD: Report June 1992 (2002). This is Table 55-4 in the original report.

¹Decreased risk for type 2 diabetes, hypertension, and CVD.

²Increased waist circumference also is a marker for increased risk, even in persons of normal weight.

Table A-18-a-1 Classification of Overweight and Obesity by BMI, Waist Circumference, and Associated Disease Risks

Height in inches (cm)	BMI 20 (kg/m ²)	BMI 25 (kg/m ²)	BMI 30 (kg/m ²)
	Weight in Pounds (kg)	Weight in Pounds (kg)	Weight in Pounds (kg)

77 (194.5)	281 (126.4)	341 (160.4)	332 (126.2)

Metric conversion formula = weight (kg)/height (m)². Non-metric conversion formula = height (square of height in inches)² x BMI. Example of BMI calculation: A person who weighs 150 pounds and is 5'7" (tall) has a BMI of 25. weight (150 pounds)/height (5'7" in)² = 25. Example of BMI calculation: A person who weighs 150 pounds and is 5'0" (tall) has a BMI of 27. weight (150 pounds)/height (5'0" in)² = 27.

Table A-24-c Choline Content of Some Common Foods

SECTION V. EXCHANGE LISTS AND THERAPEUTIC DIETS

Table A-25-a Standard Exchange Lists for Meal Planning

Food Group	Food	Portion
Starch/bread	Flour bread, 4-in diameter	1
Meats and substitutes	Caribou	1 oz
	Caribou (leathery chiton)	2 oz
Lean meats	Halibut	1 oz
	Herring eggs, plain	1/2 cup
	Mussels	1 oz
	Pike	1 oz
	Shrimp	1 oz
	Walrus	1 oz
Medium-fat meats	Whale	1 oz
	Dried fish	1/2 oz
High-fat meats	Alaskan	1 oz
	Salmon	1 oz
High-fat meat = 1 fat	Smoiled hoodigan (cutchond)	1 oz
Vegetables	Kakukuk	1 x 1 x 2 in
	Snowweed, dried	
or 1 cup cooked	Subweed fern	
	Willow greens	
Fruits	Snow apple	
	Highbush cranberries	1 1/2 cups
Fat	Huckleberries	1 cup
	Sabroberries	1 1/2 cups
Free food	Snow oil	1 tsp
	Bear's asparagus	

From the American Diabetes Association and the American Diabetes Association, Inc. Ethnic and regional food practices: a series. Alaska native food practices, customs, and habits, 1985, with permission. Currency being revised to reflect updated information based on the American Diabetes Association's 1994 recommendations for nutrition management of diabetes.
 *Nutrition practitioners who work with Alaska Native clients with diabetes should use the exchange system in strict consultation with them. This listing is presented for the few occasions when nonconventional (Alaskan) values may be needed.

Table A-25-b Supplementary Exchange Lists for Traditional Alaskan Native Foods^a

Food Group	Food	Portion
Breads	Alaskan, cornmeal/bran/rye flour	1/2 cup
	Alaskan, whole wheat flour	1/2 cup
Breads, corn and bran/rye flour	Alaskan	1/2 cup
	Alaskan, whole wheat flour	1/2 cup
Lentils	Alaskan	1/2 cup

Table A-26-b Diets for Weight Management

	Lean Persons	Obese Persons
Energy	Enough to maintain desirable body weight Men and physically active women require 20 kcal/kg desirable body weight Sedentary persons and persons older than 50 years require 20 kcal/kg desirable body weight	Enough to achieve desirable body weight* 20 kcal/kg desirable body weight
Carbohydrate		
Sugars	Can be included with an individualized diet plan†	Low nutrient density, limit on discretionary fats
Fiber	15 to 40 grams, with emphasis on water-soluble fiber	25 g/1000 kcal
Protein	Recommended dietary allowance is 0.8 g/kg body weight	Minimum of 0.8 g/kg when restricted to 2500 kcal/day†
Fat		
Saturated†	≤ 10% of energy	Same
Unsaturated†	< 10% of energy	
Monounsaturated	15 to 20% of energy	
Polyunsaturated	< 10% of energy	
Alcoholic Beverages	Limit to occasional (2005) servings	None
Dietary Supplements	Optional as an aid, limit to 1 to 2 alcohol equivalents	None
Pharmaceuticals	Use judiciously; limit diabetes-related medications	Not necessary; if desired, should be included in total day's meal plan. For insulin, coordinate with insulin schedule or adjust insulin as needed

*From Reeds CK, Ripstein EJ. Protein intake as a nutrition management for individuals with non-insulin-dependent diabetes mellitus in the 1990s: a review. In: Diabetes Care and Associated Chronic Disease. Philadelphia, PA: WB Saunders; 1999: 105-120.
†Recommendations apply to total energy intake and may vary for the patient's specific situation. For example, a desirable weight gain for a woman weighing 150 lb would be 20 to 25 kcal/kg desirable body weight, not 20 kcal/kg. Limiting fat to 10 to 15 percent of energy is not necessary for a patient with a normal weight and low blood lipids.

Table A-27 Nutrition Guidelines for Persons with Non-Insulin-Dependent Diabetes Mellitus (NIDDM)

A-28. NUTRITION MANAGEMENT OF CHRONIC RENAL INSUFFICIENCY

A-28a Purpose, Use, and Modifications

Chronic renal insufficiency (CRI) is characterized by a decrease in the kidney's ability to remove waste products as reflected by an increased serum creatinine level. Goals for nutritional management of chronic renal insufficiency include the following:

- Prevent or minimize uremic symptoms by reducing the accumulation of nitrogenous waste products
- Slow the progression of renal failure and possibly delay the need for maintenance dialysis
- Control hypertension by minimizing fluid and electrolyte disturbances

- Maintain nutritional status
- Translate the nutritional modifications into a meal plan that is understandable and practical for the patient

This diet (often called the predialysis diet) is indicated for patients with chronic renal insufficiency who do not yet require dialysis. This diet has two major restrictions—protein and phosphorus. The levels of sodium, potassium, fluid, and calories are based on individual needs. General recommendations are outlined in [Table A-28-a-1](#).

Parameter	Modification
Protein	0.6–0.8 g/kg desirable body weight (DBW) ^a or adjusted body weight (ABW) ^b
Energy	
Desired weight	35 kcal/kg
Calorie	20–30 kcal/kg DBW or ABW
Underweight or cachectic	25 kcal/kg
Fat (% of total energy intake)	30% ^c
Polysaturated/unsaturated fatty acid ratio	1:1
Carbohydrate	5:0:1:0
Phosphorus	Fluorinated nonprotein calories generally accepted
Sodium	30–50 mEq/day
Fluid	1000–3000 mL/day; additional fluid may be required with salt-loading nephropathy
Potassium	Generally not restricted unless serum potassium is elevated and urine output is less than 1 L/day
	Generally unrestricted; balance fluid intake with urine output in patients with edema or congestive heart failure

© 1995, The American Dietetic Association, Manual of Clinical Nutrition, 5th ed. Chicago, IL, pp 921–924. Used by permission. For references see the original diet on pp. 922–924.
^aBased on "standard" or desirable body weight (DBW) as determined from weight-for-height tables for females used and as used during the NIDDK Study.
^bAdjusted body weight (ABW).
^cThis ratio and all other ratios is performed for patients with diabetes mellitus or renal insufficiency. Suggested protein intake for patients with nephrotic syndrome is 0.8–1.0 g/kg.

Table A-28-a-1 Nutrient Recommendations for Adult Patients with Chronic Renal Insufficiency

Adequacy

Chronic uremic patients are prone to develop deficiency of water-soluble vitamins because of the restrictive diet, decreased consumption associated with anorexia and uremia, and altered metabolism of certain vitamins. Therefore, supplementation with water-soluble vitamins is advisable. Dietary supplementation of iron, calcium, vitamin D analogue, and zinc might be beneficial and should be individualized.

A-28b. Meal Planning

[Table A-28-b-1-a](#) presents a sample menu for a 70-kg man with chronic renal insufficiency. It summarizes the average energy, protein, sodium, and phosphorus content of the food group lists in [Table A-28-b-2](#). These food lists were developed specifically for use in meal planning for patients with kidney disease not requiring dialysis. Food lists for patients receiving hemodialysis can be found in the chapter “Nutrition Management of Chronic Renal Failure.” Additional food lists for patients receiving peritoneal dialysis and for patients with diabetes and renal disease are also

available.

Breakfast	Lunch	Dinner	Snack
Orange juice (1 cup)	Roast beef (1 oz)	Beef chicken thigh (11 oz)	Apple pie (1 slice)
Cranberry apple sauce (1 cup)	Rice (2 cups)	White rice (1 cup)	Lemon-lime soda (1 can)

A-29. GUIDELINES FOR DIETARY SODIUM RESTRICTION

A-29-a. Purpose and Modifications

The goal of a sodium-restricted meal plan is to manage hypertension in sodium-sensitive persons and to promote the loss of excess fluids in edema and ascites. Numerous national health agencies concur that Americans should limit daily sodium intake to less than 3000 mg/day. This is based on findings from epidemiologic studies and clinical trials that support the correlation between reduced sodium intake and blood pressure lowering. The National Research Council recommends that the daily intake of sodium be limited to 2400 mg or less. The National High Blood Pressure Education Program (NHBPEP) recommends that sodium intake be reduced below 2300 mg sodium per day. A public health recommendation is not a mandate; instead, it provides guidelines for menu planning and offers directions for persons who wish to exercise free choice in selecting more healthful alternatives. The Nutrition Facts panel of food labels lists the Daily Value for sodium at 2400 mg/day.

A therapeutic sodium-restricted meal plan should be prescribed in terms of milligrams or milliequivalents of sodium desired on a daily basis. Depending on the severity of cardiac or vascular disease, the amount of edema, and the type of drug therapy, varying degrees of sodium restriction are prescribed. Traditionally, more liberal

sodium-restricted diets have allowed up to 4000 to 5000 mg of sodium daily. However, this is inconsistent with public policy recommendations.

Diets containing less than 2000 mg of sodium per day may be used in the hospital setting on a short-term basis but are considered impractical on an outpatient basis. Special low-sodium food products are often expensive and unpalatable, leading to poor patient compliance. The following levels of sodium restriction may be prescribed.

- 3000 mg sodium (130 meq): Eliminate or eat sparingly high-sodium processed foods and beverages such as fast foods; salad dressings; smoked, salted, and “koshered” meats; regular canned foods; pickled vegetables; luncheon meats; and commercially softened water. Allow up to 1/4 tsp of table salt in cooking or at the table.
- 2000 mg sodium (87 meq): Eliminate processed and prepared foods and beverages high in sodium. Do not allow any salt in the preparation of foods or at the table. Limit milk and milk products to 16 oz daily. Check labels of canned and instant products for sodium content and replace with low-sodium versions when available. [Table A-29-a-1](#) lists standard definitions for sodium claims on food labels.

Sodium free	Less than 5 mg sodium per serving
Salt free	Meets requirements for sodium free
Low sodium	140 mg sodium or less per serving
Very low sodium	35 mg or less sodium per serving
Reduced sodium	At least 25% less sodium than in a reference food ^a
Light in sodium	50% less sodium per serving; restricted to foods with more than 40 calories per serving or more than 3 g of fat per serving (if pertaining to sodium content)
Unsalted, Without added salt, No salt added	(1) No salt is added during processing; (2) the product it resembles and substitutes for is normally processed with salt; and (3) the label bears the statement “not a sodium-free food” or “not for control of sodium” in the diet if the food is not sodium free

^aA reference food is the regular version of the labeled product. It may be either a group of foods, such as an average of the three market leaders, or an individual food product.

Table A-29-a-1 Sodium Claims on Food Labels (FDA)

- 1000 mg sodium (45 meq): Eliminate processed and prepared foods and beverages high in sodium. Omit the following regular items: canned foods, cheeses, margarines, and salad dressings. Look for low-sodium or low-salt varieties of these foods (check the label). Omit many frozen foods, deli foods, and fast foods. Limit regular breads to two servings per day. Limit milk and milk products to 16 oz daily. Do not allow any salt in food preparation or for table use. This meal plan is used in the inpatient setting on a short-term basis only.
- 500 mg sodium (22 meq): Omit canned or processed foods containing salt. Do not use any salt in food preparation or at the table. Omit vegetables containing high amounts of natural sodium. Limit meat to 5 oz daily and milk and milk products to 16 oz daily. Use low-sodium bread in place of regular bread, and distilled water for cooking and drinking. This meal plan is used in the inpatient setting on a

short-term basis only.

Adequacy

Depending on individual food choices, sodium-restricted meal plans (1000 mg or more) are adequate in all nutrients, based on the 1989 Recommended Dietary Allowances. Meal plans with daily sodium intakes below 1000 mg may be inadequate in calcium because of the restriction of milk and milk products. However, this level of restriction is not recommended for long-term use.

Guidelines for Food Selection for 500-mg Sodium Diet

Use the 1000-mg sodium diet guidelines ([Table A-29-b-3](#)) with the following modifications:

- Use low-sodium bread only
- Omit sherbet and flavored gelatin
- Limit meat to 5 oz per day; one egg may be used daily in place of 1 oz of meat
- Omit the following vegetables: beets, beet greens, carrots, kale, spinach, celery, white turnips, rutabagas, mustard greens, chard, peas, and dandelion greens
- Use distilled water
- Limit milk and milk products to 16 oz daily

Breakfast	Lunch	Dinner	
Orange juice (1 cup)	Low-sodium vegetable soup (1 cup)	Green salad (2 1/2 cup)

A-30. DIETARY THERAPY OF HIGH BLOOD CHOLESTEROL

(From Detection, Evaluation and Treatment of High Blood Cholesterol in Adults. Second Report of the Expert Panel: Adult Treatment, National Cholesterol Education Program. NIH publ. no. 93-3095, September, 1993.)

A-30-a. Step I and Step II Diets—Nutrients and Rationale

The Step I Diet emphasizes the choice of fruits, vegetables, grains, cereals, and legumes, as well as poultry, fish, lean meats, and low-fat dairy products instead of foods high in saturated fat and cholesterol, such as whole milk dairy products and high-fat meats. For many patients this diet can be achieved with a moderate change in dietary habits. The Step II Diet further reduces saturated fat and cholesterol; neither of these is an essential nutrient, and they can be reduced to very low intakes without harm ... Any therapeutic diet must be nutritionally adequate and meet Recommended Dietary Allowances ...

[The original report reviews the roles of various nutrients and alcohol as they affect risk factors for hypercholesterolemia. The following tables reflect the text in terms of specific recommendations for foods. The Appendix editors]

(The image shows a very faint and illegible table, likely representing the nutritional data for the Step I diet mentioned in the text.)

A-31. FAT-CONTROLLED DIET (25 OR 50G)

A-31-a. Purpose, Use, and Modifications

A fat-controlled diet is used to relieve symptoms of diarrhea, steatorrhea, flatulence, abdominal pain, and/or to control nutrient losses caused by the ingestion of excess dietary fat.

This diet may be used in the treatment of diseases of the hepatobiliary tract, pancreas, intestinal mucosa, and the lymphatic system as well as in malabsorption syndromes in which digestion, absorption, or utilization and transport of dietary fat is impaired. The latter include small bowel resection, intestinal lymphangiectasia, abetalipoproteinemia, chronic pancreatitis, Crohn's disease, malabsorption in the elderly, and patients with acquired immune deficiency syndrome (AIDS). The excretion of more than 6 g to 8 g of fat (or over 10% of fat consumed) per day over a 3-day period following a fecal fat assay indicates overall fat malabsorption. Further testing is needed to determine whether the steatorrhea is caused by small intestinal, pancreatic, or hepatobiliary disease. This diet is not designed for use in lowering serum lipid levels. Refer to the chapter on Nutrition Management of Hyperlipidemias in Adults in the original reference for further information.

A low-fat diet may also be useful in the treatment of patients with gastroesophageal reflux. A decreased fat intake will increase lower esophageal sphincter pressure, thus reducing symptoms of heartburn and dysphagia. Although steatorrhea is often a presenting symptom in celiac sprue (gluten-sensitive enteropathy), adherence to a strict gluten-free diet often brings about an end to steatorrhea, thus obviating the need for a low-fat diet. Refer to chapter on Gluten-Restricted, Gliadin-Free Diet for further information.

In individuals with cystic fibrosis, generally a low-fat diet is no longer recommended since the advent of enteric-coated pancreatic enzymes. Adequate doses of these supplements can normalize fat excretion in these individuals. Liberalizing fat intake may increase the likelihood that a nutritionally adequate diet will be consumed.

Many persons with malabsorption also may have difficulty tolerating excess dietary fiber and/or lactose. Refer to the chapters on Lactose-Controlled Diet, and Fiber- and Residue-Restricted Diet for further information.

In general, the 50-g-fat diet allows 6 oz of lean meat or meat substitutes and three to five fat equivalents per day. A 25-g-fat diet allows 4 oz of lean meat or meat substitutes

per day and one fat equivalent per day ([Table A-31-b](#)). The food plan should be adjusted and individualized based on food preferences and a person's ability to monitor total fat intake. Individual tolerance should be monitored closely and the level of fat restriction adjusted if symptoms persist. Medium-chain triglycerides may be substituted for some fat in the diet. Additional carbohydrates in the form of starches and sugars also may be indicated for some patients to meet caloric requirements. Protein intake can be increased with the use of nonfat dairy products, as tolerated. Low-fat dietary supplements also may prove useful to increase nutrient intake. Pancreatic enzyme replacements may be prescribed by the physician. Mean fat excretion may be significantly decreased when enzymes are given prior to meals.

Table A-31-b Guidelines for Food Selection for Fat-Restricted Diet (25 or 50 g of fat)

In patients with acquired immune deficiency syndrome (AIDS) who present with steatorrhea, dietary restriction of fat may be ordered. Since weight gain is often difficult to achieve, however, these individuals should also receive nutritional supplementation, with particular emphasis on protein.

(From *The Manual of Clinical Dietetics*, 5th ed. Chicago: the American Dietetic Association, 1996:431–439. With permission. *Note:* For references, see original diet, p. 439.)

Adequacy

The diet is adequate in all nutrients based on the 1989 Recommended Dietary Allowances. Prolonged diarrhea or steatorrhea may lead to nutrient deficiencies including calcium, iron, magnesium, potassium, zinc, fat-soluble vitamins (A, D, E, and K), folic acid, and vitamin B₁₂. While other water-soluble vitamin deficiency states are rarely associated with malabsorption, the vitamin B complex is also sometimes supplemented.

Vitamin and mineral deficiencies can be treated with supplements and control of causative factors. Medium-chain triglycerides can be incorporated to provide additional calories.

Breakfast	Lunch	Dinner	Snack

(From The Manual of Clinical Dietetics, 5th ed. Chicago: the American Dietetic Association, 1996:397–401, with permission. *Note:* For references, see original diet, pp.

Purpose and Modifications

The fiber- and residue-restricted diet is designed to prevent blockage of a stenosed gastrointestinal tract and to reduce the frequency and volume of fecal output while prolonging intestinal transit time.

In planning a fiber-restricted diet, indigestible carbohydrate intake is reduced by using limited amounts of well-cooked or canned vegetables and canned, cooked, or very ripe fruits, and by replacing whole-grain breads and cereals with refined products. Legumes, seeds, and nuts are omitted.

A low-fiber diet is not synonymous with a low-residue diet. Fiber is the portion of carbohydrates not capable of being digested by enzymes in the human digestive tract, thus contributing to increased fecal output. Residue is the unabsorbed dietary elements and total postdigestive luminal contents present following digestion. Residue-containing foods tend to increase the fecal residue and stool weight despite their low-fiber contents. However, since low-residue diets are based on old literature, tradition, and studies on laboratory animals, tolerance to residue-containing foods should be assessed on an individual basis. Limited data are available on the actual residue content of foods and the efficacy of the low-residue diet.

The fiber content of some common foods can be found in [Table A-20-a](#). Adherence to the guidelines in [Table A-32-a-2](#) generally results in a diet that contains less than 20 g of fiber per day.

Food Category	Recommended	May Cause Distress
Beverages	Coffee, tea, carbonated beverages, sweetened fruit drinks, milk as tolerated ^a	Any containing fruit or vegetable solids (fruit juice) ^b
Breads	Refined breads, rolls, biscuits, muffins, crackers, waffles or waffles, grain cereals	Any made with whole-grain flour, bran, seeds, nuts, oatmeal, or oat or wheat-flour branched, germ, or wheat
Cereals	Refined cooked cereals including grits and farina	Unrefined, any whole-grain, bran, or grains cereal, any containing seeds, nuts, oatmeal, or wheat flour
Deserts and sweets	Plain cakes and cookies are made with all-purpose flour, plain shortening, fruit (see frozen jams, jellies, gelatin, and custard jelly, plain hard candy, marshmallows, ice cream as tolerated) ^c	Any made with whole-grain flour, bran, seeds, nuts, oatmeal, or wheat flour
Fats	Negative butter, vegetable oil, margarine, mayonnaise, shortening, grease	Any containing whole-grain flour, bran, seeds, nuts, oatmeal, or wheat flour
Fruits	Most canned or cooked fruit ^d , applesauce ^e , fruit cocktail ^f , "ice cream" ^g	Dried fruit, all berries, most raw fruit
Meats and meat substitutes	Ground or minced, tender beef, pork, lamb, veal, veal, poultry, fish, organ meats, eggs and cheese	Tough, fibrous meats with gristle ^h any made with whole-grain ingredients, seeds or nuts, wheat bran, peas, lentils, soybeans, alfalfa/soybean meal ⁱ
Vegetables and potato substitutes	Cooked white and sweet potatoes without skin, white rice, refined pasta	Any others
Spices	Black, white, or cream sugar made with allowed ingredients, vanilla, salt, or flour	Any others
Vegetables	Most well-cooked and canned vegetables without leafy greens; frozen vegetables; frozen or canned, preserved vegetables and	Raw/steamed, white seaweed, peas, and corn, most raw vegetables and vegetables with seeds
Miscellaneous	Salt, glucose, sugar, spices, herbs, vinegar, ketchup, mayonnaise	Nuts, coconut, seeds, and popcorn

^aSmall amounts of dairy products may be tolerated if they do not cause distress. Some patients may tolerate small amounts of dairy products if they are well tolerated. ^bSome patients may tolerate small amounts of dairy products if they are well tolerated. ^cSome patients may tolerate small amounts of dairy products if they are well tolerated. ^dSome patients may tolerate small amounts of dairy products if they are well tolerated. ^eSome patients may tolerate small amounts of dairy products if they are well tolerated. ^fSome patients may tolerate small amounts of dairy products if they are well tolerated. ^gSome patients may tolerate small amounts of dairy products if they are well tolerated. ^hSome patients may tolerate small amounts of dairy products if they are well tolerated. ⁱSome patients may tolerate small amounts of dairy products if they are well tolerated.

Table A-32-a-2 Guidelines for Food Selection for Fiber- and Residue-Restricted Diet

Adequacy

Depending on individual food choices, the diet is adequate in all nutrients based on the 1989 Recommended Dietary Allowances (RDA). However, the diet does not meet the RDA for iron in pregnant, lactating, and premenopausal women. Vitamin and mineral supplementation may be indicated for these individuals or for those with suboptimal intakes and increased requirements resulting from illness. The potential risks and benefits of long-term restriction of dietary fiber should be addressed before using the diet for any extended period. Strict reductions in vegetables and fruits may necessitate supplementation of ascorbic acid, folate, and others depending on actual intake. In persons with lactase deficiency who do not tolerate milk, calcium also may need to be supplemented. Individual response, particularly in the patient with ulcerative colitis and Crohn's disease, must be monitored to avoid an overly restrictive regimen and to determine continued indications for using the diet.

[Table A-32-a-2](#) and [Table A-32-a-3](#) provide guides to meal planning and to a sample menu for restricted diets.

Fiber Type	Components	Food Sources
Soluble fibers		
Hydrated, resulting in gellike viscous substance, and fermented by colonic bacteria	Gums, mucilages, pectin, some hemicelluloses, β -glucan	Fruits, vegetables, barley, legumes, oats and oat bran
Insoluble fibers		
Remain essentially unchanged during digestion	Cellulose, lignin, some hemicelluloses	Fruits, vegetables, cereals, whole-wheat products, wheat bran

Table A-32-a-1 Fiber Components and Food Sources

	Lunch	Dinner	
Crackers (1/2 cup)	Vegetable broth (1 cup)	Steamed tomatoes (1 cup)	
Puffed rice cereal (1/2 cup)	Saltine crackers (6)	Broiled skinless chicken breast (3 oz)	
Canned peaches (1 cup)	Lean beef jelly (2 oz)	White rice (1 cup)	
Wholesome corn (2 slices)	Marinara sauce without seeds (1/2 cup)	Cooked spinach (1/2 cup)	
Margarine (1 tsp)	Mashed (1/2 cup)	White rice (1/2 cup)	
Jelly (1 tbsp)	Sauces (1/2 cup)	Margarine (2 tsp)	
2% milk (1/2 cup)	Canned fruit cocktail (1/2 cup)	Low-fat frozen yogurt (1/2 cup)	
Coffee or tea	Hot/water cookies (2)	Applesauce (1/2 cup)	
	2% milk (1/2 cup)	Collard greens	
	Collard greens

Table A-32-a-3 Sample Menu for Fiber- and Residue-Restricted Diet

A-32-b. High-Fiber Diet

(From *The Manual of Clinical Dietetics*, 5th ed. Chicago: the American Dietetic Association, 1996:403–9, with permission. *Note:* For references, see original diet, pp. 408–9.)

Purpose and Modifications

A high-fiber diet is designed to exert a variety of physiologic and metabolic effects depending on the physical properties, chemical composition, and form in which the fiber is consumed. Both soluble and insoluble fibers exert physiologic effects, whereas only soluble fibers exert metabolic effects.

The high-fiber diet is a general diet with an emphasis on fiber-rich food sources including fruits, legumes, vegetables, whole-grain breads, and cereals. To date there is no Recommended Dietary Allowances for fiber. Actual intake data indicate that the average fiber intake for all persons is approximately 7 g per 1000 kcal, which translates into approximately 10 g for children, 12 g for women, and 18 g for men.

The American Dietetic Association recommends a daily dietary fiber intake of 20 g to 35 g from a variety of sources, combined with a low-fat, high-carbohydrate diet. Increased fiber intake should come from a variety of food sources, rather than from dietary fiber supplements, to ensure adequate intake of vitamins, minerals, and other nutrients. Consumption of adequate amounts of liquid (at least eight 8-oz glasses per day) in conjunction with high-fiber intake is recommended.

Fiber intake should be increased gradually to minimize potentially adverse side effects such as abdominal distress, bloating, flatulence, cramps, and diarrhea. These effects are usually temporary and subside within several days; however, if they persist, the fiber content of the diet should be reduced and a physician consulted. High-fiber diets may be inappropriate for persons with autonomic neuropathy. [Table A-32-b-1](#) offers a guide to meal planning for a high-fiber diet. When combined with a general diet, this plan provides approximately 25 g to 30 g of dietary fiber depending on actual foods chosen. The diet can also be planned using the food composition table of fiber contents found in A-20-a.

Food and Serving Size	Approximate Amount of Dietary Fiber (g)	Recommended Daily Servings
Breads and Breads	0	8 (plus 12 additional servings of refined breads and starches)
White yeast or hot bread (1 slice)		
White yeast bread or pita bread (1)		
Old-fashioned (1)		
White refined crackers, crisp (serving 16)		
White refined pasta, torti, or pizza (1 cup)		
Pappardelle, egg-based (1 cup)		
Whole grain (1) flour		
Cornmeal	4-6	
Kohlrabi or bean casseroles, cold (1 cup)		
Tomato, raw (1/2), or (1/2) (1 cup-1/2)		
Vegetables	0	3 (plus 12 additional servings of other vegetables or fruits)
Cornish-onion, green beans, broccoli, cabbage, carrots, cauliflower, green peas, onions, snow peas, spinach, squash, canned tomatoes (1 cup), onions with skin (1 small)		
Raw—broccoli, cabbage, carrots, cauliflower, tomatoes, celery, green peas, squash (1 cup)		
Fruits	0	3 (plus 12 or additional servings of other fruits or juices)
Apple, peaches, oranges, pears, lemons (1 medium), grapefruit (1/2)		
Beans	6	Optional
Garbanzo beans, kidney beans, lentils, lima beans, split peas, pinto beans, other beans and peas (1 cup-canned)		
Nuts and Seeds	0	Optional
Almonds (1/2 ounce), walnuts (1/2 ounce), pecans (1/2 ounce), sunflower seeds (1/2 ounce), sesame seeds (1/2 ounce), sunflower seeds (1/2 ounce)		

Table A-32-b-1 Guide to Meal Planning for a High-Fiber Diet

Adequacy

Depending on individual food selection, the high-fiber diet is adequate in all nutrients (Table 32-b-2). Some studies suggest that excessive (>30 g per day) intakes of some dietary fiber sources may bind and interfere with the absorption of calcium, copper, iron, magnesium, selenium, and zinc. However, it is hypothesized that long-term adaptation to high-fiber intakes may occur; therefore, consumption of a varied high-fiber diet may not cause mineral or nutrient imbalances in the general population. Limiting total dietary fiber intake to 35 g per day so that mineral absorption is not inhibited appears to be an adequate safeguard while obtaining the benefits of a high-fiber diet. Intake of adequate fluid is necessary due to the hygroscopic nature of fiber.

	Breakfast	Lunch	Dinner
	Orange juice (1 cup)	Egg (one whole) (1 cup)	Green salad (1 cup)
	Cornmeal (1 cup)	White-chicken chicken (1)	Orange and oil dressing (1 tbsp)
	Peas (1/2 cup)	Lean beef (1/2) (1 cup)	Grated cheddar cheese chicken breast (1 cup)
	Whole-wheat toast (2 slices)	Hamburger (1/2)	Hard-boiled eggs (1 cup)
	Margarine (1 tsp)	Mashed (1/2 cup)	Seasoned tomato (1 cup)
	Jelly or jam (1 tbsp)	Apple (1/2)	Whole-wheat (1/2)
	2% milk (1/2 cup)	Shred tomato (1 cup) and lettuce	Margarine (1/2 cup)
	Coffee or tea	Roast beef (1 cup)	Low-fat frozen yogurt (1 cup)
		Beer (1/2 cup)	Medium peas (1/2)
		2% milk (1 cup)	Coffee/tea
		Coffee/tea	
	Approximate Nutrient Analysis

A-33. SOFT DIET

(From The Manual of Clinical Dietetics, 5th ed. Chicago: the American Dietetic Association, 1996:141–3, with permission. *Note:* For references, see original diet, p. 143.)

A-33-a. Purpose and Related Physiology

The soft diet is designed for patients who are unable to tolerate a general diet. It has traditionally been used to prevent nausea, vomiting, gas, and distension in the postsurgical patient. However, the rationale for this premise is poorly documented, since symptoms of nausea, vomiting, gas, and distension are more likely to be caused by anesthesia and gut immobility than by diet. If gas or distension is a problem, smaller, frequent meals may provide some relief. If nausea or vomiting interferes with food intake, it may be helpful to provide dry foods in small quantities and to progress to frequent, small feedings of simple palatable foods. Hot beverages (tea, clear broths) and cold beverages (iced tea, carbonated liquids, especially ginger ale) are usually well tolerated.

Adequacy

Based on individual food choices, the diet is adequate in all nutrients according to the 1989 Recommended Dietary allowances. [Table A-33-a-1](#) lists recommended foods, and [Table A-33-a-2](#) presents a sample meal plan.

Food Group	Recommendation	Not Allowed/limited
Beverages	Milk and milk products, all other beverages	Alcoholic beverages
Breads and cereals	White, refined wheat, or light-colored enriched breads, soft rolls, and crackers, cooked or ready-to-eat cereals	Coarse cereals (e.g., bran), whole-grain breads or products with seeds, bread or breakfast products with nuts or dried fruits
Desserts	Cakes, cookies, pies, pudding, custard, ice cream, sherbet, and gelatin made with allowed foods, fruit ice and frozen fruit	All sweets and desserts containing nuts, coconut, or dried fruits not allowed; fruit pastries (e.g., doughnuts)
Fats	Butter or margarine (unsalted), seed dressings, oil, soft margarine	Highly seasoned salad dressings
Fruits	All fruit juices, cooked or canned fruit, applesauce, berries, melon, grapefruit and orange sections without membranes, other raw soft fruits without seeds	Other fruit and dried fruits
Meats and small seafoods	Roast, broiler meats, poultry, fish, and shrimp; eggs; mild-flavored cheeses; cream; ground beef; southern and other moist substitutes; plain or flavored yogurt	Strong-smelling or highly seasoned meats, seafoods, or fish (e.g., turbot); meats, fish, poultry, sausage; yogurt with nuts or dried fruits
Proteins and protein substitutes	Pork chops, enriched rice, barley, spaghetti, macaroni and other pasta	Pasta chips, rice cakes
Vegetables	All vegetables, cooked vegetables and lettuce or lettuce salads made from allowed foods	Raw and fried vegetables, whole kernel corn, germinating vegetables (e.g., broccoli), Brussels sprouts, collards, green peas, cauliflower, asparagus, green pepper, hot peppers, turnips, sweetbreads, dried peas, dried beans
Soups	Soups made with allowed foods	Highly seasoned soups and soups made with germinating vegetables
Sweets	Sugar, honey, jelly, and seedless jam, hard candies, plain chocolate candies, mints, peppermint	Jelly with nuts or coconut
Miscellaneous	Instant soft-flavored soups, flavored gelatin and pudding, frozen fruit, frozen fruit bars, custard, orange or mandarin	Strong-flavored seasonings and condiments (e.g., garlic, chili sauce, hot sauce, horseradish), pickles, pickled fruits and vegetables

Table A-33-a-1 Soft-Diet Foods

Breakfast	Lunch	Dinner	
Orange juice (1 cup)	Vegetable soup (1 cup)	Tomato juice (1 cup)	
Canadian wheat (1 cup)	Salmon croquette (1)	Baked, soft-boiled chicken breast (2 oz)	
Banana slices (1 cup)	Lean beef patty (2 oz)	Cooked rice (1 cup)	
White toast (2 slices)	Hamburger bun (1)	Steamed green beans (1 cup)	
Margarine (2 tsp)	Mashed (1 cup)	Soft drink (1 cup)	
Jelly (1 tbsp)	Mashed (1 cup)	Margarine (2 tsp)	
2% milk (1 cup)	Carrot (1 cup)	Low-fat frozen yogurt (2 cup)	
Coffee or tea	Grain crackers (16)	Applesauce (1 cup)	
	2% milk (1 cup)	Coffee/tea

Table A-33-a-2 Sample Menu for Soft Diet

A-34. NUTRITIONAL MANAGEMENT OF DYSPHAGIA

A-34-a. Purpose, Use, and Modifications

The goal of the dysphagia diet is to provide adequate calories, protein, vitamins, minerals, and fluids in a consistency best tolerated by the patient. Dysphagia connotes a disturbance in the normal transfer of food from the oral cavity to the stomach and refers to difficulty in swallowing liquids, solids, or both. The nutritional implications of dysphagia result from inadequate dietary intake. They can include weight loss, dehydration, and vitamin and mineral deficiencies. Untreated, these problems can result in protein-energy malnutrition, which can be a significant complication in otherwise healthy people and especially devastating for debilitated patients.

Dysphagia refers to a swallowing impairment that results from an anatomic or physiologic abnormality. Neurologic illnesses, surgical procedures involving mechanical and anatomic alterations, anticancer therapy, and aging may lead to dysphagia and risk of aspiration. Psychologic factors may exacerbate, but rarely cause, dysphagia.

Diagnosis or conditions of patients who may have swallowing problems include

Alzheimer's disease/dementia	Myotonic dystonia
Amyotrophic lateral sclerosis (ALS)	Parkinson's disease
Cerebral palsy	Poliomyelitis
Closed head injury	Sjögren's disease
Dermatomyositis	Stroke/cerebrovascular accident
Dysautonomia	Torticollis
Head or neck cancer	Guillain-Barré syndrome
Huntington's chorea	Inflammation of the pharynx or esophagus
Multiple sclerosis	Throat webs
Muscular dystrophy	History of aspiration or pneumonia

Myasthenia gravis

History of nonspecific respiratory problems

Warning signs of swallowing problems include

Pocketing of food under tongue, in cheeks, or on the hard palate

Spitting food out of the mouth, tongue thrusting Poor tongue control

Facial weakness

Excessive tongue movement

Slow oral transit time

Delay or absence of elevation of the larynx (Adam's apple/ thyroid cartilage)

Coughing before, during, or after swallowing

Choking

Excessive secretions, drooling

“Gurgly” (wet) voice after eating or drinking

Hoarse, harsh, or breathy voice

Slurred speech

Regurgitation of material through nose, mouth, or tracheostomy tube

Inadequate intake of food or fluid; weight loss

Excessive eating time

Mealtime resistance—clenching teeth, pushing food away, or clenching throat

Recurrent pneumonia (due to aspiration)

No two patients with dysphagia are alike; thus, diets must be individualized on the basis of swallowing ability and patient preference. A dysphagia menu plan should

- Provide foods and beverages that reduce the risk of choking and aspiration
- Be modified when the impairment level changes, as assessed by the speech-language pathologist or designated clinician
- Provide foods that stimulate the swallowing reflex

- Promote positive nutritional balance to achieve or maintain a desirable weight and optimal nutritional status
- Facilitate independent eating and swallowing, if appropriate
- Provide a variety of foods that are visually appealing and nutrient dense
- Provide moist foods or thickened beverages as needed for adequate hydration

(From The Manual of Clinical Dietetics, 5th ed. Chicago: the American Dietetic Association, 1996:145-163, with permission. *Note:* For references, see original diet on p. 163.)

Problem	Management	Food Modifications
Choking	<ul style="list-style-type: none"> • Stop eating immediately • Call for help • Perform Heimlich maneuver • Call 911 	<ul style="list-style-type: none"> • Avoid hard, round, or sticky foods • Avoid large pieces of food • Avoid foods that are difficult to chew • Avoid foods that are difficult to swallow • Avoid foods that are difficult to digest

Table A-34-a-1 Review of Dysphagic Problems and Dietary Management Strategies

Consistency	Examples
Smooth, traditionally prepared foods that are common	<ul style="list-style-type: none"> • Soups, stews, casseroles, soft fruits, soft vegetables • Foods that are soft, moist, and easy to chew • Foods that are soft, moist, and easy to swallow • Foods that are soft, moist, and easy to digest
Soft foods that hold to form or shape and may be difficult to control	<ul style="list-style-type: none"> • Foods that separate into liquid and pulp (e.g., the cooked fruits and vegetables) • Pureed soups • Pureed meats • Pureed fruits
Foods that are sticky, bulky, and firm	<ul style="list-style-type: none"> • Foods of firm or sticky consistency (e.g., certain fruits, pasta, and eggs with shells) • Vegetables, seeds, or grains • Hard bread • Chewy meats • Chewy pastas • Nuts • Soft fruits • Soft and thin cream soups • Soft, fat, and fat-free soups • Cream soups, fruit soup • Water, milk, and alcohol • Hot, iced, and carbonated beverages • Spicy soups • Fruit salads
Thickened liquids	<ul style="list-style-type: none"> • Thickened or cream soups • Fruit salads • Soups, stews, casseroles • Soft fruits, soft vegetables • Soft and thin cream soups • Soft, fat, and fat-free soups • Cream soups, fruit soup • Water, milk, and alcohol • Hot, iced, and carbonated beverages • Spicy soups • Fruit salads
Specialized foods	<ul style="list-style-type: none"> • Thickened or cream soups • Fruit salads • Soups, stews, casseroles • Soft fruits, soft vegetables • Soft and thin cream soups • Soft, fat, and fat-free soups • Cream soups, fruit soup • Water, milk, and alcohol • Hot, iced, and carbonated beverages • Spicy soups • Fruit salads

Table A-34-a-2 Food Consistencies and Representative Foods

-
- Eliminate distractions
 - Do not use liquids to clear the mouth of food, use liquids only after the food has been cleared
 - Encourage small bites, especially if the ability to manage food is impaired
 - Allow frequent dry swallows to help clear the mouth of food between bites
 - Watch for the rise of the Adam's apple, make sure food is being swallowed and not pocketed in the cheeks
 - Check frequently for voice quality, a wet or gurgling voice indicates that food may be resting on the vocal cords
 - Place patient ear before meals since machine can be very noisy
 - Ensure correct positioning, the patient should be sitting upright with the hips at a 90° angle, shoulders slightly forward, and feet flat on the floor or firmly supported
-

Table A-34-a-3 Compensatory Techniques

A-34-b. Dysphagia Diet Levels

A-34-b-1. Dysphagia Diet Level I

Rationale This diet is designed for patients just beginning to eat by mouth or who need maximum restriction due to dysphagia and cannot swallow chewable foods and thin liquids safely. Foods that are sticky or require bolus formation or controlled manipulation in the mouth (e.g., melted cheese, peanut butter) are omitted. This diet is mechanically nonirritating and low in fiber. It is based on modifications of pureed diets, except that all thin liquids are omitted or thickened. This diet consists of thick, smooth, semiliquid textures and may be appropriate for persons with severely reduced oral preparatory stage abilities, impaired lip and tongue control, delayed swallow reflex triggering, oral hypersensitivity, reduced pharyngeal peristalsis, and/or cricopharyngeal dysfunction.

Description

- Thick, homogeneous textures are emphasized
- No coarse textures, nuts, raw fruits, or raw vegetables are allowed
- Liquid or crushed medications are required and may be mixed with pureed fruits
- No water is allowed
- All liquids are thickened with a commercial thickening agent (see [Table A-34-b-1-a](#))

Type of Thickener	Comments
Gelatin*	Inexpensive—provides a light density and moisture, stabilizes viscosity of liquids held at body temperature, forms a soft gel when used with soups, broths, and puddings; can be used flavored or unflavored; often utilized with pureed chilled fruits, juices, broths, soups, frozen beverages, regular beverages, pureed cold vegetables, salads
Commercial thickeners†	Moderate- to high-cost—provides a smooth texture, can be used in hot foods; provides an excellent thickness at the high-viscosity level but not at low-viscosity levels; best used with meats, soups, beverages, breads, and dinner breads; commercial thickeners can usually be obtained through community pharmacies
Pureed thick vegetables	Inexpensive—can alter flavor depending on the pureed vegetable used; best used with soups and meat-based dishes
Pureed fruits or applesauce	Inexpensive—alters the flavor; separates when used with thin liquids; best used with fruit juices; more appropriately used as a flavoring agent with thickened products
Baby rice cereal	Inexpensive—excellent thickness at high-viscosity level but not at low-viscosity level; fortified cereals may be a significant source of iron
Baby apple flakes	Expensive—excellent thickness at all viscosity levels

*Gellan made with SunSweet (SunSweet Co., Denville, NJ 07834) is a low-based alternative to non-fermentable, and can compete with the standard gelatin source.
†High-quality commercial thickeners do not have an aftertaste, do not curdle or thicken after heating (1-2 min), and are fully digestible. Thickening agents like xanthan gum, but a gum (guar) and locust bean gum are recommended to they will not be available for tubular.

Table A-34-b-1-a Clinically Appropriate Thickening Combinations

Food Group	Recommended Foods
Breads and cereals	Cream of wheat, cream of rice
Eggs	Soft-poached
Milk products	Yogurt without fruit; thickened milk
Fruits	Pureed fruits without seeds or skins; thickened juices
Vegetables	Pureed vegetables without seeds or skins; thickened juices
Fats	Gravy, margarine, thickened sauces or broths
Meats and meat substitutes	Pureed, tender meats or casseroles with gravy or broth to moisten
Soups	Pureed, strained soups; thicken as needed
Desserts	Shakes, custard, pudding, ice cream, sherbet, Pudding Pops, Jello Flavored
Beverages	All liquids must be cold and thickened with a commercial thickening agent, no water

Table A-34-b-1-b Dysphagia Diet Level I: Recommended Foods

Table A-34-b-1-c Sample Menu for Dysphagia Diet Level I

Nutritional Adequacy This diet does not meet the 1989 Recommended Dietary Allowances (RDAs). Amount of intake may be limited because of the increased time required for eating and swallowing. Additional tube feeding or a vitamin and mineral supplement is recommended. Fluid intake should be monitored.

A-34-b-2. Dysphagia Diet Level II

Rationale This diet is designed for patients who can tolerate a minimum amount of easily chewed foods but cannot swallow thin liquids safely. This diet has a pureed base with the addition of *some* texture, flavor, and variety. Small amounts of liquids may be added to achieve the appropriate consistency for the food. This diet may be appropriate for persons with moderately impaired oral preparatory-phase abilities, edentulous oral cavity, decreased pharyngeal peristalsis, and/or cricopharyngeal muscle dysfunction.

Description

- Liquids are thickened only as needed with a commercial thickening agent (see [Table A-34-b-1-a](#))
- The patient may begin to drink beverages such as very thick juices and milk products without thickeners, if tolerated
- No coarse textures, nuts, raw fruits, or vegetables are allowed
- Liquid or crushed medications may still be required
- No water is allowed

Nutritional Adequacy Depending on individual selection and amounts consumed, this diet is designed to provide an adequate quantity of nutrients as indicated by the RDA. More-frequent feedings are recommended, and fluid intake should be monitored.

[Table A-34-b-2-a](#) lists recommended foods for the dysphagia diet level II. [Table A-34-b-2-b](#) shows a sample menu.

Food Group	Recommended Foods
Breads and cereals	Cream of wheat, cream of rice, thinned oatmeal, pancakes with syrup if tolerated
Eggs	Soft poached, soft scrambled
Milk products	Yogurt, cottage cheese
Fruits	Pureed fruits without seeds or skins; applesauce; ripe, mashed bananas; thickened juices or nectars
Vegetables	Pureed vegetables without seeds or skins; moist mashed potatoes; mashed winter squash; thickened juices
Fats	Gravy, sauces, margarine, seasonings as tolerated
Meats and meat substitutes	Pureed, tender meats or casseroles with gravy or broth to moisten; macaroni and cheese if tolerated
Soups	Pureed or strained creamed soups
Desserts	Shakes, custard, pudding; ice cream, sherbet; Pudding Pops, Jello if tolerated; avoid hard candies and nuts
Beverages	Very thick juices, nectars, and milk products if tolerated; all other liquids must be cold and thickened with a commercial thickening agent; no water
Miscellaneous	Syrup if tolerated

Table A-34-b-2-a Recommended Foods for Diet Level II

Breakfast	Lunch	Dinner	
Thickened orange juice (1/2 cup)	Strained cream pea soup (1/2 cup)	Strained cream of chicken noodle soup (1/2 cup)	
Thinned cereal (1/2 cup)	Pureed chicken (2 oz)	Pureed beef (2 oz)	
Soft, scrambled egg (1)	Avocado (2 oz)	Pureed carrots (1/2 cup)	
Butter or margarine (1-2 tsp)	Moist mashed potato (1/2 cup)	Moist mashed potato (1/2 cup)	
Sugar (1-2 tsp)	Gravy (1 tbsp)	Gravy (1 tbsp)	
Thickened coffee/tea	Pureed apples (1/2 cup)	Pureed pear (1/2 cup)	
Thickened 2% milk (1/2 cup)	Pudding or custard (1/2 cup)	Sherbet (1/2 cup) or yogurt without fruit (1/2 cup)	
	Pureed peas (1/2 cup)	Pureed peaches (1/2 cup)	
	Thickened coffee/tea	Thickened coffee/tea	
	Sugar (1-2 tsp)	Sugar (1-2 tsp)	
	Thickened 2% milk (1/2 cup)	Thickened 2% milk (1/2 cup)

Table A-34-b-2-b Sample Menu for Diet Level II

A-34-b-3. Dysphagia Diet Level III

Rationale This diet is designed for patients who may have difficulty chewing, manipulating, and swallowing certain foods. It is based on a mechanically altered or edentulous diet and consists of soft food items prepared without blenderizing or pureeing. It may be appropriate for persons beginning to chew or with mild oral preparatory-phase deficits.

Description

- Textures are soft, with no tough skins
- No nuts or dry, crispy, raw, or stringy foods are allowed
- Meats should be minced or cut into small pieces

- Liquids can be used as tolerated
- Liquid or crushed medications may still be required

Nutritional Adequacy Depending on individual selection and amounts consumed, this diet is designed to provide an adequate quantity of nutrients as indicated by the RDA. [Table A-34-b-3-a](#) lists recommended foods for the dysphagia diet level III. [Table A-34-b-3-b](#) suggests a sample menu.

Food Group	Recommended Foods
Breads and cereals	Soft breads and Graham crackers only; cooked and cold cereals in milk; waffles, pancakes; rice, pasta; avoid Grape Nuts, granola, and whole grain crackers or crackers with seeds.
Eggs	Poached, scrambled, egg salad
Milk products	Yogurt, cottage cheese; American or processed cheese, ricotta, cream cheese
Fruits	Any fresh or canned fruit without seeds, orange slices, or slices such as peeled apples, applesauce, bananas, canned peaches cherries, canned apricots, peaches or canned peaches and pears; juices, nectars
Vegetables	Well-cooked or canned vegetables; avoid spinach, lettuce, and peas
Fats	Grease, sauces, margarine, seasonings as tolerated
Meats and meat substitutes	Small pieces with gravy; meat salads; macaroni and cheese; soft sandwiches; casseroles made with allowed foods; smooth peanut butter if tolerated
Soups	Mixed textures if well-cooked with small pieces
Desserts	Soft desserts; avoid nuts and hard candies
Beverages	Juices, nectars, milk products if tolerated; hot liquids and water may be attempted in small amounts (1/2 tsp); thicken as needed with a commercial thickening agent
Alcohol/caffeine	Alcohol, caffeine

Table A-34-b-3-a Recommended Foods for Diet Level III

	Lunch	Dinner	
Beans, small (1)	Vegetable soup (1 cup with 4 salt-free crackers no seeds)	Chicken noodle soup (1 cup with 4 salt-free crackers no seeds)	
Cold, unspiced macaroni (1/2 cup)	Hot, unspiced chicken (2 oz) or turkey chopped chicken (1 cup)	Hot, unspiced beef (2 oz) or turkey chopped chicken (1 cup)	
White bread (1 slice)	Rice (1 cup)	Mashed potato (1 cup)	
Butter or margarine (1/2 tsp)	Onion (1 slice)	Onion (1 slice)	
Sage (1/2 tsp)	Coated pasta (1 cup)	Coated green beans (1 cup)	
Coffee/tea	Pudding or custard (1 cup)	Shrimp (1 cup) or yogurt without fruit (1 cup)	
2% milk (1 cup)	Canned peas (1 cup)	Canned peaches (1 cup)	
	Coffee/tea	Coffee/tea	
	Sage (1/2 tsp)	Sage (1/2 tsp)	
	2% milk (1 cup)	2% milk (1 cup)	
Approximate Nutrient Values			
Energy (kcal)	2528.2	Phosphorus (mg)	1801.7
Protein (g)	89.6	Potassium (mg)	3606.5
(27.1% of total)		Sodium (mg)	2711.6

Table A-34-b-3-b Sample Menu for Diet Level III

Food Group	Recommended Foods
Breads and cereals	Soft or lightly toasted breads and crackers; cooked or cold cereals in milk; waffles, pancakes, pasta; avoid crunchy or chewy foods such as hard bagels or English muffins, hard breadsticks, unleavened bread, or Melba toast
Eggs	All eggs
Milk products	Any milk and dairy products if tolerated; cheeses
Fruits	Canned, cooked, or overripe fruits; juices, nectars; peeled fresh fruits in small pieces; soft dried fruits if tolerated
Vegetables	Tender, cooked vegetables
Fats	Any as tolerated
Meats and meat substitutes	Flake, moist meats; meat loaf; meat salads; any other soft foods; small amounts of smooth peanut butter if tolerated
Soups	Any soups
Desserts	Soft desserts and candies; avoid chewy desserts such as hard marshmallow or caramel
Beverages	Full strength liquids
Miscellaneous	Any as tolerated, avoid chips, popcorn, chewing gum

Table A-34-b-4-a Recommended Foods for Diet Level IV

	Lunch	Dinner	
Beans, small (1)	Vegetable soup (1 cup) with 8 salt-free crackers (6 seeds)	Chicken noodle soup (1 cup) with 8 salt-free crackers (6 seeds)	
Cold, scrambled egg (1)	Soft baked chicken (2 oz) or casserole (1/2 cup)	Soft-cooked beef (3 oz) or casserole (1/2 cup)	
White bread (1 slice)	Casserole (1/2 cup)	Macaroni salad (1 cup)	
Butter or margarine (1-2 tsp)	App (1 cup)	Onion (1 cup)	
Sugar (1 tsp)	Starchy (1 cup)	Cooked green beans (1 cup)	
Coffee/tea	Cooked carrots (1 cup)	Shrimp (1 cup) or yogurt without fruit (1 cup)	
2% milk (1/2 cup)	Pudding or custard (1/2 cup)	Canned peaches (1 cup)	
	Canned peas (1 cup)	Coffee/tea	
	Coffee/tea	Sugar (1-2 tsp)	
	Sugar (1-2 tsp)	2% milk (1/2 cup)	
	2% milk (1/2 cup)

Table A-34-b-4-b Sample Menu for Diet Level IV

A-34-b-4. Dysphagia Diet Level IV

Rationale This diet is designed for patients who chew soft textures and swallow all liquids safely. This is based on a soft diet and may be appropriate for persons with mild oral preparatory-stage deficits. The patient may progress from level IV to a soft or general hospital diet.

Description

- Soft textures that do not require grinding or chopping are used
- No nuts; no raw, crisp, or deep-fried foods are allowed
- All liquids and medications are used as tolerated

Nutritional Adequacy Depending on individual selection and amounts consumed, this diet is designed to provide an adequate quantity of nutrients as indicated by the RDA. [Table 34-b-4-a](#) suggests foods recommended for the dysphagia diet level IV. [Table 34-b-4-b](#) presents a sample menu.

A-34-c. Special Considerations

Food Preparation The diet can be adequate in all nutrients if it is chosen and prepared appropriately. The use of blenders and food processors assists in altering solid foods to an acceptable consistency. Blenders require the addition of fluids for processing, resulting in increased volume, which may be a concern for appetite-depressed patients. Food processors, on the other hand, do not require the addition of liquid to alter the consistency of food and, therefore, may be preferred.

Thickened liquids can be used in any stage of the dysphagia diet. [Table A-34-b-1-a](#) provides some clinically appropriate thickening combinations for foods and liquids. The following is a list of some commercially available thickeners:

- THICK-IT by Milani Foods, a division of Diafood, Melrose Park, IL
- NUTRA-THICK by Menu Magic, a division of NALCO, Indianapolis, IN
- THICK'N EASE by American Institutional Products, Lancaster, PA
- THIXX by Bernard Foods, Evanston, IL
- THICKENUP by Delmark, a division of Novartis Nutrition, Minneapolis, MN.
- INSTANT FOOD THICKENER by Diamond Crystal Specialty Foods, Inc., Wilmington, MA

The following are some common food thickeners:

Instant cereal	Unflavored/flavored gelatin
Baby strained bananas or banana flakes	Powdered skim milk
Potato flakes	Cottage cheese
	Cream cheese
Finely chopped crackers	Heavy cream
Flavored plain yogurt	Bread crumbs

Slurry Preparation The term *slurry* refers to thickener dissolved in liquid. Pureed fruits and vegetable salads, cakes, cookies, sandwiches, and other items that are served chilled can be softened, thickened, or made cohesive with gelatin. Gelatin is generally used in a ratio of 1 tsp to 2 cups of liquid.

Any hot item can be softened, thickened, or made cohesive with a commercial thickener. Thickeners are used in varying ratios depending on the density of the original product.

- Gelatin slurry: To soften or stiffen bread, cake, or cookies, 1 tsp of gelatin is dissolved in 2 cups of the liquid to be poured over the food item.

- To stiffen or gel purees: 1 tbsp of gelatin is dissolved in 1 cup of liquid and added to 1 cup of a pureed item for a total volume of 2 cups.
- Commercial thickener slurry: To thicken or gel meat, chicken, and fish purees, 2 tbsp, 3 tbsp, and 4 tbsp, respectively, of commercial thickener are dissolved in 4 oz of liquid. One tablespoon of this preparation is used for every 1 oz of meat, chicken, or fish puree. To soften or gel bread, cake, and cookies, 1 tbsp of thickener is dissolved in 4 oz of liquid.

Mucus Problems Although the association between milk products and mucus production is poorly documented in the literature, it is frequently cited by some health professionals. It may be that the opaque quality of milk makes mucus more apparent and that milk does not actually stimulate mucus production. However, patient tolerance should be assessed on an individual basis. For patients with thick mucus, citrus juices and cranberry juice may be helpful in cutting or thinning the mucus. Papain, either on a swab or in tablet form, can be given before mealtime in severe cases.

Hydration Thin liquids, such as water and similar liquids, are usually the most difficult consistency for dysphagic patients to control, especially in the oral phase of the swallow. Therefore, adequate hydration must be ensured in the patient with dysphagia. Thickening these liquids will assist with increased control and optimize the intake of fluids for hydration. Typically, liquids are thickened to the consistency of honey, using a variety of substances. Thickening agents change the caloric and carbohydrate content of foods, which must be noted particularly in monitoring the intake of patients with diabetes. Patients who are unable to maintain adequate hydration status through diet modification may require hydration by an alternate method.

Nutrition Support Patients undergoing chewing and swallowing rehabilitation while making the transition from tube feedings to oral feedings should be tube-fed at a time that is least likely to interfere with their desire to eat orally, such as overnight. Oral intake should be documented to determine how quickly the tube feeding rate can be decreased. Increasing the nutrient density of mealtime foods can help a patient reach an oral intake goal more rapidly. For some patients it may be necessary to continue a tube feeding to provide adequate nutrition and hydration.

A-35. POSTGASTRECTOMY DIET

A-35-a. Purpose, Use, Modifications and General Guidelines

The postgastrectomy diet is designed to provide adequate calories and nutrients to support tissue healing and prevent weight loss and dumping syndrome after gastric surgery.

A postgastrectomy diet is used for persons who undergo a surgical procedure involving bypass or excision of the pyloric sphincter, resulting in an inability to regulate normal emptying of the stomach. Surgical procedures include vagotomy, pyloroplasty, hemigastrectomy involving Billroth I and II anastomosis, total gastrectomy, esophagogastrectomy, Whipple's procedure, gastroenterostomy, gastrojejunostomy,

Roux-en-Y procedure, and gastric resection.

The diet limits beverages and liquids at meals, limits the intake of simple carbohydrates, and is high in protein and moderate in fat ([Table A-35-b](#)). Small, frequent feedings should be provided daily. If no complications occur, additional foods are added as tolerated.

Food Group	Recommended	Not-Quite Allowed*
Beverages[†]	Milk as tolerated; coffee, tea, unsweetened or diluted fruit drinks, unsweetened carbonated beverages	Alcohol; chocolate milk drinks, milk shakes, sweetened fruit drinks, sweetened carbonated beverages
Breads and cereals	Whole-grain or enriched breads and cereals, English muffins and bagels, unsweetened cooked cereals	Breads made with dried fruits, rich and acidic pastries, doughnuts, muffins
Cereals	Unsweetened dry and cooked cereals	Sugar-coated cereals, cream cereals (e.g., bran)
Deserts	Peanut butter, cookies, sugar-free pudding, gelatin, dessert, custard, yogurt, frozen yogurt	All sweets and deserts made with chocolate or dried fruits, sweetened gelatin, deserts, fruit pastries, ice cream, ice milk, regular frozen or frozen yogurt, fudge
Fats	Butter, margarine, salad dressings, mayonnaise, vegetable oil, sour cream, cream cheese as tolerated	Unsweetened creamed fruits and fruit jams [‡] , fresh fruits
Fruits	Unsweetened creamed fruits and fruit jams [‡] , fresh fruits	All dried fruits, sweetened fruit cubes, fruits opened in liquid syrup
Meats and meat substitutes	Lean tender meats, fish, poultry, shellfish, eggs, peanut butter, cottage cheese, mild cheeses, lightly seasoned and spicy meats	Fruit jams or eggs
Potatoes and substitutes	Lean tender meats, fish, poultry, shellfish, eggs, peanut butter, cottage cheese, mild cheeses, lightly seasoned and spicy meats	Any to which sugar has been added (e.g., candied sweet potatoes)
Pasta and substitutes	Pasta, enriched rice, cereal, noodles, spaghetti, macaroni, and other pastas	Sauces prepared with heavy cream or high-fat ingredients
Sauces	Sauces made with allowed fruits, herbs, soups as tolerated	Sugar, sugar-free, jelly, jam, molasses, marshmallows
Sweets	Sugar substitutes and sweets made with sugar substitutes	Sugar, sugar-free, jelly, jam, molasses, marshmallows
Vegetables	Cooked (fresh, frozen, canned) vegetables or vegetable jams [‡] ; raw vegetables as tolerated	Any to which sugar has been added
Miscellaneous	Substituted, pepper, mildly flavored soups and gravies, strongly flavored seasonings as tolerated	None

[†]This section applies only to those foods on the initial diet.
[‡]For fruit substitutes, consume 30-60 minutes after meals and substitute 1 to 2 tablespoons.

Table A-35-b Guidelines for Food Selection for Postgastrectomy Diet

After surgery, the diet generally progresses as follows:

1. All fluids and foods by mouth are withheld for 3 to 5 days and the patient is fed by nasogastric tube.
2. Next, ice chips are held in mouth or small, infrequent sips of water are given. Some people tolerate warm water better than ice chips or cold water.
3. Then, low-carbohydrate, clear liquids such as broth, bouillon, unsweetened gelatin, or diluted unsweetened fruit juices are given.
4. The postgastrectomy diet then begins, with gradual progression to a general diet as tolerated. Bland foods are usually started first, but a more important priority is offering the patient foods he or she likes and can tolerate. By the 5th to 7th day, most patients can tolerate solid foods.

It is important to note that the stated guidelines must be tailored to each patient's surgery, food tolerances, and nutrition problems and deficiencies.

Dumping Syndrome

- Avoid taking liquids with meals. Liquids should be taken 30 to 60 minutes after meals and limited to 0.5- to 1-cup servings. However, at least 6 cups of fluid should be consumed daily to replace losses resulting from diarrhea. Carbonated beverages and milk are not recommended in the initial stages of the diet.

- Small, frequent feedings should be provided. The number of feedings depends on the patient's tolerance to specific portions of food. Foods should be eaten slowly and chewed well. Avoid foods known to cause individual problems.
- The diet should be low in simple carbohydrates, high in complex carbohydrates and protein, and moderate in fat. For persons near desirable body weight, about 1.5 g to 2 g protein per kilogram should be given and 35 kcal to 45 kcal per kilogram.
- All food and drink should be moderate in temperature. Cold drinks tend to cause increased gastric motility.
- If “dumping” is a problem, it may be helpful to lie down 20 to 30 minutes after meals, or even up to an hour, to retard transit to the small bowel.
- Introduce small amounts of milk to determine tolerance. If milk intolerance is found to be caused by a lactase deficiency, a lactose-restricted diet may be necessary.
- If adequate caloric intake cannot be provided due to steatorrhea, use of medium-chain triglyceride products (e.g., Lipisorb [Mead Johnson Enteral Nutritionals, Evansville, IN 47721, USA], Nutrisource Lipid [Novartis Nutrition, Minneapolis, MN 55440, USA]) may be needed.
- Pectin, a dietary fiber found in fruits and vegetables, may be helpful for treating dumping syndrome. Pectin delays emptying, slows carbohydrate absorption, and reduces the glycemic response, though small dry meals are of more benefit.

Alimentary Hypoglycemia

- Avoid concentrated sweets such as candy, sugar, cola drinks, cookies, cakes, and ice cream unless made with sugar substitutes.
- Have concentrated forms of sugar available *only* for treatment of hypoglycemia.
- Eat small meals six times each day.

Adequacy

The adequacy of the diet depends on the extent of surgery as well as individual food tolerances. With careful selection, this diet is adequate in all nutrients ([Table A-35-c](#)). After gastric surgery, some patients experience malabsorption, which may be specific for macronutrients (e.g., carbohydrates, proteins, and fats) or micronutrients (e.g., folate, vitamin B₁₂, iron, vitamin D, and calcium). Vitamin and mineral supplementation may be necessary depending on the extent of surgery and whether the symptoms of dumping syndrome persist.

Breakfast	Lunch	Dinner	
Grapefruit 1/2 Oatmeal 1/2 cup White whole wheat 1/2 slice Margarine 1/2 tsp 2% milk ^{1/2} 1/2 cup Coffee/tea ^{2/3} 1/2 cup	Lean hamburger patty 1/2 lb Hamburger bun 1/2 Mayonnaise 1/2 tsp Swiss cheese 1/2 oz and lettuce Fresh fruit salad 1/2 cup 2% milk ^{1/2} 1/2 cup Coffee/tea ^{2/3} 1/2 cup	Baked chicken chicken breast 1/2 lb Herbed brown rice 1/2 cup Sweetened corn 1/2 cup Margarine 1/2 tsp Unsweetened applesauce 1/2 cup 2% milk ^{1/2} 1/2 cup Coffee/tea ^{2/3} 1/2 cup	
Wine/beer 1/2 cup	Malt liquor 1/2 cup	Beef/steak 1/2 cup	
Cheese 1/2 oz Salads, crackers 1/2 Berries 1/2	Roast beef 1/2 lb Bread 1/2 slice Mustard 1/2 tsp Vegetables 1/2 cup ³	Peanut butter 1/2 tbsp Cakes, crackers 1/2 2% milk ^{1/2} 1/2 cup	
Approximate Nutrient Analysis			
Energy (kcal)	2188.4	Phosphorus (mg)	1739.3
Protein (g)	171.4	Potassium (mg)	2673.2
20-45% alcohol		Sodium (mg)	1782.4
Carbohydrate (g)	228.7	Zinc (mg)	51.8
60-70% alcohol		Iron (mg)	10.1
Total fat (g)	82.4	Thiamin (mg)	1.8

A.36. GLUTEN-RESTRICTED AND GLIADIN- AND PROLAMIN-FREE (WHEAT-, RYE-, OAT-, AND BARLEY-FREE) DIET

This menu pattern is designed to provide adequate nutrition while eliminating wheat, rye, oats, and barley from the diet. The fraction of gluten protein in wheat that injures the intestine of susceptible persons is gliadin. The equivalent toxic protein fractions in barley, rye, and oats are prolamins. When all sources of gliadin and prolamins are removed from the diet, the intestine is able to regenerate, and normal function is usually restored.

Gliadin and prolamins may be either present in foods as a basic ingredient (i.e., listed as wheat, rye, oats, or barley) or added as a derivative when a food is processed or prepared. Thus, reading labels carefully is very important! A great deal of confusion occurs about the presence of gliadin- and prolamins-containing additives in foods. This table includes lists of both nebulous ingredients and common additives.

Since flour and cereal products are quite often used in the preparation of foods, it is important to be aware of the methods of preparation used, as well as the foods themselves. This is especially true when dining out.

Table A-36-a is a table with multiple columns and rows, likely containing detailed nutritional data or food group classifications. The content is very small and difficult to read, but it appears to be organized in a grid-like structure.

Table A-36-a Food Group with Suggested Daily Intake

Nebulous ingredients ¹	Grain	And
"Hydrated vegetable protein" or "hydrolyzed protein"	Those from soy, corn, or milk	Mixture of wheat, corn, and soy ²
"Flour" or "wheat products"	Flour, corn flour, corn meal, protein flour, soy flour	Wheat, rye, oats, barley, amaranth, quinoa, spelt, soft, millet, durumwheat
"Vegetable protein"	Soy bean	Wheat, soy, barley, lentils
"Vegetable both"	In the United States, this must contain two or more of the following: beans, collards, carrots, celery, garlic, onions, parley, peas, potatoes, green leafy pepper, red leafy pepper, spinach, or tomatoes; it cannot contain any other ingredients, if any (in use)	
"Map" or "map flavoring"	Those derived from corn	Those derived from barley or barley malt and/or rice plus barley malt enzyme
"Starch" or "starch derivative"	None only	
"Modified starch" or "modified food starch"	In the United States, it must be considered: Arrowroot, corn, potato waxy maize, tarrar	Wheat starch
"Vegetable gum"	Cash bean, locust bean, carboxy, gum, gum arabic, gum acacia, gum tragacanth, xanthan gum	Gum arabic
"Dry milk" or "dry milk solids"	Those that do not contain wheat (in any)	Those brewed from wheat and soy
"Milk" and "dairy products"	Those using non-wheat based casein	Those using a wheat based casein

¹These nebulous ingredients may be found with the manufacturer below the amount. A sample size quantity information is not provided and packaging information is available in this table.

²Hydrated vegetable protein is a combination of wheat, corn, and soy. Wheat is used in the United States for hydrated vegetable protein (HVP) when wheat is not used. It is important to note that some HVP products may contain wheat gluten. Some manufacturers of HVP products in the United States may include wheat in their list of ingredients. However, wheat is not used in the United States for hydrated vegetable protein (HVP) when wheat is not used. However, wheat is not used in the United States for hydrated vegetable protein (HVP) when wheat is not used.

Table A-36-b Nebulous Ingredients

Alginic acid	Gums: acacia, arabin, carboxy, cash bean, carboxy, guar, locust bean	Borax
Ascorbic acid	Tagarant, xanthan	Sodium and pyrophosphate
Beta	Invert sugar	Sodium ascorbate
Beta-carotene		Sodium benzoate
Biotin		Sodium benzenothioacetate
Calcium chloride	Calcium	Sodium citrate
Calcium peroxide	Calcium	Sodium hexametaphosphate
Calcium phosphate		Sodium nitrate
Calcium phosphate	Waxes: calcium hydroxide	Sodium silicoaluminate
Calcium hydroxide	Wax acid	Sorbitol-mannitol
Carboxymethylcellulose		Sucrose
Carotenoids	Monoxyethylene cellulose	Sulfonamide
Citric acid	Monoxyethylene cellulose (MSG made in United States)	
Citric acid		Talc
Citric acid		Thiamine hydrochloride
Citric acid		Tri-calcium phosphate
Dextrose		
Dextrose-derivatives	Polyphosphates	Vanillin
Dicalcium phosphate	Polystyrene (PS) resin	Vitamin A palmitate
Dicalcium phosphate	Potassium citrate	Vitamins and minerals
Dicalcium phosphate	Potassium iodide	
Dicalcium phosphate	Propylene glycol monoacetate	
Dicalcium phosphate	Propylene glycol	
Dicalcium phosphate	Pyrrolidone hydrochloride	

¹This is not exhaustive.

Table A-36-c Additives That Are Gliadin- and Prolamin-Free^a

All medications have fillers/binding agents added. These are usually lactose or corn starch. Wheat starch may also be used. Before you take any medication take the following precautions:

Over-the-counter drug: Read the list of active and inactive ingredients carefully. Use the list of "Notable Ingredients" in Table A-36d to spot potential problems. Ask your pharmacist to "translate" the terms you do not know.

Prescription drug: Inactive ingredients are not listed. Even your pharmacist must call the drug company to obtain this information! When the pharmaceutical company is contacted, they will need the lot number of the product so they can check the formulation of the batch you will be taking. A list of drug companies with addresses and phone numbers can be found in the Physicians' Desk Reference.

Liquid acid and 1% medications: These medications often contain alcohol. Check source.

Table A-36-d Medications

Alphabetize Foods P.O. Box 909 Maracle City, CA 94556 916-432-9871	Processed Foods for Good/Better/No Harm/Good. No preservatives, no added sugar, no artificial flavors or colors. Note: The "vegetarian section" in Paleo Foods and Vegetarian Foods often contains wheat flour. Other orders accepted.
Beckford Laboratories 201 S. Main Street Mesa, AZ 84006 214-762-4666	Many fine varieties of alcohol-free beverages. Selection ranges from common beverages, the white and original G series, 100% natural entomotes.
Cellulose Dartmouth College, 601 E. 104th Hanover, NH 03824	Corn protein products, including 100% noodles, macaroni, and spaghetti.
Cherry Spoon P.O. Box 107 Rochester, NY 14603 1-800-441-0000	All sorts of assortment of meats, crackers, cookies, and pasta. Many exclusive imported items. Other orders accepted.
Food & Friends, Inc. P.O. Box 30027 Seattle, WA 98107-0277 1-800-331-0000	Excellent assortment of frozen and flour mixes, including 4-ounce (128) frozen, frozen 12" baked products, dry yeast mixes, "beverages," and other entomotes.
Lundberg Family Farms Box 100 Pacifica, CA 94024 916-462-0001 800-321-1111	Imparting variety of combination meals. Brown rice cereals and rice cakes. Note: Sweet Dreams Brown Rice Syrup is made using natural fruit syrups. Products made with this syrup should be avoided. Some contain unrefined corn oil. Other orders accepted.
360° Nutrition Lane Rye Beach, WI 54981 1-800-441-0000	Carries various brands of breads, crackers, cookies, cake and muffin mixes, and pasta. Note: Their order sheet is not designed for those who must eliminate gluten and proteins. Request their list of "wheat" gluten-free foods that contain no wheat starch! so you'll know what to order!
Real Kidz Farms, Inc. 200 S. Main Street Beckley, WV 26011 716-864-2100	These suitable products that are also lactose free: Dutch Chocolate Cake, Banana/Apple Cake, and Coconut Muffins. All seasonal pastries. Other orders accepted.
Top Entomotes 6032 Pleasant Tampa, FL 33617 800-331-1111	Carry a variety of frozen, fresh, and protein-free baking. Other orders accepted.
Van Driggle's Baking Lambert, MO 63042	Expires some use (sometimes contains small trace) (check for complete product information)

Table A-36-e Special Products List

A-37. LACTOSE-CONTROLLED DIET

A-37-a. Purpose, Modifications and Related Physiology

The lactose-controlled diet is designed to prevent or reduce gastrointestinal symptoms of bloating, flatulence, cramping, nausea, and diarrhea associated with consumption of the disaccharide lactose.

The diet is a general one that restricts or eliminates lactose-containing foods. Lactose is primarily found in dairy products but may be present as an ingredient or component of various food products. (See [Table A-37-b](#) for lactose content of common foods and

beverages.) Depending on individual tolerance, limiting products with lactose may help to alleviate symptoms.

Product	Lactose (g)
Milk (1 cup)	
Whole	11
1% and 2% low-fat	9-13
Skim	12-14
Evaporated	24
Sweetened, condensed	30
Chocolate	10-12
Buttermilk	9-11
Yogurt, low-fat (1 cup)	11-15
Cottage cheese (1 cup)	5-8
Pasteurized processed cheese food (1 oz)	0.5-2
Other cheeses (1 oz)	0.4-0.8
Ice cream (1 cup)	9
Ice milk (1 cup)	10
Sherbet, orange (1 cup)	4
Half and half, light cream, whipped cream topping (1 tbsp)	0.6
Sour cream (1 tbsp)	<1

Table A-37-b Lactose Content of Common Foods and Beverages

Labels should be read carefully to identify sources of lactose. Dairy products that include milk, milk solids, whey, lactose, curds, skim milk powder, skim milk solids, sweet or sour cream, buttermilk, or malted milk are sources of lactose. Other possible sources of lactose are breads, candy, cookies, cold cuts, hot dogs, bologna, commercial sauces and gravies, dessert mixes, cream soups, some ready-to-eat cereals, frostings, chocolate drink mixes, salad dressings, sugar substitutes, and medications.

Dairy products can be consumed depending on individual tolerance. Most persons with lactase nonpersistence can consume milk without the development of symptoms, particularly if small portions of milk (4 fl oz to 6 fl oz) or lactose-containing foods are eaten at separate times during the day. The ingestion of solid food with lactose-containing beverages modifies lactose malabsorption. Food solids delay gastric emptying and/or provide endogenous lactase additional time to digest lactose. Cocoa and chocolate milk have a suppressive effect on human lactose intolerance as evidenced by significantly lowered mean breath hydrogen, bloating, and cramping.

Defining questionable ingredients or product labels and in medications is essential for those following the diet. Manufacturers are usually contacted and prompt when answering questions regarding their products. The usefulness of their reply, however, often depends on how the question is posed. Use the following letter format when you need to contact a manufacturer:

Your Address
Date

Dear Sir/Madam:

I am on a gluten-restricted, grain- and protein-free diet for the treatment of a celiac sprue dermatitis/dermatitis. I must avoid the protein found in wheat, rye, oats, and barley, since they cause an immune response that damages the lining of my intestine.

Although I would like to use your product, I need to know your ingredients listing does not give adequate information for me to determine if it would be suitable. Specifically, I need to know:

- whether your "rye source wheat" are derived from wheat
- what "natural flavorings" you use in the product
- how your source your "vegetable glycerin" is derived
- the inactive ingredients used in the medication, including those used in the coatings and capsules
- Another likely source of gluten and protein contamination is the incidental ingredients which are used in the packaging and processing of your product. Since these incidental ingredients are not listed on the packaging, I am relying on your thoroughness to clarify these substances.

If it would be possible, I would appreciate a copy of your response to be forwarded to: The Gluten Intolerance Group of North America, P.O. Box 20000, Seattle, WA 98102-0200.

This will allow your efforts to be shared with others through our national organization which reaches healthcare personnel as well as patients with celiac sprue and dermatitis/dermatitis. If you have questions regarding these disorders and the required dietary restrictions, please direct them to our national office.

Thank you for your efforts on my behalf.

Sincerely,
Your Signature

Table A-36-f Writing Effective Letters to Food Manufacturers^a

Food Category	Recommended	Not Gluten Diet
Beverages	All beverages with allowed ingredients, soybean milk, other lactose-free supplements, lactose hydrolyzed milk.	Milk, milk products, or soybean milk as beverage choices.
Breads and cereals	Whole-grain or enriched breads and cereals.	Depending on tolerance, some breads and cereals prepared with milk or milk products may need to be avoided.
Deserts	Cakes, cookies, past, frozen grain deserts, water ice, milk with allowed foods.	Any prepared with milk or milk products (e.g., sherbet, ice cream, ice milk, custard, pudding, commercial deserts, and mixes).
Fats	Butter or margarine, salad dressings, rendered tallow, all oils.	Any prepared with lactose-containing ingredients.
Fruits	All fruits and berries.	None.
Meats and meat substitutes	All meats, poultry, fish, eggs, peanut butter, dried peas and beans, lentils, eggs, and processed cheese, if tolerated; yogurt as tolerated.	Cold cuts and frankfurters that contain lactose filler; cottage cheese.
Potatoes and potato substitutes	Potatoes, enriched rice, tortilla, noodles, spaghetti, macaroni, and other pastas.	Potatoes or substitutes prepared with milk or milk products; macaroni prepared with lactose-containing ingredients.
Soups	Both bouillon soups made with allowed ingredients.	Soups made with milk or milk products.
Sweets	Sugar, corn syrup, corn maple syrup, honey, jellies, jams, pure sugar candies, marshmallows.	Chocolate, caramels, any candies made with lactose-containing ingredients.
Vegetables	All.	Vegetables prepared with milk or milk products.
Miscellaneous	All spices, seasonings, flavorings.	Any prepared with milk or milk products.

Table A-37-c Guidelines for Food Selection for Lactose-Controlled Diet

Adequacy

Lactose-reduced dairy products are available and are suitable substitutions for conventional lactose-containing products. Commercial products are available with varying degrees of lactose reduction. A 50% reduction in lactose may be adequate to relieve signs and symptoms of milk intolerance in most healthy adults with lactose malabsorption. Individuals may choose to use conventional dairy products and reduce the lactose levels themselves with commercially available lactase enzyme drops or tablets. It has been suggested that yogurt is as effective as hydrolyzed lactose milk in alleviating symptoms of lactose intolerance. Lactase activity in yogurt may vary across brands. Yogurt that has endogenous cultures added postpasteurization has more lactase activity.

Primary lactase deficiency, a condition in which lactase enzyme activity falls

postweaning, is a common development with aging. It is most commonly seen in African Americans, Hispanics, Native Americans, Asians, and people of Jewish descent. Adult lactase deficiency is the most common of all enzyme deficiencies; well over half the world's adults are lactose intolerant. Secondary lactase deficiency can be attributed to mucosal injury from a condition or disease process such as regional enteritis, ulcerative colitis, Crohn's disease, gluten-induced enteropathy, and parasitic infections or following antibiotic therapy and surgical procedures, including gastrectomy, extensive bowel resection, and gastric bypass.

Lactose tolerance is variable; if an individual is asymptomatic, no restrictions are indicated. If an individual experiences adverse reactions to lactose, following a lactose-controlled diet is advisable. Symptoms associated with lactose intolerance usually subside within 3 to 5 days on a lactose-controlled diet.

Individuals can often identify discomfort associated with digesting lactose; however, true lactase deficiency can be diagnosed clinically with a breath hydrogen test. The breath hydrogen test measures hydrogen produced by colonic bacteria in the presence of unabsorbed sugars.

Depending on individual choices, the diet can provide adequate amounts of all essential nutrients. When dairy products are limited, intake of calcium, phosphorus, vitamins A and D, and riboflavin may be deficient. Use of dairy products within individual tolerance level and/or use of lactose hydrolyzed milk and milk products could satisfy these nutrient needs. Calcium supplementation is indicated if the diet does not provide adequate calcium.

Special Product Information

Lactaid can be purchased in tablets, drops, or as lactase-treated milk and cheese products. Lactaid products are distributed by

McNeil CPC
7050 Camp Hill Road
Fort Washington, PA 19034
Lactaid Hotline: 800/LACTAID, 9 AM–5 PM Eastern time, Monday through Friday

Dairy Ease products including tablets, drops, and lactase-treated milk are produced by Sterling Health
Division of Sterling Winthrop
90 Park Avenue
New York, NY 10016

Check at a grocery and read labels for other lactose-reduced, lactose-free, and lactase-treated products. Other brands may be available.

A-39. VEGETARIAN DIETS

A-39-a. Purpose, Use and Modifications

The vegetarian diet is composed predominantly of plant foods and may or may not include eggs and dairy products. Vegetarian diets should provide a variety of foods that supply adequate amounts of all required nutrients to allow for tissue maintenance, repair, and growth.

Vegetarian diets are used by any person who chooses to omit animal products for religious preferences, health concerns, environmental considerations, humanitarian

issues, ethical concerns, or economic or political reasons.

Although the term *vegetarian* encompasses a variety of eating patterns, it generally involves mainly plant foods. Traditionally, vegetarian diets have been classified by the extent to which animal products are excluded ([Table 39-a-1](#)). However, the term *vegetarian* is often used loosely and may involve a variety of animal food exclusions/inclusions among individuals. Many people who occasionally consume beef, fish, or poultry consider themselves to be vegetarians. Therefore, a careful diet history is required to determine the specific food practices of individual vegetarians.

Classification	Foods Included	Foods Excluded
Lacto-ovovegetarian	Fruits, grains, legumes, nuts, seeds, vegetables, milk and milk products, eggs	Meat, poultry, fish
Lactovegetarian	Fruits, grains, legumes, nuts, seeds, vegetables, milk and milk products	Meat, poultry, fish, eggs
Ovovegetarian	Fruits, grains, legumes, nuts, seeds, vegetables, eggs	Meat, poultry, fish, milk, and milk products
Vegan	Fruits, grains, legumes, nuts, seeds, vegetables	Meat, poultry, fish, eggs, milk, and milk products

^aSee Chapter 100 for a comprehensive review of such diets including issues related to ensuring nutrient adequacy.

Table A-39-a-1 Traditional Classification of Vegetarian Diets^a

(From *The Manual of Clinical Dietetics*, 5th ed. Chicago: the American Dietetic Association, 1996:43–59, with permission. *Note:* For references, see original diet, p. 57–9.)

Food Group	Suggested Daily Servings	Serving Sizes
Breads, cereals, rice, and pasta	6 or more	1 slice bread, 1/2 bun, bagel, or English muffin; 1/2 cup cooked cereal, rice, or pasta; 1 oz dry cereal
Vegetables	4 or more	1/2 cup cooked or 1 cup raw; 1/2 cup vegetable juice
Fruits	3 or more	1 piece fresh fruit, 1/2 cup fruit juice, 1/2 cup canned or cooked fruit
Legumes and other meat substitutes	2–3	1/2 cup cooked beans; 4 oz tofu or tempeh; 6 oz soy milk; 1 1/2 oz soy cheese; 2 tablespoons nuts or seeds; 2 tablespoons peanut butter; 3 oz vegetarian burger patty or 1 vegetarian hot dog
Dairy products (optional)	up to 3 servings	1 cup milk or yogurt; 1 1/2 oz natural cheese; 2 oz processed cheese
Eggs (optional)	limit to 3–4 yolks per week	1 egg or 2 egg whites; 1/2 cup egg substitute
Fats, sweets, and alcohol	Go easy on these foods and beverages	Oil, margarine, and mayonnaise; salad dressings; soft drinks; candies; beer, wine, and distilled spirits

Table A-39-b Daily Food Guide for Vegetarians

Food Group	Choose more often	Choose less often
Beverages	Water, milk, low-fat milk, soy milk	Alcohol, milk, sweetened beverages, alcohol
Breads and cereals	Whole-grain and enriched breads, whole-grain cereals, muffins, bagels, tortillas, enriched or whole grains (e.g., brown rice, cracked wheat, bulgur, oats, buckwheat), enriched or whole-grain pasta	Food made from refined grains, high-fat baked goods (e.g., croissants, pastries)
Meats	Lightly salted and smoked fish (e.g., cod), poultry made from skinless, single breast cuts, game chickens, vegetable-based protein	High-fat, high-sugar desserts, such as candy, pastries, cakes, pies, cookies, white-sauce puddings, ice cream, candies or sweets, confectionery, animal-based protein (e.g., marshmallows)
Fats	Margarine and salad dressings made from polyunsaturated and monounsaturated oils	Animal fat (butter, lard, sour cream, cream, cheese), other saturated fats, animal and palm oils, hydrogenated shortening, grades with A and B labels
Fruit	All except avocados, at least one vitamin C source daily	Avocados
Legumes and other seed substitutes	Low-fat cheeses, eggs, tofu, legumes, meat substitutes made from soy protein, limited amounts of nuts, seeds, and nut and seed butters (e.g., tahini)	High-fat cheeses and eggs, commercial soft-serve ice cream, cream
Snaps	Whole from vegetable stock, low-fat milk, or soy milk	High-sodium canned or dried soups made from meat stock or that contain lard and bacon
Vegetables	Fresh or frozen, include dark-green leafy or deep-yellow ones	Dried/acid or pickled vegetables, high-sodium soups
Miscellaneous	Nuts, low-sodium seasonings	Salt, high-sodium seasonings

*Foods with increased energy needs, such as pregnant and lactating women and athletes, and children, may require some adjustments from those listed in the column "Choose less often" to meet energy needs.

Table A-39-c Guidelines for Vegetarian Diets

Quantity	Lacto	Ovo

A-40. ENTERAL AND PARENTERAL FORMULAS: CATEGORIES AND SOURCES

A-40-a. Commercial Nutrition Formulations for Oral and Tube Feeding

Most companies making commercial formulas provide updated information in reprints that are widely distributed. These reprints often contain the composition of formulas produced by other companies as well as their own. Additionally, new and revised commercial preparations appear on the market in increasing numbers, whereas some older formulas have been removed. These commercial reference guides make continued publication of detailed formulations unnecessary and actually undesirable in this volume. Thus, outdated information can be avoided.

A list is provided below of the companies currently producing and marketing such formulations. Addresses and telephone numbers are included to help the reader obtain the most current information on a specific product. Each company also produces an enteral product reference list that provides nutrient analysis on each product as well as other relevant information needed to make informed choices. They may be contacted for such publications or for other educational materials they provide. In addition, a list is included of the names of current formulations by dietary use characteristics.

A-40-a-1. Company Lists with Identification Code

McGaw, Inc. (Mc)
2525 McGaw Avenue
P.O. Box 19791
Irvine, CA 92713-9791
1-800-854-6851 (Technical Assistance)

Mead Johnson Nutritionals (M)
A Bristol Myers Squibb Company
2400 West Lloyd Expressway
Evansville, IN 47721
1-800-457-3550

Nestle Clinical Nutrition (Nes)
Three Parkway North, Suite 500
P.O. Box 760
Deerfield, IL 60015-0760

1-800-422-2752

Novartis Nutrition (formerly Sandoz) (Nov)
5100 Gamble Drive
St. Louis Park, MN 55416
1-800-999-9978

Nutrition Medical (Nut)
9850 51st Avenue North
Minneapolis, MN 55442-2283
1-800-569-7828
e-mail: info@nutritionmed.com

Ross Laboratories (R)
Division of Abbott Laboratories
625 Cleveland Avenue
Columbus, OH 43215
1-800-544-7495
(614)624-7677

A-40-a-2. Current List of Formulations for Oral and/or Enteral Feeding by Dietary Use Characteristics

Complete diet formulations containing some natural foods with varying residue

Carnation Instant Breakfast (Nes)

Carnation Instant Breakfast, no sugar (Nes)

Compleat Regular (Nov)
