Plasma zinc concentrations are reportedly lower in pregnant patients with PIH/PE (94, 95). The implications of this finding are presently uncertain. Furthermore, since plasma zinc competes with cadmium at biochemical binding sites, and cadmium toxicity is clinically very similar to the maternal manifestations of severe PIH/PE, an interaction between cadmium and plasma zinc has been postulated to play a role in PIH/PE pathogenesis (96). Whole blood lead levels may correlate with hypertension during pregnancy (97). We speculate a relationship between intracellular blood lead and PIH, albeit the precise mechanism of action between blood lead and PIH is not known. Finally, maternal multivitamin supplementation was shown to be associated with a lower incidence of PE, although the study design of the investigation limits any firm conclusions (76, 98).

In sum, pregnancy-induced hypertension/preeclampsia currently remains a mysterious disease with an uncertain etiology. The precise interaction between nutritional factors and PIH/PE is not well delineated. Poor maternal nutritional status appears to have at least some influence on the natural development of PIH/PE. Much more investigation into the interaction of nutritional factors on PIH/PE is certainly in order.

Congenital Malformations

Since 1986, almost one-fourth of all infant mortality in the United States has been associated with birth defects (99). As a percentage of infant deaths, congenital malformations have increased from 8 to 24% between 1916 and the early 1990s (95). In

1993, 1% of all live births and 11% of all fetal deaths in the state of Texas were reported to have a significant congenital malformation. Neural tube, cardiovascular, and pulmonary abnormalities, and chromosomal defects have proved the most lethal during the first year after birth ([100](#)).

We have known since the late 1940s that single maternal nutrient deficits or excesses in the experimental laboratory animal can result in an increased frequency of congenital malformations in their offspring. To date, deficiencies of seven essential minerals, five of eight water-soluble vitamins, and three of four fat-soluble vitamins are reported to cause neural, cardiac, or renal birth defects ([101](#)). In the human, it has taken over 40 years to confirm the role of a nutrient, folic acid, in the primary and secondary prevention of NTDs.

Congenital malformations have their origin, about 20% of the time, in mendelian errors; 10% are chromosomal problems, and 5% are due to environmental factors. The remaining 65% of malformations have multifactorial or “unknown” contributing factors. In normal intrauterine growth and development of the embryo from the time of conception through implantation and early fetal development, almost all the cell cleavages and fusions necessary in formation of the normal fetal architecture and their basic functions are established by the 10th week of gestation. In fact, the most critical period for neural tube closure occurs within the first 28 days of the fetus's gestational life. During this period, the pregnant woman is usually not being followed medically because entry into prenatal care usually occurs about the time of her second missed menstrual period, 45 to 60 days after conception. If we are to do anything about the prevention of congenital malformation, we must actively intervene in the 8 to 10 weeks before conception. In early pregnancy, certain vitamins (e.g., folic acid) (see also [Chapter 26](#), [Chapter 34](#) and [Chapter 95](#)) can prevent some birth defects, and others (e.g., vitamin A) can cause birth defects. Physicians and patients of reproductive age need to make sure that on the one hand, there is an adequate intake of folic acid (400 µg/day) in the preconceptional period, and on the other hand, the total daily intake of vitamin A from all sources (food and supplements) is less than 10,000 IU/day (see [Chapter 17](#)).

The following five examples further illustrate areas in which nutrition intervention before conception can play a major role in preventing life-threatening birth defects.

Diabetes Mellitus

The level of glycosylated hemoglobin (A₁C) in the diabetic patient needs to be maintained within acceptable values by tight dietary control and insulin regulation as needed. Proper management can significantly improve overall reproductive well-being, decrease the rate of spontaneous abortions, and reduce by 50% the otherwise three-to-four times greater frequency of congenital malformations in the offspring of diabetic mothers. Tight control of maternal carbohydrate metabolism throughout pregnancy has reduced perinatal mortality from 16% to less than 4% over the last 20 years.

Phenylketonuria

Over 3000 American women now of reproductive age have a significant abnormality in phenylalanine metabolism. Three hundred affected newborns are delivered annually in the United States. Since about 70% of these mothers have classic PKU, this adds each year about 105 new female offspring to our pool of future PKU mothers.

Serum phenylalanine levels are normally 1.5 to 2.0 times higher on the fetal side of the placenta. With aggressive dietary management as developed by the National Maternal PKU Collaborative Project, elevated serum phenylalanine in the mother can be lowered from more than 20 to less than 2 ng/dL within 5 to 7 days.

If such a patient is returned to the required strict dietary control before she conceives a child, and if her serum phenylalanine level is kept below 605 nmol/L (10 ng/dL) during pregnancy, the risk of congenital and developmental abnormalities in her newborn offspring can be essentially eliminated (102). In contrast, the expectant mother with uncontrolled PKU faces an 80 to 90% chance that her baby will have some type of congenital defect or cranial maldevelopment.

Spina Bifida and Other Neural Tube Defects

Each year in the United States about 3000 infants are born with the NTDs hydrocephalus, spina bifida, and anencephaly. In addition, an estimated 800 to 900 fetuses affected by these birth defects are aborted or result in early fetal deaths. All infants born with anencephaly die shortly after birth, whereas most babies born with hydrocephaly and spina bifida grow into adulthood with, in severe cases, paralysis and varying degrees of neurologic damage including bowel and bladder incontinence.

Evidence has been accumulating for several years that supplementation of folic acid and vitamin B₁₂ before conception can reduce the number of NTDs by 50 to 70%.

Supplementation with 400 µg/day of folic acid alone reduced the recurrence rate by over 70%. Primary NTDs were reduced by 50% (103, 104). In combination with vitamin B₁₂ in a multivitamin/mineral supplement, folate reduced the incidence of NTDs over 90% (105). Both of these vitamins are required by the enzyme methionine synthase, which methylates homocysteine to form methionine. Subsequent biochemical studies have confirmed that depressed methionine synthase activity is associated with NTDs (106, 107, 108, 109 and 110). Whitehead et al. (111), investigating the gene that regulates one of the enzymes that regulate homocysteine concentrations, found that people with NTDs were three times as likely to be homozygous for this abnormal gene as control subjects without NTDs. The parents of children with NTDs also had an excess of this abnormal gene.

In the randomized controlled trials sponsored by the British Medical Research Council, relatively high-dose folic acid supplements (4.0 mg/day) were taken by women who had a prior pregnancy affected by an NTD. This vitamin supplement reduced the risk of a subsequent pregnancy being affected by NTD by 70% (103). The risk of NTD was also

reduced for women without a prior pregnancy affected by NTD who consumed multivitamin/mineral supplements that included 400 to 800 µg of folic acid during pregnancy (112). The U.S. Centers for Disease Control have reviewed this literature (113). On the basis of such evidence, the U.S. Public Health Service recommended in 1992 that all women in the United States who are capable of becoming pregnant should consume 400 µg/day of folic acid to reduce their risk of having a pregnancy affected with spina bifida or another NTD. Because the effects of high folate intakes are not well known but include complicating the diagnosis of vitamin B₁₂ deficiency, care should be taken to keep total folate consumption below 1 mg/day, except under the supervision of a physician.

Because women who have had a prior NTD-affected pregnancy are at high risk of having a subsequent affected pregnancy, when these women are planning to become pregnant they should consult their physicians for advice (114). Women who have had a pregnancy affected by an NTD are advised to consume 400 µg/day of folic acid unless they are planning a pregnancy; in that instance, they are advised to consult their physicians about the desirability of taking up to 4.0 mg/day of folic acid (114). After careful review, the U.S. Food and Drug Administration followed the United Kingdom's lead and announced, in early 1996, that it would require enrichment of all cereal grain products in an amount to provide 10% of the RDA per serving, with a maximum of 1 mg/day intake of folic acid (115).

The form in which folate should be consumed by reproductive-aged women was evaluated in a 3-month, four-pronged trial by Cuskelly et al. (116) from the University of Ulster. All groups were targeted to increase their daily folate intake by 400 µg. Only the two groups that either received folic acid in the form of a pill supplement or consumed folate-fortified foods had a significant increase in their RBC folate concentration. Women ingesting natural folate-rich foods or receiving dietary advice showed no such change. Another Irish research team concluded that an effective national fortification program that provides an additional 400 µg of folic acid could be expected to reduce the overall NTD rate by 48%—a figure very similar to that reported by the multicenter and Hungarian studies (104, 105 and 106) that used a pill to provide the folate supplement (117).

Endemic Cretinism

A deficit in iodine intake by the mother will cause fetal iodine deficiency. When this occurs, one finds excess abortions, fetal deaths, and congenital malformations (55). Endemic cretinism results when maternal iodine intake falls below 25 µg/day (one-third to one-sixth the recommended intake). In the United States, prevention of iodine deficiency through iodination of salt in the Great Lakes region was begun in 1922. Iodination has essentially eliminated the development of goiters and birth of cretins among the U.S. population. Even today, however, 10% of the population in less developed mountainous regions of Africa, Asia, the western Pacific, and South America are severely iodine deficient. Development of enlarged thyroid glands (goiter; see Chapter 13) among females is higher than among males, with bursts of increased size occurring in the female with the onset of menses and during pregnancy.

Maternal Obesity

Beginning in the mid-1960s, Welsh case-control studies ([118](#)) were published that linked maternal obesity with a higher incidence of anencephalic infants. Since then, four additional American reports ([119](#), [120](#), [121](#) and [122](#)) have confirmed a twofold increased risk of NTDs in fetuses/infants of mothers who began their pregnancies with a BMI of 28 or above (PSW ³ 135%). This is independent of the folate status and supplement intake. Trends over the past 25 years reveal an ever-increasing incidence of obesity among postmenarchal young women. This trend must be stopped. We need an all-out crusade to decrease caloric intake and increase physical activity among 12- to 35-year-old American women.

LOW-BIRTH-WEIGHT PREGNANCIES: PREVENTIVE ASPECTS

Low birth weight (less than 2500 g) in the newborn infant is a problem that has resisted solution. The percentage of LBW infants delivered in the United States between 1980 and 1994 has not changed, remaining around 7% of total live births. Twice as many such infants are born to African American mothers as to white or Hispanic mothers.

The rate of intrauterine fetal weight gain follows a straight-line progression between weeks 22 and 38 of pregnancy, with the infant gaining a daily average of about 30 g, or 0.21 kg (almost half a pound) per week ([123](#)). In the obstetric management of a patient in the third trimester with premature labor and intact membranes, every effort is made to quiet the contractions, to stabilize the uterus, and to allow the intrauterine fetal growth to continue as long as the placental transfer system is functioning well. The 30 g/day of fetal weight gain inside the uterus is 50% more than the best that can be accomplished after delivery, even with the newborn infant in an intensive neonatal care nursery. Perinatal survival improves to 50% between weeks 24 and 27 of gestation (700–1000 g in birth weight). By 34 weeks (2000 g), the perinatal survival rate is over 98%. It is critical that we use the best incubator and nutrient delivery system yet designed—called “the uterus and placenta”—until adequate fetal maturation has been achieved for normal extrauterine survival.

As obstetricians and nutritionists, can we intervene and prevent the occurrence of prematurity and LBW infants? We must remember that the target is the delivery of an undamaged infant who weighs more than 2500 g, whose biologic age is more than 37 weeks of gestation, and who will be able to survive in its external environment once the umbilical cord has been severed. Weiss and Jackson ([44](#)) identified over 30 obstetric-related factors that influenced the birth weight of both black and white infants. As further described below, the most important of these factors were (a) maternal age, (b) how much weight the mother gained during her pregnancy and her height/weight status (PSW or BMI) at the time she became pregnant, (c) whether she had ever given birth to an LBW infant before, (d) whether or not she smoked a package or more of cigarettes a day, (e) whether she had entered early into prenatal care and had frequent prenatal visits (up to 10–14 per pregnancy), and (f) avoidance of weight reduction during pregnancy. Independent of the mother's age, marital status or ethnic background, appropriate weight gain, 90 to 110% of PSW at conception, no previous LBW delivery,

nonsmoking status, and early prenatal care and follow-up were all associated with improved mean infant birth weight and a reduced number of neonates weighing less than 2500 g at delivery.

Age and Maternal Weight

The highest incidence of LBW infants occurs in the youngest and oldest mothers—younger than 16 or 18 years of age or over 35 years of age—as a consequence of their biologic immaturity or advanced reproductive years, inadequate nutrient stores and/or dietary intake, and late entry into prenatal care.

Edwards et al. (124) found that when the mother was underweight at conception (less than 90% of standard weight or 20 BMI), the birth weight of the offspring was almost 230 g lower than that of matched controls. Women who were underweight (<90% PSW) at conception had an overall LBW rate twice as high as that of pair-matched controls, and the rate of gestational prematurity was nearly so.

A review of several studies indicates that the intake of energy, rather than protein, is probably the limiting prenatal factor in the reduced birth weight of LBW newborns. Apparently, the placenta can maintain an adequate concentration of the necessary amino acids in the fetal blood, even with low levels of amino acids in the maternal blood. In contrast, the concentration of glucose is always lower in fetal than in maternal blood. This implies that the fetoplacental unit is better able to compensate for a deficiency in maternal protein intake than a deficiency in energy intake. The lower limit of the protein:calorie ratio considered adequate to prevent LBW pregnancies is 11%, based on a requirement for 2200 kcal/day (125). Several longitudinal studies of maternal supplementation with 300 kcal/day during the third trimester found a relatively insignificant gain in fetal birth weight. However, when caloric supplementation was increased to 500 kcal/day, birth weight increased significantly. The total added energy cost of the pregnancy is approximately 55,000 kcal, based on 2115, 2275, and 2356 kcal/day for the three successive trimesters of pregnancy (126); this is only 70% of Hytten's old formula.

Smoking

One-third of single pregnant women and one-fifth of married pregnant women smoke at least a pack of cigarettes a day during pregnancy. Most of them are white, and they are spread evenly throughout the maternal age range. Stopping smoking completely is no easier for a pregnant woman than for one who is not. If usage can be reduced to fewer than five cigarettes per day, the nutritional and fetal consequences are likely to disappear, at least from a statistical point of view. Unpublished, fragmentary reports suggest that use of nicotine patches by the mother does not lead to adverse maternal or fetal outcomes.

Effect on Infant Birth Weight

Smoking one or more packs of cigarettes per day costs the infant's potential weight

about 220 to 250 g (127). In addition, the number of abortions and preterm deliveries and the perinatal mortality rate all increase. This impact of cigarette smoking is dose related. How does cigarette smoking reduce an infant's birth weight at delivery? Smokers have up to a 10% reduction in their oxygen-carrying capacity because of the carboxyhemoglobin formed as a byproduct of smoking. Smoking causes vascular constriction, which decreases blood flow to the placenta and may well interfere with the fetal nutrient delivery system. Smokers require an intake of almost three times as much folate as nonsmokers to maintain the same serum folate concentration (128) and twice as much vitamin C per day to maintain the same serum ascorbate concentration (see Chapter 29 on vitamin C). Passive smokers have plasma ascorbic acid levels in between those of active smokers and uncontaminated individuals. When low vitamin C intake is combined with either active or passive smoking, one should expect reduced body pools of ascorbic acid. Scottish and Danish groups found that plasma vitamin C levels increased significantly after 4 weeks in subjects who successfully quit smoking. The vitamin C change was evident within days of discontinuing cigarettes and persisted for at least 26 weeks (129). Serum levels of carotene, vitamin B₁₂, and zinc also tend to be lower in smokers (130). Consistently low vitamin C intakes and serum levels throughout pregnancy have been associated with a higher frequency of LBW (69). A low dietary intake or low serum folate level during the second and third trimesters of pregnancy was found to be associated with LBW and preterm delivery (112). We should not forget that folate deficiency is the cause of the macrocytic anemia of late pregnancy that occurs throughout the world.

Association with Vitamin C

Recent studies have confirmed an association between low vitamin C and premature rupture of the membrane (PROM), causing premature delivery. Vitamin C is specifically required for synthesis and maintenance of collagen, a major component of the chorioamniotic membrane. Subjects with PROM were found to have weakened amniotic membranes associated with low levels of collagen (hydroxyproline), low amniotic fluid vitamin C levels (128, 129), and low maternal plasma vitamin C levels in the third trimester (131). In addition, a relationship was reported between maternal prenatal vitamin C status and PROM (68, 132), both inversely correlated with maternal smoking (133, 134, 135 and 136).

In a depletion-repletion study of seven male nonsmoking volunteers aged 20 to 26 years, researchers from the National Institutes of Health developed support for an RDA for vitamin C of 200 mg/day based on the result of kinetics, bioavailability, and plasma saturation data (137). This recommendation is three times higher than the 1989 RDA, but the findings require confirmation. How these results are related to the vitamin C requirements during pregnancy and lactation remains to be seen. Forty years ago, the Vanderbilt Maternal Nutrition Study showed that only when the vitamin C intake consistently exceeded 80 mg/day did the plasma level of vitamin C remain at or above 0.8 mg/dL, rather than declining as the mother's plasma volume expanded with advancing gestation (68). Additionally, women who nursed their infants during the first 10 weeks postpartum had lower plasma vitamin C levels, regardless of their vitamin C dietary intake.

Avoidance of Weight Reduction during Pregnancy

A weight-reduction regimen should not be instituted at any time during pregnancy or lactation. A dramatic demonstration of this severe risk to pregnant women and their offspring occurred with the semistarvation imposed by the siege of Rotterdam in 1944 and 1945. A reduction of almost 50% in the intake of calories and protein, especially during the second and third trimesters, interfered with normal intrauterine growth and development of the fetus (138). The result was a 10% (330 g) reduction in the mean birth weights of the newborns (Table 50.13). When the city was freed and maternal refeeding resumed, during the second and/or third trimester, partial fetal weight catch-up was attained.

	Postpartum Maternal Weight (kg)	Birth Weight (g)
Before famine	59.0	3,338
Famine during third trimester	57.6	3,220
Famine during second and third trimester	56.5	3,011
Famine during first and third trimester	61.0	3,370
Famine during first trimester	61.6	3,312
After famine	62.0	3,308

Adapted from Stein Z, Susser M. *Pediatr Res* 1975;9:70-83.

Table 50.13 Changes in Mean Birth Weight in Dutch Women before and after Famine Conditions

The 1990s American equivalent of wartime intrauterine starvation is chronic cocaine abuse. Its impact is most severe on an infant's birth weight—causing as much as a 500-g deficit. In addition, the newborns of cocaine addicts have severely immature mental development. Whether these effects result from drug use alone or whether they are a byproduct of inadequate nutrient intake has not been fully determined.

As shown in Table 50.14, we have developed estimates of the cost to the potential birth weight of the fetus for each of seven nutrition-related maternal insults. Combinations of two or more have an additive (not concurrent) effect, which in total could reduce the potential weight of the developing infant as much as 2 lb. If identified in the months before conception, each of these maternal insults is correctable and the consequences to the fetus preventable.

Maternal Factor	Fetal Effect
<5 years postmenarchal	↓ 100–130 g
<90% standard weight	↓ 230 g
Excessive work and/or exercise	↓ 200 g
50% ↓ in kcal in 2nd and 3rd trimesters	↓ 330 g
50% ↓ in kcal in 3rd trimester	↓ 120 g
>20 cigarettes per day	↓ 250 g
Chronic cocaine addiction	↓ 500 g

Table 50.14 Estimated Impact of Maternal Risks on Birth Weight of Fetus

OTHER NUTRITIONAL AND ENVIRONMENTAL FACTORS

Use of Mineral and Vitamin Supplements

Both calcium and zinc supplements have been reported to improve maternal reproductive outcome. An additional calcium intake of 2000 mg/day decreased systolic and diastolic blood pressure and development of mild pregnancy-induced PE (139). Supplemental zinc, 22 mg/day, has been associated with less abruptio placentae, fewer preterm deliveries, and a lower rate of perinatal mortality (140). Although clinicians and scientists in the United States and United Kingdom may argue about whether it is good public health policy to provide supplemental iron during the course of pregnancy, the need for increased iron intake among women and children in most developing countries cannot be challenged (141). The problem has been how to enrich local foods to benefit all of the population. In Guatemala (142) and Venezuela (143), sugar and cereal fortification programs are showing encouraging results. Under clinical study conditions, medicinal iron supplementation for pregnant women has also succeeded in improving maternal iron status and fetal outcome. However, under routine public health clinic application there has been very limited benefit. Problems are encountered in maintaining a continuous supply of pills at each clinic site, in providing adequate patient counseling, and in patient compliance. These problems are no different from those encountered in North American clinics. Daily ingestion of an iron pill(s) alone or as a prenatal mineral/vitamin tablet remains a problem. Gastrointestinal side effects are reduced with a lower dosage of iron. A recent clinical study from Indonesia demonstrated that among pregnant women—three-quarters of whom had a hemoglobin level below 11.0 g/dL at entry into prenatal care—therapeutic effectiveness of a 60-mg iron supplement daily or a 120-mg supplement once a week for 12 weeks did not differ, although patient compliance improved from 54 to 62% with the lower dose (144).

No evidence exists that daily ingestion of a prenatal mineral/vitamin supplement containing less than twice the RDA is hazardous to either the mother or her fetus/infant during pregnancy and/or lactation in at-risk groups of mothers. There is added

nutritional protection with the ingestion of a daily prenatal mineral/vitamin supplement that contains no more than the RDA for only the essential minerals and vitamins. Such formulas are available “over the counter” at less than 3 cents/day. They are well tolerated, with a very high rate of patient compliance.

Antioxidants

The need for antioxidant vitamins during pregnancy changes with (a) changes in basal metabolic rate during pregnancy, being lower in the first trimester and gradually increasing toward labor and delivery; (b) the level of daily physical activity, which decreases in the last weeks of pregnancy; and (c) the type and degree of exposure of the mother and her intrauterine fetus to toxic substances in the environment, including carbon monoxide, formaldehyde, tobacco smoke, pesticides, polycyclic aromatic hydrocarbons, volatile organic compounds, nitrogen dioxide, phenylcyclohexane, radon, and asbestos (145). Normal metabolism and exposure to environmental pollution result in formation of molecular free radicals (discussed in [Chapter 19](#) and [Chapter 29](#)) whose excess electrons react with and destroy essential cellular components. Vitamins A, E, and C are often classified as antioxidant nutrients that protect biologic lipid phases, such as cell membranes, or as low-density lipoproteins— β -carotene and vitamin E—and the aqueous compartments of the cytosol, plasma, and other body fluids by vitamin C (146).

Caffeine

Most pregnant women (approximately 74%) consume caffeine daily from multiple sources—coffee, tea, soft drinks, and chocolate. Average total daily intake ranges from 100 to 150 mg/day of caffeine. Caffeine, which acts as a central nervous system stimulant (see [Chapter 99](#)), has a greatly lengthened half-life during pregnancy and in oral contraceptive users; however, caffeine ingestion does not appear to affect a woman's fertility or her ability to conceive. Caffeine intake is not metabolized by the fetus or, if consumed during lactation, by the infant. Earlier reports raised concerns about its safe use, citing increased risk of birth defects and intrauterine growth retardation. More-recent studies, however, found that moderate caffeine intake (less than 300 mg/day) does not increase the risks of spontaneous abortion, fetal growth retardation, or birth defects (147). The amounts of caffeine in 12 ounces of a carbonated drink, 6 ounces of tea, and 6 ounces of nondecaffeinated brewed coffee are 37, 36, and 103 mg, respectively (148).

Alcohol

Half of all women have an occasional alcoholic drink during their pregnancy, and even more consume alcohol during lactation. Less than 5% of pregnant women have a drink every day, and another 3% have a drink three times a week. It is estimated that 2 to 3% of all pregnant women are chronic, heavy drinkers. Alcoholism is more prevalent in white women than in either Hispanic or black women, and the incidence is higher among older and more educated women. (The caloric content of various alcoholic beverages is given in Appendix [Table IV-A-19](#)).

Fetal alcohol syndrome is the end result of chronic alcohol abuse during pregnancy, but

not all fetal outcomes are this severe. The consequences to the fetus range across a spectrum from no apparent sequelae, to intrauterine fetal growth retardation, to severely damaged infants. Acute maternal ethanol intoxication in late pregnancy results in suppressed fetal respiration and abnormal electrocorticographic and electrooculographic activity (149). Permanent residual effects of fetus alcohol exposure include (a) mental retardation, (b) a damaged immune system, and (c) abnormalities of the craniofacial and limb bones (150, 151 and 152) (see also Chapter 60).

Alcoholic beverages provide calories that are more difficult for the expectant mother and her fetus to metabolize; moreover, they are devoid of protein, minerals, and vitamins. The pregnant woman who has ingested up to 1500 kcal/day as ethanol from a liter of whiskey or its alcohol equivalent as beer and/or wine cannot meet her other essential nutrient requirements from the remaining third of her calories. As a result, absorption, metabolism, and use of nutrients are impaired, maternal protein synthesis is decreased, placental transfer of amino acids is restricted, and the availability of zinc, vitamin A, folic acid, and thiamin is reduced. Although an occasional glass of wine with food has not been demonstrated to have maternal and/or fetal consequences, clinicians and nutritionists should be on the lookout for, and actively seek out, the chronic alcohol abuser and weekend binge drinker, for whom fetal consequences are most likely.

Drugs

Drug-nutrient interactions are discussed in detail in Chapter 99. Whether drugs enter the body by mouth or by injection, they reach equilibrium between mother, fetus, and infant within about 30 minutes of entry. Most are readily transferred across the placenta and carried in breast milk to the nursing infant. Pregnant women often have four or more prescription medications, several of which have drug-nutrient interactions that reduce the effectiveness of the drug and/or interfere with the availability of the nutrient(s).

Between 10 and 27% of pregnant women acknowledge using marijuana during pregnancy (153). The metabolites of marijuana cross the placenta, and because they are fat soluble, they are excreted extremely slowly. Like tobacco, marijuana tends to reduce the oxygen-carrying capacity of RBC hemoglobin. Marijuana also increases heart rate and blood pressure, resulting in decreased uterine blood flow and placental perfusion. Infant birth weights are lower, and preterm deliveries are increased. Direct drug-nutrient interference has not been confirmed.

No street drug has had as severe an impact on the maternal and fetal outcome of pregnancy as cocaine and crack cocaine. Various reports indicate that about 10% (3–17%) of all pregnant women have used these drugs during pregnancy (154). Use of these drugs is higher among Hispanic and black pregnant women, and in those who live in inner cities. Cocaine readily crosses the placenta, and once on the fetal side, it may be detected in the meconium for up to 8 weeks. Chronic cocaine users have decreased appetite, food intake, and uptake of tryptophan. The fetus and newborn of the cocaine abuser is likely to be growth retarded, and the mother is more susceptible to abruptio placentae and premature labor. These street drugs are not used in isolation, but their use is complicated further by other abuses and high-risk behaviors, of which practices associated with human immunodeficiency virus (HIV) infection are currently the most

serious (see [Chapter 60](#) and [Chapter 97](#)).

Exercise

The maternal and fetal effects of exercise during pregnancy have been comprehensively reviewed ([155](#)). Walking, cycling, climbing stairs, and swimming are excellent types of activity for the normal, healthy pregnant woman when done in moderation by time and cardiovascular response. If you cannot carry on a conversation while doing it, the level of exercise is too much! Severe exercise elicits a temperature response and circulatory redistribution that takes away from the uterus and placenta and directs blood to the lower extremities. The pregnant woman needs to build up her conditioning program gradually and specifically to avoid trauma-prone exercises, high altitudes, dehydration, and serious competition. For women with complicated pregnancies, rest, not exercise, may be the prescription of choice.

Postdelivery or postweaning exercise is essential along with caloric restriction in the woman regaining her prepregnant weight status ([155](#)).

YEAR 2000 GOALS FOR MATERNAL AND CHILD HEALTH

Ten years ago, the United States set goals to significantly improve maternal, infant, and children's health by the year 2000. Six of the goals have direct or indirect nutritional implications:

1. Reduce the rate of LBW births
2. Reduce fetal alcohol syndrome
3. Increase adequate maternal weight gain during pregnancy
4. Increase the number of mothers nursing their infants to 6 months of age
5. Decrease maternal use of tobacco, alcohol, and drugs
6. Increase early entry into prenatal care

For the late 1990s and the 2000s, we believe that the following additional goals, each having nutritional implications, should be added:

7. Prevent and reduce birth defects
8. Prevent and reduce maternal obesity prior to and following pregnancy and lactation

SUMMARY

Based on the previous discussion, our prescription for optimal maternal and fetal reproductive performance as we enter the 21st century includes

- A woman who is 5 years or more postmenarchal and under 35 years of age
- Entry into prenatal care 60 to 90 days prior to conception
- Adequate expansion of maternal blood volume

- Maintenance of hemoglobin concentration at or above 11.0 g/dL throughout gestation
- Ingestion of a safe, adequate diet that provides the necessary energy and nutrients to meet all requirements of the mother, fetus, and infant during pregnancy/gestation and lactation/nursing
- Maternal weight gain between 7.5 and 18 kg, depending on maternal age, BMI, and the number of fetuses
- Use of prenatal mineral-vitamin supplements that contain no more than the RDA for pregnant women for essential ingredients, with particular attention to the contents of iron, folate, calcium, zinc, and vitamin A
- Prevention of all nutrient-dependent causes of congenital malformations, which requires prevention of excessive weight gain; maintenance of immunizations; entry into pregnancy with diabetes and phenylketonuria in tight control; and an adequate intake of iodine, folate, and vitamin B₁₂ throughout pregnancy
- Reduction, or even better elimination, of the nonnutritional hazards of excess—smoking, alcohol, and drugs

ACKNOWLEDGMENTS

For editorial and graphic assistance, we thank Mac McConnell and his Ob/Gyn Publications staff, Kristi Barrett, John Helms, and Steve Schuenke. The authors wish to gratefully acknowledge the technical assistance of Moni DeVora.

Abbreviations: **BMI**—body mass index; **CBC**—complete blood count; **LBW**—low birth weight; **MCHC**—mean corpuscular hemoglobin concentration; **MCV**—mean corpuscular volume; **NTD**—neural tube defect(s); **PE**—preeclampsia; **PIH**—pregnancy-induced hypertension; **PROM**—premature rupture of the membrane; **PSW**—percentage of standard weight; **RBC**—red blood cell(s); **RDA**—recommended dietary allowance; **WHO**—World Health Organization; **WIC**—Supplemental Feeding Program for Women, Infants, and Children.

[Chapter References](#)

The nutritional requirements of infants and children reflect this population's unique needs for growth and developmental changes in organ function and body composition as well as their maintenance needs. Moreover, since the metabolic rate of infants and children is greater and the turnover of nutrients more rapid than in the adult, the unique nutritional needs for growth and development are superimposed upon higher maintenance requirements than those of the adult. In addition, the potential impact of intake during early life on later development and health must be considered. Finally, provision of these greater needs, particularly to the smaller members of this population, is hindered by their lack of teeth as well as their limited digestive and metabolic processes.

This chapter discusses the nutritional needs of normal infants as well as those of low-birth-weight (LBW) infants. Since nutritional management of LBW infants presents some of the most pressing problems encountered by those involved in feeding infants and children, nutritional needs of this subpopulation are discussed more fully. Nutritional needs of infants and children with acute or chronic diseases that affect nutritional needs and/or management are discussed in [Chapter 64](#), which also includes a general discussion of approaches to providing the nutritional needs of compromised infants and

a detailed discussion of parenteral nutrition in pediatric patients.

NUTRITIONAL REQUIREMENTS OF THE NORMAL INFANT

The nutritional requirements of the normal infant have been addressed by many investigators over a number of years, and both estimated requirements and recommended dietary allowances for most nutrients have been established.

Requirements and *recommended allowances* must be distinguished. The former is the amount of a specific nutrient required to achieve some physiologic endpoint, most frequently the amount necessary to maintain a satisfactory rate of growth and development and/or prevent development of specific signs of deficiency. The requirement of a specific nutrient is usually defined experimentally, in a small, homogeneous study population. *Recommended allowance* is the intake of an essential nutrient deemed by a scientifically knowledgeable group of individuals to be adequate to meet the "requirement" of all healthy members of a population. In general, if the requirement of a specific population is normally distributed, the recommended allowance is set at the mean requirement of the population plus two standard deviations. Since the requirements of most nutrients are not normally distributed, other considerations of population variability frequently are necessary.

The most recent recommended dietary allowances (RDAs) of the National Research Council Food and Nutrition Board (1) are summarized in [Table 51.1](#). See also Appendices [Table A 2a-1](#), [Table A 2a-2](#) and [Table A 2a-3](#) for these data from the 1989 RDA. The 1997 U.S. dietary reference intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride are presented in Appendices [Table A-2b 1](#), [Table A-2b 2](#), [Table A-2b 3](#), [Table A-2b 4](#), [Table A-2b 5](#) and [Table A-2b 6](#). The requirements and recommended intakes of some nutrients are discussed briefly below.

Nutrient	Phenylketonuria (PKU) - 10 mg Phe/100 kcal	
	0-6 Months	7-12 Months
Energy (kcal)	450	550
Protein (g)	1.2	1.4
Carbohydrate (g)	120	120
Fat (g)	30	40
Cholesterol (mg)	100	100
Vitamin A (IU)	1000	1000
Vitamin B1 (mg)	0.2	0.2
Vitamin B2 (mg)	0.2	0.2
Vitamin B6 (mg)	0.1	0.1
Vitamin C (mg)	20	20
Vitamin D (IU)	10	10
Vitamin E (IU)	1	1
Vitamin K (IU)	1	1
Calcium (mg)	100	100
Phosphorus (mg)	100	100
Magnesium (mg)	10	10
Zinc (mg)	1	1

Table 51.1 Recommended Daily Allowances of Nutrients for Normal Infants

Energy

Per unit of body weight, the energy requirement of the normal newborn infant is 3 to 4 times that of the adult: 90 to 120 kcal/kg/day versus 30 to 40 kcal/kg/day. This greater need reflects primarily the infant's relatively high resting metabolic rate and special needs for growth and development, but the somewhat inefficient intestinal absorption of infants, compared with that of adults, may contribute.

For some time there has been concern that the RDA for energy was excessive. This issue was reviewed recently by the International Dietary Energy Consultative Group (IDECG), which concluded that energy requirements of infants should be estimated from measurements of energy expenditure and growth rather than from dietary intake data (2). Using available data, the group's estimated energy requirement was about 90 kcal/kg/day during the entire 1st year of life (ranging from 84 kcal/kg/day between 4 and 6 months of age to 94 kcal/kg/day between 2 and 3 months of age for breast-fed and formula-fed infants combined). However, more data on energy expenditure and body composition of infants was considered desirable.

Unlike the RDA for other nutrients, that for energy is the same as the estimated requirement. In other words, the RDA does not include an upward adjustment to account for individual variation. This is because the higher recommendation would likely result in excessive intakes for at least some individuals and, hence, further increase the prevalence of obesity. Individual energy requirements can, of course, vary considerably.

With respect to the source of energy, there is no evidence that either carbohydrate or fat is superior, provided total energy intake is adequate. Sufficient carbohydrate to avoid development of ketosis and/or hypoglycemia is required (<5.0 g/kg/day) as is enough fat to avoid development of essential fatty acid deficiency (0.5–1.0 g/kg/day of linoleic acid plus a smaller amount of α -linolenic acid). There is concern that infants may also require at least some of the longer-chain, more unsaturated derivatives of linoleic and α -linolenic acids (e.g., arachidonic and docosahexaenoic acids). These are present in breast milk but not in currently available formulas. Furthermore, formula-fed infants have less of these fatty acids in plasma and erythrocyte lipids than breast-fed infants (3, 4), and the brain content of docosahexaenoic, but not arachidonic, acid also is lower in formula-fed infants (5, 6). However, results of functional outcome studies comparing functional outcomes of breast-fed and formula-fed infants (7, 8) as well as infants fed formulas with and without arachidonic and docosahexaenoic acid (8, 9) are inconclusive. Overall, these studies provide no convincing evidence that the absence of these fatty acids in formulas is problematic, provided linoleic and α -linolenic acid intakes are adequate (10).

In concert with the recommendation that the dietary fat intake of the general population be reduced, particularly that of cholesterol and saturated fat, some agencies have suggested that this guideline be applied to infants. However, since fat is a major source of energy as well as a source of essential fatty acids, there is concern that such diets might limit growth. Thus, groups responsible for making recommendations for infants

have not endorsed this recommendation for infants under 2 years of age (11).

Until recently, there were few data concerning this issue, but a recent Finnish study suggests that the fear of growth failure with such diets may be overrated (12). This study involved over a thousand infants; the caregivers for half of them were counseled to limit saturated fat and cholesterol intake, the others were not. There was no difference in growth between groups. Interestingly, although energy and fat intake of the intervention group was somewhat lower than that of the control group, the mean fat intake of both groups was lower than expected (~30% of total energy). The intervention group also had a lower serum cholesterol concentration at 3 years of age or upon termination of the study.

Protein

The protein requirement of the normal infant per unit body weight is also greater than that of the adult but not as great as the requirement of the LBW infant. The infant also requires a higher proportion of essential amino acids than the adult (Table 51.2). The minimal intakes of essential amino acids consistent with normal growth were determined some time ago under conditions of maximal nitrogen sparing (13). Thus, if the required intakes of the essential amino acids are met, the total intake of nitrogen probably is more important than the particular mixture of amino acids provided. Indeed, the overall protein requirement is some two to three times the aggregate requirement for essential amino acids. Obviously, the required intake of a specific protein is a function of its quality, which usually is defined as how closely its amino acid pattern resembles that of human milk. It also follows that the overall quality of a specific protein can be improved by supplementing it with any missing essential amino acid(s). For example, soy protein in the native state has insufficient methionine but, when fortified with methionine, approaches or equals the overall quality of bovine milk protein (14).

Amino Acid	Minimum Requirement (mg/kg/day)
Leucine	76-229
Isoleucine	102-119
Lysine	88-103
Methionine (with cysteine)	33-45
Phenylalanine (with tyrosine)	47-90
Threonine	45-87
Tryptophan	15-22
Valine	85-105
Histidine	16-34

Table 51.2 Essential Amino Acid Requirements of the Term Infant

While the amino acid composition of human milk is ideal, its overall protein content,

approximately 1.0 g/dL, is such that ingestion of 180 to 200 mL/kg/day is required to ensure a protein intake equal to the current RDA (2.0–2.2 g/kg/day). This fact has led some to question the adequacy of the protein content of human milk and others to question the validity of the recommended intake. On balance, the high quality and easy digestibility of human milk protein appear to compensate for any quantitative deficiency. On the other hand, bovine milk protein, the protein source of most infant formulas, also is a very high quality protein and, if properly processed, is used nearly as well as human milk protein. Thus, the actual requirement for protein when bovine milk is the source may be very little higher, if at all, than when human milk is the source (15).

The IDECG also recently evaluated the protein and amino acid requirements of infants (16). Basing requirements on the needs for maintenance plus growth and assuming that the efficiency of nitrogen use for infant growth is 70%, the group concluded that the protein requirement during infancy ranges from about 2.0 g/kg/day during the 1st month of life to about 0.8 g/kg/day from 9 to 12 months of age. Estimates for the safe level of protein intake (equivalent to recommended daily allowance) ranged from 2.7 g/kg/day during the 1st month of life to approximately 1.0 g/kg/day from 9 to 12 months of age. The lower estimate is approximately one-third less than previous estimates. As with the revised estimates of energy requirements, the group pointed out that more research is needed.

Electrolytes, Minerals, and Vitamins

The electrolyte, mineral, and vitamin requirements of the normal infant are not as well defined as those for energy and protein. Nonetheless, RDAs for most have been established (Table 51.1), and infants who receive these intakes experience few problems. Recently, the concept that limitation of sodium intake may decrease the incidence of hypertension later in life has received some attention, but there are few data on which to base a definitive conclusion (17).

Iron deficiency is the most common nutrient deficiency syndrome in infancy. This is somewhat surprising since the normal infant has sufficient stores of iron at birth to meet requirements for 4 to 6 months. However, these stores as well as the absorption of iron are quite variable. Although human milk contains less iron than most formulas, iron deficiency is less common in breast-fed infants. To prevent development of iron deficiency, routine use of ironfortified formulas is recommended (18). Whether breast-fed infants should receive iron supplements is controversial.

If protein intake is adequate, vitamin deficiencies are rare; if not, deficiencies of nicotinic acid and choline, which are synthesized, respectively, from tryptophan and methionine, may develop. In contrast, if bovine milk and bovine milk formulas were not supplemented with vitamin D, hypovitaminosis D would be endemic among formula-fed infants, particularly those with limited exposure to sunlight. The breast-fed infant may be relatively better protected from development of vitamin D deficiency (19), but vitamin D supplementation of breast-fed infants is also recommended. Routine perinatal administration of vitamin K is recommended for all infants as prophylaxis against hemorrhagic disease of the newborn. All currently available formulas contain adequate

amounts of all vitamins for which a requirement has been established.

Water

The normal infant's absolute requirement for water probably is 75 to 100 mL/kg/day. However, because of higher obligate renal, pulmonary, and dermal water losses as well as a higher overall metabolic rate, the infant is more susceptible to developing dehydration, particularly with vomiting and/or diarrhea. Thus, provision of 150 mL/kg/day is recommended. Both breast-fed and formula-fed infants usually consume at least this volume for the first several weeks of life.

Human Milk versus Artificial Formula

The ready availability and safety of human milk coupled with the possibility that it may enhance intestinal development, resistance to infection, and bonding between mother and infant have led most to conclude that human milk is the perfect food for the normal infant (20). However, there are both theoretical and practical concerns about breast-feeding that deserve consideration.

The major nutritional concern is not that human milk contains too little protein (see above) but that its low content of calcium and phosphorus may not support optimal skeletal development. In this regard, breast-fed infants have a less well mineralized skeleton throughout the early months of life than formula-fed infants. However, since no major differences in bone density appear in older formerly breast-fed and formerly formula-fed infants, the lower calcium and phosphorus intakes of breast-fed infants do not seem to be detrimental.

Hyperbilirubinemia is more common in breast-fed than in formula-fed infants. This usually is a transient phenomenon limited to the first few days to weeks of life; thus, most feel that proscription of breast-feeding is not necessary unless hyperbilirubinemia persists or plasma bilirubin concentration is excessively high. Even in these situations, substituting formula at every other feeding and/or substituting formula for only 1 to 2 days usually resolves the problem.

Certain noxious or infectious agents (e.g., chemicals, drugs, foreign proteins, viruses) may be present in breast milk. However, the risk of infection secondary to mode of feeding is far greater in formula-fed than breast-fed infants, particularly if the artificial formula is prepared under less than optimal hygienic conditions.

As publicized recently in the lay press (21), it cannot automatically be assumed that maternal milk supply will be adequate and/or constant. Thus, breast-fed infants, particularly firstborn infants, must be followed closely over the first few days to weeks of life to ensure that growth and development are proceeding normally. With proper counseling, most problems can be corrected and/or avoided.

In large part, the problems historically associated with artificial feeding have been solved. The safety and easy digestibility of modern infant formulas, in fact, approach the

safety and digestibility of breast milk. Furthermore, the clear economic advantages and microbiologic safety of breast-feeding are less important for affluent, developed societies with ready access to a clean water supply than for less-developed, less-affluent societies. Thus, a reasonable and conservative approach is to allow the mother to make an informed choice of how she wishes to feed her infant and support her in that decision. As Fomon (22) stated, "In industrialized countries, any woman with the least inclination toward breast feeding should be encouraged to do so, and all assistance possible should be provided by nurses, physicians, nutritionists and other health workers. At the same time, there is little justification for attempts to coerce women to breast feed. No woman in an industrialized country should be made to feel guilty because she elects not to breast feed her infant."

Evidence suggesting that breast-fed infants in affluent societies have fewer common and serious infections during early life than formula-fed infants is increasing. If this difference is shown to be due to breast-feeding rather than to a myriad of other possible factors (e.g., mother's competence, education, and/or socioeconomic status), the current emphasis on promoting breast-feeding is clearly warranted.

A number of formulas are available for feeding the normal infant. Compositions of those most commonly used are shown in Table 51.3. Most are available in both a "ready-to-use" and a concentrated liquid form. Powdered products, which are somewhat lower in cost, are being used with increasing frequency. These products usually are the only ones available in many parts of the world.

Component	Infant	Infant	Adult

Table 51.3 Composition (amount/100 kcal) of Standard Formulas for Normal Infants

The most commonly used formulas contain either unmodified or modified bovine milk protein. The protein concentration of all is about 1.5 g/dL. Thus, the infant who receives from 150 to 180 mL/kg/day receives a protein intake of 2.25 to 2.7 g/kg/day. This is as much as 50% above the intake of the breast-fed infant and as much as 25% above the current RDA for protein.

Unmodified bovine milk protein has a whey:casein ratio of 18:82, whereas modified bovine milk protein has a whey:casein ratio of 60:40. Products containing the latter protein are prepared from either a mixture of bovine milk protein and bovine milk whey proteins or a mixture of bovine milk whey proteins and caseins. Modified and unmodified bovine milk protein appear to be equally efficacious for the normal term infant. Formulas containing soy protein and formulas containing partially hydrolyzed bovine milk proteins are available for feeding infants who are intolerant of bovine milk or soy protein (Table 51.4).

Table 51.4 Composition of Soy and Hydrolyzed Protein Formulas

Although lactose-free bovine milk formulas have recently been introduced, the major carbohydrate of the most commonly used bovine milk formulas is lactose. The most commonly used soy protein formulas contain either sucrose or a glucose polymer; thus, these formulas or lactose-free bovine milk protein formulas are useful for the infant with either transient or congenital lactase deficiency.

The fat content of both bovine milk and soy protein formulas usually comprises about 50% of the nonprotein energy. In general, the blend of vegetable oils present in most formulas is quite easily absorbed; most studies suggest that intestinal absorption is at least 90%.

The electrolyte, mineral, and vitamin contents of most formulas are similar, and when fed in adequate amounts (150–180 mL/kg/day), all provide the RDAs for these nutrients. Both iron-supplemented (~12 mg/L) and nonsupplemented (~1 mg/L) formulas are available; as mentioned above, iron-supplemented formulas are recommended.

The goal of both breast-feeding and formula feeding is to deliver enough nutrients to support adequate growth. As a rule of thumb, the normal term infant's weight should double by 4 to 5 months of age and triple by 12 months of age. Demand feeding is considered preferable, particularly during the early weeks of life. However, most infants

easily adjust to roughly an every 3 or 4 hour schedule and, after 2 months of age, rarely demand night feedings.

NUTRITIONAL REQUIREMENTS OF THE 6- TO 12-MONTH-OLD CHILD

Considerably less attention has been paid to the nutritional needs of the 6- to 12-month-old child than to those of the younger infant. In fact, the RDAs for the various nutrients for this age group ([Table 51.1](#)) rely heavily upon extrapolations from data obtained in younger infants, taking into account the developmental differences between the younger and the older infants as well as the greater activity and somewhat slower rate of growth of the 6- to 12-month-old child. Despite the lack of specific data, few participants in a symposium on the nutritional needs of the 6- to 12-month-old child held in 1989 felt that the most recent RDAs for this age group required extensive revision ([23](#)).

One exception concerns energy, the recommended intake of which is somewhat higher than the current energy intake of apparently normal infants ([24](#)). Infants receiving the lower intake exhibit lower rates of weight gain as well as lower rates of increase in skinfold thicknesses than the National Center for Health Statistics (NCHS) standard rates (see Appendices [Table III a14](#) and [Table III 14b](#)), but the rates of increase in length and head circumference are not compromised. Thus, proponents of a lower energy intake (i.e., 85 vs. 95 kcal/kg/day) argue that the growth response of infants ingesting the lower energy intake reflects the current concepts of parents regarding appropriate body size and proportions and that these responses are appropriate for current feeding practices (e.g., delayed introduction of solid foods). As noted above, more data are needed concerning this issue, but currently there is no evidence that the lower energy intake apparently characteristic of many modern infants is harmful.

By 6 months of age, the infant's previously compromised capacity to digest and absorb a variety of dietary components as well as to metabolize, use, and excrete the absorbed products of digestion approaches the adult capacity ([25](#)). Moreover, these infants are more active and are beginning to explore their surroundings. Hence, during this interval, diet plays a variety of roles other than delivery of required nutrients. A variety of concerns also emerge during this period. For example, with the eruption of teeth, the role of diet in development of dental caries must be considered ([26](#)). Consideration of the long-term effects of inadequate or excessive intakes during infancy also assumes greater importance as does consideration of the psychosocial role of foods during development.

These considerations are the basis for most of the recommendations for feeding during the second 6 months of life. While all nutrient needs during this period can clearly be met with reasonable amounts of currently available infant formulas, although perhaps not with exclusive breast-feeding, addition of weaning foods to the diet of infants over 4 to 6 months of age usually is recommended.

Weaning, or "follow-up," formulas that have a somewhat higher protein content than regular infant formulas are popular in Europe but not in the United States. This situation may change with the recent introduction of a second such formula. The first follow-up

formula to become available in the United States (Carnation Follow-Up Formula, Carnation Nutritional Products, Glendale, CA) contains 3 g of bovine milk protein per 100 kcal; fat content is 3.9 g/100 kcal (a mixture of corn, palm, and high-oleic safflower oils), and carbohydrate content is 13.2 g/100 kcal (a mixture of lactose and corn syrup solids). The more recently introduced follow-up formula (Similac Toddler's Best, Ross Laboratories, Columbus, OH) contains 3.5 g of bovine milk protein per 100 kcal; fat and carbohydrate contents, respectively, are 4.7 g/100 kcal (a mixture of coconut, soy, and high-oleic safflower oils) and 11 g/100 kcal (a mixture of sucrose and lactose). As the name implies, the latter formula is intended for the slightly older infant.

Aside from the association of bottle feeding with dental caries, little is known about the various issues related to the nonnutritional role of diet during the second half of the 1st year of life. Thus, feeding practices vary widely during this period. Nonetheless, most recent surveys indicate that infants fed according to current practices receive the RDAs for most nutrients (27).

One current feeding practice, the increasing use of bovine milk, particularly low-fat bovine milk, deserves comment. Although current recommendations are to limit the intake of bovine milk and to avoid low-fat or skimmed milk before 1 year of age (28), recent surveys suggest that a sizable percentage of 6- to 12-month-old infants, albeit still fewer than 25 to 30 years ago, are fed bovine milk rather than infant formula (29, 30). More important, almost half of these infants are fed low-fat or skimmed milk. The consequences of this practice are not known with certainty. However, infants fed bovine milk ingest, on average, roughly three times the recommended daily allowance for protein and 1.5 times the upper limit of the "safe range" of sodium intake but only two-thirds of the recommended daily intake of iron and only half of the recommended intake of linoleic acid. The protein and sodium intakes of infants fed skimmed rather than whole bovine milk are even higher, iron intake is equally low, and, most important, intake of linoleic acid is less than half of that recommended. Interestingly, while the most common reason for substituting low-fat or skimmed milk for whole milk or formula is to reduce fat and energy intakes, the energy intake of infants fed skimmed milk is not lower than that of infants fed whole milk or formula (30). Rather, they appear to compensate for the lower energy density of low-fat or skimmed milk by increasing intake of other foods.

Current knowledge is insufficient to support definitive statements concerning the consequences of the high protein and sodium intakes associated with feeding either whole or skimmed milk. The low iron intake clearly is not desirable but probably can be overcome by use of medicinal iron supplementation. The low intake of linoleic acid is more problematic. While signs and/or symptoms of essential fatty acid deficiency appear to be uncommon in infants fed either whole or skimmed milk, no exhaustive search for such symptoms has been made. Moreover, since essential fatty acid deficiency develops in both younger and older infants fed formulas providing roughly the same linoleic acid intake, it would be very surprising if such a search did not uncover a reasonably high incidence of biochemical essential fatty acid deficiency. On the other hand, older infants who were breast-fed or fed formulas with a high linoleic acid content prior to 6 months of age could conceivably have accumulated sufficient body stores of this fatty acid to limit the consequences of a low intake between 6 and 12 months of age. However, simply assuming that this is true could have undesired consequences;

although biochemical essential fatty acid deficiency may not result in clinically detectable symptoms, animal studies suggest that it may result in long-term deleterious effects on development (31).

Addressing the concerns raised by the practice of feeding bovine milk is important for practical as well as health reasons. For example, the cost of bovine milk is roughly one-third that of infant formula, a large enough difference to have important economic consequences for most families. In addition, if food supply programs for infants provided bovine milk rather than formula to infants over 6 months of age, the program's current funds would permit expanding benefits to many more of the country's most needy infants. While clearly desirable, this obviously cannot be done until the safety of feeding bovine milk during the second 6 months of life is substantiated.

The questions raised by the increasingly common practice of substituting skimmed or low-fat milk for whole milk or formula are even more complex. The suggestion that infants fed skimmed milk increase their intake of other foods raises the important question of whether food intake during infancy may in some way imprint intake patterns throughout life. If so, this apparent attempt to improve longevity or at least cardiovascular health, paradoxically, may be more detrimental to both than a less prudent diet during infancy.

NUTRITIONAL REQUIREMENTS OF THE 1- TO 10-YEAR-OLD CHILD

The 1-year-old child has several teeth, and the various digestive and metabolic systems are functioning at or near adult capacity. Thus, the earlier restrictions with respect to source of nutrients no longer apply. Indeed, by 1 year of age, most children tolerate table foods, either as presented to other family members or with minimal alterations. Although coordination remains poor until 3 to 4 years of age, most children begin at least attempting to feed themselves during the early part of their 2nd year of life. Until coordination improves, however, these attempts usually result in as much food on the table or floor as in the child's stomach.

Most children are walking or beginning to walk by 1 year of age. Hence, with improved coordination over the next few years, activity increases dramatically. This greater activity, in turn, increases energy needs. Concurrently, the rate of growth decreases; for example, while the birth weight triples over the 1st year of life, it does not quadruple until about 3 years of age (Table 51.5). Thus, although the energy requirement incident to activity increases dramatically after the 1st year of life, the requirement for nutrients stored during growth decreases. These changing nutrient needs are reflected in the RDAs for various nutrients for children from 1 to 3, 4 to 6, and 7 to 10 years of age (Table 51.6).

Age (year)	Height (cm)			Length (cm)		
	5th Percentile	50th Percentile	95th Percentile	5th Percentile	50th Percentile	95th Percentile

Table 51.6 Recommended Daily Allowances (RDA) of Nutrients for Normal Infants^a

As demonstrated by Davis (32) almost 75 years ago and more recently by Birch et al. (33), most young children given access to a varied diet including items from each of the major food groups consume adequate amounts of all nutrients. However, most children, particularly those under 5 to 6 years of age, are very finicky eaters. Moreover, many tend to use eating (or not eating) to exert control over parents and/or caretakers. Thus, the intake of most children at a single meal, or even over an entire day, is not necessarily well balanced. Rather, a balanced intake is achieved over a period of several days.

The erratic eating pattern of most young children is usually of considerable concern to parents, particularly those who have not witnessed this behavior before. Unfortunately, their efforts to control the child's intake usually make matters worse. They should be reassured and instructed to present the child with well-balanced meals and snacks throughout the day, to remove the food after a reasonable period of time, and to avoid

coaxing and cajoling, particularly offering preferred foods or treats as rewards.

The importance of providing items from most or all of the major food groups cannot be overemphasized. Obviously, if the child does not have access to items from all food groups on a regular basis, self-selection of a balanced diet, either in the same day or over several days, is impossible. It also is important to limit intake between regular meals and snacks. Otherwise, the child is unlikely to be hungry when the regularly scheduled meal or snack is offered. Alternatively, if the appetite is not dampened, intake between regular meals and snacks will increase total energy intake disproportionately and contribute to development of obesity. A major distinction between meals and snacks also should be avoided so that the child has access to an adequate amount and variety of food when he or she is hungry or willing to eat rather than only at conventional meal times.

As the child matures and begins to socialize more, it becomes increasingly difficult to control the content of snacks or meals. Many modern children, in fact, eat away from home as much or more than they eat at home—a practice that many think contributes to development of obesity. Perhaps the best that can be done, short of changing modern lifestyles, is to counsel parents concerning the potential problem and advise them to devise ways of assessing their children's intakes away from home. Regular monitoring of weight and height should alert the clinician to existence of a potential problem.

Perhaps the major controversy concerning the nutrient needs of the 1- to 10-year-old child concerns the extent to which the currently advocated dietary guidelines are appropriate for this population. Although the American Heart Association (34), the American Health Foundation (35), and the National Institutes of Health Consensus Development Panel (36) recommend that the current guidelines be applied to children over the age of 1 to 2 years, the Committee on Nutrition of the American Academy of Pediatrics (37) expresses a number of concerns. Chief among these concerns is the safety of a diet emphasizing lower intakes of fat, cholesterol, and salt along with higher intakes of bulky cereal grains and plant products. Such a diet, the committee points out, could result in lower than desired intakes of energy as well as many other essential nutrients (e.g., essential fatty acids, amino acids, calcium, vitamins, iron, and other trace minerals). On the other hand, as noted above, a recent study in Finland (12) provides little support for this concern.

The efficacy of such a diet during childhood in lowering serum cholesterol was confirmed by the Finnish study. However, the extent to which this reduces the risk of atherosclerosis later in life has been questioned. Although fatty streaks are present in the aortas of most 10-year-old children, the distribution of fibrous plaques, the characteristic lesion of atherosclerosis, is less ubiquitous (38). Moreover, it is not certain that fatty streaks progress to fibrous plaques (39). The committee also emphasizes that the frequency of atherosclerotic lesions in casualties of the Vietnam war was about 40% lower than the frequency of such lesions in casualties of the Korean war (45 versus 77.3%) and that this change occurred without a major change in childhood dietary habits (40, 41). The decreasing incidence of atherosclerotic disease over the past several decades (42) is cited as yet another example of the lack of compelling evidence

for the necessity of the proposed dietary changes during childhood.

Nonetheless, the committee concludes that the current dietary trends toward decreased consumption of saturated fats, cholesterol, and salt and increased consumption of polyunsaturated fats, if followed in moderation, are sensible for children over 2 years of age. A total fat intake of 30 to 40% of calories is considered reasonable for adequate growth and development. The committee also advocates counseling children and their parents on maintaining ideal weight and adopting other lifestyle practices likely to reduce the risks of atherosclerosis (exercise, avoidance of tobacco, etc.). Screening children over 2 years of age with a family history of atherosclerosis is recommended. If serum cholesterol concentration is elevated and not due to high-density lipoprotein cholesterol, appropriate dietary therapy to lower serum cholesterol is endorsed.

NUTRITIONAL REQUIREMENTS OF THE LOW-BIRTH-WEIGHT (LBW) INFANT

Approximately 7% of all infants born in the United States each year weigh less than 2500 g at birth, and over the past few decades, their survival has improved steadily. Today, for example, at least 75% of even the smallest such infants (those weighing <1000 g at birth) survive, and survival of larger LBW infants approaches 100%. This increasing number of surviving LBW infants must be fed, thus heightening awareness of the problems encountered in meeting their nutritional needs.

The importance of adequate early nutritional management of the LBW infant can be illustrated by considering the energy metabolism of the fasted infant. As in the adult, energy to meet ongoing needs during fasting is derived from endogenous stores of various nutrients. Although hepatic glycogen stores are used initially, these are quite limited and hence soon depleted. Thus, fat stores become the major source of endogenous energy, although protein stores are also used to provide amino acids from which glucose can be synthesized (gluconeogenesis) for use by tissues with an absolute requirement for glucose. Therefore, if hydration is adequate, the available endogenous stores of fat and protein ultimately determine how long a fasting infant can survive.

As illustrated in [Table 51.7](#), body content of both protein and fat, particularly fat, increases throughout gestation ([43](#)). Thus, an infant weighing 3500 g at birth has more-extensive endogenous nutrient reserves than one weighing 2000 g, and an infant weighing 1000 g has very limited reserves. In other words, the smaller the infant, the more marked is its inability to withstand starvation. Assuming on-going energy needs of 50 kcal/kg/day, the 1000-g infant who receives no exogenous nutrient intake has sufficient endogenous reserves to survive for only 4 to 5 days. The 2000-g infant has sufficient reserves to survive for approximately 12 days without exogenous nutrients, and the term infant has sufficient reserves to survive for approximately a month ([44](#)). Daily provision of glucose intravenously (e.g., 7.5 g/kg/day, the amount provided by 150 mL/kg/day of a 5% glucose solution or 75 mL/kg/day of a 10% glucose solution), theoretically, will prolong survival of the 1000-g, 2000-g, and 3500-g infant, respectively, by 7, 18, and 50 days ([44](#)).

Component	Accumulation during Various Stages of Gestation ^a		
	26-30 Weeks	30-34 Weeks	34-38 Weeks

^aBody weight increases from 550 g at 26 weeks to 1400 g at 30 weeks, 2230 g at 34 weeks, and 3160 g at 38 weeks.

Table 51.7 Intrauterine Accretion Rates of Various Nutrients during the Last Trimester of Pregnancy

These theoretical calculations depict in a semiquantitative manner the general clinical observations concerning the LBW infant's susceptibility to starvation and, hence, the necessity for careful attention to early nutritional management. In addition to this very practical role of early adequate nutrition, there is concern that inadequate nutrition at any time during the period of cellular proliferation of various organ systems, particularly the central nervous system, may result in nonrecoupable cellular deficits. This concern is based on evidence obtained primarily in rodents (45) but thought to be applicable to all species (46). If so, the prematurely born infant, whose brain would have grown considerably during the last trimester of intrauterine life, may be particularly vulnerable to inadequate nutrition. Although the period of cellular proliferation of the entire human brain encompasses at least the first 18 months of life (47) and transient cellular deficits apparently can be reversed if adequate nutrition is provided before the end of this period (48), little is known about the duration of cellular proliferation within specific regions of the brain. This uncertainty, coupled with the persistently high incidence of neurodevelopmental deficits in surviving LBW infants, suggests that better nutritional management not only might decrease mortality but also might improve neurodevelopmental outcome.

The factors discussed above are recognized by neonatologists, and the importance of early adequate nutritional management of the LBW infant is generally accepted. As a result, the general subject of the LBW infant's nutritional requirements is an area of active investigation. The discussion that follows attempts to summarize the present state of knowledge.

Goals of Nutritional Management

The most generally accepted goal for nutritional management of the LBW infant is to provide sufficient amounts of all nutrients to support, at a minimum, continuation of the intrauterine rate of growth (49). Thus, the LBW infant's minimal requirements for various

nutrients are assumed to be the amounts necessary to allow their accumulation at intrauterine rates (Table 51.7). This concept figures prominently in the recommended nutrient intakes for LBW infants proposed by the Committee on Nutrition of the American Academy of Pediatrics (Table 51.8) as well as the composition of formulas designed for feeding the hospitalized LBW infant (Table 51.9).

Nutrient	Recommended Intake (Amount/100 kcal)
Protein (g)	2.7-3.1
Fat (g)	4.3-5.4
300 mg essential fatty acids	
Carbohydrate	
Electrolytes and minerals	
Sodium (mEq)	2.3-2.7
Potassium (mEq)	1.8-1.9
Calcium (mg)	140-160
Phosphorus (mg)	6.5-7.5
Phosphorus (mEq)	30-40
Chloride (mEq)	2-2.4

Recommendations (amounts) are based on 100 kcal/100 g. Lower values are the recommended intakes for larger infants. Higher values are the recommended intakes for smaller infants (BW < 1000 g).

Table 51.9 Composition (amount/100 kcal) of Standard Formulas for Low-Birth-Weight Infants

Opposing views concerning the goals for nutritional management of LBW infants include, on one hand, the fear that failure to provide human milk will deprive the infant of factors needed for optimal development of the gastrointestinal tract and immune system and, on the other, the desire to produce the most rapid growth rate possible, thereby recouping as quickly as possible the roughly 10 to 15% of body weight usually lost over the first several days of life and also possibly reducing the duration and hence the cost

of hospitalization. Proponents of the former view advocate feeding human milk because of its theoretical nonnutritional benefits: enhanced maternal infant bonding, protection against infection and necrotizing enterocolitis, and better neurodevelopmental outcome. They also point out that the lower protein content of human milk is less likely to overwhelm the LBW infant's limited capacity to catabolize excess protein. Proponents of the latter view stress the potential advantages of catch-up growth and point out that protein intakes well in excess of those from human milk do not appear to tax the LBW infant's ability to catabolize protein.

Results from a multicenter study conducted in the early 1980s in England (50) provide considerable insight into this longstanding controversy. In this study, infants whose mothers elected to provide milk for feeding their infants were assigned randomly to receive supplements of either banked human milk or formula, and infants whose mothers elected not to provide milk were assigned randomly, at some centers, to receive either a preterm formula or banked human milk and, at others, to receive a preterm or term formula. Thus, to some extent, the usual confounding factor of the mother's intent to breast feed or not breast feed her infant was controlled, and infants also received a variety of protein intakes. Results published to date indicate that infants fed human milk, either as the sole diet or with formula, have a lower incidence of necrotizing enterocolitis during the neonatal period and also appear to be more resistant to infection (51). In addition, while developmental indices at 18 months of age were higher in formula-fed infants who received preterm formula than in those who received term formula (i.e., higher vs. lower protein intake) during the neonatal period (52), those fed human milk were less adversely affected (53). Moreover, when all groups were combined, those fed human milk during hospitalization, either their mother's milk or banked milk, had a neurodevelopmental advantage at 7 to 8 years of age (54).

Energy Requirements

LBW infants are usually assumed to require approximately 120 kcal/kg/day, 75 kcal/kg/day for resting expenditure and the remainder for specific dynamic action (10 kcal/kg/day), replacement of inevitable stool losses (10 kcal/kg/day), and growth (25 kcal/kg/day). The usual allotment for resting needs (75 kcal/kg/day) includes the basal requirement (50–60 kcal/kg/day) as well as additional requirements imposed by activity and response to cold stress. However, LBW infants are relatively inactive, and with careful control of environmental temperature, energy expenditure in response to cold stress is minimal. In fact, studies in relatively inactive infants maintained in a strictly thermoneutral environment suggest that their resting energy requirement (i.e., the basal requirement plus requirements for activity and response to cold stress) is closer to 60 kcal/kg/day (55, 56, 57, 58 and 59). The energy required for specific dynamic action, or the thermic effect of food (i.e., the difference between resting energy expenditure of the fed infant and that of the fasted infant), may be a function of the composition of the diet. Protein intake was once thought to be the primary determinant of this component, but more-recent studies suggest that energy intake may be equally important (57, 58 and 59). Fecal loss of nutrients, especially fat, appears to be inevitable in the fed LBW infant. The extent of this loss is a function of the infant's stage of development and the nature of the fat intake (see “[Fat Requirements](#)”). In infants fed either human milk or modern formulas, stool fat losses rarely exceed 15% of the fat intake, or less than 7.5%

of the total energy intake.

The precise energy requirement for growth is unknown. This requirement includes two components: the energy cost of synthesizing new tissue (which probably is small and included in the measurement of resting expenditure) and the energy value of stored nutrients. Values of 3 to 6 kcal/g weight gain have been reported for the latter component. Since this obviously depends upon the composition of the newly synthesized tissue (e.g., deposition of calorically dense fat tissue requires more calories than deposition of lean body mass), such a range is to be expected. The calculated energy value of tissue deposited by the fetus between the 30th and 38th weeks of gestation is 2.0 to 2.5 kcal/g ([Table 51.7](#)), whereas the calculated energy value of tissue deposited by the normally growing term infant between birth and 4 months of age is approximately 4.5 kcal/g ([60](#)).

Thus, the energy requirement of the LBW infant may range from 95 to 160 kcal/kg/day. Aside from growth, the factors of greatest quantitative importance are the infant's activity state and the environmental conditions under which it is nursed. For most LBW infants, an energy intake of 120 kcal/kg/day is adequate.

Protein Requirements

The then-common practice of feeding LBW infants human milk was largely abandoned about 50 years ago after Gordon et al. ([61](#)) showed that higher protein intakes resulted in a greater rate of weight gain. However, the formulas used in this study also contained more electrolytes and minerals than human milk, and some attributed the greater weight gain to water retention secondary to the greater electrolyte/mineral intake rather than to the greater protein intake. This debate was finally settled when subsequent studies demonstrated that both total body water and extracellular fluid of infants fed highprotein, high-solute intakes exceeded those observed in infants fed low-solute formulas ([62](#)). Nonetheless, that there also is a direct relationship between protein intake and deposition of lean body mass, independent of its water content ([62](#), [63](#) and [64](#)).

In general, a protein intake of approximately 3 g/kg/day appears to be adequate for the LBW infant ([65](#)). On the other hand, higher intakes are well tolerated metabolically and support a greater rate of weight gain ([64](#), [65](#)). The protein, of course, must provide sufficient amounts of all essential amino acids including, for the LBW infant, histidine ([66](#)), tyrosine ([67](#)), and cysteine ([67](#), [68](#)). In this regard, current LBW infant formulas contain "humanized" bovine milk protein (60% whey proteins and 40% caseins). However, despite a higher cyst(e)ine content, there is little evidence that this protein is more efficacious than unmodified bovine milk protein (18% whey protein and 82% caseins), particularly with respect to growth ([69](#)). Of theoretical interest is the fact that plasma threonine concentrations of infants fed "humanized" bovine milk formulas are approximately double those observed in infants fed unmodified bovine milk protein, while plasma tyrosine concentrations are higher in infants fed unmodified bovine milk formulas ([69](#), [70](#) and [71](#)).

Fat Requirements

Although fat accounts for about half of the nonprotein energy content of human milk and most infant formulas, including those designed for LBW infants, the only known requirement for fat in human nutrition is to provide essential fatty acids. Formerly, it was thought that this requirement could be met by providing 2 to 4% of the total energy intake as linoleic acid, but it is now clear that some linolenic acid also is required (72). Some also feel that the LBW infant, and perhaps the term infant as well, also may require longer-chain, more-unsaturated w-6 and w-3 fatty acids, e.g., arachidonic acid and docosahexaenoic acid (73, 74, 75 and 76). These latter fatty acids rather than their precursors, linoleic and linolenic acids, accumulate in the central nervous system during development (77, 78). However, plasma and erythrocyte lipid levels of these polyunsaturated fatty acids (PUFAs) are lower in infants who do not receive an exogenous source of these fatty acids (79). Currently, formulas containing long-chain PUFAs are available in Europe and Asia, but to date, such formulas are not available in North America. Most available studies suggest that supplementation with these fatty acids may have at least transient benefits for visual function of LBW infants (80, 81). On the other hand, since these fatty acids are quite bioactive (e.g., precursors of eicosanoids), there is concern about the safety of supplemented products.

Carbohydrate Requirements

The central nervous system and the hematopoietic tissue depend primarily on glucose as a metabolic fuel. However, glucose can be produced from either exogenously administered protein or endogenous protein stores (gluconeogenesis). Thus, in contrast to requirements for specific amino acids and fatty acids, there appears to be no absolute requirement for carbohydrate. On the other hand, exogenous glucose often is necessary to prevent hypoglycemia, particularly during the immediate neonatal period.

Carbohydrates, like fat, make up approximately half of the nonprotein energy content of human milk and infant formulas, including those designed for LBW infants. Although the predominant carbohydrate of human milk is lactose, LBW infant formulas usually contain a mixture of lactose and glucose polymers (Table 51.9). Development of intestinal lactase activity lags behind development of other disaccharidases, but most viable infants tolerate lactose quite well. In fact, satisfactory clinical progress has been observed with formulas that contain only lactose, only sucrose, only glucose, only glucose polymers, and mixtures of these sugars.

Fluid Requirements

Several bases of reference have been suggested for estimating maintenance fluid requirements: for example, body weight, body surface area, and energy expenditure. Of these, energy expenditure, which focuses attention on the physiologic and nonphysiologic factors most likely to modify fluid requirements (e.g., body temperature, ambient temperature, ambient humidity, activity, and respiratory rate), seems most relevant. In the older infant, the maintenance fluid requirement is approximately 1 mL/kcal expended. This allotment replaces usual insensible water losses through the lungs and skin as well as obligatory renal and gastrointestinal losses.

Insensible water loss varies considerably among infants, particularly LBW infants. Moreover, both pulmonary and cutaneous components of insensible water loss are related inversely to ambient humidity. Under usual nursery conditions, the insensible water loss of term infants is approximately 30 mL/100 kcal. In the very small infant with altered skin permeability to water, cutaneous losses may be considerably greater, although nursing the infant in relatively high humidity tends to decrease both this component of insensible fluid loss and pulmonary losses. Phototherapy, a common modality for treating LBW infants with hyperbilirubinemia, also increases insensible water losses (82). Thus, the insensible water losses of LBW infants usually are at least twice those of the term infant, and those of the most immature LBW infants may be severalfold greater.

Obligatory renal losses of LBW infants also are quite variable. While even very immature infants can regulate the volume of urine excreted according to the solute load and the available water, renal concentrating and diluting mechanisms are both somewhat limited (83). In general, sufficient fluid to allow a urinary volume of 50 to 60 mL/100 kcal permits excretion of the usual range of solute loads at urinary concentrations of 150 to 450 mOsm/L, which are easily achieved, even by a very immature kidney.

In unfed infants, fluid losses via the gastrointestinal tract are minimal. If the infant is fed, however, approximately 10% of the fluid intake is lost in stool. Infants receiving phototherapy lose even more water in stool (82).

The fluid requirement for growth is a function of both the rate of growth and the water content of the newly synthesized tissue. The water content of tissue deposited during the last trimester of gestation is approximately 70% (Table 51.7), whereas the water content of the tissue deposited by the term infant between birth and 4 months of age is 40 to 45% (60). An estimate of 50 to 60% for the growing LBW infant seems reasonable.

The water requirements for insensible (30–60 mL/100 kcal) and obligatory losses (50–60 mL/100 kcal) as well as for growth (10–20 mL/100 kcal) are reduced by the endogenously produced water of oxidation, approximately 12 mL/100 kcal. Thus, the LBW infant, like the term infant, seems to have a minimum water requirement of about 1 mL/kcal used. The fasting infant thus requires at least 65 to 75 mL/kg/day, while the growing infant requires at least 120 mL/kg/day; however, the very immature infant and the infant undergoing phototherapy may require much more. In general, a fluid intake of 140 mL/kg/day is well tolerated by most infants after the first few days of life. Intakes above this amount are thought to increase the likelihood of developing patent ductus arteriosus.

Electrolyte Requirements

The estimated daily obligatory electrolyte losses of the term infant after the first several days of life are approximately 0.5 mEq/kg of both sodium and chloride and approximately 0.75 mEq/kg of potassium. Since renal reabsorption mechanisms are not fully developed in the LBW infant, their renal losses are likely to be greater. Electrolyte

losses probably are greater also in infants with increased fluid losses secondary to phototherapy, etc.

The electrolytes required for tissue synthesis, of course, depend upon the rate of growth. Assuming continuation of the intrauterine growth rate ([Table 51.7](#)), the daily requirement of these nutrients for tissue synthesis would approximate the amounts that accumulate during the last trimester of gestation: 1.0 to 1.5 mEq/kg/day of sodium and 0.5 to 1.0 mEq/kg/day of both potassium and chloride. If the rate of weight gain is more or less than the intrauterine rate, or if the composition of weight gain is different, the requirements obviously change proportionally. In this regard, the neonate usually deposits less extracellular fluid than the fetus and, hence, less sodium.

The minimal daily sodium, potassium, and chloride requirements of the LBW infant receiving adequate protein and energy and growing at the intrauterine rate are, respectively, 1.5 to 2.0 mEq/kg, 1.25 to 1.75 mEq/kg, and 1.0 to 1.5 mEq/kg. Enough potassium and chloride is present in the volumes of both human milk and commonly used formulas usually ingested to provide these requirements. However, the sodium content of human milk (approximately 1.2 mEq/100 kcal), even if completely absorbed, may be low. On the other hand, the growth rate of LBW infants fed human milk is somewhat lower than the intrauterine rate; therefore, their sodium requirement for growth probably is less than 1.5 mEq/kg/day. The intakes recommended by the Committee on Nutrition of the American Academy of Pediatrics are considerably higher than these minimal intakes ([Table 51.8](#)).

Mineral Requirements

Early studies of calcium and phosphorus needs were directed toward defining the intakes necessary to prevent hypocalcemia. Since this condition develops more commonly in infants fed formulas with a high content of phosphorus relative to calcium (i.e., a low calcium:phosphorus ratio), the calcium:phosphorus ratio rather than the absolute intakes of either mineral was emphasized. Experience has shown that a ratio of roughly 1.5 to 2.0 is satisfactory.

The amount of calcium retained during the latter part of normal intrauterine growth is approximately 5 mmol/kg/day. Human milk can provide only about 0.5 mmol/kg/day, and this is not completely absorbed. Thus, if the LBW infant's requirement for calcium is assumed to be the amount necessary to support continuation of the rate of accumulation that occurs in utero, human milk obviously contains inadequate calcium. The phosphorus content of human milk also is low. Moreover, LBW infants fed human milk have less dense skeletons radiographically than those fed formulas containing large amounts of calcium, and many develop rickets and/or fractures ([84](#)). Thus, LBW infants fed human milk, including those fed their own mother's milk, require supplemental calcium and phosphorus for optimal skeletal mineralization.

Iron requirements depend upon the existing body stores and the rate of growth. The LBW infant obviously has more-limited stores of iron than the term infant and, therefore, is more susceptible to development of iron deficiency, especially during periods of rapid growth. It has been estimated that the LBW infant's endogenous iron stores, in the

absence of exogenous intake, would be depleted sometime during the 2nd or 3rd month of life rather than during the 4th or 5th month of life, as occurs in the term infant. However, most LBW infants experience further depletion of iron stores secondary to blood losses incident to biochemical monitoring during periods of clinical instability. Thus, it is recommended that the LBW infant receive iron supplements or iron-fortified formulas as early as possible. Such supplements, however, may increase the infant's need for vitamin E, especially when formulas high in PUFAs are fed (see below). In addition, the bactericidal properties of the iron-binding proteins of human milk (lactoferrin and lactoglobulin) are abolished if they are saturated with iron (85). Current LBW infant formulas contain moderate amounts of polyunsaturated fats, ample vitamin E, and 0.37 to 1.88 mg/100 kcal of iron (Table 51.9).

Little information is available concerning the LBW infant's requirements for other trace minerals. In general, the recommended intakes of these minerals are based on either the amounts provided by human milk or the amounts that accumulate in utero during the last trimester of pregnancy.

The amounts listed in Table 51.8 appear adequate. A zinc intake of 500 µg/100 kcal, assuming 50% absorption from the gastrointestinal tract, should allow accumulation of zinc at the intrauterine rate. The concentration of zinc in human milk is approximately 3 to 5 mg/L; thus, it provides minimally adequate zinc to allow accumulation at the intrauterine rate. On the other hand, zinc in human milk is absorbed more efficiently than that in bovine milk (86). The recommended copper intake (see Table 51.8) is approximately the amount present in human milk, which might not allow accumulation of copper at the intrauterine rate. Thus, some recommend a higher copper intake. Since hepatic stores of copper are quite large, this probably is not necessary.

Vitamin Requirements

Specific recommendations concerning either requirements or advisable allowances of vitamins for LBW infants are not available; thus, it is usually suggested that the RDAs for term infants be given. Infants fed sufficient amounts of either human milk or artificial formulas to produce adequate growth usually receive sufficient amounts of all vitamins, although human milk may be deficient in vitamin D. Nonetheless, since consumption of sufficient volumes of formula to satisfy vitamin requirements may not be attained for several weeks, a supplement containing vitamins A, C, and D is often recommended. In addition, the LBW infant may have special needs for vitamin E.

Vitamin E functions as an antioxidant to prevent peroxidation of PUFAs in various cell membranes. Thus, it is not surprising that inadequate vitamin E intake results in erythrocyte hemolysis (87). Since the PUFA content of all membranes is related to intake of these fatty acids or their precursors, infant formulas containing vegetable oils with a high PUFA content impose a greater vitamin E requirement. Such formulas, therefore, should contain more vitamin E. In general, the aim should be to provide at least 1 IU of vitamin E per gram of PUFAs—an E:PUFA ratio of 1. This may need to be reevaluated if formulas are supplemented with long-chain PUFAs (see above).

LBW infants fed formulas containing PUFAs and given therapeutic doses of iron also

have a greater incidence of erythrocyte hemolysis and lower serum vitamin E levels than infants fed formulas containing less iron and PUFAs (88). Thus, the relationship between the vitamin E and iron contents of the formula as well as the relationship between the vitamin E and polyunsaturated fat contents of the formula are important. For this reason, careful attention must be given to vitamin E intake if iron supplements are given. The fatty acid, iron; and vitamin E contents of current LBW infant formulas appear to be appropriate.

Large doses of vitamin E have been recommended to prevent both retrolental fibroplasia (89) and bronchopulmonary dysplasia (90). However, it is not clear that these recommendations are warranted, particularly considering the potential toxicity of the large doses recommended.

Delivery of Nutrient Requirements to LBW infants

For most LBW infants, the foregoing discussion of nutrient requirements is largely academic. Underlying illnesses as well as a number of neurophysiologic deficiencies (e.g., poor or unsustained suck, uncoordinated sucking and swallowing mechanisms, delayed gastric emptying, and poor intestinal motility) make delivery of enteral nutrition virtually impossible, particularly during the early neonatal period. During this time, a nutritional regimen that prevents catabolism and allows some increment in lean body mass probably is satisfactory. This more realistic goal for the first several days of life can be achieved in sick LBW infants with a parenteral regimen that provides as few as 60 kcal/kg/day, an amino acid intake of 2.0 to 3.0 g/kg/day, and necessary electrolytes, minerals, and vitamins (91, 92). A similar regimen delivered enterally should be equally efficacious if intestinal absorption is not severely compromised.

Various methods of delivering nutrients by the intravenous route (total parenteral nutrition) as well as methods of delivering feedings by the gastrointestinal tract (e.g., continuous nasogastric or transpyloric infusions) have been proposed as alternatives to more conventional feeding techniques. Although no one method is likely to be ideal for all situations, use of a combination of these methods of nutrient delivery, allowing the particular clinical problems of an individual infant to dictate the method of delivery, should improve nutritional management. In many infants, a combination of conventional as well as these less conventional methods of feeding permits delivery of sufficient nutrients to support "normal" growth by 1 to 2 weeks of age.

Within reason, every infant should be given a trial at conventional feeding, i.e., tolerated nipple or gavage feedings of either human milk or a standard formula, plus intravenous supplementation with 5 to 10% glucose solutions. If adequate nutrients cannot be delivered in this way, a trial of continuous nasogastric or transpyloric feedings is warranted. Tolerated enteral feedings delivered conventionally or by continuous infusion also can be supplemented by intravenous infusions of appropriate mixtures of glucose, amino acids, and/or lipid. If enteral feedings are not tolerated, parenteral administration of a balanced nutritional mixture is indicated. A regimen that provides 75 kcal/kg/day plus amino acids, electrolytes, minerals, and vitamins can be delivered by peripheral vein infusion without imposing an unreasonable fluid load. Such a regimen almost certainly maintains existing body composition and, hence, is particularly applicable for

infants who are likely to tolerate enteral intake within a brief period of time. Use of a central vein catheter allows delivery of a more concentrated nutrient mixture and is particularly useful in situations associated with prolonged intolerance of enteral feedings.

Role of Human Milk in Feeding the LBW Infant

Although many advocate feeding the LBW infant human milk, evidence that it is nutritionally superior for this population is lacking. In fact, the growth rate of LBW infants fed human milk, even that of infants fed their own mother's milk, which has approximately 20% more protein than term human milk (93), is lower than that of infants fed LBW formulas (94). Moreover, plasma albumin and prealbumin (transthyretin) concentrations often fall to frankly low values (95). In addition, the low amounts of calcium and phosphorus do not support adequate skeletal mineralization.

In contrast to the nutritional disadvantages of human milk for the LBW infant, its immunologic properties may be a distinct advantage. These properties (i.e., cellular as well as humoral components), theoretically, may confer passive immunity and/or enhance immunologic maturation, thereby providing some protection against infections and perhaps necrotizing enterocolitis. Indeed, recent studies show that the incidence of both infection and necrotizing enterocolitis are lower in infants fed either banked human milk or their own mother's milk (see above). Clearly, these advantages of human milk, may far outweigh its nutritional disadvantages.

The steps involved in collecting, storing, and dispensing expressed human milk make inadvertent contamination likely. Thus, stringent hygienic techniques and bacterial screening are mandatory to ensure bacteriologic safety. Viral contamination also is a concern. For example, CMV excretion in the milk of seropositive women is relatively common (96), and CMV infection has been reported in infants fed CMV-positive milk (97). Moreover, one case of HIV infection transmitted by human milk has been reported (98). Herpes and rubella viruses and hepatitis B surface antigen also have been detected in human milk, but transmission of these viruses via milk has not been demonstrated.

Clearly, more research is necessary to elucidate the role of human milk, provided by either the infant's mother or a donor (or donors), in feeding the LBW infant. This research should be well under way before enormous expense and effort are spent in establishing milk banks to supply safe human milk for routine feeding of LBW infants. On the other hand, if an individual mother wishes to provide milk for her infant, the potential psychologic benefits of her involvement in the infant's care as well as the benefits with respect to eventual success in nursing are strong reasons for encouraging milk expression until the infant can be breast-fed. Moreover, two commercial preparations for supplementing human milk with protein, calcium, phosphorus, sodium, and vitamins are available, and use of these supplements appears to overcome many of the nutritional inadequacies of human milk for LBW infants (99, 100).

[Vitamins](#)

[Special Nutritional Problems](#)

[Effect of Nutrition during Adolescence on Adult Morbidity and Mortality](#)

[Eating Disorders](#)

[Pregnancy](#)

[Vegetarian Diets](#)

[Chapter References](#)

The nutritional requirements of adolescents are influenced primarily by the normal events of puberty and the simultaneous growth spurt. Puberty is an intensely anabolic period, with increases in height and weight, alterations in body composition resulting from increased lean body mass and changes in the quantity and distribution of fat, and enlargement of many organ systems. Adolescence is a unique period of development of physiologic, psychosocial, and cognitive levels, all of which affect the nutritional needs of the adolescent. The teenager is a rapidly changing biologic organism, and so nutritional management of adolescents must consider the rapid growth, maturation, and psychosocial changes of each individual. Three aspects of growth must be emphasized: the intensity and extent of the pubertal growth spurt, the sexual differences in the timing of growth as well as the nature of change of body composition, and individual variation in the timing of the pubertal growth spurt.

The velocity of growth exerts a major influence on nutrient requirements. Adolescence is the only time in extrauterine life when growth velocity increases. The average American female experiences her most rapid spurt in linear growth between ages 10 and 13 years; the growth spurt of the average American male occurs about 2 years later, between 12 and 15 years. (See Appendix [Table III-A-14-e-1](#) and [Table III-A-14-e-2](#) for height velocity in centiles of girls and boys, respectively. Data from NHANES I and II for stature of girls and boys are given in Appendix [Table III-A-14-c-1-a](#) and [Table III-A-14-c-1-b](#) by height, by age, and percentiles are given in Table A.15a) This time is frequently termed *the period of maximum growth*, and for both height and weight, it is greatest in girls in the year preceding menarche. The linear spurt during adolescence contributes about 15% to final adult height; its contribution to the adult weight is approximately 50%. (NHANES I and II data on weight in girls and boys by percentiles are given in Appendix [III-A-14-b-1](#) and [III-A-14-b-2](#), weight by age and percentiles in Appendix [Table III-A-15-b](#), and weight by height in percentiles for males and females in Appendix [Table III-A-15-c](#) and [Table III-A-15-d](#), respectively.) Therefore, nutrition clearly plays a significant role in the doubling of body mass during pubescence. Because

nutritional requirements are closely related to rapid increase in body mass, it is not surprising that peak nutritional requirements appear to occur during the year of maximum growth.

Although both adolescent males and females gain significant weight, gender-related differences exist with respect to the rate, quantity, composition, and distribution of tissues. During adolescence, boys tend to gain more weight at a faster rate, and their skeletal growth continues for a longer time than that of adolescent girls. Girls deposit relatively more total body fat; boys deposit more muscle mass (see [Chapter 49](#)). Patterns of body composition and distribution diverge during adolescence. Boys become leaner and paradoxically increase the number of actual adipose tissue cells while decreasing the percentage contribution of fat to total body mass. Girls have a steep rate of increase in actual fat deposition as well as increased percentage of fat to total body mass and increased lean body mass. As a result of pubertal changes, males have a larger lean body mass, a larger skeleton, and less adipose tissue as total body mass than females. As lean body mass has more active metabolic function than adipose tissue, sex differences in body composition produce sex differences in the nutritional requirements of adolescents ([1](#), [2](#)).

The large individual variance in the time at which the growth spurt begins, as well as the intensity of growth, makes chronologic age a poor index of nutritional requirements. Physiologic growth, or maturational age, is a better indicator for establishing requirements or evaluating intakes. [Figure 52.1](#) illustrates three normal males and three normal females in prepubertal, midpubertal, and postpubertal stages of development ([3](#)). Although each group is at the same chronologic age, each individual is at different physiologic age; each adolescent has a different rate of growth and different body composition, both important determinants of nutrient needs. Standards for assessing physiologic age have been developed. Tanner's sexual maturity ratings are used widely clinically and are helpful in describing the stage of development of individual adolescents ([4](#)).

Figure 52.1. Differing degrees of adolescence at the same chronologic age. *Top*, Three boys all aged 14.25 years. *Bottom*, Three girls all aged 12.75 years. (From Tanner JM. Growth and endocrinology of the adolescent. In: Gardner LI, ed. Endocrine and genetic diseases of children and adolescents. Philadelphia: WB Saunders, 1975, with

permission.)

NUTRITIONAL REQUIREMENTS

Few actual data on adolescents are available on which to base recommendations for their nutrient needs. Most recommendations are based on estimates of intakes associated with good health and growth, extrapolations from animal research, or interpolation from studies on children and adults. The most recent recommended dietary allowances (RDAs) of the Food and Nutrition Board of the National Research Council (NRC) for adolescents are given in terms of weight, sex, and age (4-year intervals, except for the age group 19–24 years; this age class has been extended in the 1989 RDAs because peak bone mass probably is not attained before the age of 25 years) (5). (See also Appendix [Table A-2-a-1](#), [Table A-2-a-2](#), [Table A-2-a-3](#), [Table A-2-b-1](#), [Table A-2-b-2](#), [Table A-2-b-3](#), [Table A-2-b-4](#), [Table A-2-b-5](#), [Table A-2-b-6](#), [Table A-2-c-1](#), [Table A-2-c-2](#), [Table A-2-c-3](#), [Table A-2-c-4](#), [Table A-2-c-5](#), [Table II-A-3-a](#), [Table II-A-3-b](#), [Table II-A-4-b](#), [Table II-A-4-c](#), [Table II-A-4-d](#), [Table II-A-4-e-1](#), [Table II-A-4-e-2](#), [Table II-A-4-f](#), [Table II-A-5-a](#), [Table II-A-5-b](#), [Table II-A-5-c](#), [Table II-A-5-d](#), [Table II-A-6](#), [Table II-A-7-a](#), [Table II-A-7-c](#), [Table II-A-7-a](#), [Table II-A-7-d-1](#), [Table II-A-7-d-2](#), [Table II-A-7-d-3](#), [Table II-A-7-d-4](#), [Table II-A-7-d-5](#), [Table II-A-7-d-6](#), [Table II-A-8-a-1](#), [Table II-A-8-a-2-a](#), [Table II-A-8-a-2-b](#), [Table II-A-8-a-2-c](#), [Table II-A-8-a-3](#), [Table II-A-8-b-2](#), [Table II-A-8-b-2-a](#), [Table II-A-8-b-3](#) and [Table II-A-8-b-4](#) for U.S. and other national and international dietary reference values for energy and various nutrients.)

Energy

The caloric requirements for the growing adolescent have not been studied enough to give an accurate expression of the energy needs of individual teenagers. Some of the best data come from a study done by Wait et al. (6). Energy intake data from bomb calorimetry determinations support the thesis that the relationship of total calories to height or calories per unit height per age are the preferred indices for determining caloric needs. From these observations, as well as supporting findings of Widdowson (7), it appears that increments in height during adolescence may best represent the anabolic effect of this growth period. The practical application of determining individual requirements using the kilocalorie per centimeter has been described. RDAs calculated on kilocalorie per centimeter of height for males and females are shown in [Table 52.1](#).

Age (years)	Average Allowance (kcal/cm height)	(kcal/day)
Males		
11-14	15.9	2500
15-18	17.0	3000
19-24	16.4	2900
Females		
11-14	14.0	2200
15-18	13.5	2200
19-24	13.4	2200

From Food and Nutrition Board, National Research Council. Recommended dietary allowances. 10th ed. Washington, DC: National Academy Press, 1989.

Table 52.1 Recommended Energy Intakes for Adolescents

In a group of normally growing teenagers followed longitudinally, Beal noted that actual energy intake for some teens fell outside the range of the RDA (8). Thus, even when using the parameter for calculating calories best supported by data (kilocalorie per centimeter height), the margin of error is considerable. Nevertheless, kilocalorie per centimeter height may represent the best way to calculate individual energy requirements of adolescents at the present time.

A review of studies of energy intake of children and adolescents in the United States shows that girls appear to consume their peak caloric intake, about 2550 kcal, at the time of menarche (around 12 years). This peak demand is followed by a slow decline. In boys, caloric intake appears to parallel the adolescent growth spurt, increasing until age 16 years to approximately 3400 kcal and then decreasing by 500 kcal by age 19 years (9).

The most accepted way of assessing adequacy of energy intake is to evaluate growth and body composition. The normal variability of pubertal growth patterns makes ideal weight during puberty an untenable concept. A common practice is to plot height and weight on the National Center for Health Statistics (NCHS) growth chart with the percentiles for each age group (10). This plot tells us the position of that teenager relative to the NCHS sample. Growth data gathered in the NCHS survey published in 1973 form the basis for the growth charts currently used in the United States (11) (see Appendix [Table III-A-12-d](#) and [Table III-A-12-e](#)). If multiple measurements over time are available, any significant changes in rates of linear growth or body mass can be detected by percentile shifts. However, the teenager in the 90th percentile for height may or may not be appropriately in the 90th percentile for weight. For example, a male at the 90th percentile weight-for-height with a triceps skinfold in the lower percentiles would be muscular. Another teenager in the 90th percentile weight-for-height with a triceps skinfold in the 95th percentile would be classified as obese (survey data summarized in Appendix Tables III-A-14-a-1 through 4).

To determine appropriate weight-for-height for an adolescent and assess whether he or

she has excess or deficient energy intake, the height and weight of youths 12–17 years, United States (11) tables (Appendix [Table III-A-14-c-1-b](#), [Table III-A-14-c-2-b](#), [Table III-A-14-d-1-b](#), [Table III-A-14-d-2-b](#), and [Table III-A-15](#).) are often used clinically. The data are problematic (such as sample size, lack of references to sexual maturity, ethnic differences, etc.), although the tables separate the percentiles of weight by age, sex, and height, providing a range of weights for a particular height and age. With the additional information gained from triceps percentiles (Appendix [Table III-A-14-b-1](#) and [Table III-A-14-b-2](#)), overweight (triceps skinfold >95th percentile) or underweight (triceps skinfold <25th percentile) can be assessed.

The National Center for Health data have been analyzed in such a sophisticated way that accurate assessment of growth and simple measures of body composition are available to measure the impact of energy excess or scarcity on the growing teenager. However, the effects of marginal energy deficits have a subtle effect on growth. The work of Dreizen et al. (12) is one of the few studies in the United States of the long-term effect of chronic mild malnutrition on growth. The net effect over time was a diminished rate of growth during late childhood and adolescence and delay of puberty by 2 years, but ultimately, this group of malnourished youths in southeastern United States reached heights and weights similar to those of a comparison group. Keeping in mind the great variation in timing and intensity of growth seen in adolescents, we must emphasize the large variation in caloric intake in this group.

Physical activity also contributes significantly to the total energy requirement of an individual, as does previous growth and nutritional status. When considering the energy requirements of adolescents, the importance of individual variation from one adolescent to another must be recognized in making nutritional recommendations. [Table 52.2](#) presents energy expenditure, expressed in three different body weights, for different activities (13). The different activities have highly variable energy costs and can be used to guide dietary advice or weight management.

Activity	kcal/min/kg	45 kg	55 kg	65 kg
Basketball	0.138	6.2	7.6	9.0
Cycling				
5.5 mph	0.064	2.9	3.5	4.2
9.4 mph	0.160	4.5	5.5	6.5
Dancing (twist)	0.168	7.6	9.2	10.9
Football	0.132	5.9	7.3	8.6
Running				
11.5 min/mile	0.135	6.1	7.4	8.8
8 min/mile	0.208	9.4	11.4	13.6
Sitting quietly	0.021	0.9	1.2	1.4
Walking, normal pace	0.080	3.6	4.4	5.2
Whiting, sitting	0.029	1.3	1.6	1.9

Table 52.2 Energy Expenditure of Selected Activities (calories expended/min activity)

Protein

As with energy recommendations, protein needs for an adolescent are more useful when physiologic age is emphasized over chronologic age. Using the RDA for protein related to height is probably the most useful method for determining protein needs for adolescents (5). For adolescent males, the daily protein recommendations are 0.29, 0.34, and 0.33 g/cm height for the age groups 11 to 14, 15 to 18, and 19 to 24 years, respectively. For adolescent females, the daily recommendations are 0.29, 0.27, and 0.28 g/cm height for the age groups 11 to 14, 15 to 18, and 19 to 24 years, respectively. The protein requirement is determined by the amount needed for maintenance plus that needed for growth of new tissue, which during adolescence may represent a substantial portion of the total need. Unfortunately, data on either of these determinants of requirements are lacking for adolescents and have been interpolated from results of studies involving infants and adults (5, 14).

The RDA for daily protein intake for adolescents ranges from 44 to 59 g (5). Peak intakes of protein coincide with the peak energy intake. The proportion of total energy intake represented by protein remains fairly constant, between 12 and 14%, throughout childhood and adolescence (9).

Results of studies show that average intakes of protein in adolescents exceed the recommended levels (9, 15, 16). Although it appears that most adolescents in the United States have sufficient protein intake, some teenagers who restrict food intake because of a desire to lose weight, eating disorders such as anorexia nervosa and bulimia, or socioeconomic problems, may be at risk of poor protein intake. Without adequate caloric intake, protein is used in gluconeogenesis and is unavailable for tissue synthesis. Heald and Hunt demonstrated that in the rapidly growing adolescent, protein metabolism is particularly sensitive to caloric restriction (17).

Anthropometric measurements generally are a simple way to assess protein status. Height, weight, and midarm circumference measurements (used to assess lean body mass) can be used as growth indicators. Midarm circumference measurements and arm muscle area between the 25th and 75th percentiles probably indicate good nutritional status (18).

Biochemical assessments of protein nutriture include creatinine/height index and serum concentrations of certain proteins: albumin, transferrin, prealbumin, and retinol-binding protein (19, 20, 21 and 22). Determinations of prealbumin and retinol-binding protein are the most sensitive indicators of changes in diet that may indicate subclinical malnutrition (22). A detailed evaluation of assessment procedures is given in [Chapter 56](#).

Minerals

Because of the adolescent growth spurt, the need for three minerals is of particular importance: calcium to sustain increased skeletal mass, iron to aid expansion of red cell and muscle mass, and zinc to generate new skeletal and muscle tissues. In addition to

significant increases in need, intake of these nutrients has been shown to be below the recommended levels for adolescents (15, 16, 23, 24 and 25).

Boys take in more calcium than do girls and are closer to achieving the recommended intakes (26). Daily iron intakes reported by the Ten State Nutrition Survey were relatively lower. Most (80%) girls 10 to 16 years of age were below the recommended 18 mg of iron per day (15). Some evidence shows an association between low concentrations of zinc in hair and poor growth. An analysis of food intake suggests poor eating habits (27). The full extent of zinc deficiency and its adverse effect on puberty needs more inquiry.

Calcium

With approximately 99% of total-body calcium in the skeleton (28), the adolescent growth spurt associated with increased skeletal length and mass obviously has a significant impact on dietary requirements for calcium. Skeletal growth during adolescence accounts for approximately 45% of the adult skeletal mass. Because the absolute amount of calcium in the skeleton of a boy in the 95th percentile for height and that for a boy in the 5th percentile for height will differ by 36%, the calcium needs of these two boys will differ sharply because of the difference in skeletal size. The problem is compounded further by the normal differences in pubertal development, making age and sex alone poor predictors of individual calcium needs. Lastly, growth of skeletal mass and gains in height and muscle mass continue until the third decade of life (29, 30 and 31). Table 52.3 shows the average increments of body calcium for adolescence and the daily increments of body calcium at the peak of the growth spurt. At the peak of growth, daily deposition of calcium is approximately twice the average increment during the adolescent period. The daily peak increment of calcium during the growth spurt is greater, occurs later, and lasts longer in boys than in girls (28).

Mineral	Average for Age 10-20 years (mg)		At Peak of Growth Spurt Period (mg)
	M	F	
Calcium	M	210	400
	F	110	240
Iron	M	0.57	1.1
	F	0.23	0.9
Nitrogen	M	320	610 (3.8 g protein)
	F	160	360 (2.2 g protein)
Zinc	M	0.27	0.50
	F	0.18	0.31
Magnesium	M	4.4	8.4
	F	2.3	5.0

From Forbes, GS. Nutritional requirements in adolescence. In: Suskind RVI, ed. Textbook of pediatric nutrition. New York: Raven Press, 1981, with permission.

Table 52.3 Daily Increments in Body Content Due to Growth

The amount of calcium absorbed from different dietary sources varies. During peak periods of growth in adolescence, the average calcium retention is approximately 300

mg/day. Because the lower range of absorption is approximately 30%, a minimum of 900 mg/day of calcium would be necessary during active skeletal growth (32).

A wide difference exists in the daily allowances of calcium recommended by two expert committees. The WHO recommends intakes of 600 to 700 mg/day for 11- to 15-year-old adolescents and 500 to 600 mg/day for 16- to 19-year-old adolescents (30). The National Institutes of Health Consensus Conference recommended 1200 to 1500 mg/day for adolescents and young adults (11–24 years) (33). The Food and Nutrition Board's 1997 dietary reference intake value for ages 9 through 18 years is 1300 mg/day (33a) (see Appendix [Table II-A-2-b-1](#); see also [Chapter 7](#)). These differences in recommended intakes show that the amounts of dietary calcium needed to sustain growth and to provide maintenance require further study.

Establishing requirements for the teenage group is difficult because many individuals can achieve equilibrium on a wide range of dietary intakes. A large error is likely in calculating calcium balance because of errors in measuring intakes and excretions, individual differences in rate of biologic maturation; and effects on calcium metabolism of protein, vitamin D, phosphorus, fiber (31), caffeine, and sucrose (32).

Surveys in the United States reveal that adolescent girls are less likely to meet the recommended levels of calcium than are teenage boys (15, 16, 23). In addition, preliminary evidence suggests that adolescent females may need more calcium to reach optimal bone mass. In a recent study, 1500 mg/day of calcium was needed for maximal calcium retention in a small group of 14-year-old girls (34).

Data from retrospective studies indicate that low calcium intakes during adolescence are associated with lower bone densities in women (35, 36). In a recent study, bone density was correlated with calcium intake in a group of boys and girls 2 to 16 years of age. Those ingesting more than 1000 mg/day of calcium had greater bone density than those ingesting less. Most serum determinations of calcium, phosphate, magnesium, alkaline phosphate, parathyroid hormone, 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D levels were normal and not correlated with bone mineral status (37). Decreased bone density may increase the risk of osteoporosis in later life (38, 39). Teen mothers who breast-feed may also be at risk for poor calcium balance. Lactating adolescents who consumed about 900 mg/day of calcium had a 10% decline in bone mineral content. Lactating teen mothers who consumed 1600 mg of calcium remained in calcium balance (40).

Iron

Iron deficiency is found in all races, both sexes, and all socioeconomic groups (see [Chapter 10](#) and [Chapter 88](#)). Teenagers require additional iron to synthesize substantial amounts of new myoglobin and hemoglobin. As puberty is initiated, boys accumulate more lean body mass than girls. In fact, at the end of puberty, boys have twice the lean body mass of girls. Thus, Hepner calculated that for each additional kilogram of added tissue, males require 42 mg iron/kg body weight, compared with 31 mg iron/kg body weight for girls (41). In addition to the described sex differences, the normal biologic differences in body size make a tremendous difference in iron requirements. For

example, a boy in the 97th percentile for body weight requires twice as much iron as a boy in the 3rd percentile.

Dietary intake of iron must suffice to account for losses in feces, urine, skin, and menstruation, as well as to provide for expansion of red cell volume and for tissue growth in adolescence. The NRC recommends an additional 2 mg/day for males during the pubertal growth spurt (between ages 10 and 17 years), for a total of 12 mg/day of iron (5). With menarche, the adolescent girl has additional iron loss from menstruation. The NRC recommends an additional 5 mg/day for females, starting with the pubertal growth spurt and menstruation, which begins at approximately 11 to 14 years. The iron recommendation for adolescent females is 15 mg/day (5).

In a comprehensive review of iron requirements, Bowering et al. could find only one report on a controlled study with adolescents (42). In the iron balance study of six adolescent girls, Schlaphoff and Johnson found that 0.62 to 1.82 mg/day (mean, 1.0 mg/day) was retained, which included iron required to replace menstrual losses (43). Assuming a rate of 10% absorption, they recommended a daily intake of 12 to 13 mg iron. Similar balance data are not available for boys. Finally, the amount of iron available in the American diet is estimated at 6 mg/1000 calories. Therefore, teenage girls whose caloric intake varies between 2000 and 2400 calories may find it difficult to ingest 15 mg of iron from dietary sources alone. Bioavailability of dietary iron is critical in iron nutrition. Diets high in lean meat and ascorbic acid and low in phytate cover the iron requirements of most nonpregnant women (44).

In the Ten State Nutrition Survey, between 5 and 10% of teenagers had hemoglobin or hematocrit levels below normal (15). Analysis of data from the Health and Nutrition Examination Survey (HANES) II showed the highest prevalence of impaired iron status (ferritin model) was in teenagers—14.2% of the 15- to 19-year-old females and 12.1% of the 11- to 14-year-old males (45). The results of other studies vary (46, 47), generally reporting more iron deficiency than iron deficiency anemia in adolescents.

Results of several large surveys—the Ten State Nutrition Survey (48), the HANES I (47), and the HANES II (49)—have shown a racial difference in hemoglobin level in adolescents. Blacks have approximately 1 g less hemoglobin than whites, which apparently is unrelated to socioeconomic level, education, diet, or obesity (50). These differences have led many authors to recommend race-specific standards in screening for anemia (48, 51, 52, 53, 54 and 55). Although use of different standards for hemoglobin concentration has been proposed, the biochemical basis for the racial difference in hemoglobin is unknown. The factors affecting hemoglobin differences, including genetic, socioeconomic, and dietary, are complex. At the present time, no data indicate that iron needs of black and white adolescents are different. Clearly, the standards for “normal” values used in any study determine the amount of iron deficiency or anemia in any population. Measurements of hematocrit and hemoglobin, the most widely used screening procedures for anemia, are relatively insensitive indicators. The diagnosis of iron deficiency can be made by using the serum ferritin level, which provides the most accurate assessment of iron stores. The true nature of iron deficiency anemia in adolescents awaits more sophisticated studies.

Adolescent athletes may be at risk of iron deficiency caused by red blood cell destruction, increased need for red blood cell and tissue synthesis during puberty, or poor dietary intake (53, 54). Many (34–44%) teenage female runners have been found to be iron deficient, as assessed by low iron stores (53, 54). This deficiency is associated with abnormal gastrointestinal bleeding (54).

Sports anemia may also be common; increased destruction of erythrocytes and a transient drop in hemoglobin concentration in the adolescent athlete results from an acute stress-response to exercise training. However, because the causes and treatments of sports anemia remain controversial, no basis currently exists for recommending iron supplementation for this transient condition (55, 56).

Zinc

Zinc affects protein synthesis and is essential for growth. Zinc is particularly important in adolescence because of the rapid rate of growth and sexual maturation. Table 52.3 reveals that during the adolescent growth spurt, zinc retention in both males and females is much higher than the average for the adolescent period. This striking increase in zinc retention is related to the increase of lean body mass during this period (57).

The 1989 RDAs (5) reduced the daily zinc intake to 12 mg for adolescent females on the basis of their lower body weight. The recommendation for males remained at 15 mg/day.

Zinc deficiency has been associated with growth retardation and hypogonadism in adolescents (58, 59); zinc supplementation resulted in accelerated growth and sexual maturation (58, 60). Poor dietary zinc sources and inhibition of zinc absorption by phytates in high-cereal diets contributed to the evolution of zinc deficiency and were major factors in growth retardation and delayed sexual maturation (59).

Evidence that adolescents undergoing rapid growth may be highly susceptible to inadequate dietary zinc is provided by Butrimovitz and Purdy (61). These investigators found low plasma zinc concentrations during infancy and puberty, both periods of rapid growth. For adolescent girls and boys, plasma zinc levels were lowest at the ages when puberty was expected to occur.

Mild zinc deficiency has been reported in the United States. Hambidge et al. studied zinc status in apparently healthy children in Denver and found an association between low growth percentiles, diminished taste acuity, and low hair zinc levels (62). Apparently, marginal zinc status may be a health problem in American children. Adolescents undergoing rapid growth are at risk for inadequate zinc levels. Young pregnant teenagers may be particularly susceptible to zinc deficiency, because of the rapid cell division and growth of the developing fetus as well as continued growth of the biologically immature teenager. These teenagers should be encouraged to include such zinc-rich foods in their daily intake as poultry, lean meats, lowfat and nonfat dairy

products, legumes, and grain products, particularly whole grains (63).

Vitamins

Data on vitamin requirements for adolescents are even more limited than those for mineral requirements. The vitamin requirements for youth are interpolated from data on infant and adult allowances; few data are derived directly from studies on adolescents. Emphasis should be placed on vitamins necessary for the additional nutrient requirements of the pubertal growth spurt.

Vitamin A is required for vision, growth, cellular differentiation and proliferation, reproduction, and immune system integrity. Vitamin A levels and intake in adolescents are considerably below the recommended amount (15, 16, 64, 65). Vitamin D is involved in maintaining homeostasis of calcium and phosphorus in the mineralization of bone. No controlled studies exist on vitamin D requirements for adolescents.

Vitamin C is essential for collagen synthesis, and intakes in adolescents are often below the recommended levels (66, 67). Added to the unknown demands of growth and changes in vitamin C status because of smoking (68, 69) and oral contraceptive use (70), some teenagers may have problems with vitamin C adequacy.

Because of its role in DNA synthesis, folate is important during periods of increased cell replication and growth. Folate status may be at risk in some adolescents, particularly those from low-income populations (71) and pregnant teenagers (72). The recent association of folate deficiency with neurotubal defects emphasizes the importance of adequate folate intake in teenage girls (73). The FDA has recently mandated fortification of standard enriched grain products with folate. Dietary intakes and serum folate levels have indicated poor folate status in adolescent girls (74, 75 and 76) and boys (76).

Adolescents appear to have increased need for vitamin B₁₂, which is required for rapid cell growth, particularly during the growth spurt. Vitamin B₆ is involved in a large number of enzyme systems associated with nitrogen metabolism. The rapid growth of muscle mass, particularly in boys, makes vitamin B₆ adequacy important during puberty. Riboflavin, niacin, and thiamin are involved in energy metabolism and thus are also important during puberty.

SPECIAL NUTRITIONAL PROBLEMS

Effect of Nutrition during Adolescence on Adult Morbidity and Mortality

Prospective studies of adults who are overweight or obese generally show increased morbidity and mortality. Does any of the risk in morbidity and mortality result from obesity originating during childhood or adolescence? (For discussion of adolescent obesity see [Chapter 63](#).) Or does the risk result from adult obesity? What about thinness during the juvenile period as a predictor of disease or increased mortality during maturity in adults? Is promotion of growth in height and weight during childhood

and adolescence consistent with optimal adult health? The answers to these questions have significant implications for health professionals advising adolescents on nutritional matters. This discussion only applies to populations in which food supplies are adequate and available.

Many studies associate obesity in adults with increased morbidity and mortality from a variety of clinical disorders. As Bray indicates, cardiovascular disease, hypertension, diabetes mellitus, gallbladder disease, osteoarthritis, and colon cancer are major coconditions seen more frequently in obese adults (77). Bray goes on to say that in adults whose BMI exceeds 30 kg/m², more than 50% of all-cause mortality among those in the United States aged 20 to 74 years can be attributed to overweight.

Until recently, little was known about the effect of overweight during adolescence as a predictor of disease in adults. Subjects from the Harvard Growth Study (1922–1935) were followed for 55 years. They were then classified as overweight or lean. Morbidity and mortality data from this cohort clearly predicted additional health risks for adults who were overweight adolescents compared with those who were lean. The risk of death from all causes and of coronary heart disease is elevated in men who were overweight as adolescents. Men have a higher risk of atherosclerotic cerebrovascular disease and colon cancer. In contrast, in women overweight as adolescents, all cause or cause-specific mortality is not increased in adulthood.

Other studies have shown a risk of increased morbidity from coronary heart disease and atherosclerosis in men and women who were overweight as teenagers. Morbidity from colorectal cancer and gout was elevated in men overweight during adolescence. Arthritis was significantly higher in women who were overweight as adolescents. These risks were strongly predicted by overweight during adolescence, compared with adult-onset obesity (78). This concept is further supported by other long-term studies (79, 80).

There are no population studies on the effect of thinness during adolescence on adult morbidity and mortality. Waaler suggests that the excess morbidity and mortality associated with short stature and low weight may result from poor nutrition during growth (81). The one model that may give clues to the effect of thinness on adult health is anorexia or bulimia. These disorders are most common in adolescent girls when bone growth is at its peak. Once puberty is complete, very little bone growth occurs. Osteopenia is a common complication of anorexia nervosa during adolescence (82). The concern is raised that osteopenia developed by anorectic girls may not be reversible. Thus, osteoporosis may be the eventual outcome of this undernutrition during adolescence. Further research will determine whether this is true.

Brain mass is reduced in anorexia nervosa. Cognitive defects have been described during the acute phase of this disorder. Reduction in brain mass is important as it occurs during brain development. Long-term follow-up is necessary to determine whether these deficits result in significant brain malfunction as an adult.

The state of nutrition during adolescence is important in determining morbidity and mortality during adult life. How much and what kind of food is enough for growth

compatible with optimal adult health? Is maximal growth the same as optimal growth? These important questions must await the results of more research.

Eating Disorders

As mentioned above, two major eating disorders, anorexia nervosa and bulimia (or bulimia nervosa), may pose major problems in adolescence ([83](#), [84](#) and [85](#)) (see also [Chapter 93](#)). Most eating disorder patients develop the problem during adolescence. Some of the psychologic changes in adolescence may make it difficult to distinguish an adolescent with “normal” eating habits from one with an eating disorder. Adolescents may use food as a means of experimenting, gaining control, or establishing themselves as individuals. Dissatisfaction with body weight, fear of obesity (resulting in unhealthy eating behavior), and preoccupation with dieting are common among today's youth, particularly adolescent girls ([86](#), [87](#), [88](#) and [89](#)). Mellin et al. ([90](#)) found a high prevalence of disordered eating, particularly dieting; fear of fatness; and binge eating in a group of middle-class predominantly white girls and adolescents. Additional studies suggest that unhealthy weight-control behaviors occur in adolescents of other ethnic/racial subgroups ([88](#), [91](#)) and in adolescents with chronic illness ([92](#)).

Adolescents with eating disorders should be evaluated and treated by an interdisciplinary team of professionals with expertise in treating adolescents ([93](#), [94](#)). Interdisciplinary treatment should be appropriate for the teenager's developmental needs. Recent findings from a group of over 33,000 adolescents suggest that frequent dieting and eating-disordered behaviors should not be viewed in isolation. These eating-disordered behaviors occur in a broader social context of adolescent health and risk-taking behavior ([95](#)).

Pregnancy

Nutritional care of the pregnant adolescent must consider the health of both mother and infant. Knowledge of the role of nutrients is vital, as is consideration of the principles of adolescent growth and development. Physiologically, the adolescent is at risk if she has not completed her growth ([96](#), [97](#), [98](#) and [99](#)). Individual variability is great, but most growth occurs before menarche. Linear growth in the adolescent female typically is not completed until approximately 4 years after the onset of menarche. Although the rate of growth after menarche has decelerated considerably, growth allowances should still be considered.

Gynecologic age (the difference between chronologic age and age at menarche) can give some indication of physiologic maturity and growth potential. A young adolescent (gynecologic age, 2 years or less) who becomes pregnant may still be growing. Her own needs for growth and development, along with the extra demands of fetal growth, make the nutrient requirements of this young teen higher than those of a pregnant adult ([96](#), [100](#)) (see also [Chapter 50](#)).

The few studies that have focused on the energy needs of pregnant teenagers generally report that the teenagers frequently do not achieve the caloric intake recommended by the NRC ([5](#)). Naeye hypothesized that optimal weight gains for fetal survival may be

higher in young teenagers because mother and infant compete for nutrients (101). Recent findings appear to support such a competition (102, 103 and 104). Results of further studies (104, 105, 106, 107 and 108) suggest that optimal weight gains for adolescents during pregnancy, particularly for girls who are biologically immature (104), are greater than the adult recommendations.

The Institute of Medicine (109) recommends (by prepregnancy weight-for-height) that young adolescents strive for weight gains at the upper end of the ranges suggested for adults. Young adolescents (<2 years postmenarche) may deliver smaller infants for a given weight gain than do older women (109, 110). Inadequate weight gain during pregnancy has been associated with low-birth-weight infants (111) and preterm delivery in pregnant teens (112). Inadequate weight gain during early stages of adolescent pregnancy was associated with significant deficits in infant birth weight and increased risk of low-birth-weight and small-for-gestational-age infants (112, 113 and 114).

Recent studies have found that adolescents deliver a disproportionate number of very low birth weight infants (115) and low-birth-weight infants, compared with adult mothers (116). In addition, low-birth-weight infants of teen mothers were associated with higher neonatal mortality (116). Teenagers who smoke may be at increased risk of low prenatal weight gain and reduced infant birth weight (107, 117).

Preliminary data from our research using anthropometric measurements as predictors of low-birth-weight outcome in pregnant teenagers suggest that mothers of low-birth-weight infants tend to exhibit prenatal depletion of fat reserves (estimated from triceps skinfold measurements and from calculating arm fat area), while mothers of normal-birth-weight infants accumulate fat (118). In addition, prenatal protein stores of mothers of low-birth-weight infants changed little, whereas mothers delivering normal-birth-weight infants gained protein stores (estimated from midarm circumference measurements and arm muscle area calculations). Scholl et al. (104) found that despite weight gain and accumulation of fat stores during pregnancy, growing adolescents delivered infants with lower birth weights than those of nongrowing teenagers and adult women. Estimates of energy requirements indicate that sedentary adolescents needed at least 2400 to 2600 kcal/day. Physically active or rapidly growing adolescents needed additional energy, perhaps 50 kcal/kg pregnant body weight/day (119).

The issue of protein requirements for the pregnant adolescent is complex. Using careful nitrogen balance studies on pregnant teenagers, King et al. presented the best experimental data on which to base protein recommendations (120). Their data suggested greater nitrogen retention than was previously reported. In addition, maternal lean tissue of these adolescents increased during pregnancy, particularly during the last half of pregnancy.

Iron deficiency anemia in pregnancy has been associated with increased risk of preterm delivery and low birth weight (121, 122 and 123). The recommended intake of iron for pregnant adolescents is 30 mg/day, which is twice the recommendation for the nonpregnant teenage girl (5).

Zinc metabolism is an important consideration during pregnancy. Data from a study of a

small group of teenagers (124) are consistent with results of studies in adults, indicating that prenatal iron supplementation impairs zinc retention. However, these adolescents did not show lower serum zinc concentrations during the second and third trimesters, as observed in adults, implying differences in zinc metabolism between adolescent and adult pregnancy (124). Prenatal zinc supplementation in low-income teenagers was associated with improved pregnancy outcome and reduced numbers of premature births, compared with a placebo group (125).

On the basis of recent data, it appears pregnant teenagers, particularly those who may still be in their own growth phase, do have increased needs for nutrients during pregnancy. The pregnant adolescent needs an additional 300 calories and 14 to 16 more grams of protein daily, which can be supplied by addition of foods such as those shown on Table 52.4 (126).

Food	Calories	Protein (g)
Cereal (1 c), low-fat milk (8 oz), banana	330	
Peanut butter (2 tbsp) sandwich	320	
Cheese (2.5 oz) and 4 saltine crackers	320	
Cheeseburger (regular)	300	
Pizza, pepperoni (1/8 of 12" pizza)	160	
Baked or refried beans (1 c)		16
Meat or poultry (2 oz)		15
Peanut butter (2 tbsp) sandwich		13
Pizza, pepperoni (1/8 of 12" pizza)		10
Spaghetti with meat sauce (1 c)		12
Milk (12 oz)		12
Macaroni and cheese (3/4 c)		11

Table 52.4 Foods to Increase Calories and Protein for the Pregnant Adolescent

Vegetarian Diets

During a time of increased independence and decision making and greater influence by peers and role models, adolescents may use food as part of the process of individuation. Because nutritional needs are high, vegetarian teenagers may be particularly at risk for nutritional deficiencies, especially at the time of the growth spurt (see also Chapter 106).

Growing adolescents who are vegetarians may have problems meeting their energy requirements because of the high-bulk content of vegetarian food patterns. In addition, vegetarian diets that are low in animal products are low in fat content (127, 128). Without sufficient energy intake, protein is used as an energy source and thus is unavailable for tissue synthesis and growth. Hence, protein quality, protein quantity, and energy intake of the individual must be assessed. Other nutrients of concern for the teenage vegetarian, particularly the strict vegetarian (who excludes all foods of animal

origin), include calcium, iron, zinc, and vitamins D and B₁₂ ([127](#), [128](#), [129](#), [130](#) and [131](#)).

Conscious effort and careful planning are necessary to ensure adequacy of these nutrients. Supplements may be necessary to meet the recommended allowances. The vegetarian should carefully plan a diet from a variety of foods. Protein complementation (combining different plant foods so that low essential amino acids from one protein source are complemented by essential amino acids from another protein source, resulting in a complete protein) can ensure that the qualitative aspects of protein adequacy are met. Evaluation of the quantitative aspects of protein adequacy of the vegetarian is also necessary. The RDA for total protein intake during adolescence ranges from 44 to 59 g/day ([5](#)), providing energy requirements are met.

Vegetarian adolescents can generally meet their nutritional requirements for growth if they consume well-planned diets ([129](#), [132](#)). Vegetarian food guides for adolescents are available in such sources as reports by Marino and King ([133](#)), the University of California's *Creative Eater's Handbook* ([134](#)), Messina and Messina ([130](#)), and Johnston and Haddad ([135](#)). Haddad has developed daily dietary patterns for vegetarians at three different energy levels ([136](#)).

[Selected Readings](#)

Currently, 25 million Americans are over the age of 65; by the year 2030, 57 million will be 65 or older. The increasing numbers of elderly and aged, especially in Western societies, present challenges to those concerned with their physical and emotional well-being. An understanding of the role of both early and later nutrition in slowing or modulating the aging process and in providing adequate nutrition for the elderly is important. Further, nutrient needs may change with aging, and the interaction of drugs and nutrients may play a major role in the nutrient needs of some elderly persons. A thorough and comprehensive review of all aspects of nutrition, aging, and the elderly can be found in the work of Munro and Danford (1).

THEORIES OF AGING

Aging is a gradual process taking place over many decades. Most theories of aging relate to impaired DNA replication and loss of viability of the cell and hence of the body's organs. The most common theories of aging relate to one or more of the following: immunologic breakdown, cellular proliferation, basal metabolic rate, rate of DNA repair, free radical damage, and/or rate of protein synthesis and catabolism. One classification of general theories of aging is shown in [Table 53.1](#).

Cellular

Free radical damage
Glycosylation and other cross-links
Changes in DNA or chromatin
Decreased accuracy or quantity of protein synthesis
Limited cell division capacity ("Hayflick limit")
Decreased DNA repair activity

Organ systems

Role of immune phenomena
Role of neuroendocrine phenomena

Population

Theories associating aging with differentiation or growth cessation
Rate of living
Theories based on the evolution of life span in mammals

Adapted from Weindruch RH, Walford RL. The retardation of aging and disease by dietary restriction. Springfield, IL: Charles C Thomas, 1988.

Table 53.1 Selected Theories of Aging

Dietary Restriction Experiments with Animal Models

Animal studies yield the strongest evidence that diet plays a major role in longevity and the aging process (2). The most consistent finding from experimental rodent studies is that moderate dietary restriction markedly extends the life span of experimental animals, compared with control animals fed ad libitum. Dietary restriction also decreases the incidence of several chronic diseases such as glomerulonephritis, atherosclerosis, and tumors.

Dietary restriction by selective removal of individual macronutrients (fat, carbohydrate, or protein) has also been carried out. However, without a concomitant decrease in energy intake, little extension of life span has been found. Dietary excess of protein or fat, however, (a) increases the incidence of tumors and certain organ pathologies and (b) shortens the time of appearance of several physical, biochemical, and immunologic indices of early maturational development and aging.

The severity, age of initiation, and duration of the dietary perturbation are important in determining the eventual response to the dietary restriction. Many other factors, including the species and strain of laboratory animal used, are important variables in determining the outcome of these experiments. Individual micronutrients also have effects on life span and modulate the mechanisms of aging, at least to some extent. For example, increased levels of dietary antioxidants (ascorbic acid, α -tocopherol, carotenoids) may partially decrease cellular free-radical concentrations (3). It is yet unclear whether any of these changes are related to the mechanism of aging.

FACTORS AFFECTING NUTRITIONAL STATUS

The elderly are a more diverse population than any other age group; individuals have widely varying capabilities and levels of functioning. On the whole, elderly persons are more likely than younger adults to be in marginal nutritional health and thus to be at

higher risk for frank nutritional deficiency in times of stress or health care problems. Physical, social, and emotional problems may interfere with appetite or affect the ability to purchase, prepare, and consume an adequate diet (4). These factors include whether or not a person lives alone, how many daily meals are eaten, who does the cooking and shopping and any physical impediments that would make this impossible, problems in chewing and denture use, adequate income to purchase appropriate foods, and alcohol and medication use.

NUTRITIONAL REQUIREMENTS

A decline in organ function normally accompanies the aging process, especially in the older elderly (i.e., those above 80 years old). Many of these changes in normal function might reasonably be expected to influence nutrient needs of the individual (5, 6 and 7) (Table 53.2).

Organ Function	Physical Change	Importance to Nutrition
Taste and smell	Lower taste buds and papillae on tongue Decrease in taste and olfactory nerve endings Change in taste and smell threshold	Loss of ability to detect salt and sweet Decreased palatability causing poor food intake
Saliva secretion	Saliva flow may be reduced	Dietary/clinical significance
Esophageal function and swallowing	Minor changes including shortened esophagus	Dietary/clinical significance
Gastric function and emptying	Decreased secretion of hydrochloric acid, intrinsic factor, and pepsin in 25% of healthy population Jitteriness of age atrophic gastritis Rapid rate of emptying of liquids; increased pH in the proximal small bowel; bacterial overgrowth in bowel	Decreased bioavailability of minerals, vitamins, and proteins Decreased absorption of protein-bound vitamins B ₁₂ and folic acid Increase in bacterial flora synthesis to counteract malabsorption
Intestinal and biliary function	Decreased size and blood flow Minor structural and biochemical changes Activity of drug-metabolizing enzymes reduced	Rate of albumin synthesis may be decreased Drug dosages may need to be lower
Pancreatic secretion	Slightly lower lipase and amylase outputs	Dietary/clinical significance
Intestinal morphology and function	Significant changes in small bowel morphology	Dietary/clinical significance
Intestinal microflora	Bacterial overgrowth in proximal small bowel in atrophic gastritis	Functional significance unknown; influences supply of water-soluble vitamins and minerals

Table 53.2 Changes in Organ Function with Aging That May Influence Nutrient Status

Energy

Several studies have documented decreased energy needs in the elderly. In the Baltimore Longitudinal Study of Aging, energy intakes of a sample of males decreased from 11.3 MJ (2700 kcal) per day at age 30 years to 8.8 MJ (2100 kcal) per day for those about 80 years. Two-thirds of this reduction was attributable to decreased physical activity, and the remainder to decreased basal metabolism (8). These findings have generally been supported by other studies. In NHANES III (preliminary), young men and women, aged 20 to 29, consumed 12.6 and 8.2 MJ (3025 and 1957 kcal), whereas men and women aged 50 to 59 consumed 9.8 and 6.8 MJ (2341 and 1629 kcal), and those 80+ consumed 7.4 and 5.6 MJ (1776 and 1329 kcal), respectively.

The recommended energy intake from the 1989 *Recommended Dietary Allowances* (RDAs) is 9.6 MJ (2300 kcal) for the reference 77-kg elderly male and 7.9 MJ (1900

kcal) for the reference 65-kg female 51 years of age and older (9), both similar to the mean energy intake of the 50- to 59-year-old age group (see Appendix [Table II-A-2-a-1](#)). The RDAs and estimated intakes based on population studies both appear to underestimate total energy expenditure (TEE) for men, derived from using the excretion of administered $^2\text{H}_2^{18}$ to estimate the usual energy consumption of healthy elderly people. The TEE for men, aged 68 years, was 11.3 MJ (2700 kcal) (10) and for women, aged 74 years, was 7.6 MJ (1800 kcal) (11). The discrepancy between the RDA and the TEE for men could suggest that the small group studied in the TEE experiment was not an accurate subsample of the total population or that individuals actually are consuming more than they record. In either case, this higher TEE is not a recommendation for elderly men to consume more calories.

Protein

High-protein diets may be less well digested and absorbed in the elderly, judged by a minor increase in fecal nitrogen content in response to a protein load (12). However, little quantitative information is available regarding absorptive changes in the elderly for amino acids and peptides in more usual amounts.

The current RDA for protein (0.8 g/kg/day) is adequate for the elderly when excessive energy intakes are observed (i.e., 3167 kJ (40 kcal/kg) per day) (13) (see Appendix [Table II-A-2-a-2](#)). However, when an energy intake more usual for the elderly is used (e.g., 125 kJ (30 kcal/kg) per day), nitrogen balance is not attained in more than half of elderly subjects (14). The degree of adaptation of the individual to the lower energy or lower protein intake before the actual experimental trial began may account for many of the discrepancies in nitrogen needs reported in the literature (15). Furthermore, whereas 0.92 g/kg/day was needed to maintain nitrogen balance and tissue protein stores in sedentary elderly persons (16), possibly less suffices if resistance training is part of the daily routine (17). The average protein consumption among free-living elderly persons in Boston was 1.05 g/kg/day in one study, with no evidence that lower intakes were correlated with protein-energy malnutrition (18). On the whole, a daily intake of 1 g/kg (and probably less) meets the needs of this population (1).

Carbohydrate

Carbohydrate absorption (mannitol, xylose, 3-O-methyl glucose) may be slightly impaired with advanced aging, although decreased renal function may interfere with interpretation of “absorption” test results based on urinary excretion (19, 20 and 21). In one study in elderly persons 65 to 89 years of age, breath hydrogen was measured in response to a 100- to 200-g carbohydrate challenge to estimate carbohydrate malabsorption (22). At the highest carbohydrate load, 80% had increased breath hydrogen. The increased breath hydrogen found in most elderly persons could result from carbohydrate malabsorption with age, increased bacterial enzyme activity in the small bowel, or both. Lactase activity decreases with age (especially in early life), but other brush border hydrolase activities appear to remain fairly constant (23 and 24). The diminished lactase activity with age may create only a minor problem because most lactose-intolerant individuals can tolerate the lactose present (12.5 g) in a glass of milk (25). Furthermore, in a double-blind study of healthy elderly persons given either

lactose-containing or lactose-free products, about 30% of both groups showed bloating and discomfort associated with lactose intolerance. Although the elderly tend to avoid consumption of milk products (which are excellent sources of riboflavin, vitamin D, and calcium), the perceived bloating and discomfort may not be due to lactose intolerance. Therefore, the true prevalence of lactose intolerance in the elderly is difficult to define.

There is no RDA for dietary carbohydrate. However, the United States Department of Agriculture (USDA), American Heart Association, and American Cancer Society, among others, recommend a dietary carbohydrate component of 55 to 60% of calories, with an increase in the proportion of complex carbohydrates to simple sugars.

Fat

Fat digestion and absorption in the elderly is equivalent to that of young adults when measured at normal consumption levels (100 g) ([21](#), [22](#), [23](#), [24](#), [25](#) and [26](#)). At higher dietary levels (120 g/day), the elderly showed slightly less fat absorption than did the young adults ([11](#)), and institutionalized elderly persons may absorb even less ([27](#)). Although not too common, fat malabsorption in the elderly, when found, is most often due to bacterial overgrowth of the small intestine, causing deconjugation of bile salts. However, most bacterial overgrowth in hypochlorhydric subjects is not associated with clinical malabsorption of fat or carbohydrate, despite the presence of positive indicators such as abnormal ¹⁴[C]-D-xylose absorption ([28](#)). Chylomicron appearance in blood after a 100-g fat meal is somewhat slower in elderly persons than in young adults; however, an observed difference in gastric emptying times might explain this apparently slower lipid hydrolysis and uptake ([29](#)).

There is no RDA for total fat. However, it is widely felt that a prudent diet with 30% or less of calories as fat (less than 10% saturated, 10 to 15% monounsaturated, and no more than 10% polyunsaturated fatty acids) may be just as important in the elderly as in young adults for preventing or ameliorating chronic diseases such as heart disease or cancer. At the same time, these amounts of polyunsaturated fat are consistent with a diet providing adequate amounts of essential fatty acids (linoleic and linolenic acid) ([9](#)).

Fiber

Little is known about dietary fiber requirements of either adults or elderly persons. However, the various classes of dietary fiber (see [Chapter 43](#)) found in a mixed diet have different mechanical and metabolic effects in the gastrointestinal tract. In population studies, increased consumption of dietary fiber is correlated with decreased rates of heart disease and cancer. Fiber is also included in a treatment regimen for a variety of diseases that particularly affect the elderly—constipation, hemorrhoids, diverticulosis, hiatal hernia, varicose veins, diabetes mellitus, hyperlipidemia, and obesity ([30](#)). Without evidence to the contrary, recommendations for fiber consumption for the elderly would be the same as for the adult, about 25 g/day, the recommended “Daily Value” on the new food label.

Fluid

Fluid balance is as important in the elderly as in other age groups. Nevertheless, it deserves particular attention because dehydration often goes unrecognized in the elderly. Indeed, a recent study indicated that dehydration was responsible for 6.7% of hospitalizations (31). Poor fluid balance may be due to both inadequate (lower than normal) intake and excessive losses (32). Chronically ill, immobilized, or demented patients and those with bladder control problems often fail to drink sufficient fluids. On the other hand, several clinical conditions such as fever, diarrhea, malabsorption, vomiting, and hemorrhage lead to excessive losses. Therapy with certain diuretics and laxative or hypertonic intravenous solutions also contribute to the problem. In the absence of severe clinical problems, consumption of 30 mL/kg/day is probably sufficient for the elderly.

Vitamins

Low-to-inadequate dietary intake may account for much of the poor vitamin nutriture observed in the elderly (33). In addition, physiologic changes associated with the aging gut may increase or decrease vitamin absorption, thereby influencing total dietary vitamin requirements. Table 53.3 lists the major water- and fat-soluble vitamins, the current RDA (Appendix Table II-A-2-a-2) or “safe and adequate daily dietary intake” (Appendix Table II-A-2-a-3), and an assessment of whether or not the current recommendation is appropriate for the elderly. Individual vitamins are discussed below.

Vitamin	Current RDA for Age 0-17 ¹	Adequacy of RDA for Elderly	Physiologic Reason for Change
Vitamin A	500-1000 µg RAE	May be too high	Change in unesterified retinol may lead to increased absorption in elderly; decreased uptake by the liver if needs decreased vitamin A
Vitamin B ₁	0.8 mg	Is too low	Lack of raw vegetables, decreased number of intestinal vitamin B ₁ receptors, reduced vitamin B ₁ absorption, reduced vitamin B ₁ synthesis in skin and ingested water. The Nutrition Foundation suggests that the dietary requirement might be higher
Vitamin B ₂	0.8-1.0 mg	PC: Adeq ²	—
Vitamin B ₆	0.5-1.0 mg	PC: Adeq ²	—
Folate	0.4 mg	Adequate	—
Vitamin B ₁₂	2.4 µg	Is too low	Some hematopoietic levels rise when dietary vitamin B ₁₂ is less than 2.0 mg/day and poor response to B ₁₂ supplements in normal weight suggests altered absorption or metabolism
Vitamin C	75-90 mg	PC: Adeq ²	—
Vitamin E	10-15 mg	Is too low	Some hematopoietic levels rise when dietary intake is less than 100 µg/day
Vitamin K	80 µg	Adequate	—
Biotin	30-100 µg ³	PC: Adeq ²	—
Panthenolamide	4-7 mg	PC: Adeq ²	—

³Estimated safe and adequate daily intake.

Table 53.3 Estimate of Adequacy of 1989 RDA for Vitamins for the Elderly

Thiamin. The 1989 RDA for the elderly for thiamin is 1.2 mg/day for males and 1.0 mg/day for females. When corrected for caloric consumption, intake should not decrease below 0.5 mg/1000 kcal. The NHANES I, II, and III (preliminary) data indicate that the mean intake for the 65- to 75-year-old age group was above this amount. Aging

appears to be associated with an increased erythrocyte transketolase-activation coefficient in a small percentage of normal, free-living elderly persons (34). It is not known whether this increase is normal for aging or represents nutritional inadequacy. There are no consistent changes in absorption of thiamin with age (35 and 36). Thiamin deficiency in the elderly is largely due to alcoholism accompanied by low thiamin intake. However, the RDA for thiamin appears to cover the needs of most well elderly persons.

Riboflavin. The 1989 RDA for riboflavin for the elderly is 1.4 and 1.2 mg/day for males and females, respectively. Deficiency of the vitamin as diagnosed by increased erythrocyte glutathione reductase activity coefficient (37 and 38) or decreased urinary riboflavin excretion (33) has been most often associated with low dietary intake of riboflavin. Little evidence exists for altered absorption of the vitamin (39) or for altered tissue concentration with age (40). However, Boisvert et al. (41) recently demonstrated that the riboflavin requirement for a group of elderly people does not differ from that previously reported for younger adults (42). Therefore, current RDAs are generous for the elderly.

Ascorbic Acid. The current 1989 RDA for vitamin C is 60 mg/day for both sexes. Although the vitamin is widely abundant in many foods, intakes in the elderly vary widely. Factors such as smoking, medications, and emotional and environmental stress all adversely affect vitamin C nutriture (9, 43). Leukocyte and plasma vitamin C levels decline with age, although the significance of this is unclear (33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49 and 50). Maintenance of the plasma level at 1.0 mg/dL would require 75 mg/day for females and 150 mg/day for males (45); however, there is no evidence that saturating the body pool is advantageous for this age group. Changes in tissue concentration with age are not consistent, and there is little evidence that vitamin C absorption changes with aging (44, 46). There is no compelling evidence that vitamin C requirements per se change with age. However, evidence is accumulating that vitamin C in amounts above the RDA protects against cataract formation (47).

Niacin. The 1989 RDA for niacin is the same as for young adults, 15 mg/day for males and 13 mg/day for females. Individuals with low excretion of urinary *N*-methyl nicotinamide usually have a poor niacin intake or are very sick or very old (86 to 99 years) (38); in the latter case, decreased renal function should be considered. Little if any evidence indicates that niacin requirements change with age (33).

Vitamin B₆. Because the vitamin B₆ content of many foods is not known, dietary intakes calculated from food composition tables vary widely and may be low. Nevertheless, serum and plasma B₆ levels in the elderly tend to decrease with age. Studies indicating poor B₆ nutriture based on activity coefficient tests (response of whole blood B₆ enzymes to exogenous B₆ supplementation) show that with moderate oral supplementation, activity coefficients in some elderly persons still do not return to normal. The current RDA for vitamin B₆ in the elderly is 2.0 mg/day for men and 1.6 mg/day for women. However, the average requirement (without addition of 2 S.D. to ensure adequacy for most of the population) in both male and female elderly persons was recently shown to be about 2.0 mg/day (48). Further, in those above 67 years old,

Selhub et al. showed that serum homocysteine levels rise when dietary vitamin B₆ drops below 2.0 mg/day (49). Therefore, the RDA for vitamin B₆ should be considerably higher in the elderly.

Folate. Despite low folate intake levels, only 3 to 7% of persons in NHANES I (50) or free-living elderly persons have low serum folate levels (i.e., <3.0 ng/mL). In a Swedish study of 35 elderly subjects (51), intake of only 100 to 200 µg/day normalized whole-blood folate concentrations. Furthermore, although atrophic gastritis with aging causes malabsorption of folic acid due to a rise in pH of the proximal gastrointestinal tract, this is more than offset by the production and subsequent absorption of folate synthesized by bacterial overgrowth in the proximal small bowel (52). The current RDA in the elderly is 200 µg/day for men and 180 µg/day for women. Serum homocysteine levels increase, however, when dietary folate drops below 400 µg/day (49). The reliability of the data on food folate content, however, has been questioned by Beecher and Matthews, who stress a need for development of alternative methods of measuring folate in foods (53). Given the uncertainties of food folate data and the emerging relevance of homocysteine as a marker for coronary artery and cerebral vascular disease, the current RDA for folate may be too low for elderly persons.

Vitamin B₁₂. Serum or plasma vitamin B₁₂ levels in the elderly are often found to be low because of decreased body reserves (54 and 55). Low intake, especially among the poor, and impaired absorption of vitamin B₁₂ may be important factors. Decreased digestive release of vitamin B₁₂ from food and bacterial overgrowth in the small bowel (as found in atrophic gastritis) leading to competition for vitamin B₁₂ seem important in reducing absorption (56). Atrophic gastritis per se, however, is not associated with significantly decreased production of intrinsic factor. The current RDA of 2.0 µg/day is sufficient for elderly persons without atrophic gastritis but may be too low for those with atrophic gastritis.

Vitamin A. Although vitamin A is not distributed widely in foods, excess daily amounts can be stored in the liver. Most individuals consume food rich in vitamin A one or two times per week. Estimates of vitamin A intakes derived from 24-hour recalls overestimate the number of individuals having low intakes.

After a dose of vitamin A, plasma retinyl ester values in the elderly remain higher than in young adults because of reduced clearance of the lipid-rich lipoproteins carrying the retinyl esters in the elderly (57 and 58). A change in the character of the luminal epithelium or a decrease in the thickness or character of the unstirred water layer, as demonstrated in elderly rats, might increase absorption. In addition, provitamin A carotenoids (e.g., b-carotene, a-carotene, cryptoxanthin) are also a source of vitamin A. Although still an unresolved question, these compounds, consumed as part of the daily diet, may help prevent cancer and cardiovascular disease. Therefore, although the need for preformed vitamin A may be lower for the elderly, it would be prudent to obtain a large fraction of the vitamin A requirement from carotene-containing fruits and vegetables.

Vitamin D. Because vitamin D is found in only a few foods, including seafood and

fortified milk products, it is not surprising that over three-quarters of elderly persons have vitamin D intakes less than two-thirds of the RDA. The contribution of sunlight to the vitamin D status of the elderly is also reduced, because they receive less sun exposure and have a decreased efficiency of vitamin D synthesis in the skin (59). The diet may not provide sufficient vitamin D for institutionalized subjects with little access to sunlight (60). Moreover, when given in physiologic amounts, absorption of vitamin D from the gastrointestinal tract is reduced with age, (61) possibly because the number of vitamin D receptors decreases with advancing age (62). Thus, the dietary need for vitamin D may be greater in the elderly than in younger individuals. Supplementation with 10 µg (400 IU) per day (twice the RDA) is recommended for homebound elderly persons or those in nursing homes who are not exposed to sunlight.

In one study, although serum 25-OH-D levels were not decreased in elderly subjects, average 1,25-(OH)₂-D levels were significantly lower in elderly osteoporotic females than in younger females (63), suggesting impaired renal conversion (renal 1-α-hydroxylase) of vitamin D to its active form. 1,25-(OH)₂-D levels were significantly correlated with intestinal calcium absorption.

Changes in bone density have recently been used to determine vitamin D requirements of elderly persons. In one study of postmenopausal women, the experimental group received 400 IU/day of vitamin D, while those on placebo received no extra vitamin D (64). Both groups had an average dietary intake of 100 IU vitamin D. During the winter and early spring season, the placebo-fed group lost considerably more bone mineral density than did the group receiving the 400 IU supplement. This study showed that a total intake of 500 IU resulted in better bone density than only 100 IU, which is consistent with other data showing a greater need for vitamin D in the elderly. The study also illustrates the use of a disease endpoint (osteoporosis) for judging vitamin D adequacy rather than a static serum level of vitamin D.

The 1989 RDA for vitamin D of 5 µg of cholecalciferol has been modified in the 1997 adequate intake reference values to 10 µg for ages 51 through 70 and to 15 µg for older individuals (Appendix [Table II-A-2-b-4](#)).

Vitamin E. As for vitamin C, the antioxidative properties of vitamin E (tocopherol) may help to retard the aging process. The 1989 RDA for the elderly is 10 mg/day for males and 8 mg/day for females. Most populations consume adequate amounts, although in one study, 40% of a free-living population consumed less than 75% of the RDA from the diet alone (65). (Of note, one-third of this population took vitamin E supplements.) Because plasma α-tocopherol is carried passively in the lipid-rich lipoproteins (very low density lipoproteins [VLDLs] and low-density lipoproteins [LDLs]) (66 and 67), it is most accurate to express the vitamin E concentration in relation to blood lipid content (68). When this is done, the plasma vitamin E:lipid ratio is not related to age (69). The data on tissue concentrations (platelets, liver, adrenal glands, heart) of vitamin E with age are inconsistent, and the erythrocyte hemolysis test shows no evidence of increased vitamin E needs with age (33). Finally, there is no evidence for altered vitamin E absorption with aging (67).

Vitamin E given in pharmacologic amounts may have a protective effect against

coronary artery disease due to inhibition of LDL oxidation. However, the doses required for such an effect appear to be well beyond the levels that are possible in a healthful diet. Vitamin E supplementation has also been reported to benefit the immune system (70). However, once again, the doses required are probably higher than can be achieved in a healthful diet. Thus, the present RDAs for vitamin E appear adequate.

Vitamin K. A new method of measuring vitamin K metabolites in plasma has revealed that serum phylloquinone levels vary as a function of gender, age, and serum lipid levels (71). Expressed per millimole of triglyceride, plasma phylloquinone concentrations in the young subjects were 0.82×10^{-6} mmol and in the elderly 0.62×10^{-6} mmol (72). The nutritional significance of this decrease in the elderly is not yet understood. When human volunteers were purposely depleted in vitamin K, elderly subjects appeared more resistant to acute vitamin K deficiency than younger subjects (73). However, the best way to judge vitamin K sufficiency is presently uncertain. Classically, blood coagulation parameters were used, but now, bone carboxylated proteins are measurable. In fact, carboxylation of bone protein may be more susceptible to vitamin K deficiency than are the various coagulation factors (74). Thus, a functional test (carboxylation of vitamin K-dependent protein) may be more useful for defining vitamin K deficiency than static vitamin K levels in serum. The 1989 RDA for vitamin K for the elderly is 80 $\mu\text{g}/\text{day}$ for men and 65 $\mu\text{g}/\text{day}$ for women.

Minerals

Table 53.4 lists current RDAs or safe and adequate daily dietary intakes and an assessment of whether or not the current recommendation is appropriate for elderly persons. Individual minerals are discussed below.

Mineral	Current RDA to Age 50 ^a	Adequacy of RDA for Elderly	Physiologic Reason for Change
Calcium	800 mg	Too low	Absorption decreases with age; calcium balance and improved bone density achieved at higher dietary levels
Iron	18 mg	Adequate	—
Zinc	12–15 mg	Adequate	—
Copper	1.5–2.0 mg ^b	Adequate	—
Selenium	55–70 μg	Adequate	—
Magnesium	280–300 mg	Too high	Efficient renal conservation at low intake levels; markedly low intake levels in elderly do not result in deficiency
Chromium	50–200 μg ^c	Too high	Balance achieved below RDA levels

^aRDA for females only 51–years of age

^bUSDA estimated safe and adequate daily dietary intake (estimated RDI)

Table 53.4 Estimate of Adequacy of 1989 RDA for Minerals for the Elderly

Calcium. Lifetime calcium intake appears to be a factor in the incidence of osteoporosis in the elderly, and laying down sufficient bone in early life is one of the most critical factors protecting against fracture in old age. In both men and women, absorption of

calcium decreases with age (63, 75). Calcium carbonate absorption may also decrease with the achlorhydria observed in some elderly persons (76), although this may be overcome by taking the calcium with a meal (77). One study measured calcium absorption in 94 normal volunteers (aged 30 to 90) and 52 untreated women with postmenopausal osteoporosis (63). Although fractional calcium absorption decreased with age, it was not correlated with calcium intake. The elderly also appear less able than young adults to adapt to a low-calcium diet (78). Poor vitamin D nutriture and activity in the elderly is widely thought to be partially responsible for the decreased calcium absorption.

In the NHANES I and II studies, average calcium intakes for women were about 500 mg/day, below the 1989 RDA of 800 mg/day. NHANES III preliminary data show a slight improvement in calcium intakes in the older age groups, but median intakes are still below the present RDA of 800 mg/day. Studies in Yugoslavia found a greater metacarpal cortical thickness in a population that routinely consumed 1100 mg calcium per day than in a population with a typically low-calcium intake (500 mg/day) (79). Bone loss progressed with age in both districts, but the rate of hip fracture was higher in the group with low calcium intake, suggesting lower calcium reserves before osteoporosis became apparent. In another study, spinal bone loss in healthy postmenopausal elderly patients was lower in women consuming more than 777 mg calcium per day than in those consuming less than 405 mg/day. In this study, supplementation exceeding a total daily intake of 800 mg appears unnecessary (80).

Two other studies challenge these results (81, 82). In one study beneficial effects on lumbar spinal bone density were seen in individuals taking a calcium supplement of 1000 mg/day, even though the mean dietary intake of the calcium-supplemented group was in the range of 800 mg/day (the present RDA). Although the data are not clear on what the best RDA may be, these investigations show that bone density may be the most useful parameter for determining RDAs for calcium for the elderly population.

In 1994, an NIH consensus conference on optimal calcium intakes recommended 1000 mg of calcium per day for adult men and estrogen-sufficient women less than 65 years old, and 1500 mg of calcium per day for both men and women 65 years and older (83). Even greater amounts of dietary calcium may be needed in the medical management of women with established osteoporosis. However, there is a potential downside to increasing calcium in the diet too much—interference with absorption of other minerals. Such mineral-mineral interactions must be studied before fully rational and strong recommendations for calcium requirements can be made. In addition, more studies are needed on the effect of exercise on bone loss in the elderly, which could further modulate the calcium need (84).

The 1997 adequate intake reference value for calcium of the Food and Nutrition Board is 1200 mg/day for those 51 years and above. This is an increase of 400 mg/day above the 1989 RDA (see Appendix [Table A-2-a-2](#) and [Table A-2-b-1](#)).

Iron. The iron deficiency seen in the elderly is due to inadequate iron intake, blood loss due to chronic disease, and/or reduced nonheme iron absorption secondary to the hypohydria or achlorhydria of atrophic gastritis (85). Chronic use of antacids or other

acid-lowering medications can also impair intestinal iron absorption. Iron absorption per se does not appear to decline significantly with age (86), although one study showed that red cell uptake of absorbed intestinal iron was reduced by about one-third (87). In the NHANES I and II studies, average iron intakes were 14 mg/day for men and 10 mg/day for women (88). In NHANES III (preliminary) data, median iron intakes for males and females over 80 years of age were 13.2 and 9.6 mg, respectively. In these studies, a 4% prevalence of anemia in men was more often due to chronic disease than to iron deficiency; iron-deficiency anemia without apparent disease was rare for women.

Some surveys have suggested that iron may accumulate in the body with age, as reflected by elevated serum ferritin levels (88, 90). However, these studies for the most part did not control for chronic inflammation or diseases known to alter ferritin levels. Although a ferritin level of 12 µg/L has been used as a cutoff to indicate depleted iron stores, two recent studies have reported that patients presenting with anemia had no stainable iron in their bone marrow despite apparently normal serum ferritin (91 and 92). Additional research is needed to define appropriate age-sensitive values for ferritin and other iron indices.

In the NHANES survey, iron overload was found in 0.2% of adults who were probably homozygous for the hereditary hemochromatosis gene (93). Although individuals who are heterozygous for this gene are more common (10% of the population of white northern Europeans), heterozygous individuals in Canada have normal serum ferritin and transferrin saturations (94). A reported direct relationship between iron intake, serum ferritin, and the risk of myocardial infarction (95) has not been confirmed by others. Therefore, the RDA of 10 mg/day for elderly persons seems adequate and appropriate.

Zinc. Zinc intakes of the elderly, 10 mg for males and 7 mg for females, are well below the 1989 RDA of 15 mg/day for men and 12 mg/day for women (65, 96). However, no consistent relationship has been found between dietary zinc and plasma zinc (97). Zinc absorption as measured by isotopic studies decreases with age, although zinc balance remains intact (98). There are conflicting data in the literature indicating normal or decreased plasma zinc concentrations in the elderly (99). The significance of any decrease in plasma levels is difficult to ascertain, however, because diagnosis of zinc deficiency is problematic.

Since zinc nutrition may affect immune competence, the question arises whether poor zinc status may partially explain decreased immune function in the elderly (97). Both immune suppression and immune stimulation by zinc supplementation have been reported in the elderly (100 and 101). The present RDAs for zinc for elderly men (15 mg) and women (12 mg) appear to be justified, at least until better measures of zinc status are available.

Copper. As determined by isotope studies, copper absorption in the elderly is similar to that in young adults (102). Copper absorption is affected by the presence of other trace minerals and factors in the diet that inhibit or enhance cation absorption (e.g., phytates, zinc, oxalates). A study in elderly males suggests that only 1.1 mg of copper is necessary for copper balance, less than the usual intake of 2 to 3 mg (also the RDA)

observed in the elderly ([102](#)).

Selenium. The RDA for selenium for adults 51 years or older is 70 µg/day for men and 55 µg/day for women. Because age-related changes in absorption or metabolism of selenium have not been described, poor selenium intake is probably responsible for the prevalence of poor selenium indices reported among most elderly people. Nevertheless, in one study of housebound elderly people, the mean selenium intake of 37.5 µg/day did not result in a negative selenium balance ([103](#)). Further, although selenium is part of the body's antioxidant defense system, it is uncertain that higher selenium intakes would decrease the incidence of chronic disease. For now, the RDA for selenium appears adequate.

Magnesium. In 1989, the magnesium RDA for adults of both sexes was set at 4.5 mg/kg, which translates into an intake of 350 mg for a reference 76-kg male and 280 mg/day for a reference 62-kg female. Various surveys show that older men and women consume only about two-thirds of the current RDAs. Despite this low intake, there is no evidence that magnesium deficiency is prevalent in this age group. Further, little or no information suggests significant alteration in magnesium absorption or metabolism with advancing age. This may, in part, reflect efficient renal conservation on low dietary intakes of magnesium. Although the serum magnesium level has been criticized as a measure for total body magnesium status, tissue levels (e.g., red blood cell, white blood cell) of magnesium have not been shown to decline with age. Thus, it appears that the magnesium RDA is probably set too high for the elderly and is in need of reexamination. As noted in Appendix [Table II-A-2-b-3](#), the RDAs for magnesium for those 51 years and above have been increased by 70 and 40 mg/day for men and women, respectively, above the 1989 RDA.

Chromium. The estimated safe and adequate daily dietary intake for chromium is set between 50 and 250 µg/day. However, accurate data on the chromium content of foods are scarce, and several studies indicate that the elderly have chromium intakes far below the recommended range ([102](#)). In fact, a chromium intake of 50 µg/day might well require an energy intake of 3000 kcal/day. Balance studies among elderly people have shown that positive chromium balance can be maintained at levels below the current RDA ([102](#)). Although chromium enhances the activity of insulin, glucose tolerance in the elderly is not consistently improved after chromium supplementation. In one study, chromium supplementation increased HDL cholesterol ([104](#)); however, the amounts needed could not be achieved by diet alone (i.e., the effect appeared to be pharmacologic rather than physiologic). One autopsy study reported apparent accumulation of chromium in various tissues with advancing age ([105](#)). Since chromium balance can be achieved at intakes quite a bit below 50 µg/day, the recommended lower limit appears too high for the elderly and should be reexamined.

Other Trace Minerals. The nutritional status and requirement of manganese, molybdenum, phosphorus, iodine, and fluoride in relation to aging have not been adequately studied.

NUTRITIONAL STATUS

Dietary Intake

Dietary intakes and nutritional status of the elderly have been examined in several studies over the last 25 years: the large nationwide NHANES I for 1971 to 1974 ([106](#)), NHANES II for 1976 to 1980 ([107](#)), NHANES III preliminary data for 1988–1991 ([108](#) and [109](#)), the Third Report on Nutrition Monitoring in the United States ([110](#)), the Continuing Survey of Food Intakes by Individuals, 1994 ([111](#)), and several smaller studies of specific populations of free-living and institutionalized elderly persons ([112](#), [113](#), [114](#), [115](#), [116](#), [117](#), [118](#) and [119](#)). The sample population studied, the type of dietary instrument used, and the standards used to interpret the actual intake data influence the results of the study.

Methodology of Diet History

Three instruments are currently in use: dietary food records, food recall, and food frequency. The food record requires that an individual record current food intake for 3 to 7 days. The recall method is used for consumption during the previous 24-h period but may be particularly inappropriate for older persons with short-term memory problems. Finally, food frequency methods cover usual food consumption patterns for a 3-, 6-, or 12-month period including seasonal variations. Each of these methods incorporates questions on the use of dietary supplements and alcohol. The various advantages and disadvantages of each method have been reviewed ([120](#)) (see also [Chapter 58](#)). Many of these methods tend to underestimate food intake. For some nutrients, especially vitamin B₆ and zinc, the actual content in foods is not well established.

Dietary Intake Standards

Standards used to interpret dietary data in the elderly range from the RDA in use at the time of the survey to a special standard set up for a particular study, such as two-thirds of the RDA. Since the RDAs of 1974, there have been separate categories for individuals 51 years of age or older.

Nutritional Evaluation

Biochemical Standards

The biochemical standards recommended for use for the elderly are currently the same as for adults ([121](#)). Although some studies had speculated that serum albumin concentrations declined with aging, a recent study of 1066 healthy elderly persons found only minimal decreases ([122](#)).

Hematologic Standards

Standards for interpreting hematologic data (e.g., red blood cells, white blood cells, hemoglobin) for the elderly are slightly lower than those for young and middle-aged

adults (123). By convention, values below the tenth percentile for NHANES II are considered “at risk.” There are no reliable standards to indicate significant ethnic differences in the elderly.

Anthropometric Standards

Body Weight. The correlation of obesity with increased morbidity and mortality is well known (124, 125, 126, 127, 128 and 129). The pattern of distribution of the body fat (higher risk with increased waist:hip girth) is also a factor in the excess morbidity and mortality (129, 130, 131 and 132). However, determination of obesity in the elderly is problematic, because few body weight standards specifically for the elderly are currently in use. One of the earliest standards is based on accumulated body weight data on 5600 elderly men and women (65–94 years of age) who reported on an ambulatory basis to their respective doctors (133).

Data on the elderly up through age 74 are also available from the NHANES I and II studies. (See Appendix [Table III-A-15-a](#), [Table III-A-15-b](#), [Table III-A-15-c](#), [Table III-A-15-d](#) and [Table III-A-15-e](#) [134a].) Using these data, Frisancho (134) established body weight standards for persons 25 to 54 and 55 to 74 years of age for sex, age, height, and frame size (estimated from elbow breadth) (135) (data are presented in Appendix [Table A-12-c-2](#), [Table A-12-c-3](#) and [Table A-12-d](#)). These standards agree closely with data from the Baltimore Longitudinal Aging Study (136 and 137) (see also Appendix [Table III-A-12-b](#)). Because the mean body mass index (BMI) in the NHANES I, NHANES II, and several other studies was approximately 22.5 kg/m² for both sexes, Frisancho's summary tables (134) were prepared in weight ranges according to height and age but not gender. NHANES I and II data for BMI by age and gender are given in Appendix [Table III-A-13-a](#). There are also body weights in the USDA dietary guidelines (138) but no data showing that they apply to the elderly (139). BMI has been shown useful in predicting body fatness (140) or risk of morbidity in elderly women (141).

The Metropolitan Life Tables (127) (see [Appendix](#)) are based on persons aged 25 to 59 and do not account for possible changes in body weight and height with age; thus, they are probably not useful for the elderly. Furthermore, because these tables represent the experience of the insurance industry, they are certainly not a truly representative sample of the general population. Thus, the Metropolitan Life Tables are not accurate or desirable for use in persons over the age of 54.

Other Anthropometric Standards. Anthropometric data such as triceps skinfold have also been used to assess nutritional status of populations (142), as well as to monitor response to treatment of patients in a hospital setting (143). Lean body mass declines with aging whereas body fat stores increase (144). The increased body fat is stored intraabdominally and intramuscularly in the elderly rather than subcutaneously as in the young (145). Thus, triceps skinfold thickness alone and measures derived from it (e.g., midarm muscle area) do not accurately predict body fat content in the elderly. Several groups have addressed the problem of using anthropometry to study body composition of elderly persons (146 and 147).

Review of Studies of Institutional and Free-Living Elderly Populations

A review of 28 dietary surveys that included data from elderly persons concluded that the mean caloric intake was most often below the standard used (148). In several large surveys of note (65, 106, 107, 108, 110, 117, 118 and 119), mean energy intakes (kcal/kg/day) averaged 1792 to 2171 for males and 1168 to 1770 for females, generally below the 1989 RDA of 2300 for males and 1900 kcal/day for females. Caloric intakes of sedentary elderly persons may indeed be below current estimates. The low intakes may also result from the tendency of many methods to underestimate food intake. Indeed, when the doubly labeled water method was used on an elderly population, TEE exceeded that estimated from food intake (10, 11).

Protein nutriture has been assessed in the elderly by dietary intake and accompanying biochemical parameters. The average protein intakes in NHANES I, II, and III (preliminary) as well as in other surveys of institutional and free-living elderly were above the 1989 RDA. Thus, protein nutriture, in the absence of chronic disease, appears adequate. In some studies, certain serum proteins (albumin, transferrin, prealbumin, retinol-binding protein) appear to decline with age (118, 149, 150). A lower serum albumin level is often not correlated with protein intake and may represent a normal decrease for the elderly (1, 15, 18). A study of serum albumin levels in healthy elderly persons appears to show minimal decreases with age (122).

The nutritional status of the elderly with respect to several vitamins and minerals has been assessed. Based on both dietary intake and/or biochemical measures in the NHANES I, II, and III (preliminary) studies as well as in other studies (60, 117, 118), low intakes of calcium and vitamin D appear most frequently and can be attributed to the low intake of dairy products among certain groups in this population.

The situation with vitamin B₆ nutriture is complex. Several studies show vitamin B₆ intakes well below the RDA and up to 28% of individuals with abnormal erythrocyte aspartate aminotransferase stimulation tests (117, 118, 151). However, reported vitamin B₆ intakes might be somewhat higher if the food table values for vitamin B₆ (as well as for zinc, folate, and vitamin B₁₂) were more complete. As for any nutrient, current standards for biochemical tests of nutrient status for vitamin B₆ may be inappropriate for the elderly. In addition, inferring deficiency on the basis of a single screening should be tempered by the fact that intraindividual variance in biochemical measures is large enough to account for a portion of the "deficiency" at any one measurement time (152).

Mean intakes of most other vitamins and minerals (with an adequate database) appear adequate, although in a few studies, biochemical tests indicate that 5 to 20% of elderly people may have low serum levels of thiamin, riboflavin, iron, zinc, and folate (109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 133a, 134, 134a, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152 and 153).

Supplement Use by the Elderly

In a study of a Meals on Wheels program, 14 of 33 subjects were considered at risk for protein-energy malnutrition. Supplementation with a liquid polymeric supplement for 4 months increased weight in most subjects; the weight gain was associated with increases in serum albumin, total iron-binding capacity, folate, vitamin C, and vitamin B₁₂, thus providing evidence of improved nutritional status (154).

Supplement use was also examined as part of the nutritional status survey of free-living elderly in Boston (155). Daily vitamin and mineral use was reported by about half of the elderly; use of vitamin C and E supplements was most common. Supplement use markedly decreased the number of individuals whose total daily intake (diet plus supplement) of vitamins B₆, B₁₂, and D, of folate, and of calcium would be considered low. Of concern, both elderly males and females consumed excessive levels (at least 10 times the RDA) of vitamin A. These results are consistent with other studies of supplementation in the elderly (156). However, an even greater prevalence of supplementation (72%) was observed in a survey of an affluent community of “health conscious” residents (157).

DRUG-NUTRIENT INTERACTION

Nutrients can affect drug action by altering the digestion, absorption, distribution, metabolism, and/or excretion of the drug. Less often recognized is that for all age groups, drugs may influence the nutritional status of the individual. Drugs may affect nutritional status in several ways: effects on food intake, alteration of nutrient absorption, alteration of nutrient metabolism, and alteration in nutrient excretion (158). This is particularly important for the elderly, who often have multiple chronic diseases and are taking several medications or drugs concurrently. Risk of adverse side effects increases with the number of drugs taken simultaneously and with the duration of exposure to the drugs.

Alcohol and Nutritional Status in the Elderly

Alcohol is the most common drug used by the population at large. In large amounts taken chronically, the overall nutritional status is adversely affected, including reduced appetite and impaired nutrient absorption, metabolism, and excretion. Ethanol is also associated with several serious medical and social problems such as hepatic cirrhosis, adenocarcinoma of the gastrointestinal tract (particularly mouth, pharynx, larynx, and esophagus) and liver, and impaired driving. Most elderly individuals who consume alcohol, however, consume small amounts (159). A survey of 554 nonalcoholic subjects who had participated in a nutritional status assessment of the elderly in the Boston area, classified alcohol use into three categories: less than 5 g/day, 5 to 14 g/day, or more than 15 g/day (160). The extent of alcohol use was related to nutritional, biochemical, and physical parameters of these individuals. Plasma retinol, ferritin, and high-density lipoprotein cholesterol concentrations were significantly higher, and serum copper, zinc, and potassium were significantly lower in those consuming more than 15 g/day than in

those consuming less than 5 g/day. The statistically significant effects were small, however, and thus of questionable biologic significance, and alcohol only affected potassium and copper levels in patients using diuretics.

[Selected Readings](#)

Nutritional status assessment in children is essential for identifying either the undernourished or overnourished state and estimating the optimum energy intake to promote growth and well-being. In children with moderate-to-severe disabilities or many of the chronic diseases, nutritional assessment is complicated by interaction of the primary disease process (i.e., muscle atrophy, contractures, chronic malabsorption), drug-nutrient interactions, and acute and/or chronic malnutrition.

This chapter aims to provide the reader with an appropriate knowledge base, current references, and methodology for assessing the nutritional status of healthy infants and children and the methodologic modification required for children with chronic disease. Nutritional assessment in children has several components, including evaluation of dietary intake, growth status, body composition, energy expenditure, and laboratory data in the context of the medical history, diagnoses, and current therapy. Dietary and biochemical assessment are important tools for evaluating the nutritional status of the child and are presented thoroughly in [Chapter 57](#) and [Chapter 58](#). Nutrition is a major determinant of growth patterns in infants and children; thus, this chapter focuses on assessment of growth, body composition, and energy expenditure.

ELEMENTS OF NUTRITIONAL ASSESSMENT

The elements of complete nutritional assessment are based on the standard pediatric medical evaluation that includes a medical history, a physical examination, and laboratory assessment. Children are usually assessed by the primary physician, pediatric caregiver, physician's assistant, or nurse practitioner, though others (dietitians, speech therapists, occupational and physical therapists, social workers) may also participate in the assessment, depending upon the setting. Because nutritional assessment of the child is multidisciplinary, cooperation of the interdisciplinary team is important. For example, the medical history and physical examination may be completed by the pediatric caregiver, the dietary history and anthropometry by the dietitian, and any effects of family structure on food availability and/or meal planning completed by the social worker. For children with special needs, other disciplines (e.g., speech and occupational therapy) may be involved in assessing oral motor function and/or proper positioning for feeding the child. No single test provides an adequate measure of overall nutritional status; instead evaluation is based on a variety of somewhat nonspecific indicators.

Medical History

The medical history includes assessing acute and chronic medical conditions, medications, allergies, activity pattern, and a diet history since infancy. The diet-intake history includes review of a typical day's food intake; past dietary history and recent changes in diet pattern; use of caloric, vitamin, or mineral supplements; general appetite; presence of pica; food aversions or special food practices by the child or family; food and/or formula preparation; behaviors that may interfere with feeding; and caregiver nutritional knowledge. Past growth patterns, growth charts, and pubertal history are reviewed. Pubertal rating, most commonly assessed by the Tanner stages (1), is divided into five anatomically defined stages based on phallus and pubic hair development in boys and breast and pubic hair development in girls (Table 54.1). For screening purposes, a self-assessment instrument has been devised using pictographs of Tanner's pubertal stages (2). The medical history also includes a review of systems with emphasis on the dental and oral motor function and the gastrointestinal tract (emesis, gastroesophageal reflux, diarrhea, and constipation).

Pubic hair development for males and females

Stage 1: There is no pubic hair.
Stage 2: Sparse growth of lightly pigmented hair on labial or only slightly curled, primarily on either side of the base of the penis or along the labia.
Stage 3: The hair becomes more the adult type, darker and is more noticeably darker and coarser and tends to be curled.
Stage 4: The hair is more adult in character but covers an area considerably smaller than in adult males. There is no spread to the medial surface of the thigh.
Stage 5: The hair is distributed in an inverted triangle as in the female. Hair is dark in quantity and type with extension to the thighs.

Male genitalia

Stage 1: The infantile testis which persists from birth until puberty begins. During this time the genitalia increase slightly in overall size. The scrotum is more orange in general appearance.
Stage 2: Enlargement from testis to epididymus, and there is some redness and change in texture of the scrotal skin.
Stage 3: The penis has increased in length, and there is a smaller increase in breadth; there has been further growth in the scrotum.
Stage 4: Further growth of testis and epididymus and increase in size of the penis especially in breadth.
Stage 5: The genitalia are adult in size and shape.

Female

Stage 1: The infantile stage persists, anterior of the penis only.
Stage 2: This is the bud stage, a small mound is formed by the elevation of the breast and paps, the areolar diameter enlarges.
Stage 3: Further enlargement of breasts and areola with the beginning of their contour.
Stage 4: The areola and paps are further enlarged and form a secondary mound projecting above the contour of the breast.
Stage 5: This is the typical adult stage with a smoothly rounded contour, the secondary mound absent in stage 4 having disappeared.

Table 54.1 Typical Stages of Male and Female Pubertal Development

Physical Examination

The nutritionally oriented physical examination may include the following measurements: current weight, height/length or alternative linear growth measure, head circumference, midarm circumference, and skinfold measurements. Details of anthropometric methodology and reference standards are presented in the next section. Reviews of physical findings associated with nutritional deficiencies are available (3, 4), and a summary is presented in Table 54.2. Though specific nutrient deficiencies are not as common in infants and children in the United States as in developing countries, deficiencies of certain nutrients (e.g., iron, vitamin A, and zinc) have been observed in otherwise healthy children; thus, primary care providers *must* be aware of the clinical presentations. Children with chronic diseases, syndromes, or developmental disabilities are at particular risk for developing specific nutrient deficiencies because of poor intake, feeding problems, food aversions/food specificity, altered nutrient or energy needs, and/or long-term medication use (5). Though not specifically listed in Table 54.2, obesity is a form of malnutrition that is increasingly prevalent in U.S. children and adults. The problem of obesity in children is reviewed thoroughly in Chapter 63.

Clinical Sign	Possible Nutrient Deficiency
Head	
Abnormal "steely" hair	Protein, zinc
Eyes	
Bluish sclerae, conjunctivitis	Vitamin A
Corneal xerosis, Bitot's spots	Vitamin A
Oral signs	
Glossitis	Folate, vitamin B ₁₂
Angular stomatitis	Niacin
Atrophic stomatitis, cheilosis	Protein, riboflavin
Perleche, cracked lips	Niacin
Stomatitis, bleeding gums	Vitamin C
Neurologic	
Ataxia, choreoathetosis	Vitamin B ₁₂ , B ₆
Encephalopathy	Protein, thiamine B ₁ , zinc
Parosmia, anosmia	Niacin, riboflavin
Peripheral neuropathy	Vitamin B ₁₂ , B ₆
Optic atrophy, optic chiasmatic hypoplasia	Vitamin A, C, zinc
Cardiovascular	
Cardiomyopathy, arrhythmias	Iron
Cardiac	
Palpitations, tachycardia	Iron
Orthostatic hypotension	Vitamin B ₁₂ , vitamin B ₆
Hematologic	
Microcytosis	Protein, zinc
Neurologic	
Ataxia, weakness	Protein, zinc, cobalamin B ₁₂
Encephalopathy	Protein, thiamine B ₁
Parosmia, anosmia	Niacin, riboflavin
Cardiac	
Palpitations, tachycardia	Protein, zinc
Orthostatic hypotension	Vitamin B ₁₂ , B ₆
Cardiac	
Palpitations, tachycardia	Protein, zinc
Orthostatic hypotension	Vitamin B ₁₂ , B ₆
Cardiac	
Palpitations, tachycardia	Protein, zinc
Orthostatic hypotension	Vitamin B ₁₂ , B ₆

Table 54.2 Summary of Clinical Signs of Nutritional Deficiency

ANTHROPOMETRY

Anthropometric evaluation is an essential component in determining nutritional status and monitoring care. It is a rapid, inexpensive, noninvasive means of assessing both short- and long-term nutritional status. However, the assessment is only as good as the

accuracy and reproducibility of the measurements; therefore, a well-trained anthropometrist is required. A variety of anthropometric measurements exist, each offering different information, and no single measure suffices for full characterization of nutritional status. Comparing the child with national reference norms for growth and nutritional status provides the means for interpreting these measurements. A description of measurement error and a summary of reference data are available for growth and body composition of normal children (6). A recent publication by Johnston and Ouyang (7) highlights the importance of the criteria selected to compare with reference data. Anthropometric measurements are most commonly recorded as percentiles above or below the mean reference data. However, when measurements for children are far below the 5th percentile or far above the 95th percentile, these rankings are difficult to interpret. Therefore, a z-score, or standard deviation score, is used frequently in some clinical and research settings to avoid these problems. The z-score is calculated as

$$\frac{(\text{the observed value}) - (\text{median value for the reference population})}{(\text{standard deviation for the age and gender})}$$

A z-score of -1 corresponds to the 16th percentile on the National Center for Health Statistics (NCHS) growth charts, whereas a z-score of -2 corresponds to the 2.5th percentile. Computer programs are available for these calculations (8). Methodology of anthropometry is reviewed thoroughly by Cameron (9) and Lohman et al. (10) (see also [Chapter 56](#)). Commonly used pediatric anthropometry is summarized below.

Weight

A single measurement of body weight cannot provide sufficient information to differentiate between acute and chronic malnutrition and may result in improper classification. Serial measurement of body weight is the most common assessment of growth in children. Weight should be measured on a calibrated, digital electronic or beam balance to the nearest 0.1 kg in older children and to the nearest 0.01 kg in infants; standard international units are preferred. Children should be weighed after voiding, wearing little or no outer clothing and no shoes; infants should be measured unclothed and without diapers.

Weight is plotted by age and gender and compared with the reference standards from the NCHS (see Appendix [Table III-A-14-b-1](#), [Table III-A-14-b-2](#), [Table III-A-14-d-1](#) and [Table III-A-14-d-2](#)). Tracking the weight of an individual over time in combination with his or her height improves the measurement as a diagnostic tool (see Appendices [Table III A 14b-1](#) and [Table III A 14b-2](#) and [Table III A 14d-2](#)). Reference standards for weight (11) and 1-, 3-, or 6-month-interval weight-gain velocity are available (12, 13) (see also Appendix [Table III-1-A-4-e-1](#) and [Table III-1-A-4-e-2](#)).

Height

Linear growth, as a component of a child's nutritional history, enables the clinician to distinguish between short- and long-term malnutrition. Length or stature measurements

are appropriate for children who can be properly positioned as described below. For children less than 2 years of age, a supine length is taken. For children more than 2 years of age who cannot stand erect unsupported or have spinal curvature and/or contractures or other body habitus abnormalities precluding accurate length or height measurement, upper-arm length and lower-leg length are alternative stature measurements (described below) (see Appendix [Table III-A-14-f](#) and [Table III-A-14-g](#)).

To measure supine length, an infantometer or an inflexible length board with a fixed headboard and movable footboard is used. Supine length measurement requires two people to position and hold the child. The infant's head is placed at the top of the board, knees are flattened to fully extend the legs, and feet are placed together and flexed to a 90° angle ([9](#), [10](#)). For stature, a stadiometer should be used with a head paddle that glides smoothly but is firmly perpendicular to the back of the stadiometer. Position the child with heels, buttocks, and back of the head against the stadiometer and arms down and relaxed. The head is positioned so that the Frankfort plane is parallel to the floor. The anatomic Frankfort plane extends from the lower margin of the orbit to the upper margin of the auditory meatus. Both length and stature measurements are accurate to 0.1 cm; three measurements are taken, and the mean is recorded. When comparing a supine length measurement with a growth chart for stature, the length is decreased approximately 2 cm to adjust for the known difference between length and stature due to gravity ([14](#)).

Length/height is plotted by gender and age and compared with NCHS growth charts ([11](#)) (Appendix [Table III-A-14-e-1](#) and [Table III-A-14-e-2](#)). As with weight, multiple measurements taken over time are more useful than a single plot of height. Height velocity is more sensitive for determining delayed or accelerated growth. To calculate velocity, two height measurements are taken at least 6 months apart, preferably 12 months; shorter periods reflect seasonal variations in growth. The height difference is divided by the time between the two measurements, and a rate is calculated in centimeters per year. Height velocity charts are available for normal, early, and late-maturing children ([15](#)) (Appendix [Table III-A-14-e-1](#) and [Table III-A-14-e-2](#)).

Whenever possible, the stature of both biologic parents is obtained and midparental stature is computed to identify the genetic potential for linear growth and make corrections when necessary ([16](#)). If the parents are stunted secondary to poor nutritional status during growth, it is not appropriate to use their statures for patient height adjustment.

Head Circumference

Brain growth is most rapid in the first 3 years of life, and head circumference (HC) is a good indicator of brain growth and malnutrition in otherwise healthy children. Of all anthropometric indicators, HC is best preserved in the presence of malnutrition and is included in the assessment of growth and nutritional status in children up to 36 months of age. In general, weight and then height are affected when a child is nutritionally compromised before brain and HC growth are slowed. HC is of limited use for nutritional assessment of patients with central nervous damage (micro- or macrocephalus of

nonnutritional etiology) and of healthy patients with familial micro- or macrocephalus.

A flexible metal or nonstretchable plastic-coated measuring tape scaled to 0.1 cm is used. The tape is placed over the supraorbital ridge and around the occiput so that a maximum circumference is obtained. Care should be taken that the tape is evenly placed on all sides and flat against the skull. Three measurements are taken, and the mean is recorded. Reference data for HC are available by age from birth to 18 years of age ([17](#)).

Anthropometric Assessment of Body Composition

Anthropometric indicators of body composition are very useful in assessing clinical nutritional status because they are quick, inexpensive, clinically available indexes of energy and protein reserves that may reflect more subtle changes in nutritional status than measures of weight and height alone.

Midarm Circumference

Mid-upper-arm circumference (MAC) is a composite measure of muscle, fat, and bone in the arm. It is sensitive to current nutritional status and is used frequently in combination with the triceps skinfold thickness. The method is described in detail in [Chapter 56](#) and reference data for MAC are available for children ([18](#)).

Skinfold Measurements

Skinfold thickness estimates subcutaneous fat stores at specified sites. The triceps and subscapular skinfold measures taken together generally indicate whole-body fat stores and are sensitive to changes in nutritional status. However, of all skinfold measures, the triceps skinfold appears clinically the most sensitive to changes in energy balance ([25](#)). The specific method of measurement and a description of how to optimize precision are presented in [Chapter 56](#). References for skinfold thickness for children are available ([19](#), [20](#)). (See Appendix [Table III-A-16-a](#) and [Table III-A-16-b](#).)

Because of the variability of fat-free mass (FFM) density in infants and children, equations developed to estimate body fat from skinfold measurements in adults are inappropriate for the pediatric population. A variety of equations have been developed for use in children. The most reliable equations are those developed by Brook ([21](#)) for use in prepubescent children aged 1 to 11 years and by Durnin and Rahaman ([22](#)) for older children ([Table 54.3](#)) using four skinfold sites. For children aged 8 to 18 years, body fat can be estimated from two skinfold sites (triceps and subscapular) using the prediction equations of Slaughter et al. ([23](#)) ([Table 54.4](#)). These equations are specific to pubertal status, age, and ethnic background and correlate well with body composition measured by stable isotopes in normal children ([23](#)) as well as in children with cystic fibrosis ([24](#)) and cerebral palsy ([25](#)). Reilly et al. recently compared the most frequently used equations for estimating body fat from skinfolds in children ([26](#)).

- Measure the following skinfolds in mm: triceps, biceps, subscapular, suprailliac.
- Add the four skinfold measurements (Σ) and compute the log Σ .
- For children between the ages 1 and 11 years, compute body density (D) using one of the following equations^a:
 - Males:** $D = 1.169 - 0.0788 \times (\log \Sigma)$
 - Females:** $D = 1.2003 - 0.0999 \times (\log \Sigma)$
- For children between the ages of 12 and 17 years, compute body density (D) using one of the following equations^b:
 - Males:** $D = 1.1533 - 0.0643 \times (\log \Sigma)$
 - Females:** $D = 1.1369 - 0.0598 \times (\log \Sigma)$
- Percentage body fat is calculated from D using the following formula^c:
 - Body Fat: % = $[(4.95/D) - 4.5] \times 100$**

^aAdapted from ref. 21.

^bAdapted from ref. 22.

^cAdapted from ref. 54.

Table 54.3 Anthropometric Equations for Predicting Percentage Fat from Four Skinfold Sites

White males	
Prepubescent:	$1.21 (TSF + SUBSF) - 0.008 (TSF + SUBSF) - 1.7$
Pubescent:	$1.21 (TSF + SUBSF) - 0.008 (TSF + SUBSF) - 3.4$
Postpubescent:	$1.21 (TSF + SUBSF) - 0.008 (TSF + SUBSF) - 5.5$
Black males	
Prepubescent:	$1.21 (TSF + SUBSF) - 0.008 (TSF + SUBSF) - 3.2$
Pubescent:	$1.21 (TSF + SUBSF) - 0.008 (TSF + SUBSF) - 5.2$
Postpubescent:	$1.21 (TSF + SUBSF) - 0.008 (TSF + SUBSF) - 6.8$
All females:	$1.33 (TSF + SUBSF) - 0.013 (TSF + SUBSF) - 2.5$
If (triceps + subscapular) greater than 35 mm	
Males:	$0.783 (TSF + SUBSF) + 1.6$
Females:	$0.546 (TSF + SUBSF) + 9.7$

NEONATAL NUTRITIONAL ASSESSMENT

Infants born preterm, less than 37 weeks gestation, are at increased risk for nutritional deficiency because of limited stores of energy and nutrients, confounded by decreased absorptive and digestive capacity. Rapid growth normally occurs between postconceptual ages 24 to 40 weeks. During this period there is increased muscle and fat accumulation, bone mineralization, micronutrient storage, brain myelination, and lung and gastrointestinal maturation. Interruption of these growth processes through suboptimal nutritional support may result in acute and/or chronic malnutrition and developmental repercussions. Infants born in the United States are not immune to malnutrition during the neonatal period; low birth weight and prematurity remain leading causes of infant mortality ([Chapter 50](#)). A thorough review of nutritional assessment for

the neonate is available (27).

Methodology used to assess the neonate is similar to that used for the infant and child, with a few modifications. When completing a medical history for a premature or growth-retarded neonate, a review of the mother's pregnancy is important. Premature infant growth charts are available for both weight and length (28), which were developed from cross-sectional data of infants born between 24 and 42 weeks gestation. Though a sufficient number of infants were assessed, the sample from which the charts were derived has an undetermined bias because "premature birth itself is probably related to unphysiological states of either the mother or fetus" (29). These charts are often used until the infant reaches 40 weeks postconceptual age (full term), after which the NCHS growth charts (cited above) are used, and the child's age is adjusted for the degree of prematurity until the child is 2 years of age. However, the time at which catch-up growth is complete remains controversial (30, 31). For neonates in an intensive care unit, HC is the preferred assessment tool because clinical instability makes it difficult to measure weights and lengths accurately and reproducibly. Weights may vary daily due to fluctuations in fluid status and attached clinical equipment (e.g., intravenous catheters, endotracheal tubes, and chest tubes). HC should be measured 3 days postnatally to allow head edema and molding to resolve and then repeated for longitudinal assessment. HC data are commonly combined with MAC to provide information on the proportionality of body growth. MAC:HC reference data have been published for premature infants from 24 to 42 weeks postconceptual age (32).

ALTERNATIVE ASSESSMENT TOOLS FOR THE PHYSICALLY DISABLED CHILD

Body composition assessment of children with chronic diseases is essential in understanding their patterns of growth and development. Chronic disease is frequently associated with inadequate food intake, feeding problems, pica, drug-nutrient interactions, constipation, diarrhea, and/or altered energy needs resulting in poor nutritional status defined as decreased weight and/or height velocity accompanied by depletion of normal fat or fat-free mass stores (5, 33 and 34). Comparing the growth of children with moderate-to-severe physical and/or developmental disabilities with NCHS growth charts is inappropriate; special growth charts are available (Table 54.5).

Disease/ Syndrome	Growth Charts Available*	Reference
Achondroplasia	HT for age, HT velocity, HC	Horton et al., 1978 (55)
Down syndrome	HT for age, WT for age	Cronk et al., 1988 (56)
Fragile X syndrome	HT for age, WT for age, HC	Butler et al., 1992 (57)
Marfan syndrome	HT for age, WT for age	Pevitz et al., 1985 (58)
Myelomeningocele	HT for age, WT for age	Elvall, 1993 (63)
Noonan syndrome	HT for age	Ranke et al., 1988 (59)
Prader-Willi syndrome	HT for age	Holms, 1968 (60)
Turner syndrome	HT for age, HT velocity	Ranke et al., 1983 (61)
Williams syndrome	HT for age, HC	Pankau et al., 1992 (62)

Adapted from refs. 8 and 64.

*HT: height, WT: weight, HC: head circumference.

Table 54.5 Growth Charts Available for Specific Diseases/Syndromes in Children

Upper-Arm Length and Lower-Leg Length

Upper-arm length and lower-leg length are alternative measures of linear growth when length and stature measurements are not possible because of body habitus abnormalities such as scoliosis, spasticity, contractures, and/or poor cooperation due to cognitive or motor deficits. Both upper-arm length and lower-leg length are reliable and valid indexes of stature in children with developmental disabilities (36).

For young infants, sliding calipers (0–20 cm; Seritex Inc., NJ) are used; older infants and children require a Harpenden digital anthropometer (0–57 cm; Seritex Inc., NJ). These instruments are recommended for ease and accuracy of measurements. For infants and young children (0–24 months), upper-arm length is measured as shoulder-elbow length, and lower-leg length is measured as knee-heel length. A detailed description of the measurement technique is provided in Spender et al. (35), and revised reference percentiles for upper-arm length and lower-leg length are given for boys and girls aged 3 to 18 years (25, 36) (see Appendix [Table III-A-14-f-1](#) and [Table III-A-14-f-2](#) and [Table III-A-14-g-1](#) and [Table III-A-14-g-2](#)). Percentiles and/or z-scores can be assigned and used as a proxy for length/height measurement. In nonambulatory children it is common for lower-leg length to be more severely affected than upper-arm length relative to reference standards (25).

OTHER METHODS OF BODY COMPOSITION ASSESSMENT

An extensive review of body composition assessment methods is found in [Chapter 49](#). Total-body electric conductivity (TOBEC), bioelectric impedance, and isotope dilution are some of the safe and reliable methods for assessing body composition in infants and children, more often used for research purposes. A discussion of these methods is presented in [Chapter 49](#), and reviews are available (37, 38, 39, 40 and 41).

One method in particular, dual-energy x-ray absorptiometry (DXA) is being used increasingly to assess body composition in adults and more recently in children in both clinical and research settings. A thorough review is available (42). DXA exposes the child to low-level radiation, approximately 1/10th that of a chest x-ray. The ratio of low- to high-energy attenuation in soft tissue is used to distinguish between fat, FFM, and bone. DXA correlates well with densitometry, considered the gold standard for FFM measurement in adults (43). However, validation of new body composition methods in children is more problematic because of variation in FFM composition with age and change in the total-body water component (see [Chapter 49](#)); consequently, there is no accepted gold standard technique for infants and young children. DXA has been validated by carcass analysis of piglets (44) as well as by comparison with other frequently used methods of body composition in children (45). Body composition

assessment by DXA has many advantages to densitometry; in particular, it was shown to be more precise in repeated measurement analysis (46). DXA can measure the body as a whole or in regions to obtain specific information about regional fat distribution and FFM. DXA has the potential to become the gold standard for body composition analysis in children because, in addition to the advantages listed above, it is less dependent on the assumption of biologic consistency than other methods.

USE OF RESTING ENERGY EXPENDITURE IN CLINICAL PEDIATRICS

The energy requirement for children, as stated by the World Health Organization (WHO), “includes the energy needs associated with the deposition of tissues (growth) ... at rates consistent with good health” (47). For infants, children, and adolescents, the goal is to provide energy to achieve normal growth at the individual's genetic potential, achieve normal body composition, and maintain a normal pattern of activity. [Chapter 5](#) provides a comprehensive review of the estimation and measurement of energy requirements. The focus here is on the estimation and measurement of energy expenditure in children, in both the inpatient and outpatient settings, with specific reference to indirect calorimetry.

Various sources in the literature provide tables of the predicted total daily energy needs for groups of healthy, normally grown children with the RDA being the standard for the United States (see Appendix [Table II-A-2-a-1](#); for those of other countries see [Table A-2-a-1](#), [Table A-3-b](#), [Table A-4-b](#), [Table A-4-c](#), [Table A-4-d](#), [Table A-4-e-1](#), [Table A-4-e-2](#), [Table A-4-f](#), [Table A-5-a](#), [Table A-5-b](#), [Table A-5-c](#), [Table A-5-d](#), [Table A-6](#), [Table A-7-a](#), [Table A-7-b](#), [Table A-7-c](#), [Table A-7-d-1](#), [Table A-7-d-2](#), [Table A-7-d-3](#), [Table A-7-d-4](#), [Table A-7-d-5](#) and [Table A-7-d-6](#)). Yet in the practice of clinical medicine, the medical team needs to know the energy requirement of an individual patient who has a medically significant illness and possibly abnormal body composition, growth, and/or physical activity. The estimate of energy required is translated into a prescription for the appropriate number of calories from food, tube feeding, or intravenous nutritional support.

Estimating Resting Energy Expenditure

For many years, the only alternative to population-based recommendations for energy intake was using one of the various mathematical formulas to predict the basal metabolic rate or resting energy expenditure (REE), and then adjusting the REE with sets of physical activity and illness factors reflecting the patient's condition to predict the total daily energy needs of that patient. The most commonly used calculations were developed almost 80 years ago, mostly from adults, and therefore are not appropriate for the pediatric population (48). More recently, the WHO created new pediatric REE prediction equations ([47], Appendix [Table II-A-8-a-2-a](#) and [Table II-A-8-a-2-b](#)). A more detailed evaluation of the WHO data resulted in the Schofield equations ([Table 54.6](#)), which use both weight and height, as well as age group and gender to predict REE (49). These equations assess the energy needs of normal healthy children quite well; however, the energy needs of hospitalized or chronically ill children are difficult to predict because of variations in metabolic demands of growth, body composition, and extra energy needs for the disease state. Many common pediatric gastrointestinal

diseases (i.e., inflammatory bowel disease, cystic fibrosis, and liver disease) directly affect energy expenditure because of the associated malabsorption, inflammation, chronic infection, or changes in body composition. Thus, the energy needs of children with illnesses are difficult to predict accurately from standard dietary recommendations designed from the requirements of healthy children. REE measurement is the best available method of accurately determining individual energy needs for use in clinical medicine to promote weight gain or loss or provide for weight maintenance.

Age Range (years)	Kcal/day ^{a,b}
Males	
0-3	0.167 W + 15.174 H - 617.6
3-10	19.59 W + 1.303 H + 414.9
10-18	16.25 W + 1.372 H + 515.5
Females	
0-3	16.252 W + 10.232 H - 413.5
3-10	16.969 W + 1.618 H + 371.2
10-18	8.365 W + 4.65 H + 200.0

Adapted from Schofield WN: Hum Nutr Clin Nutr 1985;39C(1):5-42.

Table 54.6 Schofield Equations for Predicting Resting Energy Expenditure in Children (0 to 18 Years)

Measuring Resting Energy Expenditure

The study of energy metabolism in clinical settings is now possible because of the availability of open-circuit ventilated-hood indirect calorimeters. The indirect calorimeter, or metabolic cart, measures oxygen consumption and carbon dioxide production by the patient, and these values are used to calculate the REE, expressed in absolute terms as kilocalories or kilojoules per day, or relative to body size as kilocalories or kilojoules per kilogram body weight. The instrument provides minute-by-minute values that are averaged over the testing interval to provide the final REE value. Clinical and research REE measurements are conducted under standardized conditions to ensure the accuracy of the data and thus that of the clinical interpretation. Detailed instructions on using indirect calorimetry to measure REE in children have been published ([24](#), [25](#)).

REE is measured to estimate the total caloric needs of an individual patient to achieve a specific clinical goal (weight maintenance, loss, or gain). To estimate the total daily energy requirements of a patient from measurement of the REE over a 1-h period requires further calculations and an understanding of the components of the total energy expenditure in health and disease. Children who are significantly ill and/or hospitalized have less spontaneous physical activity, and an activity factor of 1.3 to 1.5 times REE is usually an adequate estimate of the total energy needs. However, an additional correction factor for disease severity may be used to adjust the REE in some settings

(i.e., burn patients, sepsis, significant protein losses). For example, the REE for children with cystic fibrosis is adjusted for the degree of pulmonary disease and/or fat malabsorption (51).

If indirect calorimetry is not available to measure REE, the WHO and/or Schofield equations are preferred and should be used to estimate the energy needs of the hospitalized child rather than the RDA values, which are based on population data. After calculations are made, recommendations may be adjusted for activity and disease factors, as stated above. Weight *must* be monitored routinely and caloric intake adjusted according to the nutritional goals for the child.

USE OF BONE MINERAL MEASURES IN CLINICAL PEDIATRICS

Bone mass accounts for up to 80% of the variance in skeletal strength and thus is the most important factor in preventing fracture. Since most bone mass accretion occurs during childhood and adolescence, increasing attention is focused on the components of bone health during the pediatric years. Bone mass is estimated from indirect, noninvasive measurements of bone mineral content (BMC) in grams or bone mineral density (BMD) in grams per square centimeter in selected skeletal regions or the whole body. Several methods were used previously; however, DXA is increasingly available in clinical settings and has several advantages for pediatric care (48). The precision of the measurement is excellent, 1 to 2%, and the radiation dose is small, less than 3 mrem (53). The most commonly performed scan for bone mineral determination is at the anterior-posterior (AP) lumbar spine site and can be completed within 3 minutes.

In most settings, data from the DXA scan of the AP view of the lumbar vertebrae (L1–4) is used for clinical interpretation and compared with results from healthy children of the same gender and chronologic age. The report includes information such as bone area (square centimeters), BMC, and BMD for each vertebral body and the mean of all four. The z-score for the patient is given, which allows comparison with the reference database. A z-score of zero is the mean (similar to the 50th percentile on a growth chart) for the reference data, with +1, +2, and –1 and –2 representing plus or minus one and two standard deviations of the reference mean. Since DXA measurements are new to clinical pediatrics, the approach to interpretation of the scans is evolving. In general, a DXA result that shows the patient with a z-score less than –2 (two standard deviations below the mean) for age and gender is clinically significant and treatment should be considered. In some high-risk settings, such as a child with significant malabsorption, steroid medications, poor oral intake, and/or decreased physical activity, intervention may be considered with a z-score below –1.

MANAGEMENT OF NUTRITIONAL PROBLEMS

Identification and treatment of nutritional and growth abnormalities are clearly standard pediatric practice. In general, dietary intake, food practices, and food beliefs are reviewed at each major well-child evaluation from infancy through adolescence. This information is the basis of individualized dietary and nutritional guidance provided by the primary care provider or dietitian. Therapeutic diets and vitamin or mineral supplements

are prescribed on the basis of specific diagnoses and poor dietary patterns.

Monitoring incremental growth and development is also essential to the care of children and the detection of nutrition-related abnormalities. Care providers are concerned when a child's weight, height, or HC changes unexpectedly from the established growth channel on the standard NCHS growth charts or disease-specific charts. Crossing the chart percentile channel, either accelerating or faltering, requires careful review of the patient's general health, nutritional intake and needs, and psychosocial environment. This evaluation may again involve several members of the health care team. Management of undernutrition in otherwise healthy infants and premature infants is presented in [Chapter 51](#), obesity in [Chapter 63](#), and nutritional problems specific to disease in [Chapter 59](#), [Chapter 61](#), [Chapter 62](#) and [Chapter 64](#).

CONCLUSIONS

Assessment of growth, body composition, and energy requirements are essential components in the overall nutritional assessment and clinical care of children. Together with dietary and biochemical assessment, they reflect the current and previous nutritional status of the child and are essential for both monitoring changes in nutritional status that occur with normal growth and monitoring clinically indicated nutritional intervention.

[Nutritional History](#)
[Physical Examination](#)
[Integrated Bedside Assessment](#)
[Subjective Global Assessment](#)
[Functional Assessment](#)
[Acknowledgments](#)
[Chapter References](#)

Malnutrition, defined as an unintentional weight loss of more than 10% associated with a serum albumin level below 3.2 g/dL (1), is not infrequent in hospitalized patients in the modern era of medicine (2). Two different studies in the 1970s reported the prevalence of malnutrition in adult medical patients at 48% and in adult surgical patients at 50%, respectively (3, 4). Regardless of etiology, malnutrition is associated with a suboptimal surgical outcome (5), increased rate of infection (6), longer hospital stay (3), impaired wound healing (7, 8), frequent hospital readmission for the elderly (9), more frequent postoperative complications (10), and increased risk of death (5).

Determining the optimal approach to nutritional assessment in the clinical setting is difficult because nonnutritional factors alter many of the parameters used to determine nutritional status. For example, the serum albumin level can be affected by body fluid redistribution, sepsis, hepatic or renal disease, or the postoperative state (11, 12). Furthermore, the long half-life of serum albumin makes this measurement insensitive to rapid changes in nutritional status (12, 13). Urine and fecal nitrogen excretion and immune skin tests require up to 48 hours for results (14). Difficulty in obtaining complete 24-hour collections of urine and feces poses another potential clinical limitation on assessment of nitrogen balance (12). While there is no single irrefutable measure of nutritional status, proficiency in detecting malnutrition in its early stages is essential for effective treatment and prevention of adverse clinical outcomes, and interval assessments of nutritional status are required to evaluate the efficacy of any nutritional intervention (15, 16).

Malnutrition results from alterations in the intake, digestion and/or absorption, metabolism, excretion, and/or metabolic requirements of dietary energy, protein, and other nutrients. Understanding the pathophysiology of the patient's disease is essential to the likelihood of finding a component of malnutrition. Furthermore, the severity of clinical illness may be an independent variable of nutritional compromise (17, 18). Bedside nutritional assessment requires integration of the medical history, the physical examination, selected laboratory data, estimation of nutritional requirements, and approaches to nutritional intervention and its outcome. Accurate bedside assessment allows the physician to determine which patients may benefit from nutritional intervention, and careful patient selection is essential to the cost-benefit of nutritional

support (19).

NUTRITIONAL HISTORY

The four main components of the nutritional history include the clinical, dietary, socioeconomic, and family histories. Unintentional loss of more than 10% of usual weight in the 3 months prior to evaluation may be associated with physiologic dysfunction, while loss of between 10 and 20% of usual weight is associated with impaired organ functions (5, 20), significantly higher in-hospital morbidity, and prolonged hospitalization of surgical patients (5).

The nutrition-oriented medical history should include the present illness, past medical and surgical history, family history, a medication list, and a review of systems. Special attention should be paid to the use of supplemental vitamins, hormone replacement therapy, mineral supplements, herbal remedies, and over-the-counter medications, which sometimes are not considered medications by patients. Chronic use of alcohol and medications such as glucocorticoids, immunosuppressive and cytotoxic agents, laxatives, appetite stimulants or suppressants, caffeine, and illicit drugs should be specifically noted. The history should assess changes in diet, including amounts and types of foods eaten and dental status, especially in the elderly. Chronic diseases such as gastric cancer or esophageal strictures may present with alterations in taste or dietary pattern. Table 55.1 lists the mechanisms by which malnutrition can result from many common diseases. Important nutrition-oriented questions for the review of systems are listed in Table 55.2.

Organ System	Associated Disorders and/or Defects of Organ Function	Mechanisms of Malnutrition
Endocrine	Diabetes mellitus, Hypothyroidism, Hyperthyroidism, Cushing's syndrome, Addison's disease, Growth hormone deficiency, Hypoparathyroidism, Hypoadrenalism	Altered metabolism, Anorexia, Weight loss, Cachexia
Gastrointestinal	Gastritis, Peptic ulcer disease, Gastroesophageal reflux disease, Crohn's disease, Ulcerative colitis, Celiac disease, Lactose intolerance, Pancreatic insufficiency, Biliary obstruction, Liver disease, Alcoholism	Malabsorption, Anorexia, Weight loss, Cachexia
Cardiovascular	Heart failure, Coronary artery disease, Hypertension, Atherosclerosis, Myocardial infarction, Pericarditis, Valvular disease	Anorexia, Weight loss, Cachexia
Respiratory	Chronic obstructive pulmonary disease, Asthma, Interstitial lung disease, Emphysema, Pulmonary hypertension, Lung cancer	Anorexia, Weight loss, Cachexia
Renal	Chronic kidney disease, Acute kidney injury, End-stage renal disease	Anorexia, Weight loss, Cachexia
Neurological	Alzheimer's disease, Parkinson's disease, Multiple sclerosis, Stroke, Traumatic brain injury, Spinal cord injury, Dementia	Anorexia, Weight loss, Cachexia
Psychiatric	Major depressive disorder, Anxiety disorders, Eating disorders, Schizophrenia, Substance use disorders	Anorexia, Weight loss, Cachexia
Immunologic	HIV/AIDS, Autoimmune diseases, Immunosuppression	Anorexia, Weight loss, Cachexia
Genetic	Phenylketonuria, Cystic fibrosis, Sickle cell anemia, Hemochromatosis	Malabsorption, Anorexia, Weight loss, Cachexia
Drugs	Antibiotics, Chemotherapy, Radiation therapy, Antipsychotics, Antidepressants, Anticoagulants, Antidiabetics, Antihypertensives, Anticholinergics, Opioids, Alcohol, Caffeine, Illicit drugs	Anorexia, Weight loss, Cachexia

Table 55.1 Mechanisms of Malnutrition

General
Usual adult weight
Current weight
Prepubertal weight
Maximum, minimum weights
Weight 1 and 2 years prior
Recent changes in weight and time period
Recent changes in appetite or food tolerance
Presence of vomiting, fatigue, fever, chills, night sweats
Recent changes in sleep habits, daytime sleepiness
External or/and abnormal swelling
Abnormality
Abdominal pain, nausea, vomiting
Changes in bowel pattern (normal or abnormal)
Diarrhea (consistency, frequency, volume, color, presence of mucus, food particles, fat droplets)
Difficulty swallowing (solids vs. liquids, intermittent vs. continuous)
Early satiety
Indigestion or heartburn
Food intolerance or preferences
Lesions in the mouth (aphthous ulcers, tooth decay)
Pain with swallowing
Sore tongue or gums
Neurologic
Confusion or memory loss
Difficulty with night vision
Gait disturbance
Loss of posterior sensation
Numbness, paresthesias, and/or weakness
Skin
Appearance of a diagnostic rash
Itching of scalp
Changes in hair
Thin nails, recent changes in texture

Table 55.2 Nutritional Questions for the Review of Systems

Many socioeconomic factors contribute to malnutrition (21). Homeless patients, chronic alcoholics, and patients with low fixed incomes are examples of groups susceptible to poor dietary choices independent of the mechanisms listed in Table 55.1 (22). The absence of poverty does not ensure adequate nutrition. Factors that affect the patient's ability to participate in self-care include education level, physical or mental limitations that prevent access to food, and the ability to cook or store food. Self-prescribed or religious food preferences, food allergies, food intolerance, and the use of alcohol, illicit addictive drugs (e.g., methamphetamine), vitamins, various dietary supplements, and tobacco influence appetite and meal patterns (23). Alcohol abuse affects 5% of the population, with wide-ranging potential impact on health and increased risk of liver disease (24).

The family and dietary history are pertinent to both malnutrition and obesity (25, 26, 27 and 28). As described in the National Health and Nutrition Examination Survey (NHANES) III report, 33.4% of adults over the age of 20 are overweight, and obesity affects people of all socioeconomic strata (23). As described elsewhere (Chapter 87), obesity is associated with significant comorbidities of adult-onset diabetes, hypertension, hyperlipemia, and respiratory insufficiency. Diets high in saturated-fat calories and low in fiber are associated with increased risks for obesity (23) and colon cancer (29, 30), while diets low in vitamin B₁₂ and vegetable sources of folate may predispose to hyperhomocysteinemia and cardiovascular disease (31) (see also Chapter 34 and Chapter 88).

Details of the dietary history are provided in Chapter 58. Health care providers should use the food guide pyramid to help their patients identify problem areas in food choices (32). In addition to features related to clinical illness and socioeconomic factors, the nutritional status of hospitalized patients may be affected adversely by factors unique to the inpatient setting, including withholding of meals for diagnostic testing, failure to recognize increased nutritional needs of injury or illness, major surgery, infection, and delay of nutritional support (33). If height and weight are not recorded in the chart, a decline in nutritional status may not be detected until the patient is in a severe state of

depletion. If a patient consumes 70% of a meal but has emesis, recording only the dietary intake is misleading. Communication between the physician, nurse, and dietitian improves the quality of nutritional care (33).

PHYSICAL EXAMINATION

The physical examination confirms the presence of under- or overnutrition suggested by the history. While undernutrition is often recognized, malnutrition in the presence of overnutrition may require a higher index of suspicion. Measurements of the severity of obesity and its complications are provided in Chapter 87. The multiple physical signs of malnutrition and their interpretations are listed in Table 55.3 according to different anatomic sites and organ systems.

Table 55.3 Physical Signs of Abnormal Malnutrition

INTEGRATED BEDSIDE ASSESSMENT

Since the early reports on malnutrition in hospitalized patients (3, 4, 15), there have been numerous attempts to define a series of parameters for accurate bedside assessment of nutritional status. Comprehensive assessment tools are too sophisticated for routine use by practitioners not trained in clinical nutrition (32, 35). The Likelihood of Malnutrition (LOM) score based upon eight defined measurements correlated with the length of hospitalization but included many parameters that are influenced by nonnutritional factors (3). The eight parameters used to define the LOM score in hospitalized medical patients included serum folate level, serum vitamin C level, triceps skinfold thickness, serum albumin level, absolute lymphocyte count, hematocrit, midarm muscle circumference, and body weight. While the LOM showed that 48% of patients were malnourished upon admission, 69% of patients hospitalized longer than 2 weeks demonstrated further decline in six nutritional parameters, and worsening of the LOM score was associated with prolonged hospitalization and increased mortality (3). Twelve years later, fewer medical patients were hospitalized with a high LOM score, and patients had shorter hospital stays, underscoring the

importance of effective nutritional assessment and intervention in hospitalized patients (36).

The Prognostic Nutritional Index (PNI) that included serum albumin, serum transferrin, delayed hypersensitivity, and triceps skinfold measurements correlated with postoperative complications and mortality (37, 38). However, each of these measurements can be influenced by the severity of illness (38). The Instant Nutritional Index (INI) identifies available parameters that can alert the practitioner to a more thorough nutritional assessment. In the INI, the serum albumin level and the absolute lymphocyte count correlated with the incidence of hospital infection (39, 40), and a subsequent study added weight loss to the INI (41). However, like the PNI, the INI is limited by low sensitivity and specificity as well as the severity of the patient's illness. Another study of 216 patients assessed the significance of the seven parameters most frequently used in the various indices for nutritional assessment: weight for height, serum albumin level, serum total protein, midarm muscle area, triceps skinfold thickness, creatinine/height index, and hand grip strength. The best correlation with body cell mass was found for weight for height ($r = 0.82$), while the creatinine/height index had the worst correlation ($r = 0.37$). However, all parameters had wide 95% confidence intervals, and multiple linear regression predicted malnutrition in 22 of 69 normal subjects (32% false positives) and failed to predict malnutrition in 9 of 79 malnourished patients (11% false negatives) (42).

SUBJECTIVE GLOBAL ASSESSMENT

The Subjective Global Assessment (SGA) provides an integration of historical and physical data that allows a trained physician to make a bedside assessment of nutritional status (43). The SGA yields immediate results, which allow rapid intervention and avoidance of expensive tests with long turnaround times. Five features of the history and four features of the physical examination are combined to assess nutritional status (Table 55.4). The historical features include (a) weight loss, (b) changes in dietary intake, (c) significant gastrointestinal symptoms, (d) the patient's functional status or energy level, and (e) the metabolic demand of the patient's underlying disease state. Weight loss is expressed as kilograms lost during the preceding 6 months and the 2 weeks prior to evaluation. Changes in the dietary pattern include the types of foods eaten, reduced intake, and duration of change. Assessment of abnormal food intake includes estimates of starvation, reliance on hypocaloric liquids, a complete liquid diet, or a suboptimal solid diet. Gastrointestinal symptoms are considered significant if they persist for more than 2 weeks and include anorexia, nausea, vomiting, and diarrhea. Energy level and functional capacity are graded from bedridden to full capacity. The severity of underlying disease is assessed according to its influence on the metabolic demand and hence nutritional requirement.

Select appropriate category with a checkmark, or enter numerical value where indicated by a "0"

A. History

1. Weight change and height
 Change in weight in past 2 months: loss = 0, 1-5% = 1, 5-10% = 2, >10% = 3, height = 0, 1-2 cm = 1, >2 cm = 2
 Change in diet in past 2 weeks: increase = 0, no change = 1, decrease = 2

2. Dietary intake change relative to normal
 No change = 0, decrease = 1, increase = 2

3. Gastrointestinal symptoms that persist for > 2 weeks
 None = 0, indigestion = 1, constipation = 1, diarrhea = 1, anorexia = 1

4. Anorectal symptoms
 No dysfunction in p. = 0, full rectal = 1, dysfunction = 2, hemorrhoids = 1, fecal incontinence = 1, anal fissure = 1, proctitis = 1, fistula = 1

5. Disease state or history of nutritional requirements
 Primary diagnosis specific: _____
 Metabolic demand increased = 0, no stress = 1, low stress = 2, moderate = 3, severe = 4

B. Physical findings
 Physical findings specific: _____
 0 = normal, 1 = mild, 2 = moderate, 3 = severe

1. Loss of subcutaneous fat (triceps, chest)	0 = normal, 1 = mild, 2 = moderate, 3 = severe
2. Muscle wasting (quadriceps, deltoids, temporalis)	0 = normal, 1 = mild, 2 = moderate, 3 = severe
3. Ankle edema	0 = normal, 1 = mild, 2 = moderate, 3 = severe
4. Sacral edema	0 = normal, 1 = mild, 2 = moderate, 3 = severe
5. Ascites	0 = normal, 1 = mild, 2 = moderate, 3 = severe

C. SGA rating system
 0 = normal, 1 = mild, 2 = moderate, 3 = severe

Table 55.4 Features of Subjective Global Assessment (SGA)

Physical findings are scored as normal (0), mild (1+), or severe (3+) and include depletion of subcutaneous fat, muscle wasting in the quadriceps and deltoid muscles, and the presence of edema and ascites. The triceps region and the midaxillary line at the level of the lower rib are assessed subjectively for subcutaneous tissue loss by pinching between thumb and forefinger. Palpation of the quadriceps and deltoid muscles assesses loss of tone and bulk. Ankle and sacral edema and ascites should be interpreted cautiously in the presence of comorbid disease states such as renal failure, congestive heart failure, or liver disease. Although not included in the original description of the SGA in [Table 55.4](#), a careful neurologic examination should be included as part of the bedside nutritional evaluation. As indicated in [Table 55.3](#), several micronutrient deficiencies can be identified by the bedside neurologic examination. For example, paresthesias of the face and hands may be the first sign of magnesium deficiency, more florid tetany is a sign of hypocalcemia, altered mental status may be a sign of hypophosphatemia, nystagmus or ataxic gait may be the only sign of thiamin deficiency, and loss peripheral of vibratory and position sense is a sensitive indicator of vitamin B₁₂ deficiency.

Based on the history and physical examination findings, patients are ranked according to the following three categories: A, good nutrition; B, moderate or suspected malnutrition; and C, severe malnutrition. Weight loss, poor dietary intake, loss of subcutaneous tissue, and muscle wasting are considered the most significant factors. Conversely, the presence of ascites, edema, or a large tumor mass reduces the significance of body weight. Patients fall into rank B if there is at least a 5% weight loss in the 2 weeks prior to admission without stabilization or weight gain, together with reduction in dietary intake and mild loss of subcutaneous tissue. Patients assigned a C rank demonstrate obvious physical signs of malnutrition with ongoing weight loss, an overall decline of at least 10% of their normal weight, and change in the other parameters ([43](#)). These rankings are illustrated by the following cases.

CASE STUDIES

Case A. A 52-year-old previously healthy man was admitted for elective transverse colectomy. Over the prior 4 months, he had experienced alternating diarrhea and constipation with loss of 8% of his usual weight that had improved with use of oral supplements. The physical examination showed normal subcutaneous fat and muscle mass with no evidence of edema or ascites. In view of weight stabilization and absence of physical findings of malnutrition, the patient was classified as A.

Case B. A 47-year-old man with a history of alcohol abuse was transferred from another hospital for evaluation and management of a suspected pancreatic pseudocyst that followed a bout of acute pancreatitis 2 weeks previously. While in hospital he had lost 10% of his normal admission weight and continued to experience abdominal pain on eating. The physical examination was remarkable for moderate loss of subcutaneous fat over the triceps, a squared-off appearance of the shoulders, and pitting edema over the sacrum and ankles. The patient was classified as moderately malnourished, or B.

Case C. A 75-year-old previously healthy man had lost 20% of his usual weight in association with progressive dysphagia in the preceding 6 months. Physical examination showed obvious loss of subcutaneous fat and wasting of the deltoid and quadriceps muscles, with trace edema over the ankles. Following upper endoscopy, adenocarcinoma of the esophagus was diagnosed, and he was admitted for further evaluation and elective surgery. On the basis of marked and progressive weight loss and significant physical findings of fat and skeletal muscle loss, the patient was classified as C, or severely malnourished.

The SGA was used to evaluate 59 patients electively admitted to a general surgical ward. Two trained observers agreed on the SGA classification of 48 of the 59 patients (44). The incidence of infection, the use of antibiotics, and the length of hospital stay correlated with the clinical diagnosis of malnutrition including serum albumin, transferrin, actual weight/ideal weight, creatinine/height index, body fat/body weight, and delayed cutaneous hypersensitivity. The SGA correlated with other objective parameters but not with the total lymphocyte count (44). The sensitivity of SGA was 82% and the specificity was 72% (45, 46).

The SGA was also used to predict development of major postoperative nutrition-associated complications. Patients in SGA class C with a low serum albumin level were identified at greatest risk of complications among patients undergoing major gastrointestinal surgeries (47). Another study found no association between the SGA and the incidence of postoperative complications in surgical patients. However, the highest postoperative mortality was found in patients classified with the worst malnutrition according to the SGA; preoperative malnutrition was present in 43% of the survivors versus 100% of those who died (48). These findings are consistent with findings from the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group, in which preoperative total parenteral nutrition support was significantly beneficial only to severely malnourished patients, but not to adequately nourished patients (10).

Another group applied the SGA to 59 chronic uremia patients, including 23 patients on continuous ambulatory peritoneal dialysis and 36 patients on intermittent hemodialysis,

and found malnutrition in 30%. The SGA correlated with muscle wasting, loss of fat, or the presence of gastrointestinal symptoms, but not with weight loss or the presence of edema (49).

In general, the SGA is a widely available and low-cost technique for nutritional assessment with good reproducibility. Its quantitative scale can be successfully applied to different patient populations. However, the published applications of the SGA involved physicians who either were trained in clinical nutrition or had undergone instruction in nutritional assessment. It remains unclear whether the results of the SGA are reproducible when used by untrained physicians.

FUNCTIONAL ASSESSMENT

The physiologic impairment that accompanies significant weight loss may be the primary cause of increased morbidity and mortality (50); thus, bedside assessment of functional status may be an important component of clinical nutritional assessment (51). In a study of functional assessment, surgical patients were preoperatively categorized into three groups: 1, preoperative weight loss of less than 10%; 2, weight loss greater than 10% without physiologic dysfunction; and 3, weight loss greater than 10% with physiologic impairment of at least two systems. Physiologic function was assessed by overall activity, exercise tolerance, grip strength, respiratory function, wound healing, and plasma albumin concentration. Major complications were more frequent in group 3 than in group 2 (15 vs. 3%) and included sepsis (18 vs. 4%) and pneumonia (10 vs. 1%). Patients in group 3 had a longer hospital stay, increased incidence of wound infection, and a higher mortality (50).

In the alert and cooperative patient, impaired skeletal muscle function can be assessed by testing grip strength with a hand dynamometer (52, 53). Hand grip strength was found to be the most sensitive indicator of complications in 102 patients undergoing major abdominal surgery. Complications were predicted in 87% of patients whose preoperative hand grip strength was less than 85% of normal (54, 55). Specificity was improved when age- and sex-derived standards were used (56). Hill et al. described a bedside technique that requires a patient to squeeze the clinician's index and middle fingers for at least 10 seconds. The determination of impairment was then subjectively based upon the patient's age, sex, and body habitus (20).

Measuring the contraction of the adductor pollicis muscle in response to electrical stimulation of the ulnar nerve is an alternative technique that does not require patient cooperation but may be uncomfortable for an awake and alert patient (57). This technique assesses the relationship between the force of contraction and the frequency of the stimulus, as well as the rate of muscle relaxation. Starvation increases the force to frequency of contraction parameter while slowing the relaxation rate, and these changes are corrected by refeeding prior to improvement in body nitrogen retention (58). These measurements have been used to predict nutritional complications in preoperative surgical patients (59). Others noted that involuntary muscle function in this test can be normal (60) or even elevated (61) in the presence of significant protein depletion if the subject is receiving adequate energy. Difficulty has been experienced in applying this technique to patients requiring intensive care; when results were

obtainable they did not reflect the extent of proteolysis but were indicative of the state of cellular energetics (61).

Exercise tolerance and the ability to perform the usual activities of daily living also reflect functional status. Bedside assessment of respiratory muscle function includes static compliance in the ventilated patient, while respiratory muscle strength can be assessed in the awake and cooperative patient by holding a strip of paper 10 cm from the mouth and observing its movement in response to respiration (20). The results must be interpreted with caution in the presence of comorbid disease like chronic obstructive pulmonary disease or congestive heart failure.

Measures of immunocompetence include delayed hypersensitivity skin testing and the absolute lymphocyte count. The absolute lymphocyte count (total white count \times percentage lymphocytes; normal, $>1200/\text{mm}^2$) is available to the clinician within hours of admission. However, as an isolated value, the absolute lymphocyte count is a poor predictor of outcome, since it is also influenced by stress, injury, surgery, corticosteroids, immunosuppressive agents, and infection.

Skin testing is an uncertain means of assessing immune status because the immune response can be depressed in normal patients following major surgery (62). The clinical utility of skin testing is limited in critically ill patients by the 24- to 72-hour delay required for the test results. Anergy is associated with severe malnutrition, but lesser degrees of malnutrition do not cause anergy. The immunosuppressive effects of corticosteroids, stress, and infection; the low predictive value of the test; and the depressed response in many other disease states led to the conclusion that routine use of skin testing is not indicated in nutritional assessment of the sick patient (63).

Rapid identification of processes that increase metabolic stress and nutritional requirements is essential to risk assessment. The presence of metabolic stress is usually suggested by the history and physical examination. Sepsis, as evidenced by a temperature above 38°C , pulse faster than 100/min, respiratory rate above 30/min, white blood count below 3,000/L or above 12,000/L, a positive blood culture, active inflammatory bowel disease, or defined focus of infection, is a major cause of metabolic stress. Other causes of stress that can potentially increase nutrient requirements include major trauma or major surgery.

Depletion of body nutrient stores and ultimate loss of specific cellular functions are common to many acute and chronic diseases. A hypothetical chronic illness of long duration is shown in [Figure 56.1 \(1\)](#). Progressive loss of fat-free body mass (FFM) is associated with the evolution of various complications, including loss of cell-mediated immunity, infections, bedsores, and, ultimately, death. A series of linkages implicit in [Figure 56.1](#) is central to the nutritional assessment examination:

Figure 56.1. Natural history of protein-energy malnutrition in a patient with chronic wasting illness. (Modified from Heymsfield SB, Bethel RA, Ansley JD, et al. *Ann Intern Med* 1979;90:63–71.)

food intake < nutrient losses ® negative protein balance ® depletion of FFM ® loss of protein-mediated cellular functions ® clinical complications

With nutritional therapy, loss of nutrients can be prevented or reversed, thus minimizing or eliminating the risk of clinical complications. This chapter further explores these relations, specifically to give a general overview of the anthropometric component of the nutritional assessment examination, which can be used to evaluate acutely and chronically ill malnourished patients.

ASSESSMENT COMPONENTS

Maintaining optimum health requires adequate tissue levels of essential nutrients and a source of energy. More than 40 syndromes develop if tissue levels of these components are either too low or too high (2). The emphasis in this chapter is on protein and energy because the large majority of patients seen for clinical evaluation have a disorder of protein-energy nutriture (3, 4).

Steady-State Relations

The sequence of changes in progressive protein-energy malnutrition involves negative nutrient balance, loss of cellular functions, and finally clinical complications. This section gives an overview of the steady-state relationships that exist among energy exchange, body weight, and body composition in health and describes how they are altered in pathologic states that cause negative nutrient balance. Body weight is a fundamental component of nutritional assessment because it is an indirect marker of protein mass and energy stores. The relationships among body weight, protein mass, and body energy content are shown in [Figure 56.2](#).

Figure 56.2. Major molecular body composition level components and how they relate to total body energy content.

A major portion of tissue function can be attributed to proteins that are activated by energy derived from metabolism of organic fuels (5). Protein is also a metabolic fuel and under conditions of weight stability, oxidation of amino acids provides about 15% of daily energy requirements (6). The energy-producing reactions take the general form

Urea is not metabolized further and is excreted unchanged in urine. During periods of nutritional deprivation, approximately half the total body protein mass can be used as metabolic fuel (7). A greater loss of protein is incompatible with survival. Therefore, when food intake is less than nutrient losses, amino acids from proteins are oxidized to provide energy, various tissue functions are altered, and, ultimately, protracted negative protein balance results in a rapid rate of lean tissue depletion and death (see [Chapter 41](#) on starvation).

The main sources of nonprotein energy are glycogen and fat or triglyceride. Glycogen is distributed primarily in liver and skeletal muscle (8). Glycogen stores are small (~400 g), and carbohydrate oxidation on a usual diet in the United States accounts for about 50% of daily energy production (6). Fat is found almost entirely within adipocytes or fat cells (9). Fat stores vary widely in humans, with fatty acid oxidation representing about 35% of energy production in the average American diet (6). Both glycogen and fat are oxidized in reactions similar to that for protein ([Eq. 56.1](#)), except urea is produced only with amino acid oxidation.

The sum of protein, glycogen, and fat constitutes total body energy content ([Fig. 56.2](#)). These fuels account for over 90% of the nonaqueous portion of body weight (10). Generalizations can be made on how body weight, protein, glycogen, fat, and energy stores relate to each other. Glycogen and protein are both solubilized by water and electrolytes. About 2 to 4 g water binds to 1 g of either glycogen or protein (11). Changes in glycogen or protein balance are thus associated with greater changes in body weight than can be attributed to loss of the actual chemical component. For example, oxidation and loss of 100 g glycogen would result in approximately a 0.5-kg reduction in body weight.

The main remaining chemical components exclusive of fat are minerals, found primarily in the skeleton (9, 10). The total fat-free portion of body weight thus consists of protein, glycogen, water, and minerals. In healthy adults, the steady-state fractional contribution of three of these components to total FFM is reasonably constant: protein, 0.195; water, 0.725; and minerals, 0.08; respectively. Glycogen levels vary throughout the day and represent a fraction of FFM of 0.01 to 0.02. With long-term weight loss, the change in FFM is approximately the same as the relative reduction in protein (2). Sharp changes in body weight and FFM may also reflect alterations in glycogen and fluid balance.

Fat maintains a relatively constant, although more complex, relation to fat-free

components. [Figure 56.3](#) shows a plot of total body fat/height² (Ht) versus body weight/Ht² in 414 women. Fat was measured in the women using a four-component model ([9](#)). The ratio body weight:Ht², referred to as body mass index (BMI, kg/m²), is discussed below in more detail. This figure illustrates two important points. First, the intercept for zero total body fat is a BMI of approximately 13. This extrapolated value represents a theoretical female subject without any fat, a condition incompatible with survival. Second, the slope of the regression line (i.e., the change in fat adjusted for stature/the change in body weight adjusted for stature) of approximately 0.74 indicates that body weight added above a BMI of about 13 is about three-fourths fat and one-fourth FFM. Webster et al. refer to the weight above a BMI of 13 as “excess weight” and suggest that weight gain or loss should approximate this composition ([12](#)). The composition of “excess weight” may differ between men and women and between young and old subjects. A more complex analysis of the relations among body weight, protein, and fat is presented by Forbes ([13](#)) (see also [Chapter 49](#).)

Figure 56.3. Relationship between total body fat (measured by four-component model [9](#)) adjusted for stature and body mass index (BMI) in 414 healthy women ($R^2 = 0.91$, $P < .001$).

These associations among body weight, total body protein mass, energy content, and fluid form an important concept: under most conditions, body weight is an indirect marker of protein mass and energy stores. A loss or gain in body weight is usually assumed to reflect changes in protein mass and/or energy content. Thus, body weight, total body protein mass and energy content, and chemical components are associated according to relatively simple rules. How these rules change in disease is important in anthropometric nutritional assessment, as described below.

Balance

Body composition is in a dynamic state throughout the day. Both total body protein mass and energy content decline between meals because of obligatory amino acid oxidation and metabolism of other fuels ([8](#), [14](#)). The result is negative protein and

energy balance. With food intake, balance becomes positive, and total body protein and energy content increase. Over a typical day, net protein and energy balance are zero and body weight remains constant. These relationships are depicted in [Figure 56.4 \(2\)](#), which presents a hypothetical healthy subject at point A. Body weight is stable, and long-term balances of energy, protein, and water are zero. [Figure 56.4](#) presents protein as nitrogen (N) as the two are related by a “constant” (protein = 16% N = 6.25 × N).

Figure 56.4. Model depicting changes in metabolic balance and body composition in protein-energy malnutrition and obesity. Point A is the range of body composition and tissue function found in health. Weight is stable, and balances of energy, nitrogen (N), and water are zero. Disease causes negative metabolic balance, weight loss, and changes in body composition and tissue function. Point B_u is the minimal range of body composition and tissue function that is compatible with survival. The course of a patient moving between points A and B_u may be interrupted by a complication related to malnutrition, indicated by point C_u . Positive balance leads to obesity, and a similar set of endpoints, B_c and B_o , are designated.

If the individual at point A develops an acute or chronic illness, food intake may be inadequate to replace nutrient losses; then net energy and nitrogen balance become negative, and body weight is lost. If the condition persists and balance remains negative, the subject approaches the point at which survival is no longer possible (B_u in [Fig. 56.4](#)). As mentioned above, the limits of survival with long-term underfeeding are a 50% loss in total body protein and a BMI of about 13. Loss of functional proteins and other essential nutrients results in the clinical complications described at the beginning of this chapter ([Fig. 56.1](#)) and shown in [Figure 56.4](#) as C_u . Clinically significant abnormalities in physiologic function and loss of total body protein are seen in most hospitalized patients who lose more than 20% of their preillness body weight ([15](#)).

Overeating relative to nutrient losses results in positive balance; if sustained, the individual gains weight ([Fig. 56.4](#)). The maximum survivable body weight is approximately 500 kg or a body BMI of about 150. As with undernutrition, obesity is

associated with complications (C_c in [Fig. 56.4](#)). The proposed mechanisms that lead to these complications are described in [Chapter 87](#).

Thus, some hypothetical optimal state of health exists (point A in [Fig. 56.4](#)) in which long-term balance is zero and health risks are at a minimum. Weight loss or gain is secondary to a change in energy and nitrogen balance and increases the individual's risk of developing various medical complications.

[Figure 56.4](#) embodies the main components of nutritional assessment: to define the patient's status between points A, B, and C. These aims can be formulated into four specific questions:

1. What is the patient's body weight and body composition status relative to an arbitrarily defined healthy range?
2. If the patient is under- or overnourished, what are the mechanisms leading to either negative or positive nutrient balance?
3. Is the patient at risk of developing a complication related to altered nutritional status?
4. With nutritional treatment is balance altered, and over time, is the patient's weight and body composition moving toward the healthy range?

Question 2 is examined in other chapters and is not discussed further here. This review focuses on undernutrition ([Chapter 87](#) describes the evaluation of obese patients).

Function

An important assumption of nutritional assessment is that body composition is an indirect measure of cellular function. Body composition estimates are usually highly correlated with specific functional tests. For example, anthropometric midarm muscle area is strongly correlated with forearm grip strength ([16](#)). However, body composition should not be assumed to be equivalent to tissue function; the two are different types of biologic measurements that serve different purposes but can, under certain conditions, replace one another. An example of mass and function dissociating is the patient with cardiomyopathy. Massive enlargement of the heart muscle is possible, yet the capacity of the myocardium to generate force and eject blood into the systemic circulation is severely impaired. The distinction between body composition estimates and cellular function indices should be kept in mind in interpreting the results of a patient's anthropometric and biochemical evaluations ([15](#)).

ANTHROPOMETRY

History

Anthropometry, developed in the late 19th century by anthropologists, uses simple measuring devices to quantify differences in human form. The potential of anthropometric methods in assessing nutritional status was first realized in the late 19th century by Richer, who used skinfold thickness as an index of fatness ([17](#)). The modern

era of nutritional anthropometry began with the studies of Matiegka during World War I (18). Matiegka's interest in the physical efficiency of soldiers led him to develop methods of anthropometrically subdividing the human body into muscle, fat, and bone. Anthropometric techniques are now widely used in many areas of human biologic research, and three important multiauthor books on the subject appeared within the last decade (19, 20 and 21).

Five-Level Model

The purpose of anthropometric measurements is to quantify the amount and distribution of major compositional determinants of body weight. A full appreciation of anthropometric measurements requires an understanding of human body composition and its organizational levels. The human body composition can be studied at five levels (9): I, atomic; II, molecular; III, cellular; IV, tissue-system; and V, whole body. The five levels and their major components are shown in Figure 56.5.

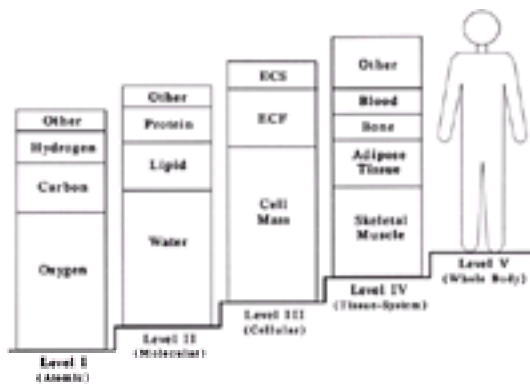

Figure 56.5. Five-level model of body composition. *ECF* and *ECS*, extracellular fluid and solids. (From Wang ZM, Pierson RN, Heymsfield SB. *Am J Clin Nutr* 1992;56:19–28, with permission.)

Atomic

The first level of body composition consists of major elements that make up body weight, such as oxygen, hydrogen, carbon, nitrogen, and calcium. Whole-body measurements at this level are usually made by research techniques such as *in vivo* neutron activation analysis (22, 23, 24, 25 and 26) (see Chapter 57). Elemental measurements are important in the study of body composition as they are used either directly (e.g., nitrogen balance as a measure of protein change) or to estimate components at other levels (e.g., total body calcium to indicate total bone mineral) (23). Anthropometric methods are available for estimating total body nitrogen, calcium, and

potassium at the atomic level (24).

Molecular

The second level of body composition consists of the major molecular components that constitute body weight, such as water, protein, glycogen, minerals (osseous and nonosseous), and fat (Fig. 56.5), which can now all be quantified in vivo except glycogen (22). It is possible to quantify hepatic and skeletal muscle glycogen stores (27). Total body protein can be estimated from total body nitrogen (an atomic-level component) (22, 25, 26) in a calculation that assumes that most total body nitrogen is incorporated into protein and that the nitrogen content of protein is 16% (28). Another component, total body fat, can be estimated by use of a two-component model in which the molecular level is simplified to body weight = fat + FFM (Fig. 56.5). Several two-component methods are used to estimate fat, such as underwater weighing, total body potassium, and total body water (TBW) (29). Each method relies on one or more assumptions that relate measurable body composition quantities to the unknown component of interest. For example, the TBW two-component method assumes that FFM has an average hydration of 73% (i.e., TBW/FFM = 0.73, or FFM = TBW/0.73). FFM and fat (i.e., body weight – FFM) can thus be estimated from TBW. Anthropometric methods of estimating total body fat are usually developed using one of these techniques as the reference standard for quantifying fat.

The second level of body composition is important in nutritional assessment because fat and FFM are the major components in which energy stores are distributed, and FFM contains all the functional components of body weight. Fat has an energy density of 9.4 kcal/g, and all but 1 to 2 kg is metabolically available during periods of protracted negative energy balance. Protein and glycogen have respective energy densities of 5.65 and 4.1 kcal/g. Assuming that the proportions of protein and glycogen are relatively normal in FFM, the metabolically available energy from FFM is 1.02 kcal/g (30, 31). Accordingly,

$$\begin{aligned} \text{Total body kcal} &= [9.4 \times \text{total fat (g)}] \\ &+ [1.02 \times \text{FFM (g)}] \quad (56.2) \end{aligned}$$

Half of the energy contained in FFM is usually available as fuel during long-term semistarvation (31). Evaluation of fat and FFM thus allows the investigator or clinician to estimate total body energy content, available energy stores, and changes in energy balance over time.

FFM, the metabolically active component at the molecular level of body composition, is generally accepted as an index of protein nutriture. Changes in FFM over time are assumed to represent alterations in protein balance. Resting oxygen consumption, carbon dioxide production, and heat production (i.e., energy expenditure) are highly correlated with FFM, and FFM accounts for about 50 to 80% of the individual variation in energy expenditure (32). For example, Cunningham pooled data from seven studies to derive the resting metabolic rate (RMR, kcal/day) prediction equation (28):

$$\text{RMR (kcal/day)} = 370 + 21.6 \times \text{FFM (kg)} \quad (56.3)$$

where FFM is in kg. Anthropometric methods are available for estimating TBW, FFM, and fat at the molecular level ([19](#), [20](#), [22](#), [24](#), [33](#), [34](#)).

Cellular

The cellular level of body composition consists of three main components: cells, extracellular fluid, and extracellular solids ([9](#)). Measurement techniques are available for quantifying extracellular fluid and solids, although total cell weight or the weight of specific cell groups is difficult to quantify in vivo. A widely used model of body weight components at this level was suggested by Moore et al. ([34](#)). Cell mass was considered as two components: fat (a molecular-level component) and fat-free cell mass. They referred to fat-free cell mass as “body cell mass” (BCM), a component responsible for most of the body’s metabolic processes. These investigators proposed that total body potassium (TBK) or exchangeable potassium (both atomic-level components, approximately equal in amount) could be used to estimate BCM because the potassium concentration of intracellular fluid is relatively constant at 150 mmol/L, and the ratio of intracellular fluid to solids is approximately 4:1 (i.e., intracellular fluid = BCM × 0.80). BCM could then be calculated using these relationships combined with an estimate of either total body or exchangeable potassium (i.e., BCM = [TBK/150] × [1/0.80], or 0.0083 TBK). Thus, according to Moore et al., body weight was equal to fat plus BCM plus extracellular fluids and solids.

Cells are the main functional components, and quantification of BCM enables investigators to explore important physiologic and functional relationships. At present, several anthropometric equations can be used to predict BCM at the cellular level ([24](#), [34](#))

Tissue-System

The tissue-system level of body composition consists of the major tissues and organs. Body weight at this level is equal to adipose tissue plus skeletal muscle plus skeleton plus residual. Adipose tissue includes fat cells or adipocytes, blood vessels, and structural elements ([9](#)). It is the primary site of fat storage, and in healthy adults, the chemical composition of adipose tissue averages 80% fat, 18% water, and 2% protein ([10](#)).

Adipose tissue is distributed mainly into the subcutaneous and internal or visceral compartments. The proportions of total adipose tissue in the subcutaneous and visceral compartments are not constant. Distribution of adipose tissue is under hormonal and genetic control, and metabolic properties of adipose tissue vary in different anatomic locations ([35](#)). Men, the elderly, and obese subjects tend to have a higher percentage of total adipose tissue in the visceral compartment than women, young, and lean subjects, respectively ([2](#), [35](#), [36](#)). Weight gain or loss is associated with different relative rates of adipose tissue change in the subcutaneous and visceral compartments and from different subcutaneous sites ([37](#)). This differential loss of adipose tissue is important in

interpreting anthropometric measurements. A strong positive correlation exists between the amount of visceral adipose tissue and the health risks of obesity (see [Chapter 87](#)).

Skeletal muscle is the largest component within the adipose tissue–free body mass (ATFM), accounting for approximately half of ATFM in healthy adults ([9](#), [10](#)). Skeletal muscle consists of muscle tissue, nerves, and tendons. Anatomic skeletal muscle also includes interstitial adipose tissue, which increases in amount in some diseases (e.g., Duchenne muscular dystrophy) and with aging. Approximately 20% of adipose tissue–free skeletal muscle is protein, and muscle is the largest tissue reservoir of amino acids ([7](#)). Depletion of up to 75% of skeletal muscle mass is possible during prolonged semistarvation ([7](#)).

The response of visceral organs to semistarvation varies. Organs decrease in weight at different rates during uncomplicated semistarvation. For example, liver mass decreases rapidly in rodents with underfeeding, whereas heart weight decreases at about the same rate as body weight ([37](#)). The pattern of visceral organ changes in protein-energy malnutrition associated with physiologic stress may differ from that of uncomplicated underfeeding. An example is the severe weight loss that often accompanies metastatic malignant disease. Cancer cachexia in both animals and humans is accompanied by preservation of some visceral organs despite loss of body weight and atrophy of skeletal muscles ([38](#)) (see [Chapter 82](#) and [Chapter 96](#)). Preservation of visceral organs with physiologic stress may represent an adaptive response to injury or infection that is the anatomic counterpart to increased synthesis of serum acute-phase reactants.

Magnetic resonance imaging (MRI) and computed tomography are used by investigators to quantify total body and regional adipose tissue and skeletal muscle ([22](#)). Imaging and ultrasonic techniques can also be used to estimate visceral organ and skeletal weights. Skeletal muscle and adipose tissue are important components in nutritional assessment because they are readily estimated by anthropometric techniques. At present, many anthropometric equations can be used to predict total and visceral adipose tissues, skeletal muscle, and bone mass at the tissue-system level ([9](#), [39](#), [40](#)).

Whole Body

The whole body level of body composition includes the main anthropometric dimensions such as stature, circumferences, breadths, and skinfold thicknesses. Other whole-body measures include body weight, density, and volume (see also [Chapter 49](#)).

Features of the Model

The five-level model has several important features. First, the model is consistent as a whole and each component is distinct ([9](#)). Connections between components are important in relation to anthropometric methods, however; for example, a group of related components at atomic to tissue-system levels: calcium, bone mineral, extracellular solids, skeleton, and bone breadths. Each of these components is distinct, and yet all five are linked because they are different constituents or dimensions of the

human skeleton (9).

Second, steady-state relationships exist between many components at the same or different levels (9). Steady state as used here means a stable relationship between components over a specified time interval, usually months or years. Some steady-state relations were described above (e.g., the hydration of FFM = 0.73, and intracellular potassium concentration = 150 mmol/L). These quantitative associations are important in developing body composition models that relate a known component to an unknown component of interest. For example, TBW can be measured and FFM then calculated as $TBW/0.73$ (9). Steady-state relationships are particularly important in anthropometry because although all anthropometric measurements are at the whole-body level, they are used primarily to infer information about the first four body-composition levels. Steady-state relationships allow us to establish connections between the whole-body level and other levels. Additionally, they are often altered across gender, age, and ethnic groups and with disease, thus changing the quantitative associations established between anthropometric dimensions and other body components.

Following is a summary of anthropometric methods in the context of the five-level model.

Measurements

The anthropometric measurements in general use for evaluation of malnutrition include body weight, stature, skinfold thicknesses, circumferences, and bone breadths. These whole-body measurements can be used in nutritional assessment, in indices, or in equations that estimate an absolute value component at one of the other levels (Table 56.1). The following discussion groups the various anthropometric measurements and techniques into three categories: (a) body weight and stature; (b) estimates of fatness and energy stores; and (c) lean tissue indices, protein mass, and functional components.

Level	Characteristic Components			Anthropometric Dimensions Level V				
	Level I	Level II	Level III	BM	Stature	Circumferences	Skinfolds	Breadths
TBC	fat	fat cells	adipose tissue	X			X	
TBD	TBM	BCM + ECF	ATM	X			X	
TBCa, TBP	Mb	ECS	bone, skeleton	X	X			X
TBM, TBN	Pro, Mo	BCM	muscle + viscera	X	X		X	
TBM, TBD	Mb	ECF	total + SF	X	X			

ATM, adipose tissue; BCM, body cell mass; BM, body weight; ECF, extracellular fluid; ECS, extracellular solids; FFM, fat-free body mass; ECF, extracellular fluid; Mb, muscle; Mo, mineral; Pro, protein; SF, skinfold; TBM, total body mass; TBC, total body cell mass; TBCa, total body calcium; TBP, total body protein; TBN, total body nitrogen; TBD, total body deuterium; TBC, total body carbon; TBM, total body magnesium; TBN, total body nitrogen; TBP, total body phosphorus; TBM, total body mass.

Table 56.1 Some Characteristic Components at Levels I to IV and Related Anthropometric Dimensions at Level V

Body Weight and Stature

Body weight is the sum of all components at each level of body composition. As described above, body weight is a rough measure of total body energy stores, and changes in weight parallel energy and protein balance. A significant correlation exists ($r = 0.6$, $P < 0.05$) between loss of body weight and change in total body protein in seriously ill adults (15).

Body weight usually varies less than ± 0.1 kg/day in healthy adults (2). A weight loss of more than 0.5 kg/day either indicates negative energy or water balance or a combination of the two. Clinically significant weight loss is considered a relative decrease in weight of more than 10% over an interval of less than 6 months (2).

The severity of weight loss in an individual is determined by two factors: the rate of weight change over time and the total reduction in weight. The rate of weight loss in total starvation is approximately 0.4 kg/day, and survival is sustained to about 70% of desirable (i.e., ideal) body weight (2). Semistarvation, the more typical cause of negative energy balance in patients, results in a more gradual weight loss than total starvation. In patients with chronic disease, the weight change may occur over years or decades. The minimal survivable body weight in humans is between 48 and 55% of desirable body weight, or a BMI of about 13 (i.e., point B_u in Fig. 56.4). Body weight at this point consists of less than 5% metabolically available fat (2). Exhaustion of the remaining usable fat mass results in rapid depletion of lean tissue and death.

The absolute body weight and rate of change in weight have prognostic value, and two aspects are recognized. First, an absolute body weight below 55 to 60% of desirable places the subject at or near the survival limits of starvation (2); further negative balance could not be tolerated for long. Second, a significant weight loss from preillness weight (between 10 and 20%) over an interval of less than about 6 months places the patient at risk of developing functional impairment of multiple organ systems and an adverse clinical outcome.

Studley was among the first to associate weight loss with disease outcome (41). In 1936, this pioneering investigator made the classic observation that marked weight loss prior to surgical procedures for peptic ulcer resulted in a higher postoperative mortality rate than in weight-stable patients. Modern workers have identified weight loss as a major determinant of prognosis in many disease states and conditions, such as survival time in patients with carcinoma of the colon (42) and chronic obstructive lung disease (43). Seltzer et al. found a 19-fold increase in mortality in adult patients undergoing elective surgery who lost more than 10 lb body weight preoperatively, compared with patients with little or no weight loss (44). Hirsch et al. (45) observed a 21% preoperative weight loss in patients who died postoperatively, compared with a 12% preoperative weight loss in survivors.

An important study by Windsor and Hill refined Studley's classic observation by

demonstrating that the postoperative patients with weight loss who are at the highest risk of complications are those who also have clinically obvious impairment in organ function (46). Postoperative patients with clinically apparent organ impairment in this study also had significant abnormalities of a variety of measured physiologic functions and a reduced weight of total body protein. Summarizing this and other studies from his laboratory, Hill concluded that a loss of less than 10% of preillness body weight is usually not associated with functional abnormalities; loss of between 10 and 20% of preillness body weight is accompanied by functional abnormalities in some patients; and a loss of >20% of preillness body weight is associated with protein-energy malnutrition and multiple functional abnormalities in almost all patients (15). Weight loss is thus an important indirect index of multiple physiologic functions and the underlying severity of disease and is a guide to a patient's prognosis. Body weight is measured longitudinally to establish the effectiveness of nutritional therapy. A change in weight reflects energy, protein, and water balance.

Measurement. In the hospital, body weight should be measured within ± 0.1 kg on a calibrated physician's scale. Special scales should be used for bedridden or wheelchair-bound patients. Edema, if present, should be recorded with the weight. The general procedure is to obtain a morning weight following evacuation of the bladder. The weight of the hospital gown can be subtracted from the total weight to obtain nude weight. When comparing the patient's weight with standard values, the attire is usually presented in a footnote on the table. Serial weights should be measured on the same or a carefully calibrated scale. Intake and output records may be useful in interpreting the significance of weight changes.

Reference tables provide a standard weight for height, and in some cases, an adjustment is made for frame size (see Appendix [Table A-12-a-1](#), [Table A-12-a-2](#), [Table A-12-a-3](#), [Table A-12-a-4](#), [Table A-12-a-5](#), [Table A-12-b](#), [Table A-12-c-2](#), [Table A-12-c-3](#), [Table A-12-d](#), [Table A-12-e](#), [Table A-13-a](#), [Table A-13-b](#), [Table A-14-a](#), [Table A-14-b-1](#), [Table A-14-b-2](#), [Table A-14-c-1-a](#), [Table A-14-c-1-b](#), [Table A-14-c-2-a](#), [Table A-14-c-2-b](#), [Table A-14-d-1-a](#), [Table A-14-d-1-b](#), [Table A-14-d-2-a](#), [Table A-14-d-2-b](#), [Table A-14-e-1](#), [Table A-14-e-2](#), [Table A-14-f-1](#), [Table A-14-f-2](#), [Table A-14-g-1](#), [Table A-14-g-2](#), [Table A-15-a](#), [Table A-15-b](#), [Table A-15-c](#), [Table A-15-d](#) and [Table A-15-e](#)). Height is usually measured by a sliding bar attached to the physician's scale, although more-accurate techniques are used for research purposes. Height can be estimated in bedridden patients using knee-height or arm-span prediction equations (47, 48, 49 and 50) ([Table 56.2](#)). Knee height is measured in the sitting position with an anthropometric caliper. The bottom of the foot is placed flat on the floor to form a right angle with the knee. The heel is raised, and the caliper blade is placed under the heel. The caliper's movable blade is then lowered to the top of the thigh at a minimum of 2 inches posterior to the kneecap. Methods for recumbent measurement of knee height are also available. Arm span is defined as the distance between the tips of the longest finger of each hand with subjects standing erect against the wall and both arms fully stretched horizontally (48, 50). The body weight reference table usually specifies the technique used to estimate frame size.

Group	Age Group	Equation	Reference
White men	18-80	Stature = 1.88 (knee/height) + 71.88	47
	18-80	Stature = 2.31 (knee/height) + 51.1	48
	80-80	Stature = 2.28 (knee/height) + 50.71	48
Black men	18-80	Stature = 2.20 (knee/height) + 0.000 (age) + 54.9	48
	18-80	Stature = 2.192 (arm span) + 40.7	48
	18-80	Stature = 1.79 (knee/height) + 75.42	47
White women	18-80	Stature = 1.87 (knee/height) + 0.000 (age) + 73.25	47
	22-71	Stature = 1.86 (knee/height) + 70.3	48
	22-71	Stature = 1.81 (knee/height) + 0.000 (age) + 71.3	48
Black women	18-80	Stature = 1.81 (knee/height) + 0.17 (age) + 70.99	48
	22-71	Stature = 1.8602 (arm span) + 30.5	48
	18-80	Stature = 1.86 (knee/height) + 0.000 (age) + 68.10	47
White boys	8-10	Stature = 1.86 (knee/height) + 58.72	49
	6-10	Stature = 2.25 (knee/height) + 40.84	47
Black boys	6-10	Stature = 2.18 (knee/height) + 38.80	47
	4-10	Stature = 1.75 (lower segment) + 25.98	50
Chinese boys	4-10	Stature = 2.00 (arm span) + 10.88	50
	6-10	Stature = 2.18 (knee/height) + 40.21	47
White girls	6-10	Stature = 2.20 (knee/height) + 40.88	47
	4-10	Stature = 1.81 (lower segment) + 22.70	50
Black girls	4-10	Stature = 1.80 (arm span) + 10.24	50
	6-10	Stature = 2.18 (knee/height) + 40.21	47

*Knee span, knee height, and stature are in cm; lower segment (lower body height) is in cm + standing height minus sitting height; age in years

Table 56.2 Recommended Equations for Predicting Stature in Adults and Children

Interpretation. Interpretation of body weight as an index of available energy supply must be done with caution in four conditions:

1. Edema and ascites cause a relative increase in extracellular fluid and may mask losses in chemical or cellular components.
2. Massive tumor growth or organomegaly can mask loss in fat or lean tissues such as skeletal muscle.
3. Lean tissue and cellular atrophy are partially masked by residual fat and connective tissue in obese patients undergoing rapid or severe weight loss. Patients may still be overweight and yet suffer severe protein-energy malnutrition and also be at increased risk of adverse health outcomes secondary to semistarvation.
4. Large changes in energy intake cause corresponding changes in glycogen mass and bound water over several days. Similarly, large changes in sodium intake are associated with brief periods of fluid readjustment and body weight change.

For these reasons, and also to characterize body composition more completely, anthropometric methods are used for further assessment of body weight. These methods are described under two general headings as they relate to nutritional assessment: measures of fat stores and measures of lean tissues.

Fat

Although fat refers specifically to a chemical component at the molecular level of body composition, this section as a whole relates to the following five-level sequence: atomic, carbon; molecular, fat; cellular, fat cells; tissue-system, adipose tissue; and whole-body, anthropometric dimensions (e.g., skinfolds/circumferences) (see [Table 56.1](#)). Although more accurate and reproducible methods of estimating fatness exist, anthropometric methods are the simplest, safest, most practical, and least costly of the available

techniques because of easy access to subcutaneous adipose depots.

The amount of fat in healthy subjects varies greatly, with relatively small amounts in some highly trained athletes and relatively large amounts during the later stages of pregnancy. During protracted undernutrition, all but a small amount of total body fat can be used as metabolic fuel (2). Two factors determine the adequacy of fat: the amount of total body triglyceride present and energy balance. Very little fat is sufficient if the individual is healthy and in zero energy balance. In contrast, a small amount of fat in the presence of marked negative energy balance implies a limited survival time. The usual practice is to compare fat values from an individual patient with reference standards and also to follow trends over time. During nutritional therapy, the fat measurement provides an indirect guide to energy balance.

Measurement and Interpretation. Three methods of assessing fatness are available: (a) the single skinfold method; (b) the limb fat area method; and (c) total body fat (or adipose tissue) calculated from multiple anthropometric measurements. The measurements common to all three techniques are now briefly reviewed, and the interested reader should consult additional references for added details (19, 20 and 21).

Measuring body fat requires two instruments: a skinfold caliper and a tape measure. The caliper should be a rugged and light instrument, and jaw pressure should be maintained at 10 g/mm² throughout the measurement range. The contact surface area of the jaws can vary between 30 and 100 mm², and the jaws on some calipers remain parallel as they are opened wider. A calibration block is usually supplied with the instrument.

The tape measure should be durable, resist stretching, and have an accuracy of ±0.1 cm. Plastic and fiberglass tapes meet these criteria, and calibration should be checked periodically against a meter stick.

Two types of measurement are usually made: skinfold thicknesses and limb or trunk circumferences. The location of six widely used skinfold sites and circumferences is described in [Table 56.3](#) and [Table 56.4](#) (2). Skinfolds represent a double layer of subcutaneous tissue, including a small and relatively constant amount of skin and variable amounts of adipose tissue. Components at all five levels of body composition are thus represented by a skinfold measurement. For arm measurements, the most important aspect is to use the same arm for repeated measurements. Some workers recommend evaluating the nondominant arm; when comparing the patient's measurements with standard values, consult the arm selected in the reference table. Measuring techniques and methods of optimizing precision are presented in reference 19 and in [Table 56.5](#) and [Table 56.6](#). Skinfold measurements are not accurate in massively obese patients.

-
1. **Biceps skinfold thickness.** Lift the skinfold on the anterior aspect of the upper arm, directly above the center of the cubital fossa, at the same level as the triceps skinfold and midarm circumference. The arm hangs relaxed at the patient's side, and the crest of the fold should run parallel to the long axis of the arm.
 2. **Triceps skinfold thickness.** Grasp the skin and subcutaneous tissue 1 cm above the midpoint between the tip of the acromial process of the scapula and the olecranon process of the ulna. The fold runs parallel to the long axis of the arm. Care should be taken to ensure that the measurement is made in the midline posteriorly and that the arm hangs relaxed and vertical.
 3. **Subscapular skinfold.** The skin is lifted 1 cm under the inferior angle of the scapula with the patient's shoulder and arm relaxed. The fold should run parallel to the natural cleavage lines of the skin; this is usually a line about 45° from the horizontal extending medially upward.
 4. **Suprailiac skinfold.** Pick up this skinfold 2 cm above the iliac crest on the midaxillary line. The crest of this fold should run horizontally.
 5. **Thigh skinfold.** The skin is picked up on the posterior aspect at the same level as the thigh circumference. The crest of the skinfold should run parallel to the leg.
 6. **Calf skinfold.** This skinfold is picked up on the posterior aspect of the calf at the same level as the calf circumference. The crest of the skinfold should run parallel to the leg.
-

Table 56.3 Skinfold Measurement Sites

-
1. **Midupper arm.** This circumference is taken at the midpoint between the acromial and olecranon processes of the scapula and the ulna, respectively. The arm should hang relaxed at the patient's side.
 2. **Midthigh.** The subject stands with feet slightly apart and with weight evenly distributed on both feet. The tape is placed around the thigh horizontally at the midpoint between the lower extent of the gluteal fold and the crease immediately posterior to the patella.
 3. **Midcalf.** With the subject standing in the same position as for the thigh circumference, the measurement is made with the tape horizontal at the maximal circumference of the calf.
-

Table 56.4 Circumferential Measurement Sites

-
- Skinfolds
1. Arrive at the anatomic site as described in Tables 56.3 and 56.4
 2. Lift the skin and fat layer from the underlying tissue by grasping the tissue with the thumb and forefinger.
 3. Apply calipers about 1 cm distal from the thumb and forefinger, midway between the apex and base of the skinfold.
 4. Continue to support the skinfold with the thumb and forefinger for the duration of the measurement.
 5. After 2 to 3 seconds of caliper application, read skinfold to the nearest 0.5 mm.
 6. Measurements are then made in triplicate until readings agree within \pm 1.0 mm; results are then averaged.
- Circumferences
1. The tape should be maintained in a horizontal position touching the skin and following the contours of the limb, but not compressing underlying tissue.
 2. Measurements should be made to the nearest millimeter, in triplicate, as previously described for skinfolds.
-

Table 56.5 Methods of Measuring Skinfolds and Circumferences

-
1. Train observers by skilled professionals.
 2. Use one rather than multiple observers for the same subject over time.
 3. Mark the anatomic site of the skinfold and circumferential measurement with indelible ink when repeatedly measuring the same patient over a short time span.
 4. Learn the anatomic landmarks, how to grasp the skinfold, how long to compress the skinfold site, and how to properly read the caliper scale.
 5. Periodically assess interobserver and between-day measurement differences of the staff.
-

Table 56.6 Methods for Optimizing Precision

The absolute skinfold thickness can be used directly for comparison with reference tables and for longitudinal follow-up (see Appendix [Table III-A-14](#) and its subdivisions). The limitation of evaluating one skinfold thickness is that a single measurement is a relatively poor predictor of the absolute amount and rate of change in total body fat because (a) large interindividual differences exist in fat distribution, (b) as total body fat changes, each skinfold site responds differently, and (c) the relationship between skinfold thickness and total body fat is complex (e.g., an exponential relationship exists between subcutaneous skinfold thickness and total body fat and between subcutaneous fat and visceral fat) ([39](#), [51](#)). Other factors that limit a single skinfold thickness as a measure of fatness include changes in the composition of adipose tissue with age and nutritional status, variation in skinfold distribution and compressibility with age, and the inclusion of a small amount of nonadipose tissues (e.g., skin) in the measurement ([2](#), [20](#), [39](#)). The final consideration is that the day-to-day variability in measuring the same skinfold is large, even when the rigorous procedures outlined in [Table 56.5](#) and [Table 56.6](#) are followed. Skinfold thickness should thus be considered a qualitative measure of the amount and rate of change in total body fat. The advantages are ease and rapidity of measurement, especially in bedridden patients.

Combining a limb skinfold thickness with a corresponding circumference allows calculation of limb fat areas ([Table 56.7](#)). Most of the problems related to a single skinfold measurement also occur with the limb fat area. The advantage generally ascribed to area calculations is that the result includes the contribution of limb circumference; two limbs with equal skinfolds but unequal circumferences have different amounts of fat.

Gender	Equation	Comments
Upper arm	Arm fat area (cm ²) = $\left[\frac{MAC \times TGF}{2} \right] - \left[\frac{\pi \times (CSF)^2}{4} \right]$	The general equation assumes a circular limb and muscle concentration and a symmetrical distribution of fat; the accuracy of this equation in predicting midupper arm fat area is unknown
Thigh	Thigh fat area (cm ²) = $\left[\frac{MTC \times TGF}{2} \right] - \left[\frac{\pi \times (CSF)^2}{4} \right]$	TGF, thigh skinfold (cm); MAC, midarm circumference (cm); TGF, thigh skinfold (cm); MTC, midthigh circumference (cm)
Calf	Calf fat area (cm ²) = $\left[\frac{MCC \times CSF}{2} \right] - \left[\frac{\pi \times (CSF)^2}{4} \right]$	CSF, calf skinfold (cm); MCC, midcalf circumference (cm)

Table 56.7 Equations for Calculating Limb Fat Areas

Many prediction equations are available for calculating total body fat from measured skinfold thicknesses (see Appendix [Table III-A-17-a](#), [Table III-A-17-b](#) and [Table III-A-17-c](#)), circumferences, body weight, and stature. All methods presently in use are “descriptive” in that measured anthropometric dimensions are converted to total body fat or other components using statistically derived equations in the absence of an underlying theory of mechanism. In contrast, some body composition methods are based on theoretical or mechanistic models (e.g., BCM is calculated from exchangeable potassium by use of a model that assumes a constant intracellular potassium concentration). All descriptive methods, including anthropometry, share in common the following: development in a well-defined subject group, use of a criterion method for estimating total body fat, and a prediction model formulated by use of regression analysis. Some methods, for convenience and speed, are based only on gender, body weight, stature, and circumferences ([52](#), [53](#)). As all prediction formulas are population specific, they should be cross-validated in new subject groups prior to application. Ideally, the fat-prediction formula is used in a group similar to the population on whom it was developed.

A good example and the most widely applied total body fat–prediction formula was developed by Durnin and Womersley using underwater weighing as the criterion for fat estimation ([54](#)) ([Table 56.8](#)). The sample contained 209 Caucasian men and 272 women, less than 68 years of age, and on average normal or slightly overweight. Once total body fat is known, it can be subtracted from body weight to provide a value for FFM.

- Determine the patient's age and weight (kg).
- Measure the following skinfolds in mm: biceps, triceps, subscapular, and suprailiac (Tables 56-3 and 56-5).
- Compute Σ by adding the four skinfolds.
- Compute the logarithm of Σ .
- Apply one of the following age- and sex-adjusted equations to compute body density (D, g/ml):
 Equations for men:
 Age range
 17-19 $D = 1.1620 - 0.0630 \times \log \Sigma$
 20-29 $D = 1.1634 - 0.0632 \times \log \Sigma$
 30-39 $D = 1.1422 - 0.0644 \times \log \Sigma$
 40-49 $D = 1.1620 - 0.0700 \times \log \Sigma$
 50+ $D = 1.1715 - 0.0779 \times \log \Sigma$
 Equations for women:
 Age range
 17-19 $D = 1.1569 - 0.0678 \times \log \Sigma$
 20-29 $D = 1.1609 - 0.0717 \times \log \Sigma$
 30-39 $D = 1.1423 - 0.0632 \times \log \Sigma$
 40-49 $D = 1.1333 - 0.0612 \times \log \Sigma$
 50+ $D = 1.1333 - 0.0645 \times \log \Sigma$
- Fat mass is then calculated as fat mass (kg) = body weight (kg) $\times \left[\frac{4.95}{D} - 4.5 \right]$
- Fat-free body mass is then calculated as FFM (kg) = body weight (kg) - fat mass (kg)

Table 56.8 Calculation of Fat and Fat-Free Body Mass According to the Method of Durnin and Womersley

A literature search will turn up many fat-prediction formulas that are applicable in specific populations and that vary in measurement type (i.e., circumferences and skinfolds) and anatomic location. Some examples of methods in current use for females are presented in [Table 56.9](#). In most of these formulas the dependent (i.e., predicted) variable is body density. These methods were developed using underwater weighing as a reference for body density estimation and setting anthropometric dimensions along with such other covariates as age in regression models as independent variables. The anthropometric “predicted” density can be converted to percentage fat by use of traditional two-component body composition models as outlined in [Table 56.8](#).

Author (Date ref)	Equation	n	Mean Age	r	SEI
Geel and Winkler (1970:84)	Density = 1.9846 - 0.0048 (biceps SF) - 0.0075 (triceps SF) + 0.0070 (C2) - 0.0021 (log C)	89	25.6 ± 6.4%	0.84	0.008
Jackson et al. (1980:85)	Density = 1.470 - 0.00403 (chest SF + midaxillary SF + triceps SF + subscapular SF + abd SF + suprailiac SF + thigh SF) + 0.000005 (W) - 0.0000075 (H) + 0.000074 (5) (quadr C)	240	4-44%	0.87	0.029
Wright et al. (1980:86)	Density = 1.001 (biceps C) + 1.002 (triceps C) - 0.007 (neck C) + 0.008 (waist C) + 0.009 (thigh C) + 0.007 (leg C) + 0.001 (heel C) + 0.001 (ankle C)	187	2-37%	0.75	0.1%
Hogdson and Buckner (1984:52)	Density = -0.0004 (log ₁₀ waist C + log ₁₀ neck C) + 0.021 (H)	274	16-47%	0.80	0.020
Vogel et al. (1988:57)	% Body fat = 0.173 (log C) + 108.228 (log ₁₀ W) - 0.018 (H) - 0.154 (biceps C) - 0.030 (neck C) - 0.006 (heel C) - 35.8	288	5-50%	0.77	0.0%
Tan and Helmer (1985:88)	Density = 1.98207 - 0.00294 (abd C) + 0.000722 (biceps C) - 0.0070728 (thigh C) + 1.00019477 (H) - 0.00021816 (A)	480	25.3 ± 17%	0.80	0.026

^a log = base 10; log₁₀ = base 10; log_e = base e; C = circumference (cm); SF = skinfold thickness (mm); H = height (cm); W = weight (kg). Covariates are shown for the groups unless otherwise specified. The standard error of the estimated regression coefficient is shown in parentheses to the right of each equation.
^b Density in g/ml.

Table 56.9 Anthropometric Equations That Predict Body Density in the Female Population^{a,b}

The advantages of calculating total body fat are (a) more than one skinfold site is

usually included in the calculation and (b) the result (in kilograms) can be used directly to calculate energy reserves as fat. The latter values can then be integrated with estimates of energy balance calculations, thus providing a more physiologic description of the patient's nutritional state. A cautionary note, as with all prediction equations, results are most accurate on populations on which the equation was derived. The accuracy of the Durnin-Womersley equation (Table 56.8) and those presented in Table 56.9 is unknown in patients with severe weight loss, and the techniques should not be applied when a gross distortion in body habitus or obvious fluid accumulation is present (54). As emphasized by Damon and Goldman, skinfold thicknesses describe, but do not measure, total body fat (55). The error of prediction of total body fat from skinfolds may be considerable in some individuals, even when group means are accurate. More-accurate methods of measuring fat are therefore usually applied in research studies of body composition.

It is customary to express total body fat estimates as a percentage of body weight. However, as an individual gains or loses weight, both fat and FFM change, which leads to problems in interpretation. Additionally, the relationship between body fat and body weight has a nonzero intercept (Fig. 56.3), so that a curvilinear relationship exists between total body fat (12), expressed as a percentage of body weight, and body weight or BMI (Fig. 56.6). These complex relationships can result in some confusing situations, as when a severely obese patient loses a relatively large amount of weight with a relatively small change in the percentage of fat. A highly trained athlete and a severely malnourished patient might have an equivalent percentage of body weight as fat. They could also have a similar absolute fat weight. To overcome these difficulties, Van Itallie et al. suggest calculating a fat (or FFM)-stature index similar to BMI as fat/Ht² (56). A low or high "fat mass index" would then represent a reduced or increased actual fat mass relative to stature, respectively. For example, the fat mass index of a malnourished patient would be lower than that of a highly trained athlete, even though they had an equivalent percentage of body weight as fat. This is because the athlete with a similar percentage of body weight as fat would have a much larger absolute fat mass and also a much larger FFM and greater body weight than the malnourished patient.

Figure 56.6. Percentage of body weight as fat in 413 healthy women versus body mass

index (BMI). Fat was measured by the four-component model (9).

Lean Tissues

Lean tissues refer in general to the following sequence of components at the five levels of body composition: atomic nitrogen, potassium, and calcium; molecular FFM, water, and protein; cellular BCM; tissue-system skeletal muscle, skeleton, and visceral organs; whole body anthropometric measurements (e.g., skinfolds/circumferences) (see [Table 56.1](#)). These various components are associated with the major portion of whole-body metabolic activity and biologic functions.

Semistarvation. Semistarvation results in negative balances of energy, protein, water, and minerals, a reduction in FFM and BCM, and atrophy of tissues and organs (2, 57) (see [Chapter 41](#)). Not all lean components change at the same rate during periods of negative balance. At the molecular level, cellular proteins are depleted rapidly, and connective tissue proteins are lost at a slower rate (2). Similarly, at the cellular level, rapid changes can occur in BCM, whereas extracellular fluid is lost more slowly or may even increase in volume (57). Organs and tissues also differ in their rate of weight loss during semistarvation. Liver mass decreases rapidly and brain weight changes little if at all in uncomplicated semistarvation; liver and other visceral organs may be preserved in chronic catabolic conditions such as metastatic malignant diseases (37). Skeletal muscle is a major reservoir of amino acids for acute-phase protein synthesis and can decrease by up to 75% in weight during protein-energy malnutrition (7, 37). The malnourished patient with a reduced body weight therefore differs in composition at each of the five levels from his or her normally nourished counterpart. This explains why anthropometric equations developed in normal subjects may not predict a specific component with equal accuracy in an undernourished seriously ill patient.

In anthropometrically assessing the severity of malnutrition, an important goal is defining the amount and rate of change in total body or skeletal muscle protein (7, 37). The main anthropometric indices used for this assessment are FFM (molecular level) and limb muscle areas (tissue-system level). As lower limits compatible with survival are known for both types of measurement (2), the severity of protein-energy malnutrition is usually judged as the patient's value relative to the normal range on the one hand and the minimal range on the other. In terms of prognostic value, these measurements provide some index of potential survival time; given the patient's anthropometric FFM or muscle index and nitrogen balance, progression toward or away from potentially lethal starvation can be established. During nutritional therapy and follow-up, the anthropometric FFM indices are used as measures of nitrogen balance; specific details regarding interpretation are presented in the following paragraphs.

Measurement and Interpretation. FFM is measured by anthropometric methods, such as those described above in the section on [fat](#) ([Table 56.8](#) and [Table 56.9](#)). The cautions in measurement technique and selection of patients noted in that earlier discussion also apply to FFM. With regard to interpretation, in theory, multiplying FFM

(in grams) by 0.195 and 1.02 provides the amount of total body protein in grams and metabolizable energy in kilocalories. Of the metabolizable energy in the healthy subject, about half of that in FFM is available during prolonged periods of semistarvation (2). Combined with balance data and information on total body fat, these bedside calculations often provide an interesting insight into a patient's course. Unfortunately, the information needed for accurate prediction of total body protein cannot be derived from anthropometric FFM because of the changes in body hydration and variability of skinfold measurements described above. A large tumor burden or organomegaly of any cause may also add metabolically unavailable mass (as water, protein, and mineral) to FFM. In patients without serious derangements in body composition, FFM can be used in [equation 56.3](#) to calculate RMR (28). This FFM-based calculation of RMR is largely independent of sex and age (28, 32), although evidence is accumulating that ethnic RMR difference exist, even after controlling for body composition.

Calculating the amount of limb muscle tissue from anthropometric data requires only two measurements: the limb circumference and the corresponding skinfold thickness. The midportion of the upper limb is usually studied, and little additional information is gathered by also measuring thigh and calf muscle areas (37). Calf muscle measurement would, of course, be useful in subjects whose upper extremities are burned, amputated, edematous, or immobilized by casts or traction devices. The upper arm muscles tend to atrophy slightly more rapidly during semistarvation than the muscles of the thigh or calf, but the differences are not large (37). The equations for calculating the limb muscle indices are provided in [Table 56.10](#).

Equation	Comment
$(1) \text{ Calf muscle area (cm}^2\text{)} = \frac{(\text{MC} - \pi \times \text{CFP})}{4\pi}$	Includes bone area; assumes circle limb and muscle compartment and symmetric for the observations as in Table 56.7 (Table 56.7)
$(2) \text{ Thigh muscle area (cm}^2\text{)} = \frac{(\text{MC} - \pi \times \text{TSFT})}{4\pi}$	Bone correction area available
$(3) \text{ Arm muscle circumference (cm)} = \text{MC} - \pi \times \text{TSF}$	Some assumption as for equations 1 and 2; includes bone; note that as muscle mass in volume is protein-energy equivalent, circumferential measurements will change proportionally less than area measurements; the latter therefore more reliably depict severity of muscle atrophy
$(4) \text{ Arm muscle area (cm}^2\text{)} = \frac{(\text{MC} - \pi \times \text{TSF})}{4\pi}$	Some assumption as equations 1 and 2; includes bone; equation overestimates actual muscle area by expressing absolute value as a percentage of standard; the error is partially corrected
$(5) \text{ Arm muscle area (cm}^2\text{)} = \frac{(\text{MC} - \pi \times \text{TSF})}{4\pi} - 10 (\text{cm}^2)$	Some assumption as equations 1 and 2; the overestimate in equation 4 is corrected and the average value for bone area is also subtracted; resulting value is therefore bone-free arm muscle area as for all muscle compartments in the table; the resulting value remains an approximation (25%) of actual muscle area; arm muscle area estimates may be particularly inaccurate in obese and elderly subjects
$\text{Arm muscle area (cm}^2\text{)} = \frac{(\text{MC} - \pi \times \text{TSF})}{4\pi} - 8.5 (\text{cm}^2)$	
$(6) \text{ Total body skeletal muscle mass (g)} = 0.010 \times \text{CFP} + 0.087 \times \text{FP} + 0.033 \times \text{CCF} - 348$	Based on cadaver studies; ¹⁰ CFP, stature (cm), CFP, thigh circumferential circumference for the femoral skeletal midline limb; ¹¹ FP, anteroposterior forearm circumference (cm); ¹² CCF, calf circumference corrected for the medial calf skeletal thickness (cm)

Table 56.10 Anthropometric Equations for Calculating Muscle Mass

Limb muscle measurements are used primarily to obtain a measure of the amount and rate of change in skeletal muscle protein. The following three factors should therefore be considered (2):

1. The mass of a skeletal muscle represents a three-dimensional measurement (i.e., volume), whereas limb muscle area and circumference are two- and

one-dimensional indices, respectively (2, 37). As the muscle volume changes, the corresponding proportional changes in muscle area and circumference are smaller. For example, a 50% decrease in muscle volume corresponds to theoretical decreases in muscle area and circumference of 37 and 21%, respectively. As a rule, the relative change in muscle area is larger than the change in muscle circumference.

2. The equations for calculating limb muscle indices are based upon simple theoretical assumptions regarding arm geometry (2, 37). Actually, the calculated arm muscle area overestimates the amount of skeletal muscle by 15 to 25% in relatively young, nonobese subjects. Half of this overestimate is due to the inclusion of bone in the calculated area, and the remainder is due to errors in the assumptions and the inclusion of nonmuscle tissue (e.g., neurovascular bundle) in the result (58). Two methods of correcting this overestimate of muscle area are available. The first is to express results as a percentage of standard, because the standard value also contains these “nonskeletal muscle” components. The second approach is to calculate a value for bone-free arm muscle area, as described in Table 56.10. Studies by Forbes et al. and Baumgartner et al. suggest that arm muscle area assumptions are also inaccurate in obese and elderly subjects, respectively (59, 60). Rolland-Cachera et al. recently proposed a new anthropometric approach for calculating upper midarm muscle area (61). In this model, the unrolled fat rim is assumed to be a rectangle with length equal to upper arm circumference (C) and width equal to triceps skinfold thickness/2. Upper mid-arm fat area then equals $C \times (\text{triceps skinfold thickness}/2)$, and the remaining tissue, mainly muscle, is derived as total upper midarm area minus upper midarm fat area. Promising correlations were observed in normal-weight and obese children with MRI as the midarm cross-sectional component area reference method. This approach has not yet been examined in adult populations. Further studies are needed to improve our understanding of the relationship between anthropometric muscle estimates at the whole-body level and actual skeletal muscle mass at the tissue-system level.
3. Atrophic skeletal muscle differs in chemical composition from normal tissue. Per gram of muscle, the amounts of water, total lipid, and collagen are increased, whereas noncollagen protein is reduced (Fig. 56.7). Thus, the concentration of functional proteins per unit arm muscle area or circumference is relatively lower in atrophied muscle. Another chemical consideration is that muscle size can abruptly change by ± 5 to 10% in response to rapid changes in muscle glycogen resulting from the water-binding properties of glycogen (37).

Figure 56.7. Muscle composition per gram of wet muscle weight in control subjects and in protein-energy malnourished (*PEM*) humans. Muscle specimens were collected at autopsy. Undernourished patients had more water (including extra water), collagen proteins, and total lipids than controls. The extra water was calculated by assuming that muscle dry weight is normally 21% of wet weight. (From Heymsfield SB, Stevens V, Noel R, et al. *Am J Clin Nutr* 1982; 36:131–142; with permission.)

Thus, both anthropometric FFM and muscle indices are truly indirect markers of the active protein component of body weight. The two lean tissue indices should be considered approximate bedside guides to the amount of total body protein. Despite their approximate nature, anthropometric muscle estimates correlate with more complex methods of estimating skeletal muscle (e.g., total limb muscle area vs. total body skeletal muscle volume by MRI; [Fig. 56.8](#)) over the broad biologic range of muscle mass in humans.

Figure 56.8. Correlation between total limb muscle area (sum of arm, calf, and thigh muscle areas in cm²) and total body skeletal muscle volume in L by whole-body MRI in healthy subjects. ($N = 79$; total muscle area [cm²] = $7.6 \times$ skeletal muscle [L] + 115.4; $R^2 = 0.6423$, $P < 0.001$).

Small changes in total body protein cannot be detected by anthropometry; nitrogen balance and other techniques must be used for this assessment. An example of the limitation of anthropometry is shown in [Figure 56.9](#), where short-term changes in anthropometric arm muscle area with nutritional support show no correlation with nitrogen balance. Martin et al. (40) developed an anthropometric prediction formula for total-body skeletal muscle mass, but the accuracy of this method in monitoring changes in muscle mass and associated protein content has not been reported.

Figure 56.9. Nitrogen balance (*N*) measured on a metabolic ward versus change in arm muscle area (*AMA*) in subjects undergoing 1-week balance studies. (From Heymsfield SB, Casper K. JPEN J Parenter Enteral Nutr 1987;11:36S–41S.

Reference Values

Body Weight

The patient's body weight is evaluated using two reference sources. The first reference values are those of the patient, and these include a “usual weight” by history or previous measured weight. This is important because many obese patients who lose weight during an illness and are thus potentially malnourished are still overweight by conventional standards. The second reference source is the healthy population. In this approach, the individual's actual body weight is compared with that of a gender-, stature-, and age-appropriate reference or a desirable body weight (see Appendix [Table A-12-a-1](#), [Table A-12-a-2](#), [Table A-12-a-3](#), [Table A-12-a-4](#), [Table A-12-a-5](#), [Table A-12-b](#), [Table A-12-c-2](#), [Table A-12-c-3](#), [Table A-12-d](#), [Table A-12-e](#), [Table A-13-a](#), [Table A-13-b](#), [Table A-14-a](#), [Table A-14-b-1](#), [Table A-14-b-2](#), [Table A-14-c-1-a](#), [Table A-14-c-1-b](#), [Table A-14-c-2-a](#), [Table A-14-c-2-b](#), [Table A-14-d-1-a](#), [Table A-14-d-1-b](#), [Table A-14-d-2-a](#), [Table A-14-d-2-b](#), [Table A-14-e-1](#), [Table A-14-e-2](#), [Table A-14-f-1](#), [Table A-14-f-2](#), [Table A-14-g-1](#), [Table A-14-g-2](#), [Table A-15-a](#), [Table A-15-b](#), [Table](#)

[A-15-c](#), [Table A-15-d](#) and [Table A-15-e](#) and their subtables). The subject's actual body weight is expressed as a percentage of the desirable weight. The normal range for desirable body weight varies among different sources, but it usually is set between 90 and 120%. A body weight below or above these levels is consistent with undernutrition and obesity, respectively. A historical review of the development of reference body weight tables is provided in Appendix [Table III-A-12-a](#).

Another method of comparing the patient's weight with that of a reference population is to calculate a body weight (BW)-stature (S) index ([62](#)). Most weight-stature indices in present use take the form W/S^P ([59](#)). The term P indicates how stature is to be scaled. The main assumptions of weight-stature indices are that they are independent of height, represent an indirect index of body composition, correlate with health outcomes, and can be generalized across different populations.

At present, BMI, calculated as BW/Ht^2 , is gaining acceptance as a weight-stature index for use in diagnosing both protein-energy malnutrition and obesity ([63](#), [64](#) and [65](#)). Most of the assumptions of weight-stature indices are fulfilled by BMI, although several limitations should be noted. First, although the correlation between BMI and total body fat is relatively strong ($r = 0.5-0.8$), individual variation is large, and some subjects can be misclassified as undernourished or obese ([63](#)). For example, some athletic subjects have a large skeletal muscle mass and a high BMI but are not obese. Another example, reported by Smalley et al., is that a man with a BMI of 27 can have total body fat ranging from 10 to 31% of body weight ([66](#)). Note that in studies such as these some of the observed error may be in the reference method for estimating body fat. BMI may also have a small stature dependence, because individuals with short legs for their height have higher BMI values independent of fatness ([62](#), [64](#)). Finally, Gallagher et al. recently used a four-component model as the criterion for body fat estimation ([67](#)) and found that BMI as a measure of fatness in their healthy cohort was age and sex dependent but independent of ethnicity in their black and white adults.

Although no consistent BMI ranges are accepted by all investigators, a useful set of guidelines is presented in [Table 56.11](#). The table gives a normal range (18.5 to <25) and three grades of both chronic protein-energy malnutrition and obesity. The investigators proposing these guidelines based their criteria on extensive reviews of functional measurements and health outcomes at various levels of BMI ([21](#), [64](#), [68](#)). The BMI range considered normal is similar to the healthy weight range suggested in the "Dietary Guidelines for Americans" of 19 to 25 kg/m² ([69](#)). The diagnosis of protein-energy malnutrition or obesity and their associated risks is often multifactorial and may require additional estimates including body composition, energy expenditure, organ/tissue function, and biochemical markers.

Grade	Body Mass Index
Obesity	
III	>40
II	30-40
I	25-29.9
Normal	≥18.5- <25
Protein-energy malnutrition	
I	17.0-18.4
II	16.0-16.9
III	<16

Table 56.11 Body Mass Index and Grades of Chronic Protein-Energy Malnutrition and Obesity

Fat and Lean

Two methods are used to process anthropometric data other than body weight. The first expresses the individual's values relative to a healthy reference population. This method provides the anthropometric component used to assess whether and to what extent the patient is malnourished. Anthropometric reference tables present the results of large surveys and usually describe the general population. Appendix [Table A-13-a](#), [Table A-13-b](#), [Table A-14-a](#), [Table A-14-b-1](#), [Table A-14-b-2](#), [Table A-14-c-1-a](#), [Table A-14-c-1-b](#), [Table A-14-c-2-a](#), [Table A-14-c-2-b](#), [Table A-14-d-1-a](#), [Table A-14-d-1-b](#), [Table A-14-d-2-a](#), [Table A-14-d-2-b](#), [Table A-14-e-1](#), [Table A-14-e-2](#), [Table A-14-f-1](#), [Table A-14-f-2](#), [Table A-14-g-1](#), [Table A-14-g-2](#), [Table A-15-a](#), [Table A-15-b](#), [Table A-15-c](#), [Table A-15-d](#), [Table A-15-e](#), [Table A-16-a-1](#), [Table A-16-a-2](#), [Table A-16-b-1](#), [Table A-16-b-2](#), [Table A-16-c-1](#), [Table A-16-c-2](#), [Table A-16-d-1](#), [Table A-16-d-2](#), [Table A-16-e-1](#), [Table A-16-e-2](#), [Table A-16-f-1](#), [Table A-16-f-2](#), [Table A-16-g](#), [Table A-17-a](#), [Table A-17-b](#), [Table A-17-c](#), [Table A-17-d-1](#), [Table A-17-d-2](#), [Table A-18-a-1](#), [Table A-18-a-2](#), [Table A-18-a-3](#), [Table A-18-b-1](#), [Table A-18-b-2](#), [Table A-18-b-3](#), [Table A-18-c](#) and [Table A-18-d](#) include reference values for the United States population as a whole.

The reference tables usually present data in three forms: (a) as a mean (\bar{x}) value, (b) as \bar{x} and standard deviation (SD), and (c) as percentiles. Describing a population in terms of \bar{x} and SD assumes that the measurement under study is symmetrically (normally) distributed. If the data fit this model, then $\bar{x} \pm 2$ SD includes 95% of the population. An abnormal value is more than 2 SD units above or below \bar{x} . Some tables provide only \bar{x} ; the patient's value is then expressed as a percentage of the standard or reference value. A weakness of this approach is that tables of this type do not provide a method of determining whether the result is within the normal range. The second type of table includes the SD, or 95% range of the healthy population, thus indicating whether and to what degree the patient is abnormal. The third mode of expression is in terms of percentiles (e.g., see various Appendix [Table A-16-a-1](#), [Table A-16-a-2](#), [Table A-16-b-1](#),

[Table A-16-b-2](#), [Table A-16-c-1](#), [Table A-16-c-2](#), [Table A-16-d-1](#), [Table A-16-d-2](#), [Table A-16-e-1](#), [Table A-16-e-2](#), [Table A-16-f-1](#), [Table A-16-f-2](#) and [Table A-16-q](#)). If results are expressed as a percentile rather than as a percentage of a standard, the reference population need not be symmetrically distributed. Often anthropometric surveys of populations produce “skewed” distributions, and thus the easiest option is to present results in percentiles ([70](#)). In this approach, the values of the subject exactly in the middle of the group define the 50th percentile. If the patient's value is between the 5th and 95th percentile, the result is considered normal; below or above these respective values is abnormal.

No simple method of judging the severity or potential morbidity of protein-energy malnutrition from anthropometric data is available. Studies in adults have not yet clearly defined the “risk” of a subnormal anthropometric index, especially for results falling just below the normal range. Combining anthropometric data with the results of other components of the nutritional assessment provides some measure of potential morbidity ([71](#)).

The second method of expressing anthropometric data is in terms of the individual's total-body energy content, fat, and FFM. Combining estimated energy and nitrogen balance with these body composition data permits a whole spectrum of potential calculations. Of course, these are approximations, but they are often useful in teaching and solving simple clinical questions.

CLINICAL APPLICATIONS

The following are suggested applications of anthropometry:

1. Weight and height should be recorded in the chart of every hospitalized patient. Weight indices, such as recent weight loss, should be added to the database for all patients who have a history of weight change. All patients undergoing short-term nutritional support should be weighed daily.
2. One skinfold measurement, limb fat area, and limb muscle area are helpful
 - a. When body weight is an invalid index of energy reserves because of edema or massive tumor burden. The upper limb is usually not affected by dependent edema.
 - b. When body weight is unmeasurable because of immobilizing devices such as a cast or respirator.
 - c. When patients are seen for nutritional consultation or are seen at rounds removed from the bedside. Anthropometric estimates provide a quantitative description of what is usually visible at the bedside. Although weight alone is useful in this regard, two patients of the same height and weight may differ in body composition.
 - d. During the initial evaluation of hospitalized patients prescribed short-term nutritional support. Although changes in fat and lean tissue will most likely not be detected over a 1- to 2-week period, the baseline anthropometric data become a permanent component of the nutritional database, and are thus available if a future reevaluation is needed.
3. Total body fat and FFM are useful indices

- a. In patients who are undergoing long-term nutritional follow-up over months or years. Limb muscle area measurements, preferably of the upper arm, should also be included in this group to complete the body composition database.
- b. In groups of subjects forming the basis of nutritional studies, when a more critical assessment of body composition is often useful and more-accurate techniques of evaluating body composition are not available.
- c. In estimating RMR based upon FFM.
- d. For teaching purposes, when the interrelation of metabolic balance, body composition, and nutritional therapy are being considered.

AGING AND ANTHROPOMETRIC INDICES

Body composition changes throughout the adult life span, which must be considered in evaluating anthropometric indices. Height declines and, assuming constant body weight, an elderly subject has more fat and less FFM than a younger individual of the same sex ([48](#), [72](#), [73](#) and [74](#)). Most of the loss in FFM can be accounted for by a decrease in both skeletal muscle and visceral organs. A summary of how body composition changes with age and how anthropometric measures are affected is presented in [Table 56.12](#). Because of these changes in body size, shape, and proportions, investigators now advocate geriatric-specific anthropometric body-composition prediction equations ([75](#), [76](#)).

Anthropometric Measurement	Comment
Weight	The average population value increases until the fifth decade and then plateaus or declines.
Height	Height decreases by 1 to 3 cm/20 years after maturity; the rate of height decline is race- and sex-dependent.
Fat	Fat increases as a percentage of body weight; redistribution occurs from subcutaneous to internal fat and between different subcutaneous sites.
Skinfold	The compressibility of skinfolds changes with age; there is a loss in the elastic recoil of skin and an increase in viscoelastic recovery time; skinfolds in the elderly are often pendulous and difficult to measure.
Fat-free body mass	Fat-free body mass decreases as a percentage of body weight mainly because of a loss in skeleton and skeletal muscle mass; the mass of visceral organs remains unchanged or decreases only slightly with age; skeletal muscle undergoes compositional changes, which include a relative increase in connective tissue and fat and relative loss in myofibrillar proteins.

Based on refs. 48 and 70.

Table 56.12 Effects of Aging on Body Composition and Anthropometric Measurements

Estimation of height is difficult in the elderly, especially in the wheelchair-bound, bedridden, or kyphotic subject. Specialized approaches such as recumbent anthropometry may be useful with hospitalized or nursing home patients ([77](#)). Another useful approach is measuring knee height or arm span ([Table 56.2](#)) to predict adult stature. Knee height and arm span undergo little change with age in adults and provide an estimate of stature that is difficult to obtain by conventional methods. The estimated value for height can then be used in calculating other assessment indices and comparing these results to height-adjusted reference values. Alternatively, knee height

can be used in place of stature in such indices as fat/knee height ([2](#), [78](#)).

Anthropometric measurements may be useful in diagnosing malnutrition in hospitalized elderly subjects. Lansey et al. ([79](#)) examined 47 consecutive geriatric patients admitted to an acute care facility and found that approximately 45% of the patients had two anthropometric measures (i.e., midarm circumference and muscle area; subscapular and triceps skinfold) below the fifth percentile, indicating severe malnutrition. In contrast, only 28% of patients were below 90% of ideal body weight. Anthropometric measurements may therefore supplement, and be more sensitive than, body weight and stature in evaluating malnutrition in hospitalized elderly persons.

Anthropometric measures may also predict mortality in elderly populations. For 40 to 46 months, Campbell et al. ([80](#)) measured bone-corrected arm muscle area and triceps skinfold thickness in 758 subjects over age 70 years. In a logistic regression model, both low arm muscle area and triceps skinfold thickness were associated with significantly increased mortality risk.

Because of the ability of anthropometry to detect malnutrition and potentially predict mortality in elderly subjects, screening methods are being developed or have been reported for use in older cohorts. For example, in their “mini nutritional assessment,” Guigoz et al. ([81](#)) include as screening measures, midarm circumference, calf circumference, and BMI. The usefulness of these anthropometric measurements beyond that of weight and height alone has not been established.

EVALUATING AND CONTROLLING ERROR SOURCES

Like all measurements, anthropometric evaluations include error. This section provides an introduction to anthropometric error sources; the interested reader is referred to comprehensive reviews for an advanced discussion of this important topic ([19](#), [21](#), [82](#)). Error can be considered in the context of the fundamental body composition methodology equation as shown in [Figure 56.10](#). This equation indicates that error in the estimation of a body composition component (e.g., total body fat) from anthropometric measurements is a function of two main error sources, measurement of a quantity (Q) and mathematical function (i.e., descriptive or mechanistic). The figure also notes that errors of measurement may be either systematic (nonrandom) or random, or both. Errors due to misspecification of mathematical functions are always systematic. The following discussion first considers measurable quantity errors and then proceeds to an overview of mathematical function errors.

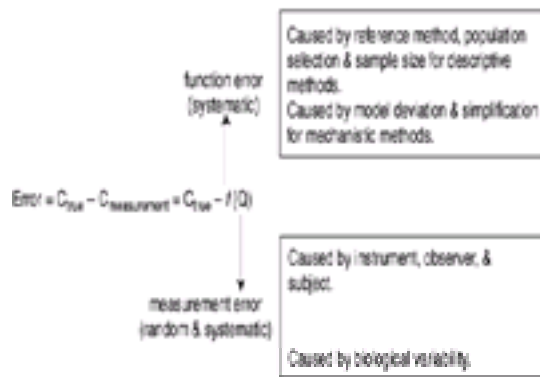

Figure 56.10. Sources of error in anthropometric methods (see text).

A subject's anthropometric dimensions can be evaluated at a single point in time or on repeated occasions over time. Measurement error is the main concern with a single evaluation, and measurement error combined with normal biologic variation must be considered with repeated measurements. Measurement error can be caused by instrument error and observer error. Methods of minimizing instrument error were reviewed above and mainly involve the correct choice of measurement instruments and accurate calibration. Observer error is related to three factors: precision, reliability, and accuracy.

Accuracy is the level of agreement between the measured value and the “true” dimension. Accuracy of an anthropometric dimension is usually established by comparison to a reference method. For example, subcutaneous adipose tissue thickness estimated using a skinfold caliper can be compared with corresponding estimates by computerized axial tomography or MRI. Of course any such analysis also includes instrument and observer errors. In clinical situations, measurements by an anthropometrist are usually compared with those of a designated “expert” (21).

Precision, distinct from accuracy, defines the quality of a measurement in terms of being sharply defined or exact. In this sense, precision refers to the scale of measurement; for example, a skinfold measured to the nearest 1 mm is more precise than one measured to the nearest 0.5 cm. A highly precise measurement (e.g., body weight measured to the nearest gram) is not necessarily accurate if the weight scale used is improperly calibrated. The definition of precision overlaps to some extent with that of *reliability*. Reliability is the degree to which a measurement can be replicated by the same or a different observer using the same instrument. This is linked to precision because it is difficult for a measurement to be precise or exact if it is unreliable (83).

The precision of an anthropometric measurement can be quantified as the variability among repeated measurements over a short time in the same subject (21). Precision can be expressed as the *technical error of measurement*, which is the standard deviation of repeated measurements on the same subject by the same or different

observers. The technical error of measurement, which is expressed in the same units as the measured quantity, can also be expressed as a percentage, a *coefficient of variation* ($SD/mean \times 100$) ([19](#), [21](#)).

Reliability is also referred to as “reproducibility” or “repeatability.” Reliability, as distinct from precision, is more commonly expressed in terms of the intraclass correlation among repeated measurements, sometimes called the “reliability coefficient.” Measures of reliability often include both measurement error and physiologic variation.

The total variation in an anthropometric measurement monitored over time includes measurement variation and biologic variation. Biologic variation occurs even in the healthy individual, as weight and fluid balance fluctuate over time. This aspect of measurement variability is the difference between total anthropometric dimension variation over time and that due to measurement error. Some measures, such as stature, are extremely stable in adults; others, such as selected skinfold thicknesses, are moderately variable over time. In practice, this biologic component of variability is often included in estimates of the reliability of anthropometric measurements.

Anthropometric dimensions are often used directly, for example, triceps skinfold thickness as a measure of fatness. Mathematically transforming an anthropometric measurement to a component estimate involves error sources. The “validity” of an anthropometric method in this context is the degree to which it accurately measures or predicts a specific component. Descriptive or type I methods are population specific, and error may arise in applying a prediction formula to a new subject group or one outside the original subject range for age, weight, and stature. Mechanistic or type II methods include “model” error. For example, calculation of arm muscle area from triceps skinfold and midarm circumference is based on a simple geometric model ([Table 56.10](#)). Actual arm muscle area may deviate from the assumed model, which introduces error into the component estimate. Both types of error are nonrandom, or systematic.

Anthropometry is applied widely in evaluating a single subject or whole populations. Professionals who apply anthropometry in their clinical work or research should fully comprehend the anthropometric error sources and apply procedures to maximize the quality of their measurements. It is a good policy to set up an evaluation program for the anthropometrists as outlined in references [19](#), [21](#) and [82](#). An approach such as that suggested in these reports will help maintain a high-quality measurement standard.

CONCLUSION

Anthropometry is one of the oldest approaches to quantifying body composition, and it is the most practical for field and clinical settings. The severity, response to nutritional treatment, and aspects of subject malnutrition risk can be established using relatively simple and easily acquired anthropometric measurements. For these reasons, anthropometry is an indispensable tool for the practitioner of clinical nutrition.

LABORATORY TESTS

Measurement of relevant individual analytes in body tissues, fluids, or excretions—feces, urine, sweat or expired air—provides specific, sensitive, and quantitative indices of a subject's nutritional status. Such measurements are often of value in supporting, modifying, or negating nutritional history and physical examination. Impaired absorption of dietary nutrients from the gut or renal tubule is a major cause of malnutrition and may be due to any one of a number of factors that have been reviewed in chapters related to specific nutrients and to clinical considerations, including [Chapter 39](#) and [Chapter 68](#), [Chapter 69](#), [Chapter 70](#) and [Chapter 71](#). To the complexity of causes of malnutrition is added the number of nutrients that may be involved singly or in combination, endpoints that result from byproducts of intestinal tract activity and/or digestive and absorptive defects, and finally the varied methodologic and technical

issues of analyses.

Caregivers must have sufficient knowledge of the value, availability, reliability, and interpretation of results of tests to use the laboratory to advantage. [Chapter 65](#) discusses the clinical approach and use of various test procedures to detect and determine the cause of malabsorption. Types of tests for diagnosing the presence, severity, and possible site(s) of suspected malabsorption are listed in [Table 57.1](#).

Tests for possible malabsorbed macronutrients: fat, carbohydrates, proteins (nitrogen)
Direct measurement of the macronutrient in feces, urine, blood
Direct measurement of surrogate compounds (e.g., xylose)
Indirect measurements (e.g., breath tests)
Load test of suspect malabsorbed substance (e.g., lactose tolerance test)
Test for possible malabsorbed micronutrients
Direct measurements in feces, urine, blood
Indirect measurements of relevant enzymes and abnormal metabolites

^aOne of the issues in making a diagnosis is deciding which specific nutrient parameters to test in the early workup to provide relevant information about the extent and severity of suspected or known malabsorption and the nutritional status of the patient.

Table 57.1 Types of Tests for Determining Presence, Severity, and Possible Site(s) of Suspected Malabsorption^a

This chapter endeavors to provide the basis for laboratory involvement in investigating nutritional status. Standards that must be met for reliable results are discussed, tests useful in diagnosis and their methodology are reviewed, and a brief discussion is appended of instrumentation useful in physical methods of assessment.

Specimen Collection and Handling

A most important, often neglected, factor in obtaining accurate results for analysis of any nutrient or its product, is the appropriateness of the procedure used in collection and subsequent handling of the specimen. This requires organization and planning at the clinical, transport, storage, and laboratory phases of the investigation. This topic has been reviewed ([1](#)). Requirements may include (a) protection of the specimen from exposure to light, (b) temperature stability of components to be measured, and (c) possible contamination from vessels used for collection or storage of samples to be tested for trace metals and other components.

Detection Limit, Sensitivity, and Specificity of Tests

Evaluation of a biochemical or biophysical method and hence selection of the most

appropriate method for a particular application requires the following considerations.

Detection Limit

The detection limit of a particular test is the smallest concentration or absolute quantity of the analyte that can be detected with reasonable certainty. The amplitude of the blank readings and the precision or reproducibility of the method on repeated performance are important considerations in establishing the detection limit (2).

Sensitivity

The sensitivity of a method is defined as a change in signal relative to a change in concentration, absolute quantity, or property of the analyte (2). A method with high sensitivity has a low limit of detection; for example, the limit of detection of copper in urine is 1.0 µg/L. This low level of detection makes the test highly sensitive.

Specificity

The specificity of a method defines the accuracy with which the method measures the true value of an analyte, especially in the presence of other analytes with similar chemical properties or substances that may interfere with the particular analytical method (3).

Matrix to Be Analyzed

In assessing nutritional status, measurement of an analyte or a metabolite of a substrate is usually made in blood—whole blood, serum, plasma, or erythrocytes, depending upon its normal distribution—or in urine, but other sources are often valuable. Leukocyte fractions isolated from whole blood and platelets isolated from plasma have been analyzed for various nutrients to assess status. Fecal analysis is extremely important in assessing the balance of a nonmetabolizable nutrient or a component, for example, nitrogen, trace metals that are excreted in bile, and components of pancreatic secretions in protein-losing enteropathy, and α -antitrypsin clearance. Analysis of expired air for a radioactively labeled metabolite—usually CO₂ or H₂ generated by bacterial action in the gut—or a stable isotope ratio (e.g., ¹³CO₂:¹⁴CO₂) enables the absorption of carbohydrates or fat to be determined. Labeled expired air is also analyzed for O₂ or CO₂ by indirect or direct calorimetry and more recently by isotope dilution methods using ²H₂¹⁸O to determine resting energy expenditure (see [Chapter 5](#)).

While depletion of a nutrient is often detected by its low concentrations, depletion may be indicated by increased concentration of a related metabolite occurring because of altered intermediary metabolism; for example, high homocysteine levels in the absence of the folate or vitamin B₁₂ coenzyme required for its conversion to methionine.

An alternative to measuring the concentration of a specific mineral, trace element, or

vitamin in blood or urine uses a test that indicates the function of a related component in the body; for example, enzymatic activities in erythrocytes for which thiamin pyrophosphate, pyridoxal-5-phosphate, or flavin adenine dinucleotide (FAD) are the coenzymes of the vitamins thiamin, pyridoxine, and riboflavin, respectively (4). If addition of the cofactor raises the respective in vitro enzyme activity more than 20% above its initial value, a deficiency of the vitamin in vivo is indicated.

IMPORTANT ANALYTICAL TECHNIQUES: PRINCIPLES AND PROCEDURES

Some analytical techniques frequently used are illustrated in [Figure 57.1](#), [Figure 57.2](#), [Figure 57.3](#) and [Figure 57.4](#) and discussed in detail elsewhere (5).

Figure 57.1. Diagrammatic representation of reactions in radioimmunoassay (RIA) techniques. A, Competitive simultaneous assay; B, competitive sequential (two-step) assay; C, noncompetitive assay.

Product is measured and this value is directly proportional to the amount of Ag in the sample

Assays

Immunoassays

A competitive simultaneous radioimmunoassay uses a radiolabeled (usually with ^{125}I) form of the nutrient being analyzed (termed the *antigen*) that competes for binding to antibody when the level of unlabeled antigen in the sample is in the range of 30 to 80% of labeled antigen. The amount of bound labeled antigen is inversely proportional to the amount of unlabeled analyte. In the competitive sequential assay, bound labeled antigen is separated, and the radioactivity counted is directly proportional to the amount of bound unlabeled antigen. In noncompetitive assays, a solid phase such as plastic beads, the surface of a tube or well, or magnetic beads permits adherence of antibody-bound antigen and labeled complex. Radio-activity counts are directly proportional to the amount of unlabeled antigen. The various assays are illustrated in [Figure 57.1](#).

Immunosorbent Assay

An enzyme-linked immunoabsorbent assay uses a solid phase on which analyte to be measured (antigen) is immobilized. Enzyme-labeled antibody and sample are added. Only those antibody-enzyme binding sites not occupied by the sample analyte will bind to the immobilized antigen. The solid-phase antigen:antibody-enzyme complex is washed with buffer prior to the addition of substrate for enzymatic reaction. The concentration of the reaction product is directly proportional to the amount of analyte in the specimen ([Fig. 57.2](#)). Alkaline phosphatase is the enzyme frequently used. An example of this assay is described below in the immunoassay for vitamin B₁₂.

High-Performance Liquid Chromatography

[Figure 57.3](#) shows the components of a high-performance liquid chromatography (HPLC) system for chromatographic separation and quantitation of components of a solution. The procedure is highly specific and sensitive for components with similar properties, such as fat-soluble vitamins, retinol, α -tocopherol, and b-carotene, which are suitably extracted in an organic solvent before chromatography.

Atomic Absorption Spectrophotometry

Atomic absorption spectrophotometry is the most specific and sensitive technique for measuring minerals and trace elements. The components of a typical instrument for flame atomic absorption spectrophotometry or the more sensitive graphite furnace atomic absorption spectrophotometry are shown in [Figure 57.4](#). High specificity is obtained by the measurement of absorption by neutral atoms in the vapor state from a lamp that emits light of a wavelength characteristic of the element being measured.

TESTS FOR ASSESSING MALABSORPTION AND MALNUTRITION

Carbohydrate Absorption

D-Xylose Tests

D-Xylose Oral Test. Carbohydrate absorption may be assessed by the D-xylose absorption test. D-xylose, a nondietary pentose, is more poorly absorbed than glucose; it is not rapidly metabolized after absorption and hence appears in the urine. An oral dose of 25 g of D-xylose (Pfanstiehl Labs, Inc., Waukegan, IL) in 250 to 500 mL water is administered over 10 minutes to a fasting subject. Preferably, D-xylose is then measured both in blood (at hourly intervals up to 5 h), and in the 5-h urine (with its creatinine level measured to ensure complete collection). For pediatric patients a smaller dose, 2 g, and a single 1-h blood analysis is reported to give a reliable index of absorption.

The recommended analytical method for D-xylose is that of Roe and Rice (6), as described in detail (7). After a 25-g dose, blood or plasma D-xylose should rise to 30 to 35 mg/dL or above within 2 hours, and then decrease gradually; at least 25% of the dose should be excreted in the 5-h urine specimen. Variation in the dose and appropriate results are given in reference 7. The test also serves to measure intestinal mucosal and renal function. Interpretation of results must consider the renal clearance of D-xylose because of its dependence on glomerular filtration. Hence, measurement of urine or serum creatinine or of blood urea nitrogen is essential. Figure 57.5 presents the results of serial D-xylose absorption tests conducted over 15 months following major bowel resection in a patient and demonstrates progressive improvement in gastrointestinal function (8). Misleading results may occur when bacterial overgrowth of the jejunum is present. In this situation, a repeat of the oral test after a trial of antibiotics provides more accurate data on D-xylose absorption and confirms the effect of the bacteria.

Figure 57.5. Changes in D-xylose levels with time following major bowel resection in a 30-year-old malnourished female patient. When first tested, she failed to achieve normal blood and urine levels from a standard 25-g D-xylose load. She was initially treated with parenteral nutrition and subsequently with tube feeding, followed by partial tube feeding with oral supplements. The data indicate progressive improvement into the normal range, presumably because of hyperplasia of the remaining jejunum in response to

improved nutrition. (Shils ME, unpublished data).

¹⁴C-Breath D-Xylose Test. Gases produced by colonic bacteria from unabsorbed carbohydrate or those resulting from bacterial overgrowth in the small intestine are absorbed into the circulation and excreted by the lungs. ¹⁴C-D-Xylose showed 85 to 100% specificity of increased exhaled ¹⁴CO₂ within 60 minutes of ingestion of 1 g of unlabeled D-xylose and 10 mCi of ¹⁴C-D-xylose (9) by subjects with bacterial overgrowth. Normally, most of the D-xylose is absorbed in the jejunum; the little that reaches the colon is subject to significant bacterial action as was shown when an oral dose of 25 g was given (Fig. 57.6). Delayed gastric emptying can complicate the interpretation of results from this test. Exhaled CO₂ collected in a vial containing 1 to 2 mmol/L hyamine hydroxide and phenolphthalein indicator is converted to carbonic acid and counted in a scintillation counter.

Figure 57.6. Concentration of ¹⁴CO₂ (percentage of administered dose expired as ¹⁴CO₂ per mmol CO₂) after oral administration of 25 g xylose and 10 μCi ¹⁴C-xylose.

Untreated patients with intestinal bacterial overgrowth exhaled significantly more ¹⁴CO₂ than controls ($P < .005$, 60–360 min) and treated patients ($P < 0.01$ after 60 min). (From King CE, Toskes PP, Spivey JC, et al. *Gastroenterology* 1979;77:75–82, with permission.)

Lactose Absorption

Oral Load Test with Glucose Determination. Lactose is hydrolyzed by the mucosal enzyme lactase to its component sugars, glucose and galactose. Plasma glucose levels are measured before administration of a 50-g oral dose of lactose, and 1 and 2 hours afterward. An increase of more than 20 mg/dL is considered a normal response,

indicating absence of lactase deficiency. Delayed gastric emptying may result in a negative response. Lactase deficiency may be confirmed by measuring glucose absorption from a glucose load.

Breath Hydrogen. General carbohydrate malabsorption may be assessed by measuring breath hydrogen 3 to 4 hours after a meal. Malabsorption of a specific carbohydrate is determined by a more rigidly controlled collection of hydrogen at hourly intervals up to 8 hours in a fasted subject who has been given a dose (usually <50 g) of the specific carbohydrate. Details of the procedure for performing the test and interpretation of results are given in reference [10](#). ^2H and methane (which is sometimes produced but does not interfere with the results) are determined by gas chromatography with a dedicated instrument ([Fig. 57.7](#)). The breath test is useful in discriminating between pancreatic insufficiency, small bowel disease, and diseases unlikely to affect carbohydrate absorption. Bacterial overgrowth in elderly hypochlorhydric subjects does not affect carbohydrate or fat absorption ([11](#)), but breath tests are not reliable in this condition.

Figure 57.7. Breath H_2 response (mean \pm SEM) to ingestion of 10 g of lactulose (*solid circle*), 10 g of glucose (*open triangles*), or Colyte (*open circle*). (From Strocchi A, Corazza G, Ellis CJ, et al. *Gastroenterology* 1993;105:1404–10, with permission.)

Fat Absorption

Classical Fat Test. Fat absorption may be determined either by weighing the isolated lipids or by titrating free fatty acids after hydrolysis of dietary and fecal specimens and lipid extraction into organic solvent ([12](#)). A 72-hour equilibration period on the diet and fecal collection for 72 hours are required. Although hospitalization is preferable, current costs prohibit this. A well-motivated patient, given precise instructions and collection devices can complete the collections. Less than 7% of the fat in the diet should normally be excreted in the fecal specimen.

$^{14}\text{CO}_2$ Breath Test. A tracer dose of radioactive ^{14}C uniformly labeled triglyceride given with 20 to 30 g of nonlabeled triglyceride provides a test meal for the semiquantitative assessment of the metabolism of fat to CO_2 and H_2O . ^{14}C is collected and counted as described above. Experience with this test showed variability in results, compared with fecal fat analysis. However, it is a semiquantitative convenient method of assessing fat absorption (13). Alternatively, a stable isotope, ^{13}C -triglyceride, may be given, but a mass spectrometer is required to quantitate the stable isotope.

ASSESSMENT OF NITROGEN BALANCE

The ultimate assessment of nutritional status is a reliable determination of the balance (positive, negative, or zero) between dietary intake and total loss from the body of a particular nutrient that is unchanged in metabolism (e.g., a mineral) or a basic element that is a marker for a nutrient (e.g., nitrogen). The metabolic basis for an inclusive scheme for balance studies owes much to Reifenshtein Albright and Wells (14). The diet and all excreta must be chemically analyzed. The patient's intake must be equilibrated on a standardized diet for varying times prior to complete collection of fecal, urinary, and any other losses from the body for 72 hours or longer. Appropriate losses in sweat, hair, and nails must be assumed for particular nutrients. The costly requirement for hospitalization in a metabolic or similarly equipped unit restricts such studies to research centers with a federally funded Clinical Research Center (CRC) or equivalent. However, with careful planning and provision of prepared meals, a well-motivated, supervised patient can make the necessary collections at home (15).

Intake of a particular nutrient by a patient maintained entirely on an enteral formula or on total parenteral nutrition can be accurately calculated from the amount of administered nutritional support. When nutrients are administered intravenously and nothing but water is being ingested, stool loss for most components of interest can be considered to be zero if stool output is insignificant.

Nitrogen Balance

Net change in total body protein may be assessed by estimating nitrogen balance. Approximately 16% of protein is nitrogen, and almost all total body nitrogen is in protein. In a stable, healthy adult, dietary intake equals nitrogen excreted in urine and feces together with losses due to hair and nail growth, sweat, and sloughing of cutaneous cells. The individual in this state is said to be in zero nitrogen balance, or equilibrium. Ideally, following a period of days for equilibration on the diet, the actual nitrogen balance is determined from analysis of complete dietary intake over 3 or more days and the collection and analysis of nitrogen in complete fecal (between markers) and urinary output over the period.

Serum levels of some specific proteins useful in monitoring changes in nutritional status are shown in [Table 57.2](#). Since factors other than nutrition (e.g., infection, hepatic and renal functions, surgery, and thyroid status) influence these, the patient's clinical status

must be evaluated carefully when interpreting results (17).

Metabolite	Method	Reference Range			Half-life		
		Age	Sex	Conv. unit			
Albumin	Dye binding	21-44	male	35-47 g/L	50-80 μmol/L	19-20 days	
		21-44	female	28-37 g/L			40-50 μmol/L
		45-54	male	29-41 g/L			40-50 μmol/L
		45-54	female	25-34 g/L			30-40 μmol/L
		55-64	male	27-38 g/L			40-50 μmol/L
		55-64	female	22-31 g/L			40-50 μmol/L
Tandem	Rate nephelometry		24-43 g/L	25-47 μmol/L	8-9 days		
Peabody	Rate nephelometry		43-64 g/L	54-77 μmol/L	2-3 days		
Retinol-binding protein (RBP)	Rate nephelometry		20-40 mg/L	1.0-1.8 μmol/L	12 hours		
Insulin-like growth factor-1			0.55-1.4 U/mL		2-6 hours		
Forcortin [®]	Turbidimetry		1.05-1.58 g/L	2.74-3.9 μmol/L	4-24 hours

Table 57.2 Nutritional Assessment: Serum Proteins, Reference Ranges, and Half-Lives

Methods of Analysis. Methods for estimation of total nitrogen include the classical Kjeldahl procedure or chemoluminescence for the measurement of nitrogen in urine or digests of fecal and dietary samples. A much simplified estimate of nitrogen balance can be obtained from assessment of nitrogen in the diet from published food composition tables for protein, estimation of urinary nitrogen from urea and ammonia excretion, and an assumed daily fecal nitrogen output (16). The nitrogen content of protein is assumed to be 16%, although for special formulae, this factor may be in error. Heymsfield et al. (17) consider that total daily urine nitrogen can be approximated as urea nitrogen plus 1.5 to 2.0 g for most hospitalized patients. Allowance for fecal loss varies, depending upon the composition of the oral intake or intravenous fluids, whether the patient has malabsorption, and other factors related to protein metabolism associated with the patient's condition (17).

TESTS FOR ASSESSING SOME INDIVIDUAL NUTRIENTS

Folic Acid

The most common causes of depletion of this vitamin are listed in [Chapter 26](#) and [Chapter 88](#). Experimental folate deficiency in man showed that the earliest biochemical change was a reduction in serum folate to less than 3 ng/mL, which was evident by day 22 of the deficiency (18). Red cell folate, which is a better indicator of tissue status, was reduced to less than 20 ng/mL by day 123. Impairment of histidine conversion to glutamate, which involves folate-dependent pathways, was evident at day 49; this may be detected by an increase in 8-h urinary excretion of formiminoglutamate (FIGLU) following an oral dose of 15 g of histidine. Normal excretion is approximately 17 mg FIGLU. In folate deficiency, levels of 185 to 2047 mg are common. The test is not specific for folate deficiency, as a percentage of vitamin B₁₂-deficient patients also have

elevated FIGLU excretion.

Methods of Analysis. Serum or plasma folate is determined by competitive binding assay ([Fig. 57.1](#)). Various instrument manufacturers provide kits that usually permit simultaneous assay for folate and vitamin B₁₂. However, as pointed out by McNeely ([19](#)), kits must be carefully evaluated, as they frequently focus on the vitamin B₁₂ assay at the expense of the folate requirements. These assays employ a specific folate-binding protein from milk. If a boiling step necessary to eliminate serum folate binding is not included, the accuracy and specificity of the procedure must be validated. Kits usually contain tritiated pteroylglutamate as a tracer, since tritiated methyltetrahydrofolate has very low specific activity and is unstable. Using liquid scintillation to count beta particles is inconvenient; kits with ¹²⁵I are becoming available for evaluation and offer more convenient counting capability. The simple procedures required for manual performance of the competitive binding assay are described in reference [19](#). Red cell folate determinations can be done on a hemolysate.

Cobalamin (Vitamin B₁₂)

Causes of depletion of vitamin B₁₂ are given in [Chapter 37](#) and [Chapter 88](#). The diagnosis of deficiency can be made with certainty by appropriate laboratory techniques, whose results are shown in [Table 57.3](#) ([20](#)).

Cause of Deficiency	Free B ₁₂	B ₁₂ -IF	Antibiotic	Pancreatic
Normal	Normal	—	—	—
Pernicious anemia (lack of intrinsic factor IF)	Abnormal	Corrected	—	—
Bacterial overgrowth syndrome	Abnormal	Abnormal	Corrected	—
Pancreatic insufficiency	Abnormal	Abnormal	Abnormal	Corrected
Ileal disease or resection	Abnormal	Abnormal	Abnormal	Abnormal

Reproduced from Table 65.2, Chapter 65, with permission. See also reference 20

Table 57.3 Diagnosis of Vitamin B₁₂ Deficiency with the Schilling Test

Methods of Analysis

The reference method for estimation of serum vitamin B₁₂ is the microbiologic assay. This method requires specialized treatment of the sample and laboratory facilities and is no longer feasible for the large volume of requests in chemistry laboratories. A second problem is the possible presence in the serum sample of antibiotics to which the

microorganisms may be sensitive.

Immunoassays. For routine purposes, microbiologic assay has been replaced by techniques that can be performed on various autoanalyzers. These use competitive binding proteins and either count a radioactive label or take a spectrophotometric reading of an immunochemistry product. Folic acid and vitamin B₁₂ assays are frequently required on the same serum sample, and kits are available to perform the two assays simultaneously. ⁵⁷Co-labeled vitamin B₁₂ and ¹²⁵I-labeled folate are used as tracers. The two radionuclides are counted simultaneously in pulse-height multichannel gamma scintillation counters without interference from the differences in energy.

For vitamin B₁₂ determination, purified intrinsic factor, free from a rapidly migrating R protein, must be used to measure the true biologically active vitamin B₁₂. If intrinsic factor is contaminated with R protein, cobinimide, an analogue of vitamin B₁₂, must be present to block binding of endogenous B₁₂ to the R protein. Most kits use purified porcine intrinsic factor and a folate-specific binder from milk, and require off-line denaturation of the endogenous serum binding proteins in a boiling-water bath with subsequent cooling. An alternative method using alkali denaturation ([21](#)) requires incubation and neutralization of the extract prior to the competitive binding reaction, and therefore is not considered to have an advantage over boiling.

An alternative competitive magnetic-separation immunoassay for vitamin B₁₂ can be performed entirely automatically on the Technicon Immuno 1 system. Serum must be used in this assay. Vitamin B₁₂ is released from serum binders and reacted with intrinsic factor. Alkaline phosphatase-labeled vitamin B₁₂ is added, which competes with vitamin B₁₂ in the serum for binding sites on the intrinsic factor. Addition of monoclonal immunomagnetic particles allows separation of bound and unbound enzyme-labeled B₁₂. Detection is by spectrophotometric measurement at 405 nm of the product *p*-nitrophenoxide from the substrate *p*-nitrophenyl phosphate.

Deoxyuridine Suppression Test. The deoxyuridine suppression test in a suspension of bone marrow cells was found highly sensitive for detection of early, subtle, or occult deficiency of vitamin B₁₂ or folate ([22](#)).

Homocysteine. The association of high plasma homocysteine levels with neurologic and cardio- and cerebrovascular disease and the inverse relationship between plasma homocysteine and plasma folate and, to a lesser extent, vitamins B₆ and B₁₂, emphasizes the possible role of administration of the appropriate vitamins for amelioration or prevention of such diseases ([23](#)). The biochemical and clinical aspects of hyperhomocysteinemia are discussed in [Chapter 26](#), [Chapter 27](#), [Chapter 34](#), [Chapter 61](#), [Chapter 75](#) and [Chapter 95](#).

Methylmalonic Acid Excretion. Isomerization of methylmalonyl-CoA to succinyl-CoA is vitamin B₁₂ dependent. Increased urinary excretion of methylmalonic acid results from

vitamin B₁₂ deficiency. The assay method of choice is isotope dilution involving gas chromatography–mass spectrometry (24, 25).

Schilling Test. The Schilling test is used to investigate absorption of vitamin B₁₂ from the ileum as affected by various conditions in the alimentary tract. There are a number of variations in the time schedule for carrying out the procedure (26). An oral dose of ⁵⁷Co radioactively labeled B₁₂ may be administered, followed 1 to 8 hours later (as specified) by a larger flushing dose of unlabeled vitamin. Urine is collected during the following 24 to 72 hours. From 8 to 15% of the radioactivity should be excreted normally if renal function is adequate. Since intrinsic factor is required for absorption, low excretion of radioactivity may be due to lack of secretion of this cofactor. The test should thus be repeated with intrinsic factor given at the same time as the labeled B₁₂. Bacterial overgrowth in the upper intestine results in loss of absorbable vitamin B₁₂ and false results are obtained; in this situation, a trial antibiotic therapy helps in making the diagnosis. Hence, this test serves to monitor gastric, pancreatic, jejunal and ileal functions (Table 57.3).

Retinol (Vitamin A)

Fasting blood samples for retinol determination should be protected from exposure to light, centrifuged promptly (preferably at 4°C), and have the serum removed and stored at –20°C or below until analysis is performed. Exposure to UV light during analysis should be avoided.

Vitamin A status is most commonly assessed by its serum level. An elevated level usually indicates an excess of vitamin A. However, increased amounts are present when renal failure increases the level of retinol-binding protein (RBP). Similarly, low serum levels may not be associated with decreased stores of the vitamin when impaired protein synthesis results in low levels of serum RPB. In zinc deficiency, low RPB synthesis or release from the liver is also associated with low serum retinol when liver stores are not depleted.

Methods of Analysis

Chromatography. The recommended method of measuring retinol in a hexane extract of serum is HPLC. A variety of solvent systems, mainly methanol based, using reverse-phase, isocratic chromatography enable the separation of retinol, a-tocopherol, and b-carotene in a single run in less than 20 minutes (27). Following addition of an internal standard and serum deproteinization, the lipid-soluble vitamins are extracted, evaporated, and reconstituted in chloroform-ethanol-BHT (butylated hydroxytoluene) prior to chromatography. This method has a sensitivity of 0.1 mg/L. The between-day coefficient of variation at a level of 0.32 mg/L is 4.4%.

A fluorometric method (28) involves ethanol precipitation of serum proteins and extraction of retinol in hexane. A silicic acid column chromatographic step is required to remove an interfering substance, phytofluene. Retinol is determined in the eluate by

measuring fluorescence at 490 nm after excitation at 340 nm.

A relative dose response (RDR) test is useful in estimating vitamin A status (29). A baseline fasting blood sample (A_0) is collected before oral administration of 1.6 to 3.5 μmol (450–1000 μg) vitamin A. A second blood sample (A_5) is taken at 5 hours.

Response is expressed as the ratio of the increment in serum retinol over the 5-h period divided by the 5-h value expressed as a percentage.

$$\text{RDR (\%)} = \frac{[(\text{Serum retinol (5 h)} - \text{serum retinol (baseline)}) \times 100]}{\text{serum retinol (5 h)}}$$

An RDR above 50% indicates severe deficiency; 20 to 50%, marginal deficiency; and less than 20%, adequate status.

Serum Retinol-Binding Protein

RPB binds one molecule of retinol and is the carrier protein for this vitamin. The complex is associated with one molecule of thyroxine-binding prealbumin. It has a half-life of only approximately 12 hours and has been shown to respond rapidly to protein and energy deprivation and to dietary treatment. Serum RPB is decreased in vitamin A deficiency and in zinc deficiency, since zinc is required for mobilization of RPB from the liver. Following vitamin A and or zinc supplementation, the serum level increases (30). A specific RPB antibody is available (Behring, San Jose, CA) for determination of the protein by rate nephelometry (Table 57.2). Radial immunodiffusion is also available, but its sensitivity is not good for the low levels of this protein normally present in serum.

Iron

Iron deficiency is a common problem in many populations, particularly in growing children. The ability to assess body iron stores in epidemiologic evaluations of nutritional status is important and has been reviewed (31). Biochemical measurements can differentiate between iron stores and those associated with depleted iron in the functional pool. Storage iron parameters for iron deficiency include the absence of hemosiderin in bone marrow smears, a total iron-binding capacity below 400 $\mu\text{g/dL}$ and serum ferritin below 12 $\mu\text{g/L}$. Serum transferrin saturation below 16%, and hemoglobin below 130 g/L in men or 120 g/L in women are functional indicators of iron deficiency. A mean cell volume below 80 fL , and erythrocyte protoporphyrin below 70 $\mu\text{g/dL}$ RBCs indicate low iron stores. In iron deficiency, low serum iron is associated with low serum ferritin and increased total iron-binding capacity of serum transferrin. Serum ferritin and serum iron increase and total iron-binding capacity decreases in iron overload. Normal total iron-binding capacity is associated with elevated serum iron and ferritin in megaloblastic anemia. Serum transfer receptor level is elevated in iron deficiency anemia (normal range 1.3–3.3 mg/L) but not in the anemia of chronic illness (31a).

Methods of Assay

Serum Ferritin. Serum ferritin can be determined by any one of a number of immunoassays. Either ferritin or antibody is labeled with ^{125}I . In immunoradiometric assays the radioactivity of the bound labeled antibody is determined and is directly related to the serum ferritin concentration. Radioimmunoassays use competition between serum ferritin and radiolabeled ferritin for antibody. The antibody-antigen complex is precipitated and counted. Radio-activity is inversely proportional to serum ferritin concentration. Enzyme immunoassays use enzyme activity as an endpoint. Antiferritin-coated solid phase is incubated with serum plus antiferritin conjugated to an enzyme (usually alkaline phosphatase or peroxidase). Serum ferritin binds to the immobilized antibody and in turn is bound by the conjugate. Enzyme reaction with the appropriate substrate yields a color for spectrophotometric endpoint. Details of the procedures and a list of the various types of assay kits and vendors who supply them are given elsewhere (32). Sensitivity varies from 1 to 4 ng/mL for most assays. Reported precision (CV) between runs ranged from 3.5 to 10.8%. The CV between laboratories ranged from 10.9 to 20.5%. Each laboratory must develop a reference range for serum ferritin for each method used.

Serum Iron. Spectrophotometric assays for serum iron involve release of ferric iron from transferrin, its reduction to the ferrous state, and reaction with one of a number of chromagens. Ferrene and ferrozine, which have absorption maxima at 600 and 560 nm, respectively, are most commonly used. Detailed procedures are described elsewhere (33). Kits for some assays are available (35).

An alternative method uses coulometry, based upon the electrochemical potential developed at the interface of the iron-containing serum and an electrode. The electrode is maintained at a constant potential that is determined from the electropositivity of the iron atom. The current required to maintain the electrode at this potential is measured. This current is a function of the electropositivity of iron and its concentration in the serum. Since the electropositivity is known, the concentration can be calculated. The technique requires a specialized instrument (36) such as that available from Environmental Sciences Associates (ESA).

A third method appropriate for research uses atomic absorption spectrophotometry (37). Iron is complexed with basophenanthroline, and the complex is extracted into methylisobutylketone. The concentrated iron can then be measured by flame atomic absorption spectrophotometry. Graphite furnace atomic absorption spectrophotometry can be applied for direct analysis of serum iron (38). It is mandatory that hemolysis of the blood specimen be avoided.

Total Iron-Binding Capacity. In addition to the total serum iron, the total amount of iron that transferrin can bind—total iron-binding capacity (TIBC)—must be determined to assess iron status. TIBC is determined by measuring excess iron in the supernatant from a known amount of iron added to serum to saturate transferrin, which is separated by protein precipitation (34). The same methods used for serum iron determination may be used to measure the unbound iron. The number of available iron-binding sites of

transferrin (UIBC) is the difference between the concentration of added iron standard (e.g., 5000 µg/L) and the free iron measured in the supernatant.

$$\text{UIBC} + \text{serum Fe} = \text{TIBC}$$

Zinc

Results of analysis of zinc in serum or erythrocytes do not consistently reflect zinc status. Approximately 65% of serum zinc is bound to albumin, and most of the remainder to α_2 -macroglobulin, hence a low serum zinc concentration may be associated with a low serum protein level. In severe zinc deficiency, serum zinc is low, but very low serum zinc levels may be attained in other conditions such as an acute phase response, in which the element is redistributed to other tissues. Erythrocyte zinc concentration is approximately ten times that in plasma, and changes that occur slowly because of the long half-life of the cell are not easily detected. Platelets, lymphocytes, and granulocytes are rich in zinc and are depleted in zinc deficiency of the host (39). Although isolation of these cells and platelets is tedious, it is easily accomplished with a little practice. Performing a zinc loading test and monitoring plasma levels with time is of limited value in assessing zinc status.

Recent application of stable isotopes of zinc (40) has provided promising results; however, the applicability of this technique for clinical use is limited because inductive plasma mass spectrometry is needed for measuring isotope ratios to monitor the disappearance from plasma following administration of an enriched isotope.

Using hair zinc levels to assess zinc status has the advantage of an easily accessible sample. Hair zinc was found to be low in preschool children whose zinc bioavailability was considered low (19a). Age- and sex-matched groups are necessary for comparison (19b). A change in the rate of hair growth was suggested in the interpretation of results of decreased zinc (µg/g hair) in children given zinc supplements (19c). In conditions of malnutrition, hair growth rate may be decreased; hence the zinc content per unit weight increases, introducing a source of error. Hair may be a useful tissue to monitor response to supplementation, provided that errors of bias are ruled out and that care in specimen preparation and analysis avoids environmental contamination, including some hair shampoos and dyes as sources of zinc.

Although many enzymes that require zinc as a cofactor (e.g., alkaline phosphatase, lactic dehydrogenase, erythrocyte carbonic anhydrase) have decreased activity and ribonuclease activity is increased in experimental zinc deficiency in animals, no consistent changes have been demonstrated in human zinc deficiency.

Methods of Analysis

Plasma, Serum, or Urinary Zinc. Zinc in plasma, serum, or urine is best measured by flame atomic absorption spectrophotometry (41). To compensate for viscosity differences, calibration standards for a five-fold dilution of plasma or serum with deionized water are prepared in 5% glycerin. Erythrocyte zinc is determined on the

hemolysate from a 50-fold dilution of cells. The result may be expressed as $\mu\text{g/dL}$ red cells or in terms of hemoglobin concentration. Leukocyte and platelet zinc determinations require graphite furnace analysis (39). Rigid adherence to a meticulous protocol is required at every stage of the procedure to prevent contamination.

Other Vitamins

Tests to assess the status of other vitamins and suggested analytical methods with normal reference ranges for adults are given in [Table 57.4](#) and discussed in relevant chapters of this book. Detailed analytical procedures by individual authors are described (42) and discussed elsewhere (42, 43), with reference ranges listed (44).

Element	Source ¹	Method/ Reference	Reference Concentration Units	Range in units
A	Retinoids	Reverse-phase HPLC	0.05-0.80 $\mu\text{g/dL}$ retinol 0.05-0.75 $\mu\text{g/dL}$ tocopherol 0.40 $\mu\text{g/dL}$	1.0-1.75 $\mu\text{g/dL}$
B ₁	25(OH) vitamin D ₃	RIA	16-160 nmol/L	
D	1,25(OH) ₂ vitamin D ₃	RIA	20-60 $\mu\text{g/dL}$	40-100 $\mu\text{g/dL}$
E	tocopherol (E) phorbol ester	Reverse-phase HPLC Radioimmunoassay	0.0-0.05 $\mu\text{g/dL}$ 11-55 nm	11.0-60.0 $\mu\text{g/dL}$
K ₁	phylloquinone	Reverse-phase HPLC	0.0-0.40 $\mu\text{g/dL}$	1.1-0.8 $\mu\text{g/dL}$
Total B ₁₂	Total B ₁₂	Reverse-phase HPLC	10-60 $\mu\text{g/dL}$	0.16-1.00 $\mu\text{g/dL}$
B ₆ (pyridoxal phosphate)	pyridoxal (B ₆) pyridoxamine pyridoxol pyridoxal	Spectrophotometry	Standard by HPLC >20%	
B ₉ (methyl cobalamin)	Cyanocobalamin methylcobalamin hydroxycobalamin B ₁₂	Spectrophotometry	Standard by HPLC >20%	
B ₁₂ (methyl cobalamin)	Hydroxycobalamin methylcobalamin hydroxycobalamin B ₁₂	Spectrophotometry	Standard by HPLC >20%	
B ₁₂ (methyl cobalamin)	Cyanocobalamin methylcobalamin hydroxycobalamin B ₁₂	Reverse-phase HPLC	1.0-4.00 $\mu\text{g/dL}$	20-50 $\mu\text{g/dL}$
Biotin	Free biotin (B ₇) Cytobiotin (B ₇)	Radioimmunoassay Radioimmunoassay	1.0-10 $\mu\text{g/dL}$ 100-900 $\mu\text{g/dL}$	4.3-21.7 $\mu\text{g/dL}$ 130-150 $\mu\text{g/dL}$
C	Ascorbic acid (B ₃) Dehydroascorbic acid oxidized	HPLC	0.0-0.05 $\mu\text{g/dL}$	0.05-0.10 $\mu\text{g/dL}$

¹Abbreviations: HPLC, high performance liquid chromatography; HPLC, radioimmunoassay; RIA, radioimmunoassay.

Table 57.4 Laboratory Tests for Assessment of Vitamin Status

Other Minerals and Trace Elements

Tests to assess the status of various minerals and trace elements are noted in the relevant chapters. Suggested analytical methods and reference ranges for serum concentrations of electrolytes and trace elements are listed in [Table 57.5](#) and [Table 57.6](#), respectively. Analytical procedures are described in detail by individual authors (42), with reference ranges listed (43, 44).

Electrolyte	Analytical Method	Reference	Range
		Conventional Units	SI Units
Sodium	Flame AA	135-145 mEq/L	135-145 mmol/L
Potassium	Flame AA	3.6-5.0 mEq/L	3.6-5.0 mmol/L
Calcium	Flame AA	8.8-10.6 mg/dL	2.0-2.6 mmol/L
Magnesium	Flame AA	1.6-2.0 mg/dL	0.75-0.85 mmol/L
Phosphate	Spectrophotometric	2.5-4.5 mg/dL	0.8-1.5 mmol/L

Prepared from references 41-44. Reference 41 is continually updated in C21-DCM, Pass 1/ Major Pathology, Inc., Columbus, OH.

Table 57.5 Laboratory Tests Values: Serum Levels Electrolytes

Trace Element	Assay	Method	Reference	Range
			Conventional Units	SI Units
Copper	Copper	Flame AA	0.7-1.4 mg/dL (male)	11.0-20.0 μ mol/L (male)
	Ceruloplasmin	Rate nephelometry	0.6-1.0 mg/dL (female)	12.6-20.4 μ mol/L (female)
	Ceruloplasmin	Colorimetric	150-400 mg/dL	1.0-4.0 μ mol/L
Iron	Iron	Flame AA	400-1000 μ g/L	110-280 μ mol/L
	Transferrin	Rate nephelometry	1.87-3.12 g/L	21-35 μ mol/L
	Iron-binding capacity	Flame AA	2.5-4.2 mg/dL	48.9-77.2 μ mol/L
	Ferritin	RIA or EIA	20-200 μ g/L	40-400 μ mol/L
Selenium	Glutathione peroxidase	Spectrophotometric	400-800 U/L	
	Selenium	Graphite furnace AA	100-150 μ g/L	1.3-2.4 μ mol/L
Zinc	Zinc	Flame AA	65-130 μ g/L	10.0-17.0 μ mol/L

Prepared from data from references 40-44. Reference 42 is continually updated in C21-DCM, Pass 0/ Major Pathology, Inc., Columbus, OH.

Table 57.6 Laboratory Values: for Serum Levels of Trace Elements and Associated Protein

PHYSICAL AND INSTRUMENTAL ANALYTIC METHODS

Stable Isotopes

Nutritional Assessment and Metabolic Studies. Radio-active isotopes as tracers for nutritional assessment cannot be given to children or pregnant women. In contrast, stable isotopes, the naturally occurring isotopes of an element, are not radioactive. Their safety is a distinct advantage, as is the absence of decay. Disadvantages of the enriched stable isotopes are their greater expense and the required larger dose, which, unlike the radioactive tracer dose, may add significantly to the body pool of the element being studied. Sample pretreatment required for stable isotope measurements is usually more extensive than for radioactivity, and equipment is more expensive. In addition, whole-body counting is not possible with stable isotopes. Sandstrom et al. (45) have

published a comprehensive discussion of various aspects of stable isotope application.

Minerals and Trace Metals

Stable isotopes of calcium, chromium, copper, iron, magnesium, manganese, selenium, and zinc have been used in nutritional studies. Ideally, the enrichment achieved should approach 100%, but this is sometimes difficult because of the cost and availability of the isotope. If a less abundant isotope is selected, a larger dose is required. Stable isotopes may be quantified by any one of a number of systems, and the advantages and disadvantages of each are discussed elsewhere (45), as are the doses of various available enriched isotopes, methods introducing the isotope, comparisons of the metabolism of intrinsically and extrinsically labeled foods for a number of elements (e.g., zinc, copper, calcium, magnesium, and selenium) (45). Numerous studies measuring absorption of zinc, copper, and iron from fecal monitoring of stable isotopes have been summarized (45). Most studies require fecal collections for up to 15 days, which emphasizes the high costs associated with these research tools. Instrumentation costs are also a major consideration.

Zinc status may be assessed from very short term observations of isotope ratios in plasma and urine following intravenous administration of stable isotope (40).

Whole-Body Counting

Whole body [K] is an accurate index of the body cell mass and can be determined by ^{40}K measurement. Instruments can accommodate a wide range of body size, from low-birth-weight infants to obese adults (46). Of the naturally occurring isotopes of potassium, ^{40}K represents approximately 0.018% of the total. This isotope emits gamma rays, which are easily detected and quantitated.

In Vivo Neutron Activation Analysis (IVNAA)

IVNAA (47, 48) enables chemical analysis of body composition. When exposed to neutrons, elements of interest undergo a nuclear reaction. The resulting gamma emissions are characteristic of the tissue elements to be determined and can be easily counted. The technique has been applied to many elements, including calcium, sodium, chloride, phosphorus, nitrogen, zinc, and carbon. Partial-body IVNAA can be applied to individual organs that are target organs for a particular element. Counting statistics may be calculated either by delayed gamma-activation analysis or prompt gamma-activation analysis, described below.

Delayed Gamma-Activation Analysis. Delayed gamma-activation analysis involves neutron capture by an atom of the element (48), transformation of the atom to another nuclear state, and radioactive decay with gamma emission. The activation time, delay time between the end of activation and the beginning of counting, and the counting time are used to correct for decay of the radioactive element. This technique has been used mainly in research in laboratories and development of instrumentation has been

innovative, so there is a lack of standardization for calculation of results.

Prompt Gamma-Activation Analysis. Capture of a neutron by a nucleus of an element results in an excited nuclear state because of the energy provided by the neutron. The excited nucleus promptly returns to its lower energy state, with emission of gamma rays. Since the excitation and gamma emission occur within a fraction of a nanosecond, the signal must be measured at the time of neutron exposure. The total activity is then directly proportional to the activation time. Prompt gamma-activation analysis is currently used to estimate total body protein, assuming that the nitrogen content of protein is 16%. The technique and instrument design, a detailed discussion of assumptions and their validity, equipment, aspects of measurement procedures, precision, accuracy of the techniques, and cost factors are presented elsewhere ([48](#)).

Bioelectrical Impedance

The water and electrolyte content of fat-free tissue permits greater conduction of an applied electrical signal than does fat. Thus, by placing electrodes dermally on the ankle and wrist and applying an electrical signal, one can determine various parameters of total body composition by applying Ohm's law. Electrical impedance measurements are used to determine total body water and subsequently to estimate fat-free mass and the percentage of body fat. The assumptions, exceptions to be considered for other than healthy subjects, and need for standardization in applying the technique are discussed elsewhere ([49](#)). (See also [Chapter 49](#) and [Chapter 56](#).)

[Selected Readings](#)

Dietary assessment began in ancient times, but only when knowledge of food composition expanded in the 20th century was it linked to intakes of nutrients and other constituents that affect health (1, 2). Technologic advances now include biochemical measures for estimating intakes of some constituents to supplement or corroborate dietary intake data (3, 4). Microcomputers and computerized dietary analysis software now permit direct data entry using structured dietary recall interviews. Semi quantitative food frequency questionnaires are available in computerized forms (5). Computerized nutrient analysis programs and automated data processing ease the burdens of calculating nutrient intakes and rapidly provide summaries of the analyses in databases and tables. These advances help standardize dietary assessment tools and extend their uses from the bedside to large surveys. Statistical techniques for analyzing dietary data

have also been refined. The pressing challenges of the future include development of better methods for rapidly screening and assessing dietary intakes and incorporating results routinely into computerized databases and other communications to optimize patient care.

This chapter guides readers in selecting appropriate dietary assessment methods for their purposes and describes the nutritionist's role in carrying out these tasks.

BASIC QUESTIONS TO ANSWER WHEN SELECTING A DIETARY ASSESSMENT METHOD

All dietary assessment methods are imperfect. Their validity and reliability depend heavily on the skill of the interviewer; the instruction, training, and cooperation of the subject; and a valid, reliable nutrient database or other system of analysis. The “best” method depends on the purpose of the investigation. Incorrect inferences may be made about nutritional status if intake data are used alone. For estimating individual nutritional status and developing dietary treatments, a combination of dietary, biochemical, clinical, and anthropometric methods will continue to be the “gold standard.” No indicator provides a definitive diagnosis of all forms of malnutrition and the information needed for shaping dietary interventions in individual cases ([6](#), [7](#)).

Why Is Dietary Intake Being Evaluated?

The answer to this question influences the type of data that must be collected, the number of observations necessary, and the best methods to use. One may collect dietary intakes to screen, assess, evaluate, plan interventions or monitor dietary intake or nutritional status of individuals, groups, or nations.

What Is Being Assessed?

Nutrients, other food constituents, foods, food groups, and dietary patterns may be assessed ([Table 58.1](#)). The methods required for each purpose differ. Information on the entire diet is usually needed if the focus is on intakes of several nutrients that are widely dispersed in the food supply (as is the case for most clinical purposes) and if nutrient-nutrient interactions exist, since the absorption, use, and health effects of one nutrient may be influenced by the presence of others ([8](#)). Collection of food frequencies or food groups is less time consuming and may suffice for screening purposes, but data are inaccurate for assessing absolute levels of nutrient intake. Special food-grouping systems such as food or diet exchange lists provided for those on modified diets furnish rough estimates of some nutrients. For descriptive purposes, additional information on food consumption patterns or dietary characteristics may also be helpful.

Entire diet	One or many nutrients or food constituents Interrelationships between these
Foods or meals	Intake frequency of a single food or foods Form of food (such as retentiveness of sugar-containing foods in studies of dental caries) Type of food (animal, plant) Cooking or preparation method Food diversity
Food groups	Source of foods (feeding or meal program) Intake frequency of food groups Conformity with a food guidance system (such as four food groups, food exchange lists, or some other system)
Dietary patterns and characteristics	Typical meals Meal frequency Temporal patterns (time of meal, snacking, drinking, breakfast eating) Location of eating (home or away from home) Use of vitamin-mineral supplements Other patterns (bingeing, spells of illness, fasting, dieting) Conformity to some recommended pattern (introduction of solids or weaning) Source of meals Associations of consumption with some other characteristics (such as mood or time in restaurant/dined) Type of feeding (breast, mixed, bottled)

Table 58.1 Types of Dietary Information of Interest

Who Is the Target of the Assessment?

The respondent's capabilities must be well matched to the assessment methods (9). [Table 58.2](#) lists some respondent characteristics that limit the choice of methods. The generalizability of results also depends on who is targeted. Population sampling techniques must be used if individuals are to be representative of a larger population. The variability of the target's dietary intake will influence how many days of observation are necessary to get a true representation of usual intakes.

Pregnant women	Intake changes over the course of pregnancy, so usual intakes must be assessed at specific points in time during pregnancy Presence of nausea owing to fear of miscarriage may be an issue Presence of certain substances such as alcohol and supplements may be of particular concern
Lactating women	Infant's intake and breast-feeding practices may limit the choice of method and the individual Maternal intake and characteristics relate to child's intake (e.g., breastfeeding) What intakes may be supplemented with nutrients or foods Composition of breast milk varies
Men	Intakes of breast milk must be assessed using special techniques such as test weighing or indirect estimates from dietary intake using weights Meal frequency (break and other food opportunities) Surrogate respondents must be used Energy balance and weight are primary focus; needs to match, depending on objective research methods Special foods (formulas, baby and weaning foods) and vitamins commonly used must be included in food intake Surrogate respondents must be used (other parents, because no one person is aware of child's entire intake) Intakes only greatly from day to day
Preschool children	Recall is limited, surrogate respondents or records may be needed to supplement recall Intakes may be limited Motivation and ability to describe foods may be limited Child or have limited attention span
School children	Intakes may vary greatly between school days and other days Intakes change rapidly, especially during adolescent growth spurt, and may be more tightly associated with physical maturation than age Meal patterns, including frequent meal skipping, variation at unusual times of day, eating, eating, eating, self-induced vomiting, binged, abuse, and eating, eating, eating may be present and not immediately apparent Recall of individual food items or intakes may be difficult (e.g., duration of between-feeding, eating patterns) Recall may be limited Distraction in eating, eating, or attention may complicate assessment Intakes may vary greatly from day to day (e.g., school days) affecting food intake are present Methods using indirect information, observations, or records cannot be used Reporting may be limited (because of focus that respondents will be provided) Intakes may vary greatly from day to day with observations in other Recall may be affected by duration of observation of "usual" diet when used Recall may be affected by duration of observation of "usual" diet when used Recall may be affected by duration of observation of "usual" diet when used
Adolescents	Intakes may vary greatly between school days and other days Intakes change rapidly, especially during adolescent growth spurt, and may be more tightly associated with physical maturation than age Meal patterns, including frequent meal skipping, variation at unusual times of day, eating, eating, eating, self-induced vomiting, binged, abuse, and eating, eating, eating may be present and not immediately apparent Recall of individual food items or intakes may be difficult (e.g., duration of between-feeding, eating patterns) Recall may be limited Distraction in eating, eating, or attention may complicate assessment Intakes may vary greatly from day to day (e.g., school days) affecting food intake are present Methods using indirect information, observations, or records cannot be used Reporting may be limited (because of focus that respondents will be provided) Intakes may vary greatly from day to day with observations in other Recall may be affected by duration of observation of "usual" diet when used Recall may be affected by duration of observation of "usual" diet when used Recall may be affected by duration of observation of "usual" diet when used
Older	Intakes may vary greatly between school days and other days Intakes change rapidly, especially during adolescent growth spurt, and may be more tightly associated with physical maturation than age Meal patterns, including frequent meal skipping, variation at unusual times of day, eating, eating, eating, self-induced vomiting, binged, abuse, and eating, eating, eating may be present and not immediately apparent Recall of individual food items or intakes may be difficult (e.g., duration of between-feeding, eating patterns) Recall may be limited Distraction in eating, eating, or attention may complicate assessment Intakes may vary greatly from day to day (e.g., school days) affecting food intake are present Methods using indirect information, observations, or records cannot be used Reporting may be limited (because of focus that respondents will be provided) Intakes may vary greatly from day to day with observations in other Recall may be affected by duration of observation of "usual" diet when used Recall may be affected by duration of observation of "usual" diet when used Recall may be affected by duration of observation of "usual" diet when used

Table 58.2 Considerations in Choosing Dietary Assessment Methods for Particular Target Groups

What Time Frame Is Important?

Typical intakes that span many weeks or months are usually the time frame of interest for nutritional purposes. Sometimes, as in investigations of food intoxication incidents, only a single day's intake is needed, greatly simplifying the task.

What Is the Focus of Analysis?

The appropriate target may be an individual or group. Intake alone may be of interest, or how it is associated with some other characteristic, such as morbidity or mortality. Methods differ in their validity and reliability for describing individual intakes (10). If the focus of analysis is to characterize the diets of individuals, more observations are usually needed than if the focus is on groups (11). For epidemiologic and educational purposes, stable relative rankings for groups of respondents rather than absolute levels of nutrient intakes may suffice. Statistical methods for analysis of dietary data have been well described (12, 13).

How Great Is Respondent Burden?

The respondent's time burden varies from a few minutes to several hours, depending on the method chosen. Psychologic burdens of respondents include the time, annoyance, and work involved in recording, remembering, and reporting minute details about food intake, especially when the reporter considers the information embarrassing or sensitive. Tradeoffs must often be made between the investigator's desire to collect information that could conceivably be of interest and respondents' willingness to give it.

What Are the Costs?

Objectives of data collection must be matched to resources. Some costs are immediately apparent: forms, food models, computers, interviewer time, and respondent honoraria. There are also hidden costs such as the time needed for protocol development, calibration, interview training, checking and coding of records, other quality assurance activities, calculating and interpreting intake data, and communicating findings. These are usually much greater than one imagines (14).

What Other Constraints Are Present?

Other limitations include the social and physical context and setting for the interview; the availability, skill, interest, and training of the interviewers; assessment techniques; and the time and facilities available for analyzing the resulting data. When patients are being assessed, their illness or the necessity for other treatments may limit the means available (15).

How Accurately Must the Characteristic Be Measured?

Accuracy depends on validity and reproducibility, and it varies from one method to another. Differences between actual and measured intakes in dietary assessment

depend not only on how representative the data are but also on the many factors that affect measurement accuracy.

Misclassification can be corrected for by sampling sufficient and representative numbers of days of observation for individuals, by using sample size formulas that take misclassification into account, by increasing the number of respondents, and by using other formulas to adjust the size of the confidence intervals (16, 17). These issues are discussed in depth elsewhere (18).

DIETARY SCREENING AND ASSESSMENT IN HEALTH CARE

Dietary evaluation is part of a continuum that begins by identifying individuals who have certain risk factors or characteristics of interest and ends with integrating the results of the assessment with other information to reach appropriate conclusions about dietary, nutritional, or general health status. Dietary data are collected in most health care settings to furnish a sound basis for developing and implementing nutritional care plans. The individual's condition and the health care delivery setting will dictate the specific focus. It may concentrate primarily on developing information for later health promotion, disease prevention and control, rehabilitation, or, if prevention or cure are not possible, guide interventions devoted to amelioration or palliation. At present, there is no consensus on the best method for assessing dietary or nutritional status in clinical settings (19).

Nutritional Screening in Acute and Chronic Care

It is no longer possible to rely solely on the goodwill and individual subjective judgments of health professionals in accurately screening for nutritional risk. Certainly, subjective impressions are useful in identifying some individuals who need further nutritional assessment, but selections based solely on such criteria tend to be idiosyncratic and vary in their validity from one practitioner to another. Moreover, those individuals who need services the most may be the very ones who are the least likely to come to the attention of health professionals, and they will be missed. Valid, objective screening criteria that are mutually agreed upon by all on the health team help to avoid these difficulties.

Screening is helpful in establishing priorities for the most efficient use of available time and money in health care settings. Standardized guidelines for nutritional screening are still in their infancy in clinical practice, but they are gradually coming into more widespread use. The Joint Commission on Accreditation of Hospitals and Health Care Organizations (JCAHO) now recognizes the need for some method of identifying all patients at high nutritional risk and requires it within 24 hours of hospital admission, although standardized methods are not specified (20). Nutritional screening is included in the U.S. Preventive Services Task Force recommendations on nutritional counseling (21, 22). Screening has also been proposed as a factor for measuring the quality of managed care services as part of the HEDIS 3.0, a set of quality indicators widely used to evaluate managed care organizations (23). In the future, it is likely that dietary intake

and nutritional status will be routinely screened in all patient assessments (24).

Changes in health care financing, constraints on economic and human resources, the advent of managed care, and the growth of comprehensive networks for care that span various delivery settings are revolutionizing medical, public health, and nutritional care delivery. In acute care settings, illness severity has increased, patient lengths of stay have decreased, and patients are often discharged while they are still very ill. Rapid patient turnover makes it essential to screen and assess quickly patients most likely to need nutritional care so that it can be provided in a timely fashion. Professionals working in outpatient, community, and public health settings are now encountering individuals with severe and complex nutritional problems who need evaluation. However, even very simple and straightforward questions about eating and diet are often omitted on standard clinical history forms and patient interviews in all of these settings (25). These trends have stimulated the need for standardized nutritional screening and assessment methods to identify those most in need of nutritional assistance, which can be performed quickly and communicated easily to all who need the findings for providing health care.

The most important attributes of risk factors for screening purposes in acute care settings are that they are already collected or are easily and rapidly abstracted from existing data, they are available on all patients, and they result in clinically meaningful categorizations of patients by risk status. Preferably, they should be available on computerized patient record summaries or other information systems that can be rapidly perused. Once risk is ascertained, it should be entered into the same system so that all providers have access to the information.

Presently, many health professionals are uncertain about what should be screened to detect malnutrition and whether screening is effective. Although many dietary and other characteristics are used for nutritional screening, few of them have been formally evaluated for specificity, sensitivity, and predictive value. This is an important area for future research.

Dietary Assessment in Health Settings

Further dietary assessment is necessary in health care practice settings because screening by any single measure is likely to identify both individuals who will respond to dietary measures and others who will not. Because the causes of malnutrition vary, dietary screening or assessment may indicate a deficit in nutritional status, but without additional information, one cannot assume that better alimentation will solve the problem. Dietary measures can only remedy forms of malnutrition that are primarily due to diet, such as inadequate, imbalanced, or excessive dietary intake. Much malnutrition secondary to physical ill health and psychosocial problems occurs even in the face of adequate food in the environment, and even if the individual is provided with an adequate diet. The presence of certain diseases or conditions provides clues that malnutrition secondary to disease may be involved. Even when it is, there is often a component that involves dietary deficiency, and this may be treated or prevented if dietary intakes are improved. Assessment aids in identifying forms of malnutrition that

are likely to respond to nutritional measures and those that require other measures.

Changes in dietary intake are among the earliest signs of nutritional problems. Theoretically, dietary intakes should be ideal for screening and assessment. However, dietary screening and assessment measures also have major limitations. These include the heterogeneity of malnutrition itself, inability to completely describe why intake is poor or whether improved intake will correct the problem, and methodological limitations such as specificity and sensitivity. These limitations make it necessary to use other types of information in the assessment process as well (26).

Many forms of malnutrition exist, ranging from starvation and deficiencies of specific vitamins and minerals to imbalances and excesses of food energy or other nutrients. No single screening or assessment indicator signals the presence of all of them. All of these need to be evaluated, since they may be present and relevant to prognosis. The best indicator for each specific form of malnutrition may be dietary in some instances, clinical, biochemical, or anthropometric in others, depending on the validity, reliability, and specificity of the indicator in question. However, few indicators of nutritional status are definitive and unambiguous in themselves; usually several indicators are necessary to signal the presence of problems.

Early, less severe, and presumably more easily remediable forms of malnutrition may signal their presence only by decreased dietary intakes, but the errors in dietary intake assessment in the clinical setting may be so large that true decreases in dietary intake are indistinguishable from the error in the method itself. Thus, dietary assessment has methodological limitations. Dietary reporting is rarely entirely valid, and some individuals may not be able to provide estimates at all. Food intake varies considerably from day to day so that intraindividual variability is high. It is time consuming and difficult to obtain estimates of food intake over a long enough time for valid qualitative descriptions of intakes in individuals, particularly if respondents are sick. Finally, memory problems confuse results with retrospective methods, and changes in intake during recording may make intakes unrepresentative with prospective methods.

Further examination of the patient found to be at risk involves not only dietary assessment but also a review of available biochemical, anthropometric, clinical, functional, dietary, and medical history information. Such a review gives more insight into the causes of the malnutrition, and the most reasonable and fruitful interventions or therapies can be determined.

HOW METHODS FOR OBTAINING INFORMATION ABOUT FOOD INTAKE DIFFER

Degree of Detail Required

The degree of detail and range of information provided by screening measures is less complete than that furnished by assessment measures.

Screening

Screening is the process of identifying individuals who have characteristics (risk factors) that potentially place them at high risk for dietary or nutritional problems. To identify such individuals, screening criteria must be simple, inexpensive, relatively straightforward, and easy to administer, preferably by generalists or those with little special expertise, in a variety of settings. However, risk factors are probabilistic; they only signify increased risk, not the definitive presence of malnutrition. Thus, they are not definitive in individual cases.

Screening and assessment must be valid and reliable to be effective (27). They must identify those who truly are malnourished and those who are not. Screening must avoid producing large numbers of false positives (persons who have the risk factor but who are not malnourished on further assessment) and false negatives (persons who are judged on screening to be well nourished but who, after later testing with more definitive standards, are shown to be malnourished). The screening test must also detect malnutrition earlier than without screening and do so accurately (i.e., without large numbers of false positives and false negatives). Finally, early detection must be effective. Those judged to be malnourished who are detected and treated early should have better clinical outcomes than those detected without screening.

Dietary Risk Factors. Dietary risk factors are easily identified characteristics that are associated with an increased likelihood of poor diet or nutritional status. They include indices of poor diet such as perceived inadequate quantity or quality of food intake, presence of certain acute or chronic diseases or conditions, need for assistance with eating, and physiologic vulnerability, evidenced by medication use and dental problems, for example. Psychosocial factors such as social isolation, demographic characteristics known to be associated with poor nutritional status such as poverty, and membership in a nutritionally vulnerable group such as extreme youth or old age, pregnancy, or lactation are also useful indicators of dietary risk. Note that they identify risk of poor diet and not necessarily dietary factors per se.

Dietary Assessment

Dietary assessment is the measurement of indicators of dietary status to identify more definitively the possible occurrence, nature, and extent of poor diet or impaired nutritional status. Assessment should follow screening and give priority to those found to be at high risk. Individuals whose characteristics at screening suggest nutritional risk require further assessment. This consists of a more detailed investigation to identify diet, eating habits, food resources, disease-related issues, or other factors that may affect nutritional status adversely.

Short Dietary Assessment Tools

Short dietary assessment tools are brief methods that provide either qualitative or quantitative information on food groups, a food, or sometimes a specific nutrient. They

include abbreviated food-frequency questionnaires, food checklists, questionnaires on specific eating or drinking behaviors (e.g., consumption of fruits and vegetables, alcoholic beverage intake), self-monitoring tools such as fat gram counters for keeping track of the intake of a nutrient, and counting the number of food groups consumed. The short dietary assessment tools fall between screening methods and the more detailed and comprehensive descriptions of diet (described below) in the time they take to administer and the information they provide. The detail they provide may suffice for some clinical purposes. Their advantages are that they are short and easy to administer by nonprofessionals and may be useful for nutritional education. Their disadvantages are that they do not provide the quantitative accuracy of the other assessment methods, nor do they provide quantitative estimates of more than a few nutrients or food groups. Specific tools for use in various settings are discussed below.

Reference Time Period

Methods differ in when the respondent is asked to provide information. Methods may focus on past intake (retrospective), on intake to be collected after the instruction (prospective), or combinations of the two. [Table 58.3](#) summarizes the major methods. Examples of existing instruments are available (Dietary Assessment Resource Manual [28] and in greater detail elsewhere [29, 30]). For research purposes, a register that lists dietary assessment calibration and validation studies comparing dietary intake estimates from two or more assessment methods is available (31). Correlations between methods vary; usually those with a correlation coefficient, r , of 0.5 or higher are considered acceptable (32). [Table 58.4](#) summarizes the advantages and disadvantages of the various methods; these are discussed briefly below. The suitability of each method for estimating specific nutrients and additional details are discussed elsewhere (33, 34).

Method	Description
Retrospective methods	
24-hour recall	Interview prompts a respondent to recall and describe all foods and beverages consumed over the past 24 hours, usually starting with the meal immediately preceding the interview. Food models, measuring cups and spoons, and other tools are used to gain rough estimates of portion sizes. May be telephone or in residence.
Food frequency questionnaires	Respondent reports on frequency and amount of a list of different foods over the frequency of consumption and the usual or average amount consumed over a period of several months or a year. The number and type of food items vary, depending on the purpose of the assessment; current practices are usually not assessed.
Semiquantitative food frequency questionnaire	Similar to a food-frequency questionnaire, portion sizes are specified as standardized portion size or choice of a range of sizes. Foods are chosen to encompass the most frequently consumed foods as well as the most common source of nutrients. The major sources of nutrients for a given population should be included for assessment to be valid.
Multiple dietary recalls	Respondent only reports all foods and beverages consumed on a recall day. Over the interview progresses to determine about the frequency and amount of consumption of those foods. Often, the respondent provides additional documentation of several days' intake in the form of food diaries, food models, measurements on food consumption, careful journaling, and other techniques as are used.
Prospective methods	
Weighted food record	With a food record, the individual weighs on a small scale of known size consumed items that weigh something greater than, at a minimum, an ounce. The individual weighs in the home after switching water or drink, including estimated portion sizes at the time of consumption for several days, or only at specified times instead of several days to save expenses. Weighing also used to report food intake as soon as the item is eaten.
Photographic or videotape records	Individual photographs or videotapes of foods to be eaten, at standardized camera distance.
Electronic records	Respondent records food intake on a specially programmed computer program or handheld computer.
Portable electronic scale or weighing scale	Respondent records intake on an electronic weighing scale recording device with a built-in memory. It operates by pressing a single button, weighing the foods to be eaten, weights are automatically recorded, then the description of the food is dictated on a microphone connected to the scale recorder and weighing scale.
Multiple portion analysis	A duplicate portion of the foods and beverages consumed by an individual is reflected. Foods are then individually analyzed to obtain a total nutrient amount, applicable to combined individuals, usually at institutions or food service and leaving the room and measuring the difference is assumed to be what the respondent(s) takes home. One can use to monitor the individual's food intake over a period period, videotapes may be reviewed and manual recorded accordingly.
Direct observation by trained observers	At controlled or highly regulated environments records may be directly watched by trained observers who use any of the methods mentioned along with keeping the observation to count.

Table 58.3 Dietary Assessment Methods

Table 58.4 Advantages and Disadvantages of Different Dietary Assessment Methods

Retrospective Methods

Retrospective methods include the 24-hour recall, food-frequency recalls, semiquantitative food-frequency recalls, and dietary histories. All rely heavily on the individual's memory and motivation to recall diets eaten in the near or more distant past. Accuracy of recall is related to interview setting, characteristics of the interviewer, effects of instruction, respondent variables such as commitment, memory, sex, age, education, recent health status and diet, the stability of the respondent's diet over time, social desirability, and other factors (35, 36). With the proper incentives and training, most adults can recall what they ate over the past day or week well enough to place them reliably in tertiles or sextiles (37). Recalls of actual food consumption during the previous 24 to 48 hours are the most reliable, with the maximum period thought to be a month (38). Usual or customary habits and relative rankings of food intake patterns going back much farther in time are probably also recalled (39). Intakes collected retrospectively usually give lower estimates of intakes than those collected prospectively because of forgetting. However, intrusions or false memories (e.g., remembering the consumption of a food that was not eaten) may also occur; these may be important in studies of food intoxication. The accuracy of long-term recall data is poor for individuals (40, 41). The reliability of recall after 1 or 2 years is insufficient to classify individuals into tertiles or quantiles of nutrient intakes, although it may be possible to do so for groups (42). Long-term recall is also biased by current diet; these errors may affect patients differently than controls in epidemiologic studies (43). In case-control studies when individuals cannot be categorized reliably with respect to differences in timing, dose, frequency, or duration of intakes of the dietary factors of interest, the associations between diet and later disease or mortality are obscured.

24-Hour Recalls. Twenty-four-hour recalls can be obtained on single or multiple occasions. They provide the respondent with the opportunity, without suggesting responses, to describe all the food, drink, and dietary supplements that may have been consumed. Underreporting can be decreased by probing, but it is still considerable—usually at least 20% for calories and most nutrients. A single 24-hour

recall cannot precisely identify individuals whose intakes are likely to be high or low in the population. Group mean intakes from single 24-hour recalls may be reliable, since those who report very high intakes on a given day are balanced out by those reporting very low intakes. However, the individuals with high intakes will not necessarily maintain their rankings on a second occasion; even though group means may be constant, their values usually exhibit regression toward the mean (44). Thus, quantitative estimates of usual intakes from single 24-hour recall data are highly suspect for individuals. With several 24-hour recalls accuracy improves. Computerized dietary assessment interview schedules permitting direct data entry by either an interviewer or the respondent are now available in English, Spanish, and other languages. They make it possible to obtain several random 24-hour recalls; these provide estimates of usual intake that are as accurate as semiquantitative food-frequency questionnaires. They have the advantage of including foods that may not be assessed with the frequency questionnaire, and they avoid the prompting of a food list. Multiple unannounced 24-hour recalls offer advantages over food records and semiquantitative food-frequency questionnaires in monitoring dietary changes during intervention studies because they are less susceptible to recording bias and show recent dietary changes (45).

Single 24-hour recalls should not be used in surveys to report the number of individuals below some cutoff point for dietary adequacy. They will overestimate those whose intakes are truly low, compared with dietary assessment measures that better reflect typical or usual intakes and rely less on forgetting. Compared with longer observation periods, distributions of nutrient intake obtained from single 24-hour recalls are more spread out, with more very high and very low values. Simply adding respondents does not compensate for this. Because intraindividual variability is high, single 24-hour recalls are poorly correlated with biochemical parameters that reflect usual diet, even when a strong association actually exists; multiple recalls are more satisfactory. Errors of estimates of usual levels of absolute intake depend on how many days are included and vary from one nutrient to the next.

Food Frequency Recalls. The first food-frequency questionnaires were used chiefly in abbreviated versions based on food groups in clinical situations and for special studies. Food frequency recalls are good for describing groups but have serious limitations for making statements about the absolute magnitude of individual nutrient intakes of respondents. If only a single nutrient is of interest, lists are now available of about 100 foods that, by virtue of their composition, portion size, and the frequency with which they are eaten contribute the most to intakes of that nutrient in national surveys of representative samples of Americans (46, 47). Special lists are available to obtain detailed information on single nutrients such as calcium (48) and lactose (49). Various approaches can be used in selecting the most informative foods to use for estimating nutrient intakes in epidemiologic studies (50). Food frequency recalls tailored for ethnic groups such as Native Americans have also been developed (51).

Burke-Type Dietary History. The Burke-type dietary history method is used infrequently today because it takes so long, it requires a trained, highly skilled nutritionist, and the results are difficult to code and process. It is less directive than list-based methods, and for some purposes it may be appropriate, because it completely

profiles an individual diet (52).

Semiquantitative Food-Frequency Questionnaires. Today, semiquantitative food-frequency questionnaires are available that are based on lists of the most common food and vitamin-mineral supplement sources of nutrients in a representative sample of the American population. These are useful for providing semiquantitative rankings to classify individuals into low, medium, and high intakes of a specific nutrient. The two semiquantitative food-frequency questionnaires presently in widespread use that have been tested most extensively are the instrument developed by Willett et al. at Harvard University (53, 54) and that developed by Block and coworkers at the National Cancer Institute (55, 56, 57 and 58). They differ from each other in their method of construction; the reference populations used to select foods; the extent to which they have been validated; the reference portion sizes used; the number of foods they contain; the nutrient intakes they are designed to assess; the proportion of target nutrients they account for; the questions they ask on vitamin, mineral, and other dietary constituents; the construction of the nutrient databases used for translating responses into nutrient intakes; and probably in other respects. Special questionnaires have also been developed to assess dietary fiber intake (59), and additional interview schedules may be included to increase the accuracy of assessment of energy and fat intake (60) or specific nutrients (61). Questionnaires for participants in the Women, Infants and Children Supplementary Food Program (WIC) (62) and for specific ethnic groups are also available (63, 64).

Recently questionnaires have been developed to assess other biologically active substances in foods, such as carotenoids (65). Questionnaires constructed from population-based surveys are good tools for estimating the usual nutrient intakes of groups. The questionnaires are now being widely and sometimes incorrectly used to provide quantitative assessments of absolute levels of intakes of individuals. The basic problem with this procedure is that the nutrient values for each food category on the questionnaire are derived from weighted averages or medians (based on group estimates) of frequency, portion size, and number of servings per occasion for each food in the category among the population used for validating the questionnaire. Thus, nutrient intakes for each food category are derived from weighted group estimates and reflect *population, not individual, values*. Individuals then provide their frequency of consumption of each food group category, with some estimate of portion and servings, and from these, individual intake profiles are derived. However, overall nutrient intakes for individuals do not reflect their own individual weighted averages of food consumption frequency within each category. Rather, they are rough estimates of intakes of food groups, whose nutrient contents are assumed to be similar to that of the reference population at a given point in time, introducing a strong group effect. Also, intraindividual variation is not measured. True differences between individuals may therefore be impossible to ascertain unless replicates are used. Finally, statistical adjustments for energy intakes may not reflect true energy intakes.

Single food-frequency, semiquantitative food-frequency, and dietary history questionnaires help minimize intraindividual variation by focusing on typical or usual intakes. However, their within-individual variation is often unknown, and threats to validity exist due to forgetting, unequal estimation errors, and the use of different periods as the interval for reporting. Correlation coefficients rarely exceed 0.5 to 0.6

from one administration to the next. Correlations of this magnitude present problems when data on usual intakes of individuals are required for correlation with biochemical or clinical parameters; unless very large numbers of subjects are available, significant correlations may be masked (66).

Prospective Methods

Table 58.3 describes the many prospective methods for obtaining food records at the time the food is eaten or shortly thereafter. These include collection of duplicate portions of all food eaten, records of weighed intakes using scales, food diaries, precoded lists for monitoring frequency of intake of foods with respect to how much of a specific nutrient it provides, other special records, telephone interviews on current intake, and photographic, videotaped, and electronic microcomputer records of consumption.

The prospective methods' strengths and limitations are presented in Table 58.3 and Table 58.4 and are discussed in detail elsewhere (67, 68 and 69). They are more reliable and precise for estimating mean intakes for individuals because they reduce the intraindividual variability attributable to day-to-day variations in diet (70, 71) and are less affected by forgetting than retrospective methods. However, the very act of recording food intake may inadvertently stimulate greater consciousness about intake or otherwise lead the respondent to alter intakes during recording periods. Before prospective studies are undertaken for epidemiologic purposes, it is important to do substudies of dietary intake measurements to correct relative risk estimates for biases due to measurement error and to account for statistical power losses when estimating the sample size requirements of the cohort (72). The results of calibration studies show that efficiency of instruments varies (73).

Combinations of Methods

Often dietary assessment studies for research purposes use several methods simultaneously to increase accuracy (74). For example, the United States Department of Agriculture (USDA) National Food Consumption Survey used a 24-hour recall combined with either 2- or 3-day written records, and the Department of Health and Human Service's National Health and Nutrition Examination Survey (NHANES) used a 24-hour recall and food frequency information (75). The monumental yearlong diet study conducted by the USDA also used a variety of methods (76). Newer national surveys are using telephone recalls and interactive computer recalls in addition to food records (77).

Mode of Administration

Methods differ in other relevant attributes, such as the mode of administration and technologies used. Many methods are observer administered. They may use in-person interviews, telephone interviews, direct observation of food consumption, collection of duplicate food samples, information on food served and plate waste, and novel methods such as closed-circuit television cameras or collection of garbage. Others are completed by the respondent, including questionnaires, food records or self-monitoring tools, interactive computerized interview schedules, and electronic aids such as tape

recorders or handheld computers for immediately recording intakes.

THE DIETITIAN'S ASSESSMENT

Standards of Nutritional Care

For optimal function, the nutritional care team today must include both clinicians and administrators who collaborate to ensure that nutritional information and tracking systems are in place and operate smoothly. The vital elements include nutritional standards for screening and assessment (with priorities for which patients will be seen and for what), care plans, and systems for monitoring and evaluating the quality, quantity, costs, and outcomes of the care provided. These fit well with the performance-based interdisciplinary delivery of nutritional services that is now mandated by the JCAHO (78).

Dietitian's Responsibilities

Dietitians have direct responsibilities in the nutritional care of patients on modified diets and special routes of alimentation and those on usual diets. In addition, dietitians have broader duties as members of the multidisciplinary health team in setting and implementing standards of care and as consultants on food and nutrition. Finally, they must serve as liaisons to ensure that patients have access to appropriate food or alimentation by other means.

Inpatient Settings

Inpatient and institutional settings are particularly challenging today. Health care restructuring has decreased the dietitian:patient ratio in most settings, so that priorities must be set in terms of which patients will be seen, by whom, and for what indications. Patients who might benefit the most from nutritional care are most likely to receive it when dietitians and others on the nutritional care team use systematic, standardized criteria to screen and identify those at nutritional risk and use standardized guidelines for subsequent nutritional care.

All patients in institutional settings must be fed; only some need pharmaceutical or other specialized medical care. It follows that dietitians working in these settings must ensure that all patients are fed appropriately for their health conditions. To do this requires patient screening, assessment, and nutritional care planning. The dietitian is responsible for ensuring that all patients receive the initial nutritional screening. Individuals found to be at nutritional risk must have their dietary and nutritional status further assessed, and relevant observations and recommendations for nutritional care or further consultation proposed. These may include modified diets, feeding assistance, or special feeding routes. The dietitian must also arrange for all patients, regardless of their risk status, to be provided with safe food in a form suitable for their condition and aesthetically acceptable. Dietitians are responsible for jointly establishing and implementing standards of nutritional care in collaboration with relevant medical, nursing, pharmacy, and food service staff to ensure that all patients receive these essential nutritional

services. The standards must be implemented, monitored, and periodically evaluated to ensure that they are having the intended results. Dietitians must serve as liaisons between the clinical and food services to ensure not only that patients are fed appropriately, but that they receive appropriate guidance and education on dietary measures that may be necessary after discharge. Dietitians also provide referrals, information, and liaison with home care and extended care services if needed.

Initial Screening. In hospital settings, high patient turnover and the need for efficient screening within the first 24 hours of admission require that the initial screening method rapidly identifies patients in greatest need of help. Initial screening may be done by the dietitian or by some other individual, such as a diet technician or nurse (79). The content of dietary screening is the same no matter who actually does the task. Many risk factors may be used for screening; the critical issue is rapid and valid triage. Table 58.5 summarizes some commonly used risk factors for screening patients in acute and chronic care settings to find those at high risk of malnutrition who need further assessment. Diet-related risk factors for screening patients in these settings mostly involve signs of obviously inadequate intake or of difficulty in eating, since these require immediate action (80). Long-standing dietary imbalances, excesses, and obesity are less amenable to immediate remediation in acute care settings. The remaining items listed in Table 58.5 rely on proxies often associated with dietary inadequacy that are sometimes readily available on charts or computerized patient information systems, such as anthropometric indices; clinical observations and diagnoses likely to be associated with disrupted intake; abnormal absorption, metabolism, or output; or biochemical tests that are routinely performed and available on all patients, which may be depressed in malnutrition.

Table 58.5 Possible Risk Factors for Screening for Dietary Inadequacy in Acute and Chronic Healthcare Facilities

Nutrition-related items that measure physical functional status (including the ability to feed oneself) are included in the widely used activities of daily living (ADL) instrument developed by Katz (81, 82) for institutionalized populations. Loss of the capacity to eat

independently is associated with both morbidity and mortality in institutionalized populations (83). The instrumental activities of daily living (IADL) measures social function and the ability of individuals to continue to live independently in the community. It includes three food-related items: food preparation, shopping, and ability to use the telephone (84, 85). The ADL and IADL are useful in identifying both serious and moderate functional impairment that is missed in usual clinical assessments, but they are not sensitive enough to identify mild impairments (86, 87). A low ADL or IADL score does not necessarily suggest that the individual is malnourished, nor does it indicate that health status will improve with nutritional rehabilitation. Other measures of eating dependency have been developed for use in screening and assessing children with special developmental and health needs and patients with specific diseases.

The nonspecificity of existing scoring systems for identifying malnutrition has stimulated efforts to develop more specific nutritional screening tools over the past two decades. The earliest composite measures, such as the Prognostic Nutrition Index (PNI), were made up of combinations of anthropometric, biochemical, and immunologic measures and were validated by examining later morbidity or mortality. Those who scored high on risk did have increased death rates, but high scores did not predict whether nutritional intervention would alter their prognosis. The PNI and similar scoring systems were not adopted for use in most clinical settings because they did not identify malnourished patients whose prognosis would benefit from nutrition interventions better than well-standardized clinical assessment by skilled professionals (88). Also some components of the indices were costly, difficult to collect, not obtained on many patients, or unavailable for several days after admission, and the scores were rarely included in hospital computerized clinical data systems.

Efforts have been devoted to developing simple screening tools based solely on questions to patients and other easy-to-obtain information to predict malnutrition, but none of these tools yet provide the specificity and sensitivity needed for a truly useful assessment battery (89). One effort is the Nutrition Screening Initiative. It initially focused on developing a consensus on nutritional risk and assessment factors for use among the elderly. However, most of the risk factors identified are also helpful in considering patients at nutritional risk at other ages.

To organize the information on characteristics predisposing to malnutrition in older Americans, the Nutrition Screening Initiative suggested the mnemonic DETERMINE, which represents the first letter in some of the most common risk factors for malnutrition and other types of ill health. These include *disease*, *eating poorly*, *tooth loss* and *swallowing difficulties*, *economic hardship*, *reduced social contact*, *multiple medications*, *involuntary weight loss or gain*, *need for assistance in self care*, and *elderly aged above 80*. Recommendations are provided for subjective and objective risk factors and indicators for further assessment. The DETERMINE list (with the addition of another risk factor, *sedentary lifestyles and physical inactivity*) summarizes most of the major risk factors commonly associated with malnutrition and ill health in older Americans, and it may be useful for identifying such persons, particularly in community settings (90, 91 and 92). Nutrition Screening Initiative manuals are available to assist those who wish to develop nutritional screening, assessment, and intervention programs. They provide specific recommendations for applications in acute and long-term care, outpatient

medical office practices (93), and community settings (94).

Other simple screening batteries, such as the Mini Nutritional Assessment (MNA), are also available to assess the nutritional status of patients in acute care hospitals, nursing homes, and other institutional settings (95, 96).

At present, screening methods vary from one institution to the next; many may be used. For example, in the author's institution, patient height and weight (measured) are entered into the computerized medical record; body mass index (BMI) is calculated automatically and appears on the computer screen along with other patient information. In addition, such obvious risk factors as NPO (nothing by mouth) status, use of special enteral or parenteral feedings, and certain diagnoses or easily ascertainable characteristics that place the patient at risk are also used. On the basis of these criteria, patients are categorized as high, moderate, or low risk. Those at highest risk are given first priority for further assessment and attention. Any patient for whom an attending physician or a nurse requests assistance is also placed in the high-risk category.

Ongoing Nutritional Assessment. In acute care settings today, half or more of all patients require modified diets or special enteral and parenteral alimentation. Ongoing nutritional assessment is required by the JCAHO and is essential to ensure that nutritional interventions are linked to outcomes (97, 98). Clinical rounds with the health care team can be helpful in making initial assessments and in updating other providers about the admitted patient's status or progress.

The most appropriate dietary assessment method to use depends on the route of administration, patient diagnosis, health status, length of stay, dietary issues others on the health team may raise, and time available. For example, with acutely ill patients, little patient participation may be possible, and intakes and outputs may need to be relied upon; whereas, for chronically ill patients in skilled nursing facilities, the focus of assessment is on collecting data for nutritional care planning to achieve long-term quality of life and rehabilitation. Both retrospective methods (e.g., food frequencies or dietary recalls) and prospective methods (e.g., monitoring intakes and outputs or enteral and parenteral alimentation received) may be used under such circumstances. The initial chart note should concisely summarize the relevant aspects of the dietary assessment. It should clearly state any suggestions about the nutritional prescription and indicate that the dietitian is informed about the patient's status (99). Long handwritten notes are usually not read. The note should contain recommendations about changes in diet orders if these are called for, and it should be signed and dated. It is illegal to remove notes from the chart. Increasingly, summaries or reassessments of risk are included in computer databases to permit other professionals to scan relevant dietary issues easily.

After consultation with the physician and other members of the nutritional team, the dietitian is responsible for ensuring that a nutritional care plan is developed, implemented, and revised as needed. Such interventions must be cost-effective (100, 101).

Reassessment is in order whenever a patient's status or mode of alimentation changes

and for any patient who remains in the hospital for more than a week or whose physician requests assistance. Follow-up notes should be concise and to the point; they may consist of no more than a single line stating that the patient is doing well and should continue on the same regimen.

Many patients leave the hospital on modified diets, on special routes of feeding, or before all of their diet-related problems are resolved. It is essential to provide a discharge dietary assessment and counseling. A timely warning system must be in place to allow the dietitian several hours before discharge to find an appropriate time to provide the needed counseling and instruction to the patient and family in an unhurried manner and to make appropriate arrangements for follow-up. It is unreasonable to assume that this can be done on a few minutes' notice as the patient is leaving. The dietitian and others on the health care team have the obligation to see that necessary dietary instructions are communicated to the patient, the referring health care provider, and any other organizations (such as home care companies, visiting nurse associations, community hospitals, or extended care facilities) that will be involved in aftercare. For patients who return to settings in which dietary assistance is unavailable, special attention must be paid to discharge planning.

It is especially important to document and communicate assessments and nutritional care plans for the many patients who require modified diets or special feeding routes after discharge. Written instructions to patients, their families, and the referring physician are helpful. Means of ensuring nutritional continuity of care, including electronic transmission of the results of nutritional assessment between acute care, outpatient, and community settings, are therefore essential.

Outpatient and Community Settings

In outpatient settings, dietitians usually do not have direct responsibility for providing appropriate diets. Rather, they counsel and educate patients and their families on how to implement necessary dietary modifications in their daily lives. They also provide consultation to other health care providers and serve as resources on nutritional care planning to optimize dietary and nutritional status. Traditionally, outpatient care mostly involved primary prevention and chronic disease control activities. In recent years, ambulatory practice has become increasingly more complex and demanding. It now includes the care of acutely and terminally ill persons and demands new skills.

In public health and community settings, the reasons for screening and assessment are more likely to involve primary prevention, health promotion, or education rather than developing nutritional care plans. [Table 58.6](#) summarizes some recent measures used for these purposes. In community settings, self-reports and sociodemographic factors must be relied on to a greater degree to infer malnutrition because the paraphernalia are lacking to carry out laboratory tests, anthropometric measurements, clinical examinations, or actual monitoring of intakes and outputs. Also, situational or general determinants of nutritional risk may be of greater interest. Rapid assessment procedures (RAPS) are early warning indices such as key infant feeding practices, anthropometric indicators, or deficiency diseases that are associated with poor nutritional status. These are already used in nutritional surveillance activities in

developing countries (102). Similar indicators are now being developed in this country. Table 58.7 presents some new dietary assessment methods for different groups that are suitable for community settings.

Topic	Examples of uses
Food security	The Food and Agriculture Organization (FAO) uses food security indicators in studies of food security, comparisons of food groups provided for these studies on the 2004 household guide and the number of meals eaten per day (per capita) (103). Indicators of risk for malnutrition (104), an indirect indicator of food security, is the composite score to identify the characteristics of families at risk. In the case of the U.S. Department of Agriculture's Family Food Plan, major dietary intake to food intake indicators and score averages of food available in area supermarkets (105). Comparisons of costs of the Family Food Plan to local food costs identify poor cost and other community policies at risk for food security (106).
Food insufficiency in households	Questionnaire to identify recurring household needs in Great Britain (107). Food sufficiency questions included in the National Center for Health Statistics Third National Health and Nutrition Examination Survey (NHANES III) of the household level on perceived food sufficiency, the number of days per month on which there was no food or money to buy food and reasons for such a lack of food. All the individual food intake specific questions about the frequency and reasons for going without food were asked along with a 24-hour dietary recall (108).
Community score Based on national Nutrition assessment with list of age- and other questions (109) (110) (111) (112) (113) (114) (115) (116) (117) (118) (119) (120) (121) (122) (123) (124) (125) (126) (127) (128) (129) (130) (131) (132) (133) (134) (135) (136) (137) (138) (139) (140) (141) (142) (143) (144) (145) (146) (147) (148) (149) (150) (151) (152) (153) (154) (155) (156) (157) (158) (159) (160) (161) (162) (163) (164) (165) (166) (167) (168) (169) (170) (171) (172) (173) (174) (175) (176) (177) (178) (179) (180) (181) (182) (183) (184) (185) (186) (187) (188) (189) (190) (191) (192) (193) (194) (195) (196) (197) (198) (199) (200) (201) (202) (203) (204) (205) (206) (207) (208) (209) (210) (211) (212) (213) (214) (215) (216) (217) (218) (219) (220) (221) (222) (223) (224) (225) (226) (227) (228) (229) (230) (231) (232) (233) (234) (235) (236) (237) (238) (239) (240) (241) (242) (243) (244) (245) (246) (247) (248) (249) (250) (251) (252) (253) (254) (255) (256) (257) (258) (259) (260) (261) (262) (263) (264) (265) (266) (267) (268) (269) (270) (271) (272) (273) (274) (275) (276) (277) (278) (279) (280) (281) (282) (283) (284) (285) (286) (287) (288) (289) (290) (291) (292) (293) (294) (295) (296) (297) (298) (299) (300) (301) (302) (303) (304) (305) (306) (307) (308) (309) (310) (311) (312) (313) (314) (315) (316) (317) (318) (319) (320) (321) (322) (323) (324) (325) (326) (327) (328) (329) (330) (331) (332) (333) (334) (335) (336) (337) (338) (339) (340) (341) (342) (343) (344) (345) (346) (347) (348) (349) (350) (351) (352) (353) (354) (355) (356) (357) (358) (359) (360) (361) (362) (363) (364) (365) (366) (367) (368) (369) (370) (371) (372) (373) (374) (375) (376) (377) (378) (379) (380) (381) (382) (383) (384) (385) (386) (387) (388) (389) (390) (391) (392) (393) (394) (395) (396) (397) (398) (399) (400) (401) (402) (403) (404) (405) (406) (407) (408) (409) (410) (411) (412) (413) (414) (415) (416) (417) (418) (419) (420) (421) (422) (423) (424) (425) (426) (427) (428) (429) (430) (431) (432) (433) (434) (435) (436) (437) (438) (439) (440) (441) (442) (443) (444) (445) (446) (447) (448) (449) (450) (451) (452) (453) (454) (455) (456) (457) (458) (459) (460) (461) (462) (463) (464) (465) (466) (467) (468) (469) (470) (471) (472) (473) (474) (475) (476) (477) (478) (479) (480) (481) (482) (483) (484) (485) (486) (487) (488) (489) (490) (491) (492) (493) (494) (495) (496) (497) (498) (499) (500) (501) (502) (503) (504) (505) (506) (507) (508) (509) (510) (511) (512) (513) (514) (515) (516) (517) (518) (519) (520) (521) (522) (523) (524) (525) (526) (527) (528) (529) (530) (531) (532) (533) (534) (535) (536) (537) (538) (539) (540) (541) (542) (543) (544) (545) (546) (547) (548) (549) (550) (551) (552) (553) (554) (555) (589) (590) (591) (592) (593) (594) (595) (596) (597) (598) (599) (600) (601) (602) (603) (604) (605) (606) (607) (608) (609) (610) (611) (612) (613) (614) (615) (616) (617) (618) (619) (620) (621) (622) (623) (624) (625) (626) (627) (628) (629) (630) (631) (632) (633) (634) (635) (636) (637) (638) (639) (640) (641) (642) (643) (644) (645) (646) (647) (648) (649) (650) (651) (652) (653) (654) (655) (656) (657) (658) (659) (660) (661) (662) (663) (664) (665) (666) (667) (668) (669) (670) (671) (672) (673) (674) (675) (676) (677) (678) (679) (680) (681) (682) (683) (684) (685) (686) (687) (688) (689) (690) (691) (692) (693) (694) (695) (696) (697) (698) (699) (700) (701) (702) (703) (704) (705) (706) (707) (708) (709) (710) (711) (712) (713) (714) (715) (716) (717) (718) (719) (720) (721) (722) (723) (724) (725) (726) (727) (728) (729) (730) (731) (732) (733) (734) (735) (736) (737) (738) (739) (740) (741) (742) (743) (744) (745) (746) (747) (748) (749) (750) (751) (752) (753) (754) (755) (756) (757) (758) (759) (760) (761) (762) (763) (764) (765) (766) (767) (768) (769) (770) (771) (772) (773) (774) (775) (776) (777) (778) (779) (780) (781) (782) (783) (784) (785) (786) (787) (788) (789) (790) (791) (792) (793) (794) (795) (796) (797) (798) (799) (800) (801) (802) (803) (804) (805) (806) (807) (808) (809) (810) (811) (812) (813) (814) (815) (816) (817) (818) (819) (820) (821) (822) (823) (824) (825) (826) (827) (828) (829) (830) (831) (832) (833) (834) (835) (836) (837) (838) (839) (840) (841) (842) (843) (844) (845) (846) (847) (848) (849) (850) (851) (852) (853) (854) (855) (856) (857) (858) (859) (860) (861) (862) (863) (864) (865) (866) (867) (868) (869) (870) (871) (872) (873) (874) (875) (876) (877) (878) (879) (880) (881) (882) (883) (884) (885) (886) (887) (888) (889) (890) (891) (892) (893) (894) (895) (896) (897) (898) (899) (900) (901) (902) (903) (904) (905) (906) (907) (908) (909) (910) (911) (912) (913) (914) (915) (916) (917) (918) (919) (920) (921) (922) (923) (924) (925) (926) (927) (928) (929) (930) (931) (932) (933) (934) (935) (936) (937) (938) (939) (940) (941) (942) (943) (944) (945) (946) (947) (948) (949) (950) (951) (952) (953) (954) (955) (956) (957) (958) (959) (960) (961) (962) (963) (964) (965) (966) (967) (968) (969) (970) (971) (972) (973) (974) (975) (976) (977) (978) (979) (980) (981) (982) (983) (984) (985) (986) (987) (988) (989) (990) (991) (992) (993) (994) (995) (996) (997) (998) (999) (1000)	
Dietary diversity and food variety	Division of major food groups used as a measure of dietary quality (164). The relationship with food variety quality (165, 166) and increased use of various dietary recommendations in studies of large surveys (167, 168).
Dietary quality	The Diet Quality Index, a composite of eight food and nutrient based recommendations for adequate and moderation from the National Academy of Sciences, was used to evaluate dietary trends in national surveys over time. It has been widely used for dietary quality, but retrospective information of food intake (169) rather than quality in these epidemiologic studies. However, based on number of food groups consumed, or foods (170) this score is more highly associated with disease risk than an individual foods or nutrients.
Food and vegetable consumption	Number of servings of fruits and vegetables is used as an index of dietary quality in this report (171).

Table 58.6 Risk Factors for Dietary Risk Used in Community Settings

Group	Examples of questionnaires
Pregnant women	Quick assessment methods are available (172)
Lactating women	Various methods used in national evaluations (173, 174)
Infants	
Preschool children	
School children	Child reporting of 24-hour recalls by telephone and using tape recorders were satisfactory when compared to personal monitoring and documentation of food frequencies and nutrient intakes (175), and 24-hour recalls have also been used (176) for groups. Fruit and vegetable frequency questionnaires, 375-item food frequency questionnaire (177) exhibited low correlation with dietary records, other food frequencies (178, 179) were higher compared with food records, 24-hour recalls used successfully in two large surveys of schoolchildren's diets (180, 181), under a concept of dietary pattern underlying food frequencies is understood at early school ages, although children are aware of what they eat (182).
Adolescents	Youth Adolescent Questionnaire (YAQ) (183, 184) is a reliable semiquantitative food frequency questionnaire that compares well with three 24-hour recalls, 24-hour recalls used successfully to describe children's diets in grades 1-12 (185), food frequency questionnaire for Norwegian adolescents correlated well with 7-day records and was reliable ranking nutrient intakes (186).
Elderly	Semiquantitative food frequency questionnaire for elders correlated well with dietary histories (187).

Table 58.7 Risk Factors for Dietary Risk Used in Community Settings

DESIGNING DIETARY ASSESSMENT STUDIES

Dietary assessment is becoming increasingly important in clinical trials and epidemiologic studies. The reader is referred to the 8th edition of this textbook and to other texts that deal with these issues in greater detail.

Dietary assessment methods differ in the ease with which representative samples of intake can be obtained. Representativeness of the study population, the period under study, and the heterogeneity of food habits in the population are important

considerations in drawing samples for study. Dietary methods also differ in their validity and reliability, and thus in their potential uses.

Validity. Validity is the degree to which a method measures what it claims to measure. Validity is affected the most by bias (systematic errors) and to a lesser extent by random response errors. Estimates of validity are needed so that suitable corrections in analysis can be made to account for errors, and comparisons can be made to other studies ([103](#), [104](#)).

Guidelines for validating methods for estimating habitual diets have been proposed ([105](#)). The most common validation technique used is “calibration,” or estimation of concurrent validity; this involves evaluating the test dietary method against a “gold standard” reference method thought to be particularly accurate and precise ([106](#)). These are important to carry out since the relationships between methods differ from one population to another ([107](#)). It is difficult to assess the absolute validity of dietary methods because diet is constantly changing, the very act of observing often alters intakes, and the reference standard itself may be flawed. Neither the test method nor the reference method may reflect true intake levels. In actuality, because subjective response errors and bias are likely to be present in both methods, concurrent validity really only measures apparent validity; it does not tell whether the assessment method is producing the correct answer, only that it is producing the same answer.

Lately, efforts have been made to obtain better estimates of validity that eliminate this subjective element. One method is surreptitious weighing or observation of food intakes at the same time that the individual keeps records. Biochemical markers to validate intakes of some nutrients are now available, including doubly labeled water to estimate energy intake. In general, energy intakes are underestimated, and the bias is greatest in those reporting the lowest intakes ([108](#), [109](#)). Calculations of predicted versus actual energy intake, using estimates of resting metabolism and a coefficient for physical activity, show differential reporting bias by those who are heavier and less well educated, especially among women ([110](#)). Comparisons of energy intakes with weight changes may also be helpful. Urinary nitrogen appearance (UNA) is used as a proxy for protein intakes ([111](#), [112](#)). However, it cannot be considered a perfect reference standard since it is not accurate if urine collections are incomplete, if the individual is in a catabolic state, or if kidney function is poor and the kidney secretes nitrogen into the urine. There are also sex differences between UNA and recalls ([113](#)). The normalized protein catabolic rate (nPCR) is a similar biochemical index of protein catabolism that is obtained from kinetic modeling to provide estimates of protein intake in hemodialysis patients ([114](#)).

Reproducibility. Reproducibility is the degree to which the method gives the same results when it is used repeatedly in the same situation. It is affected most seriously by random response errors and within-person variation in food intake. Observer training and standardized techniques can reduce random response errors. Test-retest reliability is commonly used to measure reproducibility. Larger numbers of observations can improve accuracy ([115](#)).

Causes and Control of Variation between Actual and Measured Intake

Table 58.8 summarizes the major sources of error that account for the differences between actual and measured diets, and likely vulnerabilities of each dietary assessment method. These problems and some ways to control them are described in greater depth elsewhere.

Method	Duplicate Portion	Weighted Residuals	General Residue	24-hour Recall	Diet History	Food Frequency

Table 58.8 Sources of Error in Dietary Assessment Methods

Population Sampling Errors and Biases

Differences between actual and measured intakes that are caused by unrepresentative study population or days of intake sampled can be partially controlled with good study design. The population studied must be representative of the reference population and unbiased in physical, environmental, or other significant ways that threaten inference. Population sampling error is controlled by an appropriate sampling design that selects individuals who are representative of the larger population, with appropriate substitutions for those who fail to volunteer, who drop out, or who are uncooperative.

Choice of an atypical period of observation limits generalization of measured intakes to usual actual intakes. Systematic variability within individuals may be due to fluctuations from weekday to weekend, season to season, sick and well days, or “dieting” and nondieting days. In clinical trials (116), intakes on reporting days often differ in important ways from typical diets. To avoid sampling bias, typical fluctuations in intake patterns must be identified. Then, a suitable sampling design and weighting system can be developed so that each major source of illness, event, or time-related variability is represented appropriately.

Heterogeneity of food intakes is considerable from day to day in affluent Western countries, further complicating sampling of typical intakes. Variation within individuals in

their food intake consists of day-to-day variations not accounted for in the design of the study, and other random measurement errors that cannot be disentangled from true individual biologic variation. Within-individual variation is usually much greater than the variation between individuals, and when it is high, reproducibility decreases (117). The size of the intraindividual variability in intake of a nutrient depends on the food patterns of the individual being studied, the food constituent being assessed, the time frame of interest, and the dietary assessment technique used. Within-individual variability is not constant; it varies depending on the population studied and the assessment method used. Intraindividual variability should be assessed directly when planning studies; rough estimates of its usual size among adults (118), young infants, and other special populations are available (118, 119 and 120). The stability of estimates of usual intake can be enhanced by sampling greater numbers of days for nutrients or individuals exhibiting high within-person variability.

Between-person variation is that existing between people in their habitual food pattern. It varies for each nutrient and increases with the heterogeneity of the population being studied. Within some populations, systematic but unrecognized alterations in food intake may be present in certain subgroups. These include dieting, bingeing, and periodic low intakes due to lack of money or illness. Large between-person variation in habitual food intake increases the difficulty of achieving representativeness in drawing samples from the population and increases the sample size needed. Between-person variation can be reduced by identifying causes of heterogeneity and controlling them by stratifying in sample selection or in later analysis.

Duration of Data Collection

When nutrients are of concern, intra- and interindividual variation in intakes of each nutrient determine the number of days needed to describe intakes. If these are known, the measurement periods necessary to achieve different levels of accuracy can be calculated. The number of individuals or groups to be studied also influences the number of days data must be collected to get satisfactory accuracy. Several days' worth of intakes are generally necessary to characterize usual nutrient intakes reliably. For example, to classify nutrient intakes of individuals reliably into tertiles, a week's worth of dietary records suffices for some nutrients, but for nutrients with very large intraindividual variations in intakes (e.g., vitamin A, riboflavin, iron, and cholesterol), a longer time is needed. For some nutrients, so many days of observation are needed and respondent burden is so great that the study is not feasible. Estimates of how long data must be collected that are gleaned from the literature may be helpful in preliminary planning. However, empirical evidence on the actual population to be measured is also necessary because within-individual variation is not fixed; it varies from one study to another (121).

Response Errors and Bias

Most people are only vaguely aware of what they eat. Without instruction, food records and recalls collected from people will lack sufficient detail to be useful for most research purposes. Random reporting errors include memory failures that lead to omissions and additions of foods. They arise from the type of diet eaten, assessment method used,

ability and training of the respondent, and the skill of the interviewer. Simple and stereotypical intakes are probably recalled best. Frequency of consumption errors (times per day and servings per time) are common with all methods (122). Errors in estimating the portion size are also frequent (123). When foods are not actually weighed, these are very large—as high as 50% for foods and 20% for nutrients. The quality of reporting can be improved by training respondents and by the use of probes, memory aids, food models, and cross checks on reports of intakes, but retraining is needed after about a month (124).

Response biases constitute serious threats to validity. With prospective record keeping individuals may consciously or unconsciously eat differently on reporting days, either to make recording easier or to conform to what they perceive is an appropriate food intake. This bias is common in clinical trials among dietary intervention groups; individuals “eat to the study objectives” on recording days. Retrospective recalls of previous diet are also often in-accurate. Because current diet exerts a strong influence on recollection of past diet, faulty memory may be involved. Also, with both prospective and retrospective methods, respondents may wish to provide intakes they regard as “good” eating habits that will please the interviewer (127).

Coding Errors

Coding dietary records validly and reliably requires a record with enough detail to code and coder training. The best practice is to obtain adequate information to begin with by training both interviewers and respondents so that a complete record is obtained that provides sufficient detail on foods that are major sources of the target nutrients. Whenever possible, additional information needed on portion sizes, brands, and the like should be obtained directly from the respondent, the cook, or someone else who is familiar with the respondent's eating habits. Probing should concentrate especially on foods that are consumed frequently or very rich sources of the target nutrient. Information on composition from recipes (which vary greatly in ingredients), restaurants, or manufacturers may also be helpful for key items. Supplement and condiment intakes may also be important for some nutrients. Checking records and further probing the respondent prior to coding helps resolve some of the ambiguities (130, 131). When respondents describe foods vaguely or illegibly, many plausible food-coding alternatives exist, and errors are large, especially when each coder interprets the food description differently. Even when high-quality records have been received, well-standardized decision rules and coding methods for handling unknowns and ambiguous items are necessary. Allowing coders to use their own discretion introduces error.

Precoded interview schedules such as food frequency and semiquantitative food frequency questionnaires also need to be screened and checked since some respondents misunderstand instructions.

Disaggregating Foods into Nutrients

All dietary assessment methods involve conversion of foods into nutrients or other constituents. The process involves many problems and assumptions that can lead to substantial errors in estimating intakes (125, 126). Generally, a food composition table

or computerized nutrient database is used that summarizes existing chemical analyses of the foods in question. Specialized databases with complete values and extensive detail on certain constituents are available for some purposes.

Errors in Sampling Foods

Food composition values are approximations, not absolute and immutable quantities with the accuracy of atomic weight determinations. Errors due to food composition include true random variability in composition of the individual food item and biased food composition data owing to inadequate sampling. However, some error is inevitable, since the nutrient composition of food is inherently variable. Samples of genetically similar foods differ in their composition because of inherent biologic variability. In addition, environmental factors such as the soil in which food plants are grown, the feed consumed by livestock, postharvest or postslaughter handling, time or circumstances of storage, and the effects of light, heat, humidity, and other conditions may alter nutrient composition. Food processing and inappropriate choices of ingredients in recipe or composite foods introduce additional variability. The effects of these factors vary from one food constituent to another. The best way to avoid these errors is to have an individual who is familiar with food preparation use a nutrient database or food table that is as representative of the food supply as possible and that provides complete data or reasonable imputed values when direct analyses are not available.

For calculations of nutrient intakes to be valid, they must be based on food samples that represent the food supply. The information in some food composition databases includes samples of convenience or lacks documentation for values provided, making the data of uncertain quality. Content and comprehensiveness also differ between databases. The USDA has the largest and most comprehensive program for collecting food composition data in the world and reports average values representing the nutrient composition of foods available in the United States ([127](#)). Information on food composition is best when it is based on samples drawn to be representative (as is done in the USDA program) rather than from samples of convenience. Errors may occur when nutrient values are compiled from several sources or laboratories to develop single representative values used in food tables.

Keeping food composition tables up to date is a continuing struggle. As the food supply, formulations, and processing techniques change, new analyses are required to update nutrient composition values. USDA strives constantly to upgrade the quality, quantity, and completeness of information and its documentation. The number of foods has quintupled in USDA tables of food composition over the past three decades, and the number of nutrients for which values are available has nearly doubled ([128](#)). Methods of determining many nutrients and other constituents in foods are still being developed, and data are still sparse for many items of interest, such as dietary fiber, specific fatty acids, and candidate nutrients such as glutamine, phytochemicals, and other biologic substances thought to be significant to health. Demand is currently outstripping the agency's economic resources and analytic capability; more research is needed in this important area.

Users need to be aware of the limitations of food tables. For example, recently vitamin D

toxicity was discovered among a population obtaining milk from a dairy that was overfortifying its products with the vitamin; use of food composition tables did not reveal the cause, and direct analysis of the suspected food was required.

Errors in Direct Chemical Analysis

For research purposes, values are sometimes obtained from direct chemical analysis of duplicate food samples to achieve greater precision or to provide information on food constituents that is unavailable in standard tables. Representative samples of foods in the total diets of the American population as determined from dietary surveys are collected in conjunction with chemical analysis to determine dietary intakes of selected pesticides, industrial chemicals, and radionuclides in diets (129). Military rations have also been chemically analyzed (130). Potential errors include both sampling errors in assuming that the foods chosen for analysis are representative of the entire food supply, and laboratory errors in the chemical analyses or biologic assays themselves.

Calculated and chemically analyzed values for individual foods rarely agree perfectly. For most nutrients, comparisons between calculated and chemically analyzed values for total diets are closer than those for individual foods. In general, calculated and analyzed values for protein are closest. Values for total calories, carbohydrate, and fat are also fairly reliable, although the fat content of meat and cooking, serving, and eating practices vary a good deal and may increase errors. In contrast, the vitamin and mineral content of foods, especially that of the trace elements, is subject to much greater variation, some of which is environmentally determined or affected by food preparation. Therefore, the differences between calculated and analyzed values are likely to be much greater for these nutrients (131).

Food Composition Tables

Calculations of nutrient intakes must be based on foods as actually eaten to be accurate. Once the food is purchased, food preparation, trimming, and cooking techniques may further alter nutrient content. Food composition databases must therefore provide values for processed and prepared as well as raw foods, with as much detail as possible to be helpful for most purposes.

Many different food composition tables and databases are in use in the United States today. They vary in the timeliness, number, completeness, and specificity of the information they provide on food constituents. The major source of data on food composition in all of them is that compiled by the USDA and other government agencies. However, USDA data frequently do not identify a source or brand name for prepared foods, some proprietary food manufacturer data are not included, reports of additional research on food composition since publication of the tables may not be included, not all constituents of possible interest are necessarily covered, and data availability is limited to published tables of food composition or data tapes. For these reasons, other food tables that provide information on these issues have come into common use for many purposes (132).

Some databases are in the public domain (e.g., USDA databases). Others are

proprietary and for sale commercially. Publications of the National Nutrient Database Conferences provide information on these newer systems. The advantages of the proprietary databases are that they often are produced in microcomputer-usable versions; are easy to use; provide additional values for special foods, brands of foods, and vitamin-mineral supplements, oral nutritional supplements and parenteral and enteral formulas (133); and include computer programs for manipulating and presenting the results of the analysis in a variety of ways. However, these databases differ in the criteria used to assess food quality, the composition data they accept, the number of items or nutrients included, timeliness of data updates, descriptions of the source of the data, timeliness of values, ease of use, and many other respects. Systems for reviewing databases are available (134).

Composition information on foods eaten in other countries is available from the International Network of Food and Data Systems (INFOODS), which has recently produced an international directory of food composition tables (126). Differences exist between values obtained from nutrient databases among industrialized countries and even within countries at different times (133). Some of these differences are real, and others are due to methodological and reporting conventions (136). Therefore, caution is indicated when information from various food tables is combined. Although the completeness of information on food composition leaves much to be desired in the United States and other highly industrialized countries, in developing countries, the information available on food composition is considerably more fragmentary and incomplete.

Missing Values. A major difficulty with food tables for diet assessment purposes is missing values, especially for certain nutrients, phytochemicals such as fiber or carotenoids, toxicants, environmental contaminants, and intentional food additives. New food products are being developed, and the number of food components of potential interest is immense. Few analyses are available for many components, and for others, food analytic methods are not yet developed. Thus, complete information on each component of each food consumed in this country is unlikely to ever be available.

When data are lacking, imputed values, or “best estimates,” of nutrients in similar foods can be used. Botanic and zoologic taxonomy and knowledge of food processing techniques may also be helpful in establishing the presence of some constituents and possibly produce rough quantitative estimates. However, when chemical analyses are lacking, values are only approximations, and additional assumptions and errors are introduced. Good estimates can minimize errors. Pennington (137) has developed tables of imputed values for many nutrients. Estimation of values for other food constituents is more difficult. Consensus on standard protocols for imputation will facilitate comparisons between studies. Finally, the quality and quantity of the available food-composition data may be so inadequate for many of the less-studied food constituents (e.g., biotin, vitamin K, or the flavonoids) that accurate calculations of their intakes are impossible, and only rough estimates can be obtained (137).

Bioavailability. Intakes calculated from food composition databases do not necessarily represent those actually biologically available and absorbed from the gut. Most databases include adjustments to account for usual net absorption and utilization for

energy-providing nutrients, so that biologically available nutrients can be calculated directly. However, if disease or other causes of malabsorption are present, these assumptions may need adjustment. For minerals and vitamins, estimates of net bioavailability are not incorporated in food tables because so many constituents of foods may promote or inhibit absorption; separate calculations may be necessary.

Errors in Nutrient Databases Used in Food-Frequency Questionnaires

The computerized nutrient databases used to analyze semiquantitative food-frequency questionnaires usually consist of average values for different categories or groups of foods derived from the intake of a U.S. reference population. Alternatively, foods contributing to variation among individuals are used to generate the lists. These food tables are vulnerable to errors due to differences (compared with the reference group) in frequency of consumption (which is especially important), changes in the nutrient composition of individual foods, and differences in portion size of various foods within the food groups or categories. Also, the use of closed-ended rather than open-ended questions on some food-frequency questionnaires introduces further errors (138). Because they are based on American foods and consumption patterns, these food tables are obviously inappropriate for use without adaptation in other countries. Because the food supply and consumption patterns are constantly changing, even within categories, errors arise if these questionnaires are not updated periodically. Before they are used in large-scale studies, validation is necessary. Finally, defaults and imputations may be incorrect or invalid.

Computational Errors Using Nutrient Analysis Systems

Computerized nutrient analysis systems greatly reduce inadvertent computational errors and minimize the otherwise onerous task of calculation (139). However, computerized dietary analysis systems are only computational aids, not panaceas. They cannot cope with or compensate for careless data collection, coding, or interpretation of results. Moreover, programming mistakes or assumptions in some programs introduce errors. Errors in some nutrient analysis systems are so large that they obscure the effects of treatments or changes in intakes. Differences in calculated intakes exist between systems, even when the same records are analyzed (140). Comparison across studies is facilitated by standardization. Not only the disparate nutrient databases but also assumptions in calculations give rise to these errors. Assumptions include differences in portion sizes and weight/portion equivalence, factors for conversion from raw to prepared foods, listings of ingredients in recipe foods, values provided for nutrient-fortified foods, estimates of bioavailability of nutrients, and the defaults or imputed values used. A systematic method for reviewing nutrient database capabilities has been devised (141, 142). It should be used to test programs before a dietary analysis system is chosen. It is important to know the strengths and limitations of the programs to avoid misinterpreting their outputs (143).

RESEARCH NEEDS

The growth of interest in assessing upper safe levels of nutrient intakes has implications for dietary assessment. Vitamin, mineral, botanic, herbal, and oral nutrient supplements

provide highly concentrated sources of nutrients and other substances, and thus use of such substances must be an integral part of dietary assessment. Better methods for obtaining such information and tables of supplement composition are sorely needed.

Assessing intakes of nonnutrient substances in food such as flavonoids that have biologic activity that may be relevant to health is another challenge (144). Tables of food composition of these substances are just becoming available; the major limitation is the lack of resources to perform analyses (145). Adequate food intake data are also needed for more accurate estimations of potential exposures to environmental contaminants such as radionuclides or pesticide residues and intentional or unintentional food additives (146).

Most computerized nutrient analysis programs provide outputs expressed as total intakes of nutrients per meal or per day; outputs expressed by groups of foods, dietary patterns, or food grouping systems are needed as well.

Finally, brief nutritional screening and assessment methods are needed for specific clinical and educational purposes.

Chapter References

Protein-energy malnutrition (PEM) results when the body's needs for protein, energy fuels, or both cannot be satisfied by the diet. It includes a wide spectrum of clinical manifestations conditioned by the relative intensity of protein or energy deficit, the severity and duration of the deficiencies, the age of the host, the cause of the deficiency, and the association with other nutritional or infectious diseases. Its severity ranges from weight loss or growth retardation to distinct clinical syndromes, frequently associated with deficiencies of minerals and vitamins.

Dietary energy and protein deficiencies usually occur together, but sometimes one predominates and, if severe enough, may lead to the clinical syndrome of *kwashiorkor* (predominantly protein deficiency) or *marasmus* (mainly energy deficiency). *Marasmic kwashiorkor* is a combination of chronic energy deficiency and chronic or acute protein deficit. It is difficult to recognize which deficit predominates in milder forms of the disease.

The origin of PEM can be *primary*, when it is the result of inadequate food intake, or *secondary*, when it is the result of other diseases that lead to low food ingestion, inadequate nutrient absorption or use, increased nutritional requirements, and/or increased nutrient losses. Its onset can be relatively fast, as in starvation due to abrupt withholding of food, or gradual. This chapter discusses primary PEM of a relatively gradual onset, in which the metabolic alterations and clinical characteristics of protein and/or energy deficits predominate. PEM secondary to other diseases and the metabolic and clinical manifestations of starvation and of specific vitamin and mineral deficiencies are described in other chapters.

HISTORICAL BACKGROUND

It has long been recognized that inadequate food intake produces weight loss and growth retardation and, when severe and prolonged, leads to body wasting and emaciation. It took much longer to understand the nature of the edematous forms of PEM, probably because they could be found among children who were not starving and in families in good socioeconomic position. Descriptions of the disease in the early part of this century paid special attention to dermatologic signs and led to the belief that the disease was caused by tropical parasites or a vitamin deficiency ([1](#), [2](#), [3](#), [4](#), [5](#), [6](#) and [7](#)). This was questioned by various authors in the late 1920s and 1930s. The real nature of the disease was studied more carefully after Cicely Williams' descriptions in the mid-1930s of “kwashiorkor” ([8](#), [9](#)). This term, used by the Ga tribe in the Gold Coast (now Ghana) for “the sickness the older child gets when the next baby is born,” already suggested that the disease could be associated with an inadequate diet during the weaning period.

Other pediatricians who worked in tropical countries in the 1930s showed that the edematous disease could be cured by feeding milk or other high-protein foods ([10](#), [11](#)). In the 1940s, researchers showed that most patients had low concentrations of serum proteins, which could also be related to the quality of dietary proteins ([12](#)).

The nature and importance of this disease gained worldwide recognition in the 1950s, partly owing to publications such as those of Brock and Autret ([13](#)), Autret and Behar ([10](#)), and Trowell et al. ([11](#)). By then, more than 40 names had been given to this clinical syndrome ([11](#)). Some of them, such as “Síndrome policarencial de la infancia” (infantile pluricarencial syndrome), indicated that young children were mainly affected and that a deficit of various nutrients was involved. Others, such as “Mehlnahrschade” (damage by cereal flours), “starch edema,” and “sugar babies,” indicated that it was caused by the intake of foods with high carbohydrate and low protein content. Today, the more comprehensive term *protein-energy (or protein-calorie) malnutrition* is universally accepted ([14](#)), and its severe forms are most often called “marasmus,” “kwashiorkor,” and “marasmic kwashiorkor.” The term *malnutrition* is usually used in lay language for PEM.

Studies done in the last 30 years showed that marasmus and kwashiorkor have distinct metabolic features, that some manifestations, such as anemia and reduced physical activity, are partly due to adaptive mechanisms, that the immune response of severely

malnourished patients is impaired, and that physical and emotional stimulation is important in treating malnourished children. These findings are the basis of current therapeutic measures.

ETIOLOGY AND EPIDEMIOLOGY

Protein-energy malnutrition is the most important nutritional disease in developing countries because of its high prevalence and its relationship with child mortality rates, impaired physical growth, and inadequate social and economic development. An epidemiologic analysis from 53 developing countries indicated that 56% of deaths in children 6 to 59 months old were due to malnutrition's potentiating effects in infectious diseases and that mild and moderate malnutrition was involved in 83% of those deaths (15). Associated deleterious effects on mental growth and maturation have been demonstrated in experimental animals and seem to occur in humans, but environmental support and stimulation can improve the cognitive state of malnourished children (16). PEM occurs more frequently when infections impose additional demands, induce greater losses of nutrients, or produce metabolic alterations.

Magnitude of the Problem

There are about 800 million undernourished people in the world. Most live in developing countries, about 30% each in southern and eastern Asia, 25% in sub-Saharan Africa, and 8% in Latin America and the Caribbean. Consequently, 36% (193 million) of the children under the age of 5 in the developing world are underweight, 43% (230 million) are stunted, and 9% (50 million) are wasted, on the basis of a deficit of more than 2 standard deviations below the WHO/NCHS reference values (17, 18) for weight-for-age, height-for-age, and weight-for-height, respectively. This prevalence ranges from 12% underweight, 22% stunted, and 3% wasted in Latin America and the Middle East to 62% underweight, 61% stunted, and 17% wasted in southern Asia.

A long-term analysis shows a decade-by-decade gradual improvement in the prevalence of child malnutrition, if countries are not disturbed by natural and manmade disasters such as droughts, desertification, wars, and economic crisis. However, the total number of malnourished children has not decreased because of the rise in population in the countries where malnutrition is highly prevalent. In sub-Saharan Africa, current population growth rates of about 3.0% the highest in the world suggest that the number of malnourished children will continue growing unless the prevalence of PEM and/or the population growth rates are dramatically reduced (19). In industrialized countries, primary PEM is seen mainly among young children of the lower socioeconomic groups, the elderly who live alone, and adults addicted to alcohol and drugs.

Causes

Social, economic, biologic, and environmental factors may be underlying causes for the insufficient food intake or ingestion of foods with proteins of poor nutritional quality that

lead to PEM.

Social and Economic Factors

Poverty that results in low food availability, overcrowded and unsanitary living conditions, and improper child care is a frequent cause of PEM. *Ignorance*, by itself or associated with poverty, leads to poor infant- and child-rearing practices, misconceptions about the use of certain foods, inadequate feeding during illnesses, and improper food distribution within the family. A decline in the practice and duration of breast-feeding, combined with *inadequate weaning practices* when breast milk is withdrawn or can no longer provide sufficient dietary energy and protein to the infant, is associated with growing rates of infantile PEM.

Social problems such as child abuse, maternal deprivation, abandonment of the elderly, alcoholism, and drug addiction can result in PEM. *Cultural and social practices* that impose food taboos, some food and diet fads particularly popular among adolescents and women, and the migration from traditional rural settings to urban slums can also contribute to, or precipitate, the appearance of PEM.

Biologic Factors

Maternal malnutrition prior to and/or during pregnancy is more likely to produce an underweight newborn baby ([20](#)). Intrauterine malnutrition can be compounded after birth by insufficient food to satisfy the infant's needs for catch-up growth, resulting in PEM.

Infectious diseases are major contributing and precipitating factors in PEM. Diarrheal disease, measles, acquired immunodeficiency syndrome (AIDS), tuberculosis, and other infections frequently result in negative protein and energy balance because of anorexia (reduced food intake), vomiting, decreased absorption (increased nutrient losses), and catabolic processes (increased requirements and metabolic losses). Intestinal parasites have little or no effect unless the infection is extensive and causes anemia or diarrhea ([21](#)).

Diets with low concentrations of proteins and energy, as occur with overdiluted milk formulas or bulky vegetable foods that have low nutrient densities, can lead to PEM in young children whose gastric capacity does not allow ingestion of large amounts of food and in elderly persons with anorexia or difficulty in eating without assistance. Diets poor in protein and rich in carbohydrates are particularly likely to produce kwashiorkor.

Environmental Factors

Overcrowded and/or unsanitary living conditions lead to frequent infections. This is an important cause of PEM, especially among weanlings who develop severe or frequent episodes of diarrhea. *Agricultural patterns, droughts, floods, wars, and forced migrations* lead to cyclic, sudden, or prolonged food scarcities and can cause PEM in whole populations. Postharvest losses of food because of bad storage conditions and inadequate food distribution systems contribute to PEM, even after periods of

agricultural plenty.

Age of the Host

PEM can affect all age groups but it is more frequent among infants and young children whose growth increases nutritional requirements, who cannot obtain food by their own means, and who, when living under poor hygienic conditions, frequently become ill with diarrhea and other infections. Infants who are weaned prematurely from the breast or who are breast-fed for a prolonged time without adequate complementary feeding become malnourished for lack of adequate energy and protein intake.

The long-term intake of insufficient food can result in marasmus, the most common form of severe PEM before 1 year of age. Kwashiorkor, the edematous form of the disease, is more frequent after 18 months of age and typically occurs in children with diets consisting of starchy gruels, diluted cereal-based beverages, and vegetable foods rich in carbohydrates but almost devoid of proteins of good nutritional quality (i.e., lacking one or more essential amino acid). Most often, the severe protein deficit is associated with chronic dietary energy deficit and results in a combined form of marasmic kwashiorkor. The appearance of edema is frequently preceded or accompanied by acute diarrhea or other infectious disease.

Older children usually have milder forms of PEM because they can cope better with social and food availability constraints. Infections and other precipitating factors become less severe, and early survival may imply a natural selection of the more fit. Pregnant and lactating women can also have PEM because of their increased nutritional requirements; however, their dietary deficiencies affect mainly the growth, nutritional status, and survival rates of their fetuses, newborn babies, and infants. The elderly who are unable to care properly for themselves tend to suffer from PEM. Gastrointestinal alterations can be an important contributing factor. Adolescents, adult men, and nonpregnant, nonlactating women usually have the lowest prevalence and the mildest forms of the disease because of greater opportunities to obtain food and cultural practices that protect the productive members of the family.

Severe PEM occurs as a primary disorder in conditions of extreme privation and famine or of social or chemical dependency without adequate support, as may be the case with mental patients, prisoners, alcoholics, and drug addicts. It is more frequently secondary to other illnesses, such as chronic infections, cancer, AIDS, malabsorption, and liver and endocrine diseases. In such cases, both the malnutrition and the underlying cause must be treated.

PATHOPHYSIOLOGY AND ADAPTIVE RESPONSES

PEM develops gradually over weeks or months. This allows a series of metabolic and behavioral adjustments that result in decreased nutrient demands and a nutritional equilibrium compatible with a lower level of cellular nutrient availability. If the supply of nutrients becomes persistently lower, the patient can no longer adapt and may even die. Metabolic disruptions can be due to severe nutrient deficit, complications (such as

infections), or inadequate treatment (such as abrupt administration of large amounts of dietary energy or protein). Patients whose PEM develops slowly as is usually the case in marasmus are better adapted to their current nutritional status and maintain a less fragile metabolic equilibrium than those with more acute PEM, as in kwashiorkor of rapid onset.

Energy Mobilization and Expenditure

A decrease in energy intake is quickly followed by a decrease in energy expenditure, accounting for shorter periods of play and physical activity in children (22) and for longer rest periods and less physical work in adults (23). When the decrease in energy expenditure cannot compensate for the insufficient intake, body fat is mobilized, with a decrease in adiposity and weight (24). Lean body mass diminishes at a slower rate, mainly as a consequence of muscle protein catabolism with increased efflux of amino acids, primarily alanine, that contribute to the energy sources. As the cumulative energy deficit becomes more severe, subcutaneous fat is markedly reduced, and protein catabolism leads to muscular wasting. Visceral protein is preserved longer, especially in the marasmic patients.

In marasmus, these alterations in body composition lead initially to increased basal oxygen consumption (i.e., basal metabolic rate) per unit of body weight, and it decreases in more severe stages (25). In kwashiorkor, the severe dietary protein deficit leads to an earlier visceral depletion of amino acids that affects visceral cell function and reduces oxygen consumption; therefore, basal energy expenditure decreases per unit of lean or total body mass.

Blood glucose concentration remains normal, mainly at the expense of gluconeogenic amino acids and glycerol from fats, and it falls in severe PEM or when complicated by serious infections or fasting.

Protein Breakdown and Synthesis

The poor availability of dietary proteins reduces protein synthesis (26). Adaptations lead to the sparing of body protein and preservation of essential protein-dependent functions. The gradual and inevitable loss of body protein as a result of long-term dietary protein deficit is primarily from skeletal muscle. Table 59.1 illustrates some enzymatic changes that favor muscle protein breakdown and liver protein synthesis, as well as energy mobilization from fat depots. Some visceral protein is lost in the early development of PEM but then becomes stable until the nonessential tissue proteins are depleted; the loss of visceral protein then increases, and death may be imminent unless nutritional therapy is successfully instituted.

Cells	Enzyme Activity ^a
Muscle and leukocytes	↓Aldolase ↓Amino acid dehydrogenases ↓Pyruvic kinase
Liver	↑Aminotransferases ↓Phenylalanine hydroxylase ↓Urea cycle enzymes ↑Amino acid activating enzymes

^a↓, ↑, decrease or increase in activity.

Table 59.1 Selected Enzyme Activity Changes in Protein-Energy Malnutrition

Under normal conditions about 75% of the free amino acids that enter the body pool from dietary and tissue proteins are recycled or reused for protein synthesis, and 25% are broken down for other metabolic purposes. When protein intake is reduced, there is not so much a decrease in total nitrogen or amino acid turnover but an adaptive increase to 90 to 95% in the proportion recycled for synthesis and a proportional decrease in amino acid catabolism (26, 27), which markedly reduces urea synthesis and urinary nitrogen excretion.

The half-lives of several proteins increase. The rate of albumin synthesis decreases initially, but after a lag of a few days, the rate of breakdown also falls and its half-life increases. In addition, a shift of albumin from the extravascular to the intravascular pool helps maintain adequate levels of circulating albumin in the face of reduced synthesis. When protein depletion becomes too severe, the adaptive mechanisms fail, and the concentration of serum proteins, and especially albumin, decreases. The ensuing reduction in intravascular oncotic pressure and outflow of water into the extravascular space contributes to development of the edema of kwashiorkor.

Endocrine Changes

Hormones are important in the adaptive metabolic processes. However, circulating levels of hormones do not always explain endocrine changes in PEM, because cellular responses to hormonal stimulation may also be altered. [Table 59.2](#) summarizes the main changes in hormonal activity in patients with severe energy or protein deficiencies. They contribute to the maintenance of energy homeostasis through increased glycolysis and lipolysis; increased amino acid mobilization; preservation of visceral proteins through increased breakdown of muscle proteins; decreased storage of glycogen, fats, and proteins; and decreased energy metabolism. These effects can be summarized as follows ([Fig. 59.1](#)):

Nutrient	Situation in PEM	Hormonal Activity in		Effects of Abnormality in PEM
		Energy Deficit	Protein Deficit	
Insulin	Low food intake (glucose) Glucagon Low protein intake (amino acids) Reduced carbohydrate synthesis	Decreased	Decreased	↓Muscle protein synthesis ↓Lipogenesis ↓Growth
Growth hormone (GH)	Low protein intake (amino acids) Reduced carbohydrate synthesis	Variable	Increased	↑Protein synthesis ↓Lipogenesis ↑Lipolysis
Somatostatin (inhibits growth factors)	Low protein intake Low circulating insulin High circulating glucagon	Variable	Decreased	↑Glucose uptake by tissues ↓Insulin and/or high protein synthesis ↓Lipogenesis ↓Lipolysis
Cortisol	Stress of food deficiency, infections (glucagon)	Normal but can increase	Normal but can increase	↑Protein synthesis ↑Lipolysis ↑Production of growth factors ↑Lipolysis
Glucocorticoids	Stress of hunger Fever (glucagon)	Increased	Normal or increased	↑Protein synthesis ↑Muscle protein catabolism ↑Protein synthesis ↑Lipolysis ↑Lipogenesis ↓Glucocorticoid-dependent actions of GH
Non-steroidals	↓Blood volume ↓Glucagon ↓Insulin	Normal	Increased	↑Protein retention and ↑Protein retention contributes to appearance of edema ↓Glucose oxidation ↓Blood energy expenditure ↑Reserve T ₃
Thyroid hormones	↓T ₃ (decreased) ↑T ₄ (increased) ↓Reverse T ₃	T ₃ normal or decreased, T ₄ decreased	T ₃ usually decreased, T ₄ decreased	↓Energy expenditure ↓Blood energy expenditure ↑Reserve T ₃ ↓Energy expenditure
Calcitonin	↓Protein intake? Low energy intake?	Decreased	Decreased	↓Energy expenditure

Table 59.2 Summary of Selected Hormonal Changes Usually Seen in Severe PEM and Their Main Metabolic Effects

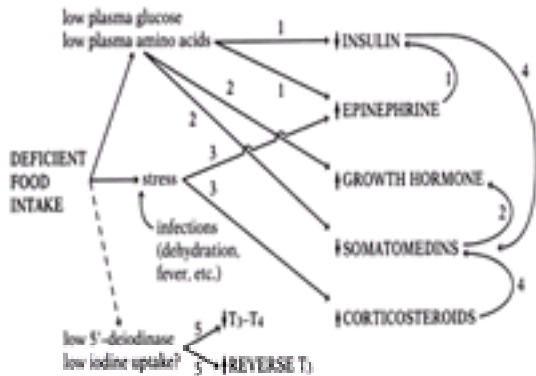

Figure 59.1. Endocrine adaptive functions in severe protein-energy malnutrition related to energy and protein metabolism. See text for an explanation of the numbered events.

1. Decreased food intake tends to reduce plasma concentrations of glucose and free amino acids, which in turn reduce insulin secretion and increase glucagon and epinephrine release; the latter further reduces insulin secretion.
2. The low plasma amino acid levels, seen mainly in kwashiorkor, also stimulate secretion of human growth hormone and reduce somatomedin activity; this produces a further increase in growth hormone levels because of the absence of feedback inhibition; the increased levels of growth hormone and epinephrine influence the reduction in urea synthesis, thereby favoring amino acid recycling.
3. The stress induced by low food intake and further amplified by fever, dehydration, and other manifestations of the infections that frequently accompany PEM also stimulates epinephrine release and corticosteroid secretion; this occurs more in marasmus than in kwashiorkor, probably because of the greater energy deficit of

marasmus. Resistance to the peripheral action of insulin increases, probably from the increased plasma free fatty acid concentration resulting from the lipolytic activity of growth hormone, glucocorticoids, and epinephrine.

4. The low levels of circulating insulin and high levels of circulating cortisol may further reduce secretion of somatomedins.
5. Decreased 5 α -monodeiodinase activity reduces triiodothyronine production with a concomitant increase in the inactive reverse T₃; thyroxine levels are also reduced, possibly by a decrease in iodine uptake by the thyroid. The reduction in active thyroid hormone levels decreases thermogenesis and oxygen consumption, leading to energy conservation.

Secretion of hormones involved in nonvital growth-related functions such as gonadotropins decreases; the functional capacities of the hypothalamic-pituitary axis and adrenal medulla are preserved, thus allowing endocrine and metabolic responses to stress conditions. Some investigators have postulated that the evolution of PEM into either kwashiorkor or marasmus may be partly related to differences in adrenocortical response, whereby the better response will preserve visceral proteins more efficiently and lead to the better-adapted syndrome of marasmus.[\(29\)](#)

Hematology and Oxygen Transport

The reduction in hemoglobin concentration and red cell mass that almost always accompanies severe PEM is, at least in part, an adaptive phenomenon related to tissue oxygen needs [\(30\)](#). The reduced lean body mass and lower physical activity of malnourished patients also lower oxygen demands. The simultaneous decrease in dietary amino acids results in reduced hematopoietic activity, which spares amino acids for synthesis of other more necessary body proteins. As long as the tissues receive sufficient oxygen, this should be considered an adaptive response, not a “functional” anemia (i.e., with tissue hypoxia). When tissue synthesis, lean body mass, and physical activity begin improving with dietary treatment, oxygen demands rise, necessitating accelerated hematopoiesis. If sufficient iron, folic acid, and vitamin B₁₂ are not available, functional anemia with tissue hypoxia will develop.

[Figure 59.2](#) shows that administration of hematinics to a severely malnourished patient does not induce a hematopoietic response until dietary treatment produces an increase in lean body mass. [Figure 59.3](#) shows that the reticulocyte response is related to protein intake when erythropoietic substances are not limiting [\(28\)](#).

Figure 59.2. Hematologic response of a child with severe protein-energy malnutrition. Treatment with iron, folic acid, and vitamin B₁₂ began on day 2; dietary energy and proteins were increased gradually to 150 kcal and 4 g protein/kg/day on day 9. No reticulocyte or hemoglobin response occurred until lean body mass, assessed by the creatinine-height index, began increasing.

Figure 59.3. Reticulocyte response of children treated for severe protein-energy malnutrition with different amounts of dietary energy and hematinics. (From Viteri FE. Primary protein-energy malnutrition: clinical, biochemical, and metabolic changes. In: Suskind RM, ed. Textbook of pediatric nutrition. New York: Raven Press, 1981.)

The severely malnourished patient may have relatively high body iron stores (31) and retains the ability to produce erythropoietin and reticulocytes in response to acute hypoxia (32, 33). Nevertheless, these patients tend to develop functional, severe anemia if there is a superimposed dietary deficiency of iron or folic acid, or a chronic blood loss, as in hookworm infection.

Other Physiologic and Metabolic Changes

Not all pathophysiologic changes lead to advantageous adjustments. Certain functions are affected, and some nutrient reserves decrease, making the malnourished individuals more susceptible to injuries that a well-nourished individual can withstand with little repercussion.

Cardiovascular and Renal Functions

Cardiac output, heart rate, and blood pressure decrease, and central circulation takes precedence over peripheral circulation ([34](#), [35](#)). Cardiovascular reflexes are altered, leading to postural hypotension and diminished venous return. In severe PEM, peripheral circulatory failure comparable to hypovolemic shock may occur. Hemodynamic compensation occurs primarily from tachycardia rather than from increased stroke volume. Renal plasma flow and glomerular filtration rates may be reduced because of the decreased cardiac output, but water clearance and the ability to concentrate and acidify urine appear unimpaired ([36](#), [37](#) and [38](#)).

Immune System

The major defects seen in severe PEM seem to involve T lymphocytes and the complement system ([39](#)). Lymphocytes from the thymus are depleted markedly and the gland atrophies. In addition, cells from the T-lymphocyte regions of the spleen and lymph nodes are depleted, probably owing to a decrease in thymic factors ([40](#), [41](#)). Alteration in monokine metabolism, particularly decreased interleukin-1 (IL-1) activity, may contribute to the low proliferation of T cells in severe malnutrition ([42](#)). Production of several complement components, the functional activity both the classic and alternative pathways of the complement system, and the opsonic activity of serum are depressed in severe PEM ([43](#)). These deficiencies may explain the high susceptibility of severely malnourished patients to gram-negative bacterial sepsis. Phagocytosis, chemotaxis, and intracellular killing are also impaired, partly because of the defects in opsonic and complement functional activities. The B-lymphocyte areas of spleen and lymph nodes and the circulating levels of B cells and immunoglobulin are relatively normal, but there may be defects in antibody production (e.g., secretory IgA) ([39](#)).

The overall consequences of all these alterations in severe PEM are a greater predisposition to infections and to severe complications of otherwise less important infectious diseases. The defects in immune functions disappear with nutritional rehabilitation, except perhaps those due to intrauterine malnutrition ([40](#)).

Monokines

Monokines or cytokines are peptide/glycoprotein mediators of the body's response to injury (see [Chapter 44](#), [Chapter 45](#) and [Chapter 96](#)). They are synthesized primarily by activated monocytic and phagocytic cells lining the liver and spleen. These peptides activate neighboring tissue in a paracrine fashion and also enter the circulation to exert

more-distant effects. The most extensively characterized monokines are IL-1 and cachectin, or tumor necrosis factor (TNF).

Macrophages from children with severe edematous PEM have decreased IL-1 activity (42). In addition to the immunologic alterations mentioned above, this might contribute to the poor febrile response and low leukocyte count in infections (44). On the other hand, serum levels of TNF seem to be increased in severe malnutrition (45). This could be associated with the anorexia, muscle wasting, and lipid abnormalities of PEM.

Electrolytes

Total body potassium decreases in PEM because of the reduction in muscle proteins and loss of intracellular potassium. The low insulin action and diminished intracellular energy substrates reduce the availability of adenosine triphosphate (ATP) and phosphocreatine. This process probably alters the cellular exchange of sodium and potassium, leading to potassium loss and increased intracellular sodium levels (46). Water accompanies the sodium influx, and although total body intracellular water is decreased because of the loss in lean body mass, there may be intracellular overhydration. These alterations in cell electrolytes and energy sources may explain, at least in part, the increased fatigability and reduced strength of skeletal muscle (47).

Gastrointestinal Functions

Impaired intestinal absorption of lipids and disaccharides and a decreased rate of glucose absorption occur in severe protein deficiency. The greater the protein deficit, the greater the functional impairment. A decrease in gastric, pancreatic, and bile production is also observed, with normal to low enzyme and conjugated bile acid concentrations (48, 49 and 50). These alterations further impair the absorptive functions. Nevertheless, ingestion of nutrients in high therapeutic amounts usually allows sufficient uptake for nutritional recovery (51). Malnourished persons, however, are prone to have diarrhea because of these alterations and possibly also because of irregular intestinal motility and gastrointestinal bacterial overgrowth. Diarrhea aggravates the malabsorption and can further impair nutritional status. Malabsorption disappears with nutritional recovery unless there is an underlying food or nutrient intolerance unrelated to primary PEM.

Central and Peripheral Nervous System

Individuals who suffer severe PEM at an early age may have decreased brain growth, nerve myelination, neurotransmitter production, and velocity of nervous conduction. The long-term functional implications of these alterations have not been clearly demonstrated, and they cannot be correlated with later behavior and level of intelligence (52). In the human, it is impossible to separate nutrition from other factors that can affect gross and fine motor skills, intelligence, and behavior. Factors that can determine developmental outcome include the severity, timing, and duration of nutritional deprivation, the quality of nutritional rehabilitation and psychosocial support, the degree

of family stimulation, and a host of positive and negative environmental factors.

FACTORS LEADING TO KWASHIORKOR

The concept that marasmus or kwashiorkor is the end result of either severe energy or protein deficiency is too simplistic. Nevertheless, the classic theory of a dietary cause of kwashiorkor and marasmus, which states that a diet deficient in protein and with a low protein:energy ratio is an important (perhaps even principal) factor in the production of kwashiorkor, still is valid. The deficiency of vitamins and minerals associated with food sources of protein, and the variability in nutrient requirements between children, may explain why some children develop the edematous and others the nonedematous form of the disease. It also explains, at least in part, some epidemiologic features of PEM, such as the predominance of marasmus in infants under 1 year of age and the predominance of either marasmus, kwashiorkor, or marasmic kwashiorkor in different parts of the world and in urban or rural areas.

Other factors such as overloading a severely malnourished person with carbohydrates, or metabolic changes induced by infections, may cause or contribute to the appearance of kwashiorkor with its characteristic edema, hypoalbuminemia, and enlarged fatty liver. Some investigators have postulated that the evolution of PEM into either kwashiorkor or marasmus may be partly related to differences in adrenocortical response, so that a greater response preserves visceral proteins more efficiently and leads to the better-adapted syndrome of marasmus (29, 53). Others have proposed that kwashiorkor results from aflatoxin poisoning (54, 55), but there is no clear difference in the amounts of aflatoxin or its metabolites in the diet, urine, or tissues of children with kwashiorkor and marasmus.

Another theory is related to the production of toxic free radicals and their safe disposal (56, 57 and 58). Among the factors that would increase free radicals are infections, toxins, sunlight, trauma, and catalysts such as iron. Formation of free radicals is decreased by the antioxidant function of vitamins A (or b-carotene), C, and E, by ceruloplasmin and transferrin that bind free iron and favor its oxidation, and by zinc-metallothionein, which acts as a free radical sink. Free radicals and the peroxides they generate are removed via reactions catalyzed by enzymes in which glutathione and trace minerals are important, such as Cu-Zn and Mn superoxide dismutase, and Se-containing glutathione peroxidase. The toxic effects of free radicals would be responsible for cell damage leading to the alterations seen in kwashiorkor, such as edema, fatty liver, and skin lesions. This theory has not been firmly established or subjected to the test of animal experiments; nevertheless, it has drawn attention to factors and processes in the pathogenesis of severe PEM that have previously been neglected, and it may have important implications for treatment (59).

When there is a severe lack of food, endocrine adjustments mobilize fatty acids from adipose tissue and amino acids from muscle tissue; plasma protein concentration remains normal, and hepatic gluconeogenesis is enhanced (60). An increase in carbohydrate intake when protein intake is very low can produce a breakdown of those adjustments, as follows:

1. Carbohydrate intake induces insulin release and reduced production of epinephrine and cortisol (61, 62).
2. Lipolysis decreases, which decreases the inhibitory effects of free fatty acids on the peripheral action of insulin, and insulin action is enhanced (63).
3. Muscle protein breakdown is reduced and the body pool of free amino acids decreases; the decreased supply of muscle amino acids to the other organs results in less visceral protein synthesis (64, 65 and 66).
4. Decreased synthesis of plasma proteins in the liver, particularly albumin, reduces intravascular oncotic pressure. Plasma water decreases and accumulates in extravascular tissues, tissue pressure rises, and cardiac output diminishes. This contributes to the appearance or increase of edema, as discussed below.
5. Increased hepatic fatty acid synthesis from the excess carbohydrate, impaired lipolysis, and reduced production of apo-b-lipoproteins for lipid transport lead to fatty infiltration of the liver and hepatomegaly.

Infections in undernourished children also can precipitate the onset of kwashiorkor. How this occurs has not been satisfactorily explained, but the following mechanisms may be involved:

1. Infections might divert the meager amino acid pool to production of globulins and acute-phase reactant proteins (APs) instead of albumin and transport proteins.
2. The increase in APs that are proteinase inhibitors, such as α_1 -antitrypsin and α_1 -antichymotrypsin, may impair muscle protein breakdown (67).
3. Impaired production and use of ketone bodies for energy during infections might lead to the use of more amino acids for gluconeogenesis (68).
4. Protein catabolism and nitrogen losses are enhanced by many viral and febrile infections, probably through increased epinephrine and cortisol actions (69, 70). Regardless of the mechanisms involved, protein losses during severe infections can amount to as much as 2% of muscle protein per day (71).
5. Leukocytes stimulated by infectious organisms produce large quantities of superoxide and hydrogen peroxide (72), which are released into the surrounding medium and contribute to the production of kwashiorkor, according to the free-radical theory (56, 57).

The pathogenesis of edema in severe PEM has aroused much discussion because of its key role in the diagnosis of kwashiorkor and because it may give clues about the patient's dietary background and other precipitating factors of the disease. The edema of kwashiorkor has been classically linked to hypoalbuminemia through a reduction in colloid osmotic pressure of the plasma, which leads to outflow of fluid from the capillaries into the interstitial space. However, serum albumin levels between edematous and nonedematous PEM in children and adults overlap. Experimental studies on dogs fed a low-protein diet showed that many animals with plasma albumin levels below 20 g/L did not have edema, but almost all edematous dogs had albumin levels below that value (73). Furthermore, the edema of kwashiorkor is reduced by treatment with protein-free or low-protein diets that contain potassium and other minerals and moderate amounts of carbohydrates. All this suggests that hypoalbuminemia may be a necessary but not sufficient cause for edema, and that

some other factors may be needed, at least in some cases (59). These factors include potassium deficiency, which promotes water and sodium retention (74), excessive administration of water and sodium, and extravasation of fluid because of increased capillary permeability in infection.

A theory for the production of edema in severe PEM involved a reduction in renal blood flow (RBF) and glomerular filtration rate (GFR) because of decreased plasma volume and decreased cardiac output as consequence of hypoalbuminemia. Decreased RBF and GFR would lead to sodium retention and production of renin and aldosterone, which in turn would increase the tubular reabsorption of sodium and water, leading to edema (75). However, there is conflicting evidence about the changes in plasma volume in kwashiorkor, and aldosterone activity may increase in children with marasmus as well as in children with edema (76, 77). Other theories include an increase in ferritin that stimulates production of antidiuretic hormone by the posterior pituitary (78, 79), energy deficiency that does not allow adequate function of the sodium pump and restoration of intracellular potassium (80), and, more recently, leakiness of cell membranes caused by the damaging effects of free radicals (56, 57 and 58). None of these theories have been fully demonstrated, and some have conflicting evidence. Possibly the pathogenesis of edema in PEM is not a single entity and it differs, depending on the multiple nutritional deficiencies, patient age, and other concomitant conditions. However, except for iatrogenic water overload, hypoproteinemia especially hypoalbuminemia is an essential component.

DISRUPTION OF ADAPTATION

When the supply for tissue and cell energy can no longer be maintained by patients with severe energy deficiency, a serious decompensation occurs, causing hypoglycemia, hypothermia, impaired circulatory and renal functions, acidosis, coma, and death. These events can occur within a few hours. Metabolic decompensation because of severe protein deficiency, in addition to the changes discussed in the onset of kwashiorkor, may include hemorrhagic diathesis and jaundice because the liver fails to synthesize several clotting factors and transport proteins; various degrees of renal failure with acidosis and water and sodium retention; decreased cardiac work, pulmonary congestion, and increased susceptibility to pulmonary infections; coma; and death.

A high-carbohydrate, low-protein diet is not the only iatrogenic cause of serious metabolic disruption in patients who have, or are prone to develop, edematous PEM. Abrupt administration of too much protein to patients with edematous PEM can also have life-threatening consequences. When such patients have been eating minute amounts of protein or none at all and they are suddenly fed large amounts of protein or given large transfusions of plasma or blood, they may experience a rapid increase in intravascular protein concentration and entry of extracellular fluid into the vascular compartment leading to cardiovascular insufficiency and pulmonary edema. In fact, premature introduction of a high-energy or high-protein diet may be fatal to a severely malnourished patient (81, 82).

DIAGNOSIS

The clinical, biochemical, and physiologic characteristics of PEM vary according to the severity of disease, the patient's age, the presence of other nutritional deficits and infections, and the predominance of energy or protein deficiency.

Classification of PEM

The classification scheme shown in [Table 59.3](#) is useful for the diagnosis and treatment of PEM and the application and evaluation of public health measures. *Severity* is determined mainly by anthropometry, because other clinical findings and biochemical indexes usually do not show changes unless the disease is well advanced. More-accurate measurements, such as assessment of body composition, are not practical or feasible in most of the settings in which primary PEM occurs, and they are usually used for research rather than for clinical purposes. The so-called functional indicators are not well standardized, can be influenced by deficits of more than one single nutrient, or may be too complex to measure routinely (83).

Severity	Course	Main Deficit
Mild	Acute	Energy
Moderate	Chronic	Protein
Severe	Both	Both

Table 59.3 Classification of PEM According to Severity of Disease, Its Course or Duration, and Predominant Nutrient Deficiency

Classification of the *course* or *duration* of the disease as acute, chronic, or acute with a chronic background is also done by anthropometry to assess current nutritional status and degree of growth retardation in children. Dietary history is useful, especially in adults, as are dietary surveys in population groups. The relative contributions of dietary *protein and energy deficits* in the mild and moderate forms of PEM are assessed mainly by the individual's dietary history or the population's dietary habits and food availability. Clinical characteristics and biochemical data confirm the diagnosis in severe PEM.

Anthropometric Measurements

The choice of anthropometric measurements depends on their simplicity, accuracy, and

sensitivity; on the availability of measuring instruments; and on the existence of reference standards for comparison.

To allow international comparisons, it is sensible to use the same standard of reference for various populations. International or universal standards based on reliable anthropometric data can be used because (a) most children have similar growth potentials, regardless of ethnic background (84, 85), (b) the relationship of various anthropometric measurements, especially weight and height, is relatively constant in normal, healthy individuals of all age groups, (c) the reference standards are merely for purposes of comparison and do not necessarily represent an ideal or target, and (d) the interpretation of the comparison (i.e., the values that separate “normal” from “deficient” and further divide the latter into “mild,” “moderate,” and “severe” forms) is a matter of judgment that comes into play when deciding whether the expected normal value for a given population should be 100%, 90%, or another proportion of the standard. Setting different cutoff points relative to a single standard is more practical than constructing local standards that, in a country with heterogeneous population groups, may pose the same problem as a “foreign” commonly used reference. At present, the World Health Organization recommends the data from the United States National Center for Health Statistics (NCHS) (86) as reference for weight and height (87).

The best anthropometric assessment of nutritional status and PEM is based on measurements of weight and height or length, and records of age, to calculate two indexes: *weight for height*, as an index of current nutritional status, and *height for age*, as an index of past nutritional history. Deficient height for age may represent a short period of growth failure at an early age or a longer period at a later age. Waterlow suggested the terms *wasting* for a deficit in weight for height and *stunting* for a deficit in height for age (88). Patients may then fall into four categories: (a) normal, (b) wasted but not stunted (suffering from acute PEM), (c) wasted and stunted (suffering from acute and chronic PEM), and (d) stunted but not wasted (past PEM with present adequate nutrition, or “nutritional dwarfs”). The intensity of wasting and stunting can be graded by calculating weight as a percentage of the reference median weight for height, and height as a percentage of the reference median height for age, as follows:

$$\% \text{ weight-for-height (or height-for-age)} = \frac{\text{observed weight (or height)}}{\text{reference weight for patient's height (or reference height for patient's age)}} \times 100$$

The use of centiles or standard deviations from the mean, instead of percentage deviation from the median, is statistically more adequate. However, percentage deviation is easier for the general public to understand and for field workers to calculate. The grading shown in Table 59.4 is suggested for most countries, although some might find it convenient to use different cutoff points for specific groups. For example, the normal height for age in populations that are genetically short could be less than 95% of the reference. Color-coded charts and graphs have been devised to simplify the measurements and their interpretation (89, 90).

	Normal	Mild	Moderate	Severe
Weight for height (deficit = wasting)	94-110%*†	84-89%†	75-79%†	<75, or with edema†
Height for age (deficit = stunting)	95-105%†	90-94%†	85-89%†	<85%†

*Operational average value in the normal WHO standard (95%).

†Upper/lower standard deviation for the WHO male, or "Caucasian" (91).

Table 59.4 Classification of Severity of Current (“Wasting”) and Past or Chronic (“Stunting”) PEM in Infants and Children, Based on Weight for Height and on Height for Age^{a,b}

The *body mass index* (BMI, or Quetelet's index), weight in kg/height in meters², is recommended for adolescents and adults. [Table 59.5](#) shows the criteria for classification of chronic energy deficiency in adults proposed by an international working party (91). We suggest using the same BMI criteria to classify current PEM in adults. There will be more body fat in women than in men at all three cutoff points, but this is an intrinsic biologic phenomenon. Therefore, the same cutoff points can be used for both sexes (91).

Body Mass Index (BMI)	PEM
≥18.5	Normal
17.0-18.4	Mild
16.0-16.9	Moderate
<16.0	Severe

Based on the classification proposed for chronic energy deficiency in James WPT, Fero-Luzzi A, Witelaw JC. *Eur J Clin Nutr* 1988;42:969-81.

Table 59.5 Classification of Intensity of Protein-Energy Malnutrition in Adult Men and Women

In adolescents, interpretation of BMI must take into account sexual maturation (92). We suggest that, in general, the diagnosis of PEM in adolescent boys and girls can be

based on a BMI *below 15.0 at ages 11 to 13 years*, and *below 16.5 at ages 14 to 17 years*. The corresponding values for *severe PEM* would be *below 13.0* and *below 14.5*, respectively.

The use of deficit in weight for age does not differentiate between a truly underweight child (current PEM) and one who is short but well proportioned in weight (past PEM); furthermore, the information about chronologic age is not always reliable. However, the classification of PEM as grades I (75–90% of reference weight for age), II (60–74%), and III (less than 60%) is useful in public health and epidemiologic studies, because it indicates the proportion of children in a population group who at some time in their lives have had malnutrition (93).

Use of the upper arm circumference has been advocated under field conditions without access to a weighing scale. It is not a sensitive index, but one can differentiate between a moderately to severely malnourished child and one with better nutritional condition.

Mild and Moderate PEM

The main clinical feature of mild and moderate PEM is weight loss. A decrease in subcutaneous adipose tissue may become apparent. When PEM is chronic, children show growth retardation in terms of height (stunting). Populations in which PEM is highly prevalent or “endemic” show slow weight gains, as illustrated in [Figure 59.4](#).

Figure 59.4. Pattern of weight gain, from birth to 5 years, in 431 boys (A) and 436 girls (B) from low-income families in rural Guatemala. (From INCAP. Evaluación nutricional de la población de Centro América y Panamá: Guatemala. Guatemala: Instituto de Nutrición de Centro América y Panamá, 1969.)

Physical activity and energy expenditure of children decrease (24, 94, 95 and 96). Other functional indicators of immuno competence, gastrointestinal functions, and behavior may be altered, but their assessment is not yet practical for diagnostic purpose (28, 40,

97). Nonspecific manifestations include more-sedentary behavior, frequent episodes of diarrhea, and apathy, lack of liveliness, and short attention spans.

In adults, mild to moderate PEM results in leanness with reduction in subcutaneous tissue. The most common change in body composition is a reduction of adiposity below 12 and 20% in men and women, respectively. Capacity for prolonged physical work is reduced, but this change is usually apparent only in persons engaged in intense, energy-demanding occupations (23, 98). Malnourished women have a higher probability of giving birth to infants with low birth weights (99). As in children, there may be other functional alterations not yet well characterized.

Biochemical information is not consistent in mild and moderate PEM. Laboratory data related to low protein intakes may include low urinary excretion of creatinine, leading to a low creatinine-height index in children (100), low urinary urea nitrogen and hydroxyproline excretions, altered plasma patterns of free amino acids with a decrease in branched-chain essential amino acids, slight decreases in serum transferrin and albumin levels, and a reduced number of circulating lymphocytes.

Severe PEM

The diagnosis of severe PEM is principally based on dietary history and clinical features. Marasmus is usually associated with severe food shortage, prolonged semistarvation, early weaning, or infrequent feeding of infants, and kwashiorkor with late weaning and poor protein intakes. Chronic or recurrent diarrhea and infections are common features.

Marasmus

Generalized muscular wasting and absence of subcutaneous fat give the patient with severe nonedematous PEM a "skin and bones" appearance (Fig. 59.5 and Fig. 59.6). Marasmic patients frequently have 60% or less of the weight expected for their height, and children have marked retardation in longitudinal growth. The hair is sparse, thin, and dry, without normal sheen; it is easily pulled out without causing pain. The skin is dry and thin, with little elasticity, and wrinkles easily. Patients are apathetic but usually aware and have an anxious look. These features and the sunken cheeks caused by disappearance of the Bichat fat pads, which are among the last subcutaneous adipose depots to disappear, give the marasmic child's face the appearance of a monkey's or an old person's face.

Figure 59.5. Marasmus in a 21-month-old child. (From Viteri FE. Primary protein-energy malnutrition: clinical, biochemical, and metabolic changes. In: Suskind RM, ed. Textbook of pediatric nutrition. New York, Raven Press, 1981.)

Figure 59.6. A. Marasmic protein-energy malnutrition in a 29-year-old man. **B.** The same patient after 3 months of treatment.

Some patients are anorectic, while others are ravenously hungry, but they seldom tolerate large amounts of food, and they vomit easily. Diarrhea may be present. There is marked weakness, and children frequently cannot stand without help. Heart rate, blood pressure, and body temperature may be low, but tachycardia may be present. Hypoglycemia can occur, especially after fasting for 6 or more hours, and is often accompanied by hypothermia of 35.5°C or less. The viscera are usually small. Abdominal distention may be present. The lymph nodes are easily palpable.

Differential diagnosis must be made from the secondary PEM of AIDS and other body-wasting diseases; dietary history plays an important role.

Common complicating features are acute gastroenteritis, dehydration, respiratory infections, and eye lesions due to hypovitaminosis A. Systemic infections lead to septic shock or intravascular clotting with high mortality rates.

Kwashiorkor

The predominant feature of kwashiorkor is soft, pitting, painless edema, usually in the feet and legs, but extending to the perineum, upper extremities, and face in severe cases ([Fig. 59.7](#)). Most patients have skin lesions, often confused with pellagra, in areas of edema, continuous pressure (e.g., the buttocks and back), or frequent irritation (e.g., the perineum and thighs). The skin may be erythematous, and it glistens in the edematous regions with zones of dryness, hyperkeratosis, and hyperpigmentation, which tend to become confluent. The epidermis peels off in large scales, exposing underlying tissues that are easily infected. Subcutaneous fat is preserved, and there may be some muscle wasting. Weight deficit, after accounting for the weight of edema, is usually not as severe as in marasmus. Height may be normal or retarded, depending on the chronicity of the current episode and on past nutritional history.

Figure 59.7. Kwashiorkor in a 36-month-old child. Note that subcutaneous tissues were preserved in the trunk and face.

The hair is dry, brittle, and without normal sheen, and it can be pulled out easily without pain. Curly hair becomes straight, and the pigmentation usually changes to dull brown, red, or even yellowish white. Alternating periods of poor and relatively good protein intake can produce alternating bands of depigmented and normal hair, termed the *flag sign* ([Fig. 59.8](#)).

Figure 59.8. “Flag-sign”: bands of depigmented and normal hair caused by alternating periods of poor and relatively good protein intake. (From Torun B, Viteri FE. Protein-energy malnutrition. In: Warren KS, Mahmoud AAF, eds. Tropical and geographical medicine. 2nd ed. New York, McGraw-Hill, 1990.)

Patients may be pale, with cold and cyanotic extremities. They are apathetic and irritable, cry easily, and have an expression of misery and sadness. Anorexia (sometimes necessitating nasogastric tube feeding), postprandial vomiting, and diarrhea are common. These conditions improve without specific gastrointestinal treatment as nutritional recovery progresses. Hepatomegaly with a soft round edge caused by severe fatty infiltration is usually present. The abdomen is frequently protruding because of distended stomach and intestinal loops. Peristalsis is irregular and frequently slow. Muscle tone and strength are greatly reduced. Tachycardia is common. Both hypothermia and hypoglycemia can occur after short periods of fasting.

Differential diagnosis must be made from other causes of edema and hypoproteinemia and from secondary PEM due to impairment in protein absorption or metabolism. The same complications occur as in marasmus, but diarrhea and respiratory and skin infections are more frequent and severe. Fatal infections may occur, frequently without fever, tachycardia, respiratory distress, or appropriate leukocytosis. The most common causes of death are pulmonary edema with bronchopneumonia, septicemia, gastroenteritis, and water and electrolyte imbalances.

Marasmic Kwashiorkor

The marasmic kwashiorkor form of edematous PEM combines clinical characteristics of kwashiorkor and marasmus. The main features are the edema of kwashiorkor, with or without its skin lesions, and the muscle wasting and decreased subcutaneous fat of marasmus ([Fig. 59.9](#) and [Fig. 59.10](#)). When edema disappears during early treatment, the patient's appearance resembles that of marasmus. Biochemical features of both marasmus and kwashiorkor are seen, but the alterations of severe protein deficiency usually predominate.

Figure 59.9. Marasmic kwashiorkor in a 22-month-old child. Note the edema in the lower part of the body, the emaciated upper part, and the skin lesions. (From Torun B, Viteri FE. Protein-energy malnutrition. In: Warren KS, Mahmoud AAF, eds. Tropical and geographical medicine. 2nd ed. New York, McGraw-Hill, 1990.)

Figure 59.10. A. Edematous protein-energy malnutrition in a 46-year-old man. **B.** The same patient after 3 months of treatment.

Biochemical and Histopathologic Features of Severe PEM

The most common biochemical findings are the following:

1. Serum concentrations of total proteins, and especially albumin, are markedly reduced in edematous PEM, and normal or moderately low in marasmus.
2. Hemoglobin and hematocrit are usually low, more so in kwashiorkor than in marasmus.
3. The ratio of nonessential to essential amino acids in plasma is elevated in

kwashiorkor and usually normal in marasmus.

4. Serum levels of free fatty acids are elevated, particularly in kwashiorkor.
5. Blood glucose level is normal or low after fasting 6 or more hours.
6. Urinary excretion of creatinine, hydroxyproline, 3-methylhistidine, and urea nitrogen is low. Edematous children have markedly reduced urinary creatinine excretion in relation to their height, leading to a low creatinine-height index (100), whereas marasmic children may have a normal or somewhat low index.

Plasma levels of other nutrients vary and tend to be moderately low. They do not necessarily reflect the body stores. For example, serum iron and retinol levels may be normal with almost depleted body stores, or in kwashiorkor they may be relatively low with adequate stores because of alterations in the transport proteins, transferrin and retinol-binding protein.

Many other biochemical changes have been described in severe PEM. Some are discussed in the section “[Pathophysiology and Adaptive Responses](#)”; others are listed in [Table 59.6](#). Although they have little practical importance in diagnosing the disease, they allow better understanding of the pathophysiologic modifications.

	Marasmus	Edematous PEM
Body composition		
Total body water	High	High
Extracellular water	High	Higher
Total body potassium	Low	Lower
Total body protein	Low	Low
Serum or plasma		
Transport proteins ^a	Normal or low	Low
Branched-chain amino acids	Normal or low	Low
Tyrosine:phenylalanine ratio	Normal or low	Low
Enzymes (in general) ^b	Normal	Low
Transaminase	Normal or high	High
Liver		
Fatty infiltration	Absent	Severe
Glycogen	Normal or low	Normal or low
Urea cycle and other enzymes ^c	Low	Lower
Amino acid synthesizing enzymes	High	Not as high

From Torun B, Viter FE. Protein-energy malnutrition. In: Warren KS, Mahmoud AMF, eds. Tropical and geographical medicine. 2nd ed. New York: McGraw-Hill, 1999.

^aFor example, transferrin, ceruloplasmin, retinol-, cortisol-, and thyroxine-binding proteins, α₂- and β₂-lipoproteins.

^bFor example, aminotransferases, aspartate aminotransferase, alkaline phosphatase.

^cFor example, xanthine oxidase, cholic acid oxidase, cholinesterase.

Table 59.6 Additional Selected Biochemical Changes Observed in Severe PEM

Body protein is lost slowly, most of it from muscle, and the greater loss of adipose tissue results in a relative increase in total body water (i.e., per unit of body mass), mainly as intracellular water. In severe protein deficiency (kwashiorkor), extracellular water also increases. The intracellular concentrations of potassium and magnesium decrease and that of sodium increases, although the serum concentrations of electrolytes do not necessarily reflect these alterations (101).

Histopathologic studies show nonspecific atrophy, mainly in tissues with greater cell turnover rates such as intestinal mucosa, red bone marrow, and testicular epithelium; intestinal villi are flattened, and enterocytes lose their columnar appearance. In marasmus there is generalized atrophy of skeletal muscle. The skin changes consist of

dermal atrophy, ecchymosis, ulcerations, and hyperkeratotic desquamation, seen primarily in areas subjected to irritation and not necessarily restricted to exposed areas, as in the case of pellagra. The liver in individuals with kwashiorkor is enlarged with fatty infiltration; periportal fat appears first and advances centripetally as severity increases. Other histologic analyses, special staining techniques, and electron microscopy reveal more alterations, not all of which result specifically from primary PEM. All do reflect generalized atrophy, however. Lesions due to superimposed infections and other nutrient deficiencies often are evident macroscopically and upon histopathologic examination. These changes usually revert to normal with nutritional recovery, although some residual lesions may persist for a long time.

PROGNOSIS AND RISK OF MORTALITY

Treatment of mild and moderate PEM corrects the acute signs of the disease, but children's catch-up growth in height may take a long time or might never be achieved. These children have been deprived not only of food but also of opportunities for development, and they may have missed critical periods for harmonic physical, mental, and social maturation. Weight for height can be restored easily, but the child may remain stunted, and a small body size may influence his or her maximal working capacity as an adult. Many severely malnourished children appear to have residual behavioral and mental problems in creativity and social interaction. However, the causal roles of malnutrition and a poor living environment are difficult to disassociate, and there is no irrefutable evidence that the damage cannot be corrected in a good, stimulating environment.

Mortality rates among children with severe PEM are associated with the quality of treatment. Worldwide, median case fatality has remained unchanged at 20 to 30% over the past 50 years, due to outmoded and faulty case management, with the highest levels (40–60%) among those with edematous PEM ([102](#)). Low mortality is attainable with adequate treatment, and in some centers it is as low as 4 to 6% for both edematous and nonedematous forms. [Table 59.7](#) lists the characteristics that generally indicate a poor prognosis and demand close surveillance.

-
- Age less than 6 months
 - Deficit in weight for height greater than 30%, or in weight for age greater than 40%
 - Signs of circulatory collapse: cold hands and feet, weak radial pulse, diminished consciousness
 - Stupor, coma or other alterations in awareness
 - Infections, particularly bronchopneumonia or measles
 - Petechiae or hemorrhagic tendencies (purpura is usually associated with septicemia or a viral infection)
 - Dehydration and electrolyte disturbances, particularly hypokalemia, and severe acidosis
 - Persistent tachycardia, signs of heart failure or respiratory difficulty
 - Total serum proteins below 30 g/L
 - Severe anemia with clinical signs of hypoxia
 - Clinical jaundice or elevated serum bilirubin level
 - Extensive exudative or exfoliative cutaneous lesions, or deep decubitus ulcerations
 - Hypoglycemia
 - Hypothermia
-

Table 59.7 Characteristics That Indicate Poor Prognosis in Patients with PEM

TREATMENT

Severe PEM

Patients with uncomplicated PEM should be treated outside the hospital whenever possible. Hospitalization increases the risk of cross-infections, and the unfamiliar setting may increase apathy and anorexia in children, making feeding more difficult. Severely malnourished children with signs of a poor prognosis ([Table 59.7](#)) or other life-threatening complications and those living under deplorable social conditions that do not permit adequate medical and nutritional treatment as outpatients must be hospitalized.

Treatment strategy can be divided into three stages: (a) resolving life-threatening conditions, (b) restoring nutritional status without disrupting homeostasis, and (c) ensuring nutritional rehabilitation.

Resolving Life-Threatening Conditions

On admission, the child with severe PEM is often a medical emergency. Restoration of nutrition should start as soon as possible, but it can be delayed until life-threatening conditions are resolved. The most frequent life-threatening conditions follow.

Fluid and Electrolyte Disturbances. The assessment of dehydration is not easy in severe PEM, because classic signs of dehydration, such as sunken eyeballs and decreased skin turgor, are frequently found in well-hydrated patients, whereas hypovolemia may coexist with subcutaneous edema, and irritability or apathy makes assessment of the mental state difficult. Useful signs are a history of watery diarrhea or vomiting, thirst, low urinary output, weak and rapid pulse, low blood pressure, cool and moist extremities, and a declining state of consciousness. The therapeutic approach differs from that in well-nourished patients because of water and electrolyte peculiarities of severe PEM: (a) hypoosmolality with moderate hyponatremia, (b) mild-to-moderate metabolic acidosis, which decreases or disappears when the patient receives dietary or parenteral energy and when electrolyte balance is reestablished, (c) high tolerance to hypocalcemia, partly because the acidosis produces a relative increment in ionized calcium and partly because hypoproteinemia makes less protein available to bind calcium ions, (d) decreased body potassium without hypokalemia, and (e) decreased body magnesium, with or without hypomagnesemia.

Fluid repletion should allow a diuresis of at least 200 mL in 24 hours in children and 500 mL in adults, or a micturition every 2 to 3 hours. Whenever possible, oral or nasogastric rehydration should be used. Many clinicians report good results with the use of the oral rehydration salt (ORS) solution promoted by the WHO for children who are not severely malnourished. But in keeping with recent WHO recommendations for the management of severe malnutrition, it is preferable to use solutions that provide more potassium,

magnesium, and (especially for edematous PEM) less sodium (103). Opinions regarding the concentration of sodium vary between 30 and 60 mmol/L (104). A practical approach is preparation of a mineral mix to complement the diet, which can be combined with WHO's regular ORS and sucrose to prepare a *modified ORS* solution for patients with severe PEM. This solution will have magnesium to begin replenishing the body stores and help potassium retention as well as other minerals that usually are deficient in severely malnourished patients. Table 59.8 shows the composition of the mineral mix, and Table 59.9 shows the composition of the modified ORS prepared by diluting one standard WHO ORS packet, two 3.12-g packets of mineral mix (or 40 mL of concentrated mineral mix solution), and 50 g of sucrose in 2 L of water (103).

Salt	Amount (g)	mmol in 1 g	mmol in 3.71 g
Potassium chloride	89.5	6.47 K	24 K
Tripotassium citrate	32.4	1.62 K	6 K
Magnesium chloride · 6H ₂ O	30.5	0.81 Mg ²⁺	3 Mg
Zinc acetate · 2H ₂ O	3.3	0.081 Zn ²⁺	0.300 Zn
Copper sulfate · 7H ₂ O	0.56	0.011 Cu ²⁺	0.040 Cu
Total	156.26 ^b		

^a1 mmol K = 39.1 mg; 1 mmol Mg = 24.3 mg; 1 mmol Zn = 65.4; 1 mmol Cu = 63.5 mg.

^bAdd water to make 1000 mL concentrated mineral mix solution that can be stored at room temperature, or prepare packets with 3.12 g of dry mineral mix. Add 20 mL of the concentrated solution or 1 packet to each liter of modified ORS solution or liquid food (based on WHO recommendations [103]).

Table 59.8 Mineral Mix for Preparation of Modified Oral Rehydration Salt (ORS) Solution and to Complement Liquid Foods^a

Component	Concentration (mmol/L) ^b
Glucose	126
Sodium	45
Potassium	40
Chloride	70
Citrate	7
Magnesium	3 (6 mEq)
Zinc	0.3
Copper	0.04
Osmolarity	300

^aPrepared by diluting one standard WHO ORS packet, two 3.12-g packets or 40 mL of concentrated mineral mix solution shown in Table 59.8, and 50 g sucrose in two liters of water (103).

^b1 mmol glucose = 186 mg; 1 mmol Na = 23.0 mg; 1 mmol K = 39.1 mg; 1 mmol Cl = 35.5 mg; 1 mmol citrate = 307.1 mg; 1 mmol Mg = 24.3 mg; 1 mmol Zn = 65.4; 1 mmol Cu = 63.5 mg.

Table 59.9 Composition of *Modified* Oral Rehydration Solution for Severely Malnourished Children^{a,b}

The ORS solution should be given *orally* in small quantities (a teaspoonful or sips from a cup) every few minutes to provide between 70 and 100 mL/kg body weight over a period of 12 hours, starting with about 10 mL/kg/h during the first 2 hours for children with mild-to-moderate dehydration and up to 30 mL/kg/h for severe dehydration. This is slower than is customary for less undernourished, dehydrated children (105). Additional ORS solution should be given to compensate for the losses of diarrhea and vomiting. As a general guide, give 50 to 100 mL after each loose stool to children under 2 years old and twice as much to older children. Breast-feeding should continue during the period of rehydration, approximately every half-hour. *Patients must be evaluated every hour.* As soon as the patient improves, usually 4 to 6 hours after beginning rehydration, small amounts of liquid dietary formula with potassium, calcium, magnesium, and other electrolytes should be offered every 2 to 3 hours. If signs of dehydration are still present after 12 hours but the condition is improving, another 70 to 100 mL ORS/kg can be given over the next 12 hours. When there are signs of overhydration, such as when the child's eyelids become puffy, edema increases, the jugular veins become full, or respiratory rate increases, only breast milk or liquid diet should be given instead of ORS.

Children who vomit constantly or who cannot be fed orally should be rehydrated by *nasogastric tube*, giving 3 to 4 mL of ORS solution/kg slowly or drop by drop every half-hour. In addition to what was described for oral rehydration, the following actions must be taken on the basis of frequent evaluations: if there is repeated vomiting or increasing abdominal distension, give the fluid more slowly and in smaller portions; if hydration is not improving after 4 hours, begin intravenous rehydration; when vomiting ceases and hydration improves, give modified ORS by mouth and, if the child tolerates oral solutions for the next 2 hours, remove the nasogastric tube.

Intravenous fluids must be used when there is repeated vomiting or persistent abdominal distension, and in severe dehydration with hypovolemia and impending shock. Hypoosmolar solutions (200–280 mOsm/L) must be used. Potassium (when urinating) and sodium should not exceed 6 and 3 mmol/kg per day, respectively, and glucose must provide at least 63 to 126 kJ (15–30 kcal)/kg/day. Solutions that have been successfully used include a 1:1 mixture of 10% dextrose in water (D/W) either with isotonic saline (i.e., 5% glucose in 0.5 N saline) or with Darrow's solution; a 1:2:3 mixture of 0.17 sodium lactate:isotonic saline:10% D/W; or Hartmann's solution (Ringer's lactated solution). One of these should be infused *during the first hour* at a rate of 10 to 30 mL/kg, depending on the patient's condition. After that, 5% glucose in 0.2 N saline (800 mL of 5% D/W, 20 mL of 50% D/W, and 200 mL of isotonic saline), or a 1:2:6 mixture of lactate:isotonic saline:5% glucose with 50 mL of 50% D/W added to each 500 mL, should be infused at a rate of 5 to 10 mL/kg/h, based on hourly evaluations of the patient, until oral therapy is initiated. When the patient is urinating, 2 g KCl (27 mmol K) is added to each liter of the infusion solution.

Increases in pulse and respiratory rate with weight gain after accounting for weight of excreta, pulmonary rales, and appearance or exacerbation of edema indicate overhydration. An increase in pulse and respiratory rate with weight loss, low urine output, and continuing losses from diarrhea and vomiting suggest insufficient fluid

therapy.

Patients with severe hypoproteinemia (less than 30 g/L), anuria, and signs of hypovolemia or impending circulatory collapse should be given 10 mL plasma per kg in 1 to 2 hours, followed by 20 mL/kg/h of a mixture of two parts of 5% dextrose and one part of isotonic saline for 1 or 2 hours. This will increase plasma protein concentration by about 5 to 10 g/L and help prevent the rapid exit of water from the intravascular compartment. If diuresis does not improve, the dose of plasma can be repeated 2 hours later. Further treatment is similar to that of well-nourished patients. Unless the patient is at risk of imminent death, only plasma tested to be human immunodeficiency virus (HIV)-negative should be used.

Hypocalcemia may occur secondary to magnesium deficiency. When the patient has symptoms of hypocalcemia and serum magnesium determinations are not available, it is essential not only to give calcium infusion but also to give magnesium intravenously or intramuscularly. When the serum concentration of calcium rises to normal or, in the absence of laboratory data, when the symptoms of hypocalcemia disappear, calcium infusion may be discontinued. Intramuscular or oral magnesium supplementation should follow the initial parenteral magnesium until the patient is repleted with this ion as indicated by maintenance of serum and urine magnesium concentrations. When there are no laboratory facilities to monitor Mg concentrations, a general therapeutic guideline is to give magnesium intramuscularly as a 50% solution of magnesium sulfate in doses of 0.5, 1, and 1.5 mL for patients who weigh less than 7, between 7 and 10, and more than 10 kg, respectively. The dose can be repeated every 12 hours until there is no recurrence of the hypocalcemic symptoms and oral magnesium supplementation of 0.25 to 0.5 mmol Mg (0.5 to 1 mEq)/kg/day can be given, as described later. Certain antibiotics, such as amphotericin, can cause loss of magnesium and potassium into the urine, increasing the need for both ions.

Infections. Malnourished patients are particularly prone to infections, which are frequently the immediate cause of death in severe PEM. Paradoxically, clinical manifestations may be mild, and the classic signs of fever, tachycardia, and leukocytosis may be absent. Antigen-antibody reactions are often impaired, and skin tests such as tuberculin, often give falsely negative results.

When an infection is suspected, appropriate antibiotic therapy must be started immediately, even before obtaining the results of microbiologic cultures. The choice of drug will vary with the suspected etiologic agent, the severity of the disease, and the pattern of drug resistance in that area. Although antibiotics should not be used prophylactically, when patients cannot be monitored closely by experienced personnel for signs of infection, as is often the case in rural hospitals of developing countries, it is safer to assume that all ill and severely malnourished patients have a bacterial infection and to treat them with antibiotics to cover both gram-positive and gram-negative microorganisms; the latter are particularly common in PEM. When septicemia is suspected, a broad-spectrum antibiotic or a combination such as ampicillin and gentamicin (two inexpensive antibiotics generally available in developing countries) is usually given intravenously. Other supportive treatment may also be necessary, such as

treatment for respiratory distress, hypothermia, and hypoglycemia.

However, clinicians should be aware that drug metabolism is likely to be altered and that detoxification mechanisms are likely to be compromised in severe PEM as a result of delayed absorption, abnormal intestinal permeability, reduced protein binding, changes in the volume of distribution, decreased conjugation or oxidation in the liver, and decreased renal clearance (106, 107). For example, in malnourished children the half-lives of chloramphenicol (108), sulfadiazine (109), and gentamicin (106) are increased, and their clearance is decreased. For this same reason, treatment for intestinal parasites, which is rarely urgent, should be deferred until nutritional rehabilitation is under way. This will decrease the risks of potential toxicity, including the possibility of absorbing drugs normally not absorbed by a healthy intestine.

Every child over 6 months old should be vaccinated against measles on admission, because of the high mortality rates associated with this disease in severe PEM. As seroconversion may be impaired at this early stage of treatment, a second dose of vaccine should be given before discharge.

Hemodynamic Alterations. Cardiac failure may develop when there is severe anemia, during or after administration of intravenous fluids, or shortly after the introduction of high-protein and high-energy feedings or of a diet with high sodium content, leading to pulmonary edema and frequent secondary pulmonary infection. These alterations may result from impaired cardiac function, sudden expansion of the intravascular fluid volume, severe hypoxia, or impaired membrane function. Diuretics such as furosemide (10 mg intravenously or intramuscularly, repeated as necessary) should be given, and other supportive measures should be taken. Many clinicians advocate the use of digoxin (0.03 mg/kg intravenously, every 6–8 hours). *The use of diuretics merely to accelerate the disappearance of edema in kwashiorkor is contraindicated.*

Severe Anemia. The routine use of blood transfusions endangers the patient; hemoglobin levels will improve with proper dietary treatment supplemented with hematinics. Therefore, blood transfusions should be given only to those with severe anemia with less than 40 g hemoglobin/L, less than 12% packed cell volume (hematocrit), clinical signs of hypoxia, or impending cardiac failure. In many developing countries with a high prevalence of infection with HIV and few or no resources for screening the blood supply, the risk of transmission of HIV is significant; the use of transfusion should be restricted except in life-threatening situations. Whole blood (10 mL/kg) can be used in marasmic patients, but it is better to use packed red blood cells (6 mL/kg) in edematous PEM. The transfusion should be given slowly, over 2 to 3 hours and repeated if necessary after 12 to 24 hours. If there are signs of heart failure, 2.5 mL blood/kg should be withdrawn before the transfusion is started and at hourly intervals so that the total volume of blood transfused equals the volume of anemic blood removed.

Hypothermia and Hypoglycemia

Body temperature below 35.5°C and plasma glucose concentration below 3.3 mmol/L (60 mg/dL) can be due to either impaired thermoregulatory mechanisms, reduced fuel substrate availability, or severe infection. Asymptomatic hypoglycemia can be treated

(and prevented) by feeding small volumes of glucose- or sucrose-containing diets and solutions every 2 to 3 hours, day and night. Severe symptomatic hypoglycemia must be treated intravenously with 10 to 20 mL of 50% glucose solution followed by oral or nasogastric administration of 25 to 50 mL of 10% glucose solution at 2-hour intervals for 24 to 48 hours.

Body temperature usually rises in the hypothermic patient with frequent feedings of glucose-containing diets or solutions. Patients must be closely monitored when external heat sources such as heavy clothing, heat lamps, and radiators are used to reduce the loss of body heat, because they may rapidly become hyperthermic. It is best to keep the seminude patients in an ambient temperature of 30 to 33°C. Treatment must also be given as for hypoglycemia and systemic infection.

Severe Vitamin A Deficiency. Severe PEM is often associated with vitamin A deficiency. A large dose of vitamin A should be given on admission, because ocular lesions can result from increased demands for retinol when adequate protein and energy feeding begins. Water-miscible vitamin A as retinol should be given orally or intramuscularly on the first day at a dose of 52 to 105 μmol (15,000–30,000 μg , or 50,000–100,000 IU) for infants and preschool children, or 105 to 210 μmol (30,000–60,000 μg , or 100,000–200,000 IU) for older children and adults, followed by 5.2 μmol (1500 μg , or 5000 IU) orally each day for the duration of treatment. The initial dose should be repeated for 2 more days in symptomatic patients. Corneal ulcerations should be treated with ophthalmic drops of 1% atropine solution and antibiotic ointments or drops until the ulcerations heal.

Homeostatic Restoration of Nutritional Status

The next objective of therapy is to replace nutrient tissue deficits as rapidly and safely as possible. This should start as soon as the measures to manage the life-threatening conditions have been established. Based on the premise that the patient is adapted to the malnourished state, nutritional treatment must begin slowly to avoid deleterious metabolic disruptions. Various regimens provide a diet that meets daily maintenance requirements for a few days, followed by a gradual increase in nutrient delivery. It is best to begin with a liquid formula fed orally or by nasogastric tube, divided equally into 6 to 12 feedings per day, depending on the patient's age and general condition. This frequent feeding of small volumes, which must be given around the clock to avoid fasting for more than 4 hours, prevents vomiting and development of hypoglycemia and hypothermia. For older children and adults with good appetite, the liquid formula can be partly substituted with solid foods that have a high density of good-quality, easily digestible nutrients. The same diet can be used to treat marasmic and edematous patients. The only difference is that the marasmic patient may require larger amounts of dietary energy after 1 or 2 weeks of dietary treatment, which can be provided by adding vegetable oil to increase the diet's energy density. Diets that derive as much as 60 to 75% of their energy from fats are usually well tolerated; there may be some steatorrhea without profuse diarrhea, and 85 to 92% of the fat is absorbed (51). Intravenous alimentation is not justified in primary PEM and can increase mortality rates (110).

The protein source must be of high biologic value and easily digested. Cow's milk is

frequently available, but some clinicians worry about the possibility of lactose malabsorption in severe PEM. However, cow's milk usually is well tolerated and assimilated by severely malnourished children and can be safely advocated ([111](#), [112](#)). Goat's, ewe's, buffalo's, and camel's milk can also be used. Human, mare's, and ass's milk, however, have very low protein concentrations. Cow's dried skimmed milk has very low energy density, which must be restored by adding sugar and/or vegetable oil. Eggs, meat, fish, soy isolates, and some vegetable protein mixtures are also sources of good protein. Most vegetable mixtures have protein digestibilities that are 10 to 20% lower than those of animal proteins, making it necessary to feed larger amounts. Their bulk might pose a problem in feeding small children, but energy density can be increased by adding sugar and/or vegetable oil. The latter will also provide the essential fatty acids needed.

The diet must be supplemented to provide daily about 5 to 8 mmol K and 0.5 to 1 mmol Mg (1–2 mEq) *per kg of body weight*, and 150 to 300 μmol Zn and 40 to 50 μmol Cu. Sodium content should be low, especially for patients with edematous PEM. This can be accomplished by adding to the diet appropriate amounts of a mineral mix, as indicated in [Table 59.8](#). Additional supplements should include daily doses of 5.2 μmol (1.5 mg, or 5000 IU) vitamin A, 1.2 mmol (0.3 mg) folic acid, and other vitamins and trace elements in the doses provided by most commercial preparations, which should be higher than the daily recommended allowances for well-nourished persons. Supplemental calcium to provide about 15 mmol (600 mg) daily should be given when nondairy diets are used. Supplemental iron (1–2.1 mmol, or 60–120 mg daily) should be given beginning 1 week after starting dietary therapy. Earlier administration of iron will not elicit a hematologic response ([Fig. 59.2](#)); it might facilitate bacterial growth, and if the free-radical theory is true, it might produce metabolic disturbances, especially in patients who have or may develop edematous PEM.

To avoid the danger of initial excessive intakes of protein and energy by hungry patients, a relatively rigid regimen is recommended to deliver small amounts of nutrients initially and increase them gradually every 2 or 3 days. A practical way to do this, which can also be applied to extremely anorectic patients who must be fed by nasogastric tube, is based on the preparation of a basic liquid food with high protein concentration and high energy density; [Table 59.10](#) gives several examples. Delivery of proteins and energy is gradually increased by use of different concentrations of the basic food, as shown in [Table 59.11](#); the additional sugar compensates for the dilution of dietary energy. The liquid preparations must be fed at a dose of 100 mL/kg/day. *Additional water* must be given to provide at least 1 mL of total fluids per kilocalorie in the diet. After day 7, the patient can be allowed larger amounts of food (*ad libitum*). The intervals for the dietary increments in [Table 59.11](#) can be lengthened to 3 to 5 days in severely malnourished children, especially those with less than 30 g/L plasma proteins or serious metabolic disturbances. The energy density of the diet of marasmic patients who are not gaining weight at an adequate rate by the second week (an average of at least 5 g/kg/day) should be increased at 5- to 7-day intervals by adding vegetable oil ([Table 59.11](#)).

Food Used As Protein Source	Amount (g)	Sucrose (g)	Oil ^a (g)	Water (mL)
Cow's milk, full-cream powder	140	100 ^b	40	900
Cow's milk, skimmed powder	110	100 ^b	70	900
Cow's, goat's, or camel's milk, fresh	1000	100 ^b	40	—
Buffalo's or ewe's (sheep's) milk, fresh	850	100 ^b	15	150

From Toxin B, Voon FE. Protein-energy malnutrition. In: Warren KS, Merimouk AV, eds. Tropical and geographical medicine. 2nd ed. New York, McGraw-Hill, 1990.
^aThe formula must be fed at 100 mL/day. The formula is supplemented with adequate amounts of vitamins, minerals, and electrolytes. Additional water must be given to give at least 1 mL of fluid/kg per hour in the first 24 hours.
^bThese formulas may require more dietary energy (2 to 3 kcal/kg) in response to expenditure of per 100 mL of liquid diet should be added in 1-day intervals until the level of weight gain becomes adequate.

Table 59.11 Example of a Dietary Therapeutic Regimen for Children, Based on Dilutions of the Basic High-Energy Foods Shown in [Table 59.10^a](#)

Another option, which is particularly useful for relief and refugee camps, is advocated by WHO (103). It consists of giving during the initial phase of treatment a liquid diet based on a mixture of skim milk, cereal flour, sugar, oil, vitamins and minerals, which provides 1.2 g protein and 75 kcal (314 kJ) per 100 mL. The child is given at least 80, but not more than 100, kcal/kg/day. After the appetite has returned, another liquid diet is used, with higher concentrations of skim milk and vegetable oil, and without cereal flour, which provides 2.8 g protein and 100 kcal (418 kJ) per 100 mL. Intake is maintained at 100 kcal/kg/day until steady weight gain is established, and then the diet is fed to satiety. Additional water is offered between feedings. The diets can be purchased as a powder that is mixed with water, or they can be made from the basic ingredients, which include a mineral mix similar to that shown in [Table 59.8](#) and a commercial multivitamin

preparation.

Therapeutic diets for older children must be adjusted to their age. Initial treatment should provide average energy and protein requirements, followed by a gradual increase to about 1.5 times the energy and 3 to 4 times the protein requirements by day 7. Dietary energy delivery to marasmic patients may have to be increased further.

The attitude of the person who feeds the patient is important to overcome the patient's lack of appetite. Patience and loving care are needed to coax the child gently to eat all the diet. The appearance, color, and flavor of the foods also affect appetite and food acceptance.

The initial response to the diet is either no change in weight or a decrease caused by loss of edema, accompanied by large diuresis ([Fig. 59.11](#)). After 5 to 15 days, there is a period of rapid weight gain or "catch-up." The catch-up is usually slower in marasmus than in kwashiorkor. In children, the rate of catch-up weight gain is generally 10 to 15 times the rate of weight gain of a normal child of the same age, and it can be as much as 20 to 25 times greater. Some patients only show a four- or fivefold increase in catch-up. Most often this is associated with insufficient energy intake (e.g., because of inadequately prepared formula, insufficient amounts of formula given at each feeding, too few feedings per day, anorexia, or lack of patience of the person who feeds the child) or with overt or asymptomatic infections; urinary infections and tuberculosis are the most commonly seen asymptomatic diseases.

Figure 59.11. Weight gain and improvement in weight for height, creatinine-height index (CHI), and plasma protein concentration of two children treated at INCAP for kwashiorkor (child A) and marasmus (child B). The *thin, downward arrows* indicate gradual increments in dietary proteins and energy, as described in [Table 59.11](#). The *thick, upward arrows* indicate the day when the lower limit of normal values was reached. The marasmic child had a normal plasma protein concentration on admission. Weight for height was calculated on child A on admission, after correcting for the weight of edema. Dietary energy was reduced on days 60 and 80 for child A and on day 100 for child B.

Ensuring Nutritional Rehabilitation

The last stage of treatment usually begins 2 to 3 weeks after admission, when the child is without serious complications, eating satisfactorily, and gaining weight. It may start in the hospital and continue on an outpatient basis, preferably at a nutrition rehabilitation center or similar facility that gives daytime care by staff trained in the rehabilitation of malnourished children. When there is no such facility, the hospital must continue to provide care until the child is ready for discharge. The patient must continue to eat adequate amounts of protein, energy, and other nutrients, especially when traditional foods are introduced into the diet. Emotional and physical stimulation must be provided, and persistent diarrhea, intestinal parasites, and other minor complications must be treated. Children should be vaccinated during this period as well.

Introduction of Traditional Foods. Other foods, especially those available at home, are gradually introduced into the diet in combination with the high-energy, high-protein formula. This step should be taken when edema has disappeared, the skin lesions are notably improved, the patient is active and interacts with the environment, the appetite is restored, and adequate rates of catch-up growth have been achieved. For children, a daily minimum intake of 3 to 4 g of protein and 500 to 625 kJ (120 to 150 kcal)/kg of body weight (or more in marasmus) must be ensured. To achieve this, the energy density of solid foods must be increased with oil, and protein density and quality must be high, using animal proteins, soybean protein preparations, and good vegetable protein mixtures. Local traditional foods can be used in appropriate combinations ([113](#), [114](#) and [115](#)) *in addition to the liquid formula*, as in the following examples: (a) one part of a dry pulse or its flour (e.g., black beans, soybeans, kidney beans, cowpeas) and three parts of a dry cereal or flour (e.g., corn, rice, wheat); fat or oil should be added to the mashed or strained pulse during or after cooking in amounts equal to the weight of the dry pulse or flour, and to the cereal preparations in amounts of 10 to 30 mL oil/100 g dry cereal product, depending on the type of preparation; and (b) four parts of a dry cereal (e.g., rice or wheat) and one part of fresh fish, fowl, or meat; fat or oil should be added in amounts equal to 20 to 40% of the dry weights. The food can be served as separate dishes or the parts can be mashed or blended and fed as paps to infants and young children.

Emotional and Physical Stimulation. The malnourished child needs affection and tender care from the beginning of treatment. This requires patience and understanding by the hospital staff and relatives. Involvement of parents or relatives must be encouraged. Hospitals should be brightly colored and cheerful, with auditory stimulation such as music. As soon as the child can move without assistance and is willing to interact with the staff and other children, he or she must be encouraged to explore, to play, and to participate in activities that involve body movements. Relatively small increments in physical activity and energy expenditure during the course of nutritional rehabilitation result in faster longitudinal growth and accretion of lean body tissues ([116](#), [116a](#)). This can be achieved with games and activities that include walking uphill, running, tumbling, or climbing stairs. Parents should be encouraged to stimulate and teach their children by playing and talking. Toys and play materials can often be made

from discarded local articles.

Adult patients should exercise regularly with gradual increments in cardiorespiratory workload.

Persistent or Recurrent Diarrhea and Other Health Problems. Mild diarrhea does not interfere with nutritional rehabilitation as long as fluid and electrolyte intakes maintain satisfactory hydration. This condition often disappears without specific treatment as nutritional status improves (117). However, persistent or recurrent diarrhea can contribute to development of a new episode of PEM and should be treated. Treatment is determined by the underlying cause of diarrhea, usually intestinal infections, excessive bacterial flora in the upper gut that ferment food substrates and deconjugate bile salts, intestinal parasites (particularly giardiasis, cryptosporidiosis, and trichuriasis), and intolerance to food components.

Lactose, milk protein, and gluten have commonly been held responsible for food intolerances. However, the apparent high prevalence of lactose malabsorption and intolerance in PEM is often based on inadequate diagnostic procedures (e.g., intolerance to 2 g lactose/kg in aqueous solution, rather than to the 7 to 15 g lactose contained in a milk meal) (49). When food intolerance is suspected, the diet should be modified, taking care to preserve its nutritional quality and density. Before branding a patient intolerant to a given food, the food should be reintroduced into the diet to confirm the diagnosis, and adequate diagnostic tests should be done.

Criteria for Recovery. Treatment until full recovery *should not* be in a hospital. Ideally, the patient should be referred to a nutrition clinic or rehabilitation center to continue treatment after all life-threatening conditions have been controlled, appetite is good, edema and skin lesions have disappeared, and the patient smiles, interacts with staff and other patients, and is gaining weight at a fast rate. The child's mother or caretaker must understand the importance of continuing the high-energy, high-protein diet until full recovery has taken place. If this can be done at home, the patient can continue treatment on an outpatient basis with regular follow-up in a nutrition clinic or its equivalent or by home visits by trained personnel.

An increase in plasma protein or albumin concentration indicates a good response but not full recovery (Fig. 59.11). The most practical criterion for recovery is weight gain, and almost all fully recovered patients should reach the weight expected for their height (see below). As shown in Figure 59.11, however, weight for height does not necessarily indicate protein repletion, and it is best to use it in conjunction with body composition indices. In children, if urine can be collected for 24 to 72 hours, the creatinine-height index (CHI) can be used as an indicator of body protein repletion. Premature termination of treatment increases the risk of a recurrence of malnutrition. As a general guideline, when body composition cannot be assessed, dietary therapy should continue for 1 month after the patient admitted with edematous PEM reaches an adequate weight for height without edema, and clinical and overall performances are adequate, or for 15 days after the marasmic patient reaches that weight. The minimum normal limits should be 92% of the weight expected for height (or 1 standard deviation below the reference median) and, especially in children, a CHI of 0.9. Some patients, however, do not reach

those values because they are in the lower end of the normal distribution curve. If they continue growing at a normal rate and have no functional impairments, treatment can be terminated after 1 month of adequate dietary intake and weight for height and CHI stabilization. Specific treatment of other nutritional problems (e.g., iron deficiency) sometimes must be prolonged beyond discharge for PEM.

Before being discharged, patients or their parents must be taught about the causes of PEM, emphasizing rational and nutritious use of household foods, personal and environmental hygiene, appropriate immunizations, and early treatment including dietary management of diarrhea and other diseases.

Adolescents and Adults

The physiologic changes and principles of management of adolescents and adults with severe PEM are the same as those for children. Clinical and dietary history, as well as laboratory tests, are particularly important to identify underlying causes and to include them in the therapeutic program. Complications and life-threatening conditions must be treated as described for children.

Initial dietary treatment should provide average energy and protein requirements for the patient's age (45 kcal and 0.75 g protein/kg/day for adolescents, and 40 kcal and 0.6 g protein/kg/day for adults), followed by a gradual increase to about 1.5 times the energy and 3 to 4 times the protein requirements by day 7. Dietary energy delivery to marasmic patients may have to be increased further. Minerals and vitamins must be added in amounts at least twice the recommended daily allowances, following the same schedule as for children. Except for pregnant women, a single dose of 210 μmol (60 mg, or 200,000 IU) retinol should be given.

The liquid diets described for infants and young children can be given, especially to weak and anorectic patients. However, adults and adolescents are often reluctant to eat anything other than habitual foods, and liquid diets must be prescribed as a medicine, rather than as a food. When appetite improves, a diet should be given based on traditional foods but with added sugar and oil to increase energy density, plus vitamins and minerals. A wide variety of foods should be provided in amounts to satisfy appetite, taking into account the patient's inclinations and taboos. The liquid diet with vitamins and minerals should be given between meals and at night.

Adolescents and adults can be discharged when they are eating well and gaining weight, they have a reliable source of nutritious food outside the hospital, and other problems have been diagnosed and treatment begun. Supplementary feeding should continue on an outpatient basis until the BMI exceeds 15.0, 16.5, and 18.5, respectively, for adolescents 11 to 13 years old, adolescents 14 to 17 years old, and adults.

Mild and Moderate PEM

The less severe forms of PEM should be treated in an ambulatory setting, supplementing the home diet with easily digested foods that contain proteins of high

biologic value, a high energy density, and adequate amounts of micronutrients. In some instances, therapy can be achieved merely by instructing the adult patient about adequate eating habits and a better use of food resources or by instructing mothers in improved child-feeding practices and more nutritious culinary habits. It is almost always necessary, however, to provide both nutritious food supplements and instructions for their use.

The quantity of food supplements will vary, depending on the degree of malnutrition and the relative deficit of proteins and energy. As a general guideline, the goal should be to provide a total intake, including the home diet, of *at least* twice the protein and 1.5 times the energy requirements. For preschool children, this would signify a daily intake of about 2 to 2.5 g of high-quality protein and 500 to 625 kJ (120 to 150 kcal)/kg of body weight, and for infants under 1 year, about 3.5 g protein and 625 kJ (150 kcal)/kg/day.

The ingestion of the food supplement by the malnourished person must be ensured. This is more likely to occur if it is appetizing to both child and mother, if it is ready-made or easy to prepare, if additional amounts are provided to feed other children living in the same household, and if it does not have an important commercial value outside the home that would make it easy and profitable for the family to sell the item for cash. A substitution effect on the home diet (i.e., a decrease in the usual food intake) is almost always unavoidable, but it can be reduced by using low-bulk supplements with high protein and energy concentrations. Special attention should be given to avoid a decrease in breast-feeding. The supplements for breast-fed infants should be paps or solid foods that will not quench the infant's thirst and thus not change the infant's demand or the mother's attitude toward lactation.

Adequate amounts of vitamins and minerals must be ensured, although mild deficiencies can be overcome by the micronutrients in the food or by use of fortified vehicles such as iron-enriched bread or sugar fortified with retinol.

PREVENTION AND CONTROL OF PEM

Poverty, ignorance, frequent infections, cultural customs, cyclic climatic conditions, and natural and manmade disasters are among the main causes of PEM. Therefore, its control and prevention require multisectoral approaches that include food production and distribution, preventive medicine, education, social development, and economic improvement. At a national or regional level, control and prevention can only be achieved through short- and long-term political commitments and effective actions to enforce the measure to eradicate the underlying causes of malnutrition.

Nevertheless, the physician, nutritionist, public health worker, and educator *can and must* play an active role in prevention of PEM, even though prevention is aimed at smaller population groups or individuals. If they have to attend only those at higher risk to develop PEM, because of limited resources, a profile of risk factors is useful. The most likely victims are children under 2 years of age from low socioeconomic strata whose parents have misconceptions concerning the use of foods, who come from broken or unstable families, whose families have a high prevalence of alcoholism, who live under poor sanitary conditions, in urban slums, or in rural areas frequently subject to

droughts or floods, and whose societal beliefs prohibit the use of many nutritious foods. Special attention must be given to the availability and rational use of foods that optimize nutrient use, the control or reduction of infections, and health and nutrition education programs for the individual, the family, and the community.

Food Availability

Animal foods are the best protein sources, but they tend to be expensive, not always available, or prohibited by religious practices. Under such circumstances, the staple vegetable foods can be complemented with other vegetable foods combined in culturally acceptable ways to permit a good essential amino acid complementation and improve the biologic value of dietary protein. For example, corn and black bean combinations that provide proteins in a proportion of about 60:40, equivalent to about three parts of dry corn and one part of dry beans, have an excellent amino acid composition and permit adequate growth and function (118). The same is true of a series of other combinations of grains and pulses (113, 114 and 115). The relatively low nitrogen digestibility of these vegetable sources must be considered in recommending the amounts to be eaten. Energy density can be increased by adding fats or carbohydrates.

It is often necessary to convince parents of the safety of using foods that, in some cultures, are fed only to adults and older children. This is especially true of foods used to complement mother's milk or to wean infants from the breast. Breast-fed infants from populations at risk of PEM should start receiving at 6 months of age or earlier, if weight gain is not satisfactory commercial preparations of cooked rice, oat, or wheat, or homemade paps prepared by mashing boiled rice, bread soaked in about 50% water, or cooked corn products (e.g., tamale, tortilla). After 6 months of age, fish, egg, or minced meat, or one part of a cooked pulse (e.g., kidney beans, soybeans, chick peas) should be added for every three parts of rice, corn, or bread to provide a better protein mixture. If the child is underweight, 1 teaspoon of vegetable oil or 2 teaspoons of sugar can be added to every 2 to 3 ounces of pap. Paps based on a pulse, such as black beans (*Phaseolus vulgaris*), a cereal, and vegetable oil can be fed to babies as young as 3 months of age without intestinal discomfort and without decreasing breast milk intake. Examples of such paps are shown in Table 59.12.

	A	B	C	D
Cooked beans (60% water) ^a	25 g	25 g	25 g	25 g
Corn dough (57% water)	75 g	—	—	—
White bread (50% water)	—	75 g	—	—
Boiled rice (55% water)	—	—	75 g	—
Boiled potatoes (33% water)	—	—	—	75 g
Water	25 mL	25 mL	25 mL	25 mL
Vegetable oil	10 mL	10 mL	10 mL	15 mL
Protein, g/100 g ^b	3.6	4.8	3.4	2.2
Energy, kcal/100 g ^b	176	176	183	147

Modified from unpublished observations by FE Veeri, B Garcia, and B Torón. Black beans (*Phaseolus vulgaris*) cooked, mashed, and strained. Corn dough cooked with limestone, according to Guatemalan customs. White bread soaked in equal weight of water.

^aIn parentheses, proportion of water added to prepare 100 g

^bProtein and energy content of 100 g of pap, ready to eat.

Table 59.12 Paps to Complement Breast Milk, Using Common Foods and Based on

Combinations of a Legume with a Cereal or Potato, and Vegetable Oil

Children who are fully weaned or only occasionally breast-fed must receive adequate amounts of energy- and protein-rich staples and, ideally, animal foods to satisfy their nutritional needs and allow adequate growth. It is also important to convince parents that food should not be withheld when a child has diarrhea, because in many developing countries children under 5 years of age have loose stools 15 to 20% of the time. Many local foods of vegetable origin that are rich in fiber can be safely used and may even shorten the duration of diarrhea (119).

Reducing Infections

The risk of infections must be reduced because of the interactions of nutrition with infection. High priority must be given to immunizations, sanitary measures to reduce fecal contamination, and early oral rehydration and feeding of children with diarrhea (119).

Education

The presence of a malnourished child in a family indicates that something is wrong in that family and suggests that other members of the household might also be at risk of malnutrition. Therefore, nutritional and health education must not be restricted to rehabilitation of the index case but should include prevention of nutritional deterioration of other family members, especially siblings and pregnant and lactating women. Similarly, a high prevalence of children with malnutrition or growth retardation indicates that the entire community is at some risk of impaired nutrition. Consequently, education programs must be devised for community leaders, civic action groups, and the community as a whole. Such programs must emphasize promotion of breast-feeding, appropriate use of weaning foods, nutritional alternatives using traditional foods, personal and environmental hygiene, feeding practices during illness and convalescence, and early treatment of diarrhea and other diseases. Personal and communal involvement should be pursued through commitments to apply the recommendations. Toward this end, all educational programs *must* incorporate the community's own assessment of their nutritional problems and their feelings toward personal participation in solving these problems.

Abbreviations: **AP**—acute-phase reactant proteins; **BMI**—body mass index; **IL-1**—interleukin-1; **PEM**—protein-energy malnutrition; **TNF**—tumor necrosis factor.

There are over 13 million children in the United States living in families with incomes below the poverty level (1, 2). Of these, approximately 10% have clinical malnutrition, mostly iron deficiency, but all poor children are at risk for the long-term consequences of malnutrition including continued poverty. It is the chronicity of poverty that leads to the consequences of malnutrition and learning failure, since the behavioral adjustments to chronic poverty may affect nutritional status adversely (3, 4). This chapter shows how poverty affects food intake, nutritional status, behavior, and intellectual performance. These consequences contribute to ongoing cycles of poverty (5, 6 and 7).

Malnutrition among the poor in the United States is neither marked protein-energy malnutrition (marasmus or kwashiorkor) nor classic micronutrient deficiency (pellagra, beriberi, scurvy). Rather, both national surveys (3, 8) and those conducted in small communities (9, 10) show that growth retardation is an expression of malnutrition among poor children. Deficient intake and biochemical measures of micronutrient status, based solely on income, are found for folate (11, 12, 13, 14, 15 and 16), ascorbic acid (12, 13, 14 and 16), vitamin A (12, 13, 14 and 16), several of the B vitamin group (14), and continued iron deficiency (14, 17), even with a decade of decrease in response to successful food programs (17). These findings are striking in contrast to measures of nutrient intake and nutritional status in other industrial societies where poverty is uncommon (8, 17, 18, 19 and 20).

Mild protein-energy malnutrition associated with growth retardation (20, 21) and nutrition-related disorders including iron deficiency (5, 6, 7, 21, 22 and 23) have contributed to observed learning failure, deprivation, and disease within poor families in the United States. Lead poisoning in childhood (24) has consequences similar to in utero exposure to drugs (25), alcohol (26), and products of tobacco smoking (25) because of its effect on diet, use of nutrients, and direct toxicity to metabolic pathways in the fetus. A covariance model is presented in which nutrition and environment operate synergistically in both cause and repair of developmental delay and associated consequences (5, 6 and 7, 27).

An international survey, the Luxembourg Income Study of Families with Children, ranked 18 developed nations on the basis of both wealth and poverty (i.e., income at 10th and 90th percentile adjusted to U.S. dollars [28]). The United States ranked first in income of the wealthy and 16th in income of the poor; the rich:poor ratio of 6 was by far the highest. Moreover, unlike other industrial societies, in the United States having children reduces income substantially, and essential services such as medical care and support for children while their parents seek education or employment are not universally available (19, 28). The dimensions of this neglect “are spelled out in the growth of children” (8). The data presented in this chapter show that poverty has both direct effects on food intake and nutritional status and indirect affects through the use of drugs, alcohol, and tobacco.

UNDERNUTRITION AS AN INDICATOR OF POVERTY

Measures used to determine the nutritional status of individuals must be distinguished from those applicable to communities (29). Poverty is associated with poor growth and other clinical signs of malnutrition. For individuals, growth retardation may or may not be the result of undernutrition. However, when a disproportionate number of children in a community are growth retarded, fail to maintain linear growth, or are anemic, it is reasonable to assume that the community provides a suboptimal environment, with undernutrition as its most predictable outcome (29, 30).

Assessing Growth Retardation

Systems commonly used for assessing growth retardation are (a) weight adjusted for age (from Gomez) (29), (b) weight adjusted for height or, below 2 years of age, for length assessed simultaneously with height adjusted for age (from Waterlow) (30), (c) that from McLaren and Reed, commonly used in clinical practice, which considers actual weight as a percentage of ideal weight for actual height (31). Though effective in determining the degree of protein-energy malnutrition in individual children, this last method is rarely used to assess nutritional status in the community.

Under 5 years of age, weight for age combined with dietary surveys of the community and a careful diet and social history of the affected child provides the most sensitive indicators of deprivation (29). For example, in 1951, Widdowson (32) observed that a group of maltreated but well-fed German children living in an orphanage failed to grow

as well as nurtured children with marginal diet in similar circumstances. Subsequently, Powell et al. (33) suggested impairment of the hypothalamic-pituitary axis as the cause. Recently, Skuse et al. (34) have documented growth hormone deficiency in growth-retarded children with excellent appetites living in stressful home situations.

Weight for age is an exquisitely sensitive indicator of disruptions in feeding and (unlike assessments that depend on measures of length or height) does not require extensive training to obtain accuracy. By contrast, as Gopalan writes, “Heights (or lengths) for age in children are more difficult to measure accurately, and height measurements are less sensitive to dietary deprivation” (29). Weight is the first parameter to change, and with longitudinal assessments, the age at which growth failure occurs tells investigators when disruption of nutrition or nurture occurs (3, 4, 29, 31). Data from the Pediatric National Nutrition Surveillance Survey (PedNSS), a poverty-weighted sample, show that 70% of low-birth-weight (LBW) babies are stunted at 3 months of age, and 30% at 1 to 2 years of age, compared with 10% of normal-weight infants at these later ages (4).

For older children, the Waterlow system considers height for age and weight for length (or height), first separately and then together as shown in Table 60.1 (30). “Wasting” (decreased weight for length or height) is associated with acute malnutrition and is distinguished from “stunting” (decreased length or height for age), seen with chronic malnutrition. This system is based on a standardized normal distribution using z-scores in which the 5th percentile is two standard deviation units below the mean. Stunted children at the 5th percentile have a height that is approximately 90% of the mean height for children of the same age and sex. Stunted growth with normalization of weight/height ratio has been misrepresented as an indicator of “nutritional adaptation” (29, 30), but children in developing countries who are either wasted or stunted are at greater risk from death from infection than children with neither wasting nor stunting (30). In the United States, growth retardation is associated with delayed neurodevelopment and school failure (3, 4, 35). Thus, of all measures of nutritional status for older children, none surpass “the great value of height measurements as an instrument for monitoring progress with respect to the state of health, nutrition and well being of communities” (29).

	Length or height for age and sex		
	Normal range	Normal	<5th percentile
Weight for length or height and sex	Normal range	Normal	Stunting (chronic PEM)
	<5th %ile	Wasting (acute PEM)	Both acute and chronic PEM

Data from Martorell R. Child growth retardation: a discussion of its causes and its relationship to health. In: Blaxter K, Waterlow JC, eds. Nutritional adaptation in man. London: John Libby, 1980,13-30.

Table 60.1 The Waterlow System for Classification and Definition of Protein-Energy

Malnutrition

Short stature in early life may be accounted for by decreased birth length; and perhaps half of all LBW children with concomitant decreased length never completely achieve “catch-up” in linear growth (4, 36). The growth of small children is heavily influenced by multiple factors including the in utero environment, duration and quality of breast feeding, appropriate use of formula substitute, introduction of transitional food (beikost) at 4 to 6 months of age, and transitions to toddler and adult diets by 2 to 3 years of age (29).

In the United States, studies of children conducted in the 1960s showed consistent correlation among income and weight, height, and hemoglobin level (3, 4). Data for 1986 from the PedNSS showed a consistent decrease in weight for age as well as short stature for poor children under 5 years old of all racial and ethnic backgrounds (4). These data were supported by findings by Scholl and colleagues in Camden, NJ, where the white-poor (37) and abused children of any ethnicity (38) were most likely to demonstrate both wasting and stunting. Using data from the National Longitudinal Survey of Youth, Miller and Korenman showed that poverty affects the growth rate. Height for age was significantly lower among poor children than among average- and above-average-income children (4).

HOW POVERTY LEADS TO MALNUTRITION

Living in poverty means having economic resources below those needed to “obtain a minimally adequate standard of living” and/or essential goods and services (39). Simply stated, the poor cannot possibly enter the mainstream of American life and become self-supporting without an adequate income, capital, or other resources such as land inheritance or kinship networks available to them (39, 40, 41 and 42).

Defining Poverty

For over 40 years, the United States has used an absolute definition of poverty—“an income three times the value of a low cost diet for a family unit” (39). This definition originated with the need to provide economic support for the miner's widow or an incapacitated worker. It assumes economic dependency. Many in the United States have beliefs about the cause of poverty that tend to distinguish between people who deserve support and those who do not on the basis of how well they harbor their resources and how they behave (40, 41, 42 and 42a). This view fails to recognize that for the poor, behavior is shaped by the power of an environment they are unable to change (42a, 43 and 44). Thus, the poor must prove their worth by higher rational and moral behavior than is required of people with higher incomes (42a, 43).

Recently, it was suggested that a relative definition of poverty should replace the absolute standard so that a recipient of support would have sufficient resources to

escape dependency and enter the work force (39). The relativist model recognizes that financial resources are needed not simply to survive (food and housing) but also to work (cost of education, health care, clothing, day care, and transportation). With this model, the percentage of family income from employment or from unearned income is almost identical for poor and nonpoor alike so total income, with supports included, is the key difference (39).

Prevalence of Poverty

In the United States, almost 18 million (22.7%) of the 62.3 million children under 18 years of age live in poverty (2). Data from the 1993 U.S. Census reports show that the numerical majority of poor are white (9.75 million children; 9.4% of total for category); 5.12 million children (46.1%) of African American ancestry and 3.87 million (40.9%) of Hispanic ancestry are similarly affected.

Cipro and Michael recommended “that the poverty threshold concept apply to a reference family of two adults and two children” with threshold adjusted for families with special needs (39). The current poverty level income for this reference family is \$14,306. They note, however, that the reference family is no longer predominant in the United States; one-adult households (25%) are most common, parents without children (22%) are second, and the two parent/two child reference (13%) is the third most common. As shown in Table 60.2, 9% of children in reference families live in poverty, with a rise from 25% to almost all children living in single-parent families of five or more; 48% of families with two children and one adult and 65% of three-children families with a single parent live in poverty (2).

Ratio = families living in poverty with children under 18 years (All in 1000s)							
	Number of Children						
	7	6	5	4	3	2	1
One adult	.15	30	74	294	690	1220	1321
Percentage of these families in poverty	100	94	95	84	65	48	37
Two adults	.47	25	101	253	581	825	578
Percentage of these families in poverty	70	37	41	25	15	9	7

^aFor one adult/three child families, the poverty level is \$14,705/year, compared with \$11,602 for one adult/two child families, and \$14,654 for reference families with two adults and two children (from Census data (2)).

Table 60.2 Children under 18 Years of Age in Families Living in Poverty^a

The “New Approach” adjustment applied to single-parent two-child families would not shift them from poor to nonpoor if they were receiving aid-to-dependent families support (39). However, a parent who was working at a full-time job with the full range of deductions and had a need to pay for child care, work expenses, and out-of-pocket

medical expenses would be recategorized as “poor” (39). Similarly, poverty status would not be changed for a similar family with a farm worker as head of household in the rural Midwest as opposed to a city-living family where the cost of living is thought to be higher. This may be an idealized view of the rural poor. In some areas, food costs are high, as is transportation for persons, goods, and services. Land is often unavailable, housing stock is expensive to rent and often deteriorated, and poor families lack the capital or credit rating to buy or rehabilitate a home.

Influence of Food Costs on Dietary Adequacy

An obvious need for poor and nonpoor alike is sufficient income to purchase food. Under pressure of rising food costs or decreasing income, food selection narrows to items containing the most energy at lowest cost (46, 47). Malnutrition ensues. This observation, called “Engels' Law” (46) from a description of eating patterns of English workers from the mid-19th century, is similar to one by Joseph Goldberger's in the rural American South at the turn of the 20th century (48). Goldberger “was well aware that pellagra was a problem of poverty and that only improvement in economic conditions would eradicate the disease” (48). More recently, evidence of iron deficiency anemia following a rise in food costs (47) and growth retardation associated with high housing costs (10) provide examples of Engels' law at work among innercity poor children.

Until recently, equal parts dairy products, meat, cereal grains, and fruits and vegetables—the “four food groups”—was the model for good nutrition, with a substantial contribution from fat to daily caloric intake (12). Recently, however, the model for good nutrition has been changed to a “food pyramid” that mimics the traditional low-income diet with its high cereal grain content but increases cost by recommending substantially more fruit (2–4 servings) and vegetables (3–5 servings) each day, with the hope of preventing the degenerative diseases of adult life. A poverty-weighted national sample of 3148 children 2 to 18 years old taken from the 1989–1991 Continuing Survey of Food Intakes by Individuals (CSFII) showed insufficient consumption of fruits and vegetables, with 25% of their intake of vegetables as french-fried potatoes.

Krebs-Smith et al. (12) compared the daily food intake of children from the poorest families (household incomes <\$10,000/year) with that of children from the wealthiest families (>\$50,000/year). They showed that 59.6% of the poorest children consumed less than one serving of fruit each day, compared with 46.5% of children from the wealthiest families. Moreover, the diet of poor children was less likely to contain the recommended five servings of fruits and vegetables (16.3 vs. 24.5%). Intake by the poor met the old standard from “four food groups” for fruits and vegetables but not the new standard. Of note, a minority of children in the United States meet the new standard, regardless of income (12).

Iron deficiency anemia affects the poor disproportionately because as incomes fall, food consumption narrows to those foods containing the most energy at the lowest cost (46). If this process continues long enough, essential nutrients disappear from the diet, and in the United States, iron deficiency occurs (47). As with growth retardation, this difference is documented in both national surveys and local studies. Using confirmatory biochemical markers to avoid overdiagnosing iron deficiency as the cause for anemia,

the Second National Health and Nutrition Examination Survey (NHANES) of 1976–80 showed that 20.6% of children 1 to 2 years of age from families living below the poverty level had iron deficiency, compared with 6.7% for nonpoor children (49). For children 3 to 4 years of age, the difference is 9.7% compared with 2.5%. Older children take in more calories and thus more iron. These differences by economic status disappear until girls reach adolescence, when iron requirements increase. As shown in NHANES II, the values are 8.2% and 2.8% for poor and nonpoor teenage girls, respectively. All comparisons are highly significant (49).

Influence of Food Choices

Economics alone do not determine the nutritional status of individual children in a family or community. Parental beliefs and practices profoundly affect how much and what kind of food is brought into the family as well as the allocation to each member (29, 50) (see also Chapter 107). Gopalan writes, “differences in the nature of intrafamilial distribution of food, in particular in infant feeding and child-rearing practices, between the families and between communities can result in important differences with nutritional status (especially of children) between households, and between communities with nearly similar overall levels of dietary inadequacy” (29). Variables to be considered include the use of breast-feeding (how long and how well), use of appropriate formulas as a substitute, and the use and choice of beikost (29, 30 and 31). Issues of parental competence, age, spacing and health of siblings, and the presence of drugs, alcohol, and tobacco affect a child's growth (51).

An important variable is the relationship that forms between the mother and the affected infant or child. Three studies in the United States (Pollitt [52], Karp et al. [53], and Casey et al. [54]) document that malnutrition is not an isolated occurrence in the families of undernourished children. In each of these studies, relationships between mothers and undernourished children were less effective than those in families with similar incomes and education and well-nourished children. In the study by Karp et al. (53), the families with an excessive use of low-nutritional-value foods ate predominantly convenience foods.

The use of convenience foods, characteristic of contemporary general food consumption patterns in the United States, illustrates how the Engels' phenomenon affects the poor. Cheaper convenience foods have lower nutrient density (high fat or sugar content) than the more expensive nutritious ones (46). A cereal grain, legume, plus a little meat diet, as recommended by the U.S. Department of Agriculture in its “Low Cost Food Plan” (LCFP), can be obtained within the allotment, but to achieve savings, families need an adult at home who can prepare food and a supermarket with low-cost staples (46). Some parents—the homeless or indigent, those living in motel rooms or in migrant labor camps—may have no alternative to convenience foods. They may be quite willing to purchase nutritious foods and prepare and distribute them to their children but are hampered by their circumstances. Their indigenous food preferences may be unique, and preferred nutritious food choices may be unavailable (46).

Thus, in the context of chronic poverty, what we see as “food choice” is a highly

complex phenomenon influenced by the cost and availability of food and the dynamics of the family. These and related issues are discussed in greater detail in [Chapter 107](#).

UNDERNUTRITION AND LEARNING FAILURE

In the United States, children from the poorest and least-educated families consistently perform poorly on measures of cognitive ability ([5](#), [21](#), [23](#), [27](#)). This section addresses links between nutrition and the environmental experience that underlies education. How children experience their environment predicts the effects of poverty better than family income or parental educational level alone ([27](#)). These standard measures of socioeconomic status are too broad to label the capability of individuals within any of these groups ([27](#)).

HISTORICAL PERSPECTIVE: HEREDITY, ENVIRONMENT, OR NUTRITION?

At the turn of the 20th century, examples of transgenerational mental retardation were widely represented by two socially dysfunctional families—the Jukes of New York State and the Kallikaks from central New Jersey ([1](#), [55](#), [56](#), [57](#) and [58](#)). The use to which their history (e.g., heredity) was put ([1](#), [58](#)) illustrates the failings of a main-effect model—heredity or environment or nutrition—as the cause for learning failure ([27](#)).

In 1877, Richard Dugdale recognized the interaction between heredity and environment among the Jukes. “In idiocy and insanity,” notes Dugdale ([56](#)), “heredity is the preponderating factor in determining career; but it is, even then, capable of marked modification for better or worse by the character of the environment.” Recognition that alcohol has toxic in utero effect is not new ([26](#)). The conceptual framework for a “fetal alcohol syndrome” (FAS) was stated by Elisha Harris in Dugdale’s 1876 description of the Jukes ([56](#)), and Dugdale noted the possibility of in utero effects of alcohol affecting the future viability and function of exposed children ([56](#)). In 1899, two British police surgeons, Sullivan and Scholar ([59](#)) effectively separated the consequence of living in families of alcoholic mothers from that of in utero exposure in their classic study of incarcerated alcoholic women. The infants of alcoholic women imprisoned during pregnancy were less likely to have epilepsy than were siblings born to the same women living (and drinking) freely.

Fifteen years later, Henry H. Goddard, director of the Vineland Training School for Feeble-Minded Boys and Girls in New Jersey, failed to recognize the potential effect of alcohol. He believed that no amount of education or good environment could change a feeble-minded individual into a normal one ([57](#)). Pauline “Kallikak,” a 19-year-old girl was photographed in 1911 as part of a series of studies of mentally retarded children conducted at Vineland ([1](#), [57](#), [58](#)). Goddard was fully aware of the alcoholism in this family. He found siblings of mentally retarded children of “drunkard” parents to be 63% more likely to be judged retarded than those of “nondrunkard” parents ([57](#)). Contemporary reanalysis of these data shows the difference to be statistically significant ([58](#)). While these findings might reflect the consequence of living in a family affected by alcoholism, Pauline’s photograph reveals the characteristic features of FAS, a

consequence of in utero alcohol exposure ([26](#), [58](#)) ([Fig. 60.1](#)).

SIMPLE CAUSES: BRAIN GROWTH AND CENTRAL NERVOUS SYSTEM EFFECTS

From 1920 to 1940, it was recognized that there are critical periods in a child's development during which malnutrition affects intellectual achievement ([5](#), [6](#) and [7](#), [60](#)). By the 1960s, nutrition, separate from environment, was shown to affect cellular and metabolic changes in developing neural tissues, and attempts were made to use nutrition influences rather than multifactorial explanations for behavioral consequences ([5](#), [6](#), [7](#), [61](#), [62](#) and [63](#)).

A “Brain Growth and/or C.N.S. Effects” model for assessing the consequences of malnutrition, shown as [Figure 60.2](#), was developed by Winick and Rosso ([61](#)) from the work of Cravioto et al. ([62](#)) and his own studies of starved pregnant rats and newborn pups ([61](#)). This model was supported by observation of marked decreases in brain weight and DNA content in infants dying of protein-energy malnutrition with decreased head circumference and developmental delay in survivors ([60](#), [61](#)).

SIMPLE CAUSES

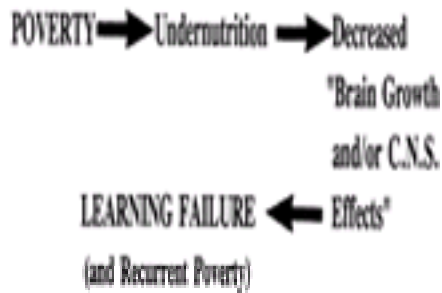

Figure 60.2. “Brain Growth and/or C.N.S. Effects” model for assessing the consequences of malnutrition.

Thus, in the 1960s, it was suggested that retarded mental development was caused by permanent cellular changes induced by early undernutrition (60, 61). Oski was among the first to suggest that learning problems associated with iron deficiency were mediated by lack of iron availability for formation of specific structures and/or key enzyme systems in the central nervous system (CNS) (23). His case-controlled studies of children from impoverished northcentral Philadelphia found that intellectual performance was directly linked to iron status after controlling for other factors (23). In Oski's first study of 12- to 14-year-old junior high school students in northcentral Philadelphia, 92 iron-deficient children were compared with 101 nonanemic controls. A composite measure of intellectual accomplishment showed increasing differences with age between anemic and nonanemic children for both boys and girls. In Oski's second study, 38 anemic and nonanemic boys were matched. Significant differences were found for “Conduct Problems” for older anemic boys, whereas scales for “Personality Disturbances and Inadequacy-Immaturity” showed no significant differences. Oski postulated that behavior is affected by (a) deficiencies in iron-catalyzed CNS monoamine and cytochrome oxidase systems, (b) decreased iron stores in brainstem nuclei, and (c) effects on the g-aminobutyric acid system in the CNS (22, 23, 63). This theory has been supported by the work of Brown and Pollitt, who writes “even at the very early stages of iron deficiency, a decrement in iron-dependent dopamine D2 receptors alters dopamine neurotransmission in the cortex, which in turn, impairs cognitive function” (6).

Neurotransmitter activity in the CNS is a direct function of the severity of iron deficiency, the decrease in hemoglobin levels (63). Studies in Latin America have shown minimal effects on learning with mild iron depletion (decreased ferritin level) and iron deficiency without anemia (decreased serum iron and percentage saturation). Learning failure occurs only in the last phase of iron deficiency in the presence of anemia. Inability to transport oxygen limits a child's ability to sustain motor activity (63), which is critical for learning by exploration and repetition (63, 64 and 65). As appealing and elegant as the simple model seems, a contemporary conceptualization is that the interaction between

nutrition and environment is more important than either taken alone ([5](#), [6](#) and [7](#), [27](#)).

HOW NUTRITION AFFECTS LEARNING

Parallel to its direct CNS effects, malnutrition contributes to learning failure by affecting transitions, transactions, and the way children experience their environment. Because of the transitional nature of learning, cumulative learning failure results when critical phases in neurodevelopment are missed. Malnourished children are often developmentally unprepared to benefit from age-appropriate educational experiences ([27](#), [64](#), [65](#)). The transactions between malnourished children and their adult caregivers fail to satisfy the emotional needs of either the children or the adults. Malnourished infants' and children's lack of attention and responsiveness to social stimuli, along with their inability to elicit responses from others ([27](#), [64](#), [65](#)), undermine the enthusiasm of parents and teachers alike. These children are “temperamentally different from well nourished ones and will be treated so during the toddler and preschool years” ([64](#)). These consequences of malnutrition lead children to learn (i.e., to receive, process, comprehend, and transmit information and concepts) differently from well-nourished ones, and this is termed the experience of environment ([27](#)). Learning experiences throughout life and the likelihood of reward for success are affected ([27](#), [64](#), [65](#) and [66](#)).

Unless parents living in poverty are taught how to respond to the special needs of malnourished children, the children's learning and nutrition will continue to cycle downward. Working with poor children in Providence, Rhode Island, Sameroff and Chandler ([67](#)) recognized that the variability in outcome of birth weight in medically compromised infants was a function of the “cluster effects” of multiple consequences of poverty. The transactional model for learning described below derives from their work.

Environment As a Cofactor

The effects of malnutrition must always be considered in the context of the particular social environment with or without evidence of direct toxic consequences of malnutrition ([5](#), [6](#) and [7](#), [21](#), [22](#), [27](#)). Ineffective relationships within families and between parents and children affect the growth of poor children. Other family members are frequently undernourished ([68](#)). The pattern of single parenthood without a support system is common ([1](#), [40](#), [41](#) and [42](#)). Medical, social, and educational resources are often inadequately available and used ([1](#), [41](#)). Delayed entry into school and poor attendance are likely ([69](#)). Often, the reduced somatic growth used to define malnutrition reflects the concomitant effects of iron and zinc deficiency ([5](#), [6](#) and [7](#)), inadequate caloric intake ([5](#), [6](#), [27](#)), exposure to lead ([24](#), [70](#)), and to alcohol and drugs in utero ([25](#), [26](#)).

Life in Northcentral Philadelphia

Data collected in northcentral Philadelphia document the deteriorated social environment in which Oski worked. Northcentral Philadelphia is among the poorest urban sections in the United States ([23](#)). In 1975 and at present, over 70% of families with school children have incomes below the poverty level. In 1975, 17.2% of infants were of low birth weight or premature (vs. 15.6% in 1993); 64.4% of infants were born to

unmarried mothers (85.6% in 1993); neonatal mortality (deaths under 1 month of age) was 23.8/1000 live births (9.5 in 1993); infant mortality (deaths under 1 year of age) was 36.6/1000 live births (18.1 in 1993). Though mortality figures have improved, these rates remain two to three times those for the United States.

Studies at the Pratt-Arnold school, a northcentral Philadelphia elementary school, showed that malnourished children were more likely to live on numbered (long-running, heavy traffic, no trees, and deteriorated housing) rather than named (short-running, little traffic, and tree lined) streets. These differences in condition of housing stock and quality of life on the streets of northcentral Philadelphia reflect the interaction between undernutrition and the environment that produces it.

At Pratt-Arnold, children with decreased height-for-age (stunting) were older than their classmates, reflecting delayed entry into school, another indicator of ineffective nurturing likely to diminish both school performance and nutritional status (5, 6 and 7, 69). The undernourished children appeared to be of “normal” size and performance by grade (but not by age), compared with their younger class-mates. Looking younger than their chronologic age, note Brown and Pollitt, would cause adults “to treat them as if they were younger than their actual age. Such a response would very likely slow cognitive development” (6). As in developing countries, these stunted children seem normal for their height/age because of the close parallel between height/age and social and intellectual development. Yet they are retarded compared with well-nourished children of the same age.

The growth-retarded children at Pratt-Arnold school had measures of perception and motor development that reflected height-age better than chronologic age (5, 21). Their height-age correlated with reading level when there was associated anemia or muscle wasting. With normal hemoglobin level and muscle mass, height and reading level were unrelated, suggesting the influence of undernutrition-associated short stature on learning (71). As Pollitt notes, the impact of various nutritional deprivations (linear growth, weight, anemia, muscle mass) occurring together is more important than an individual nutritional deprivation acting alone (72). The cluster effects of nutritional and nonnutritional influences (lead, drug, alcohol, and tobacco exposure) seem to have similar effects as cluster effects of poverty (67).

At Pratt-Arnold, nutritional status, cognitive function, and neurodevelopment were measured, along with a composite measure of school achievement. Using stepwise regression (age factored out), the data demonstrated that gradations in all anthropometric measures were significantly related to rising achievement scores, but anthropometric variables correlated better with academic achievement than with measures of cognitive ability or neurodevelopment (5, 21). This suggests common antecedents for undernutrition and learning failure—the cluster effects of poverty and consequences of failed mother/child interaction—affecting school achievement. Thus, for undernourished children, growth, nonverbal aspects of neurodevelopment, and learning seem to be on a “slow track.”

Anthropometric variables were not significantly related to nonverbal measures of cognitive ability, suggesting that the protein-energy deprivation the children at the low

end of the anthropometric scale was not significant enough to cause damage to basic cognitive processes (27). These findings explain in part why undernourished children who have been adopted into homes where they are well fed and well nurtured are better achievers in school, even when growth continues to be somewhat slow (73), and why early intervention aids the development of low- and normal-weight infants in families with limited parental education (74, 75 and 76).

Effective Interventions

Following his studies of surviving, impoverished, and starved infants left to grow in deprivation, Winick examined formerly undernourished children from Korea adopted into middle-class and professional families in the United States. He found that children adopted before 3 years of age had subsequent I.Q. scores higher than the U.S. norm but lower than their nonadopted American siblings (73). Two large, multicenter studies that included disadvantaged innercity children of all races and ethnicities showed the effectiveness of concomitant nutritional and social intervention for LBW infants in multiple centers (74, 75 and 76). In both studies, a substantial number of the children came from families with incomes below the poverty level.

According to Susser (77), proof of effectiveness requires temporal linearity, with undernutrition and learning failure followed by intervention, followed by recovery of normal nutritional status and learning ability. The intervention studies conducted in the United States fail Susser's stringent test, because linear growth is not universally recovered; perhaps one cannot expect LBW infants, especially those with simultaneous failure of linear growth to completely recover (36, 66, 66a). These studies do, however, quite effectively improve academic potential (66a). In 1990, the Infant Health and Development Program reported substantial increases in I.Q. for "socially disadvantaged" LBW premature children at a corrected age of 36 months, ranging from 6.5 points in the lightest infants to 13.2 in heavier ones (75). The intervention groups were all heavier and longer, but differences did not reach statistical significance. A contemporary review of children receiving nutritional supplements notes that infants with low birth weights are "likely to remain shorter and lighter throughout childhood, especially those who were intrauterine growth retarded rather than premature" (36, 76).

Consequences of Complacency

Iron deficiency, growth retardation, in utero exposure to alcohol or smoking, and lead poisoning cause downward shifts in the mean for any measure of behavior or learning (commonly assessed by I.Q.) of approximately 5 points (24). The effect of lead poisoning on intellectual development are shown in [Figure 60.3](#).

Figure 60.3. Effect of lead poisoning on intellectual development. (From Harris P, Clarke M, Karp RJ. The prevention of lead poisoning in disadvantaged children. In: Karp RJ, ed. Malnourished children in the United States: caught in the cycle of poverty. New York: Springer, 1993;91–100, with permission.)

Lead poisoning, a common occurrence in the “lead belt” neighborhoods of many innercities, mainly affects African American children, many of whom are iron deficient and growth retarded (24, 70). Lead and nutrition interact in three ways: (a) iron and other divalent cation deficiencies enhance lead absorption, (b) markers for iron deficiency are affected by concomitant lead poisoning, and (c) lead's unique effects on CNS functions compound other effects of undernutrition. Lead and iron deficiency each contribute independently to learning failure among children (78). The phenomenon illustrated by the two curves in Figure 60.3 could represent iron deficiency alone; however, when these conditions coexist, children are four times more likely to show behavioral symptoms usually attributed to lead poisoning alone (70, 78).

This result may have little effect on the life of an individual child, but in communities, it disqualifies all children for programs designed for the mentally gifted while greatly expanding the need for services to children with mild mental retardation. In impoverished communities, classes for the mentally gifted (I.Q. two standard deviations above the mean [>130]) are almost empty, while classes for children who are mild mentally retarded (I.Q. two standard deviations below the mean [<70]) are filled to capacity (5). It may be comforting in a peculiar way to maintain discredited racial explanations for these findings (6, 7, 27) because they allow societal or personal inaction; however, the general success of interventions that are given time to work (73, 74, 75 and 76) provide the best challenge to their validity. Simply stated, there are no effects of race and social class on the inherent capabilities of children. Of note, as shown in NHANES III, an estimated 1.7 million (almost 9%) children between 1 and 5 years of age have blood lead levels above $10 \mu g/dL$, the level at which lead effects are noted for small children (79, 79a).

An Ecology of Poverty, Malnutrition, and Learning Failure

Figure 60.4 shows an ecology of poverty, undernutrition, and learning failure (21) and suggests that learning failure is contingent on an interaction between social environment and nutrition. In developed countries, the prevalence and consequences of malnutrition in young children are related so closely to chronic poverty that one can only rarely distinguish the consequences of malnutrition from the consequences of living in the milieu in which it occurs. Giving food and micronutrients to nutritionally and socially deprived children without correcting their environment is unlikely, in the long run, to have any great effect on learning. Rather, combined social and nutritional intervention is more effective than either intervention alone (5, 6, 73, 74, 75 and 76).

Figure 60.4. An ecology of poverty, undernutrition and learning failure. (From Sewell TE, Price VD, Karp RJ. The ecology of poverty undernutrition and learning failure. In: Karp RJ, ed. Malnourished children in the United States: caught in the cycle of poverty. New York: Springer, 1993;24–30, with permission, and derived from the work of Cravioto, DeLicardie, and Birch [62] and Hallberg [7].)

NUTRITION-DRUG INTERACTIONS AND THEIR EFFECTS

Drug Abuse Increased by Poverty

Chronic poverty is associated with a sustained disproportionate use of both legal (tobacco and alcohol) (25, 80, 81) and illegal addictive mood-altering substances (marijuana, cocaine, and heroin) (25, 82). Alcohol, tobacco, and other drugs of abuse affect nutritional status in direct relation to duration of use (83, 84) (see Chapter 67). There are populations living in seemingly hopeless circumstances in which the prevalence and consequences of alcoholism are disproportionately high. These include Native Americans living on desolate reservations (an estimated 25% of infants are born with FAS), poor whites in decaying industrial cities (10% of school children with FAS in one town) (85), and inner-city, black families.

Particularly problematic is drug use during pregnancy. Among women of childbearing age, poverty engenders chronic depression (86) increasing the risk for drug abuse during pregnancy with concomitant increased risk for teratogenesis (87). As illustrated by studies of alcoholic mothers and children, there is a substantial variability in outcome for children exposed to drugs in utero (25, 87). To an extent that is not yet well determined, maternal nutrition and alcohol intake contribute to these differences. (83, 84, see Chapter 67) While there are severe consequences to the fetus from exposure to illicit drugs, the risks from alcohol consumption and smoking tobacco during pregnancy are better defined and more widespread (25, 26). Moreover, for people living in poverty, illicit drug use is unusual in a woman who neither smokes nor drinks alcohol. (The sum of research on in utero effects suggests that the order of biologic consequence is alcohol greater than tobacco greater than drugs, but punishments for sale and use of these substances are just the reverse.)

Prevalence and Consequences of Drug, Alcohol, and Tobacco Use

Alcohol

Alcohol produces a characteristic dysmorphism deriving from altered CNS growth and function. Children with FAS show midface hypoplasia, short palpebral fissures, increased distance from the base of the nose to the upper lip, absent philtrum, and narrow vermilion border of the upper lip (26, 85) (Fig. 60.1). There is concomitant growth retardation at birth with failure to “catch-up” and persistent neurodevelopmental problems. Infants born to drinking mothers have CNS depression and withdrawal syndrome (85). Alcohol-related problems after birth are common, even without the full syndrome, because drinking severely hampers parental effectiveness. Recent data show that 4.4% of 21- to 30-year-old women have two or more drinks each day, and the percentage drops to 3.5% for ages 31 to 40 years (81). Chronic abuse, as opposed to binge drinking, is characteristic of older women. Abuse and dependency are less common among black women (2.88%) (81), but with respect to FAS, race along with age, parity, and length of alcohol use is an independent risk factor (82).

Specific alcohol/nutrition interactions likely to increase in utero effects include (a) decreased gastric alcohol dehydrogenase levels with age, allowing higher blood alcohol levels, (b) maternal loss of zinc and magnesium, (c) diminution of antioxidant nutrients, and (d) failure in hepatic degradation, allowing potentially toxic substances and metabolites to affect the fetus (83, 84) (see Chapter 67).

Hepatic dysfunction associated with chronic alcoholism alters the detoxification process for other drugs of abuse as well as for environmental pollutants, allowing toxic metabolites to reach the fetus. A contemporary view, from Lieber, is that “at cellular, biochemical and molecular levels, the nutritional and toxic effects of alcohol converge” (83). Thus, polydrug abuse concomitant to aging of mothers creates a nutrient-deprived in utero environment that increases the risk for teratogenic consequences of drug exposure on the growing fetus (81, 83, 84). A model for teratogen x malnutrition effects, derived from the work of Lieber (83), is shown in Figure 60.5.

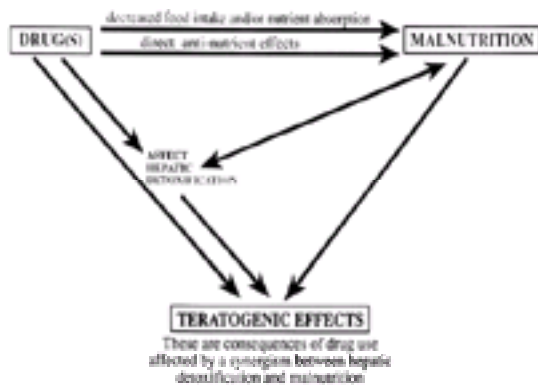

Figure 60.5. A model for teratogen [x] malnutrition effects. (From Leiber CS. *Am J Clin Nutr* 1993;58:430–42, with permission.)

Tobacco

The principal in utero consequence of smoking tobacco, growth retardation, is directly proportional to the number of cigarettes smoked per day (82). The decrease in mean birth weight for infants born to tobacco-smoking mothers is approximately 200 g, with a concomitant increase in infant morbidity and mortality above that expected from a simple shift to the left on birth weight–mortality curves (82, 87). The pattern of growth retardation tends to be symmetric, with all anthropometric measures—weight, length, and head circumference—affected equally. This pattern has been associated with failure to achieve catch-up growth and developmental delay (74). Specific smoking effects on the fetus or on the infant include (a) placental arterial spasm, (b) carbon monoxide binding of hemoglobin, (c) decreased maternal intake, and (d) reduced levels of ascorbic acid from the oxidative stress of both passive and active smoking (82, 87). Barker has provided epidemiologic data suggesting that much of the degenerative disease associated with smoking is caused by exposure in utero and during the first year of life (88). Lucas distinguishes between toxic effects of early nutritional deprivation and factors affecting perinatal health and infant nutritional status that reestablish themselves in childhood to influence the onset of cardiovascular disease (89). Recent studies show that smoking during pregnancy affects uterine artery spasm and blood pressures of infants, lasting through the first year (90), as well as older children exposed during the last trimester of pregnancy (91).

In the United States, tobacco use is more common among those with limited education and limited income (92); 35 to 40% of adults with a 12th grade education or less and income near or at the poverty level smoke, compared with approximately 20% of adults with more than 2 years of college education and an upper-middle income (93). Tobacco companies have been effective recently in reaching teenagers with special emphasis on recruiting African American and Hispanic adolescents, poorly educated boys of all

rac^{es}/ethnicities, and all girls (93).

Smoking and dietary inadequacies maintained into adult life are significant alterable contributors to the shortened life expectancies of the poor in this country (92). Data from Framingham show that 55% of attributable risk for coronary heart disease (CHD) before 55 years of age is from smoking. Data collected in the Multiple Risk Factor Intervention Trial (MRFIT) show a disproportional increase in CHD risk with smoking (94). At the highest quintile of serum total cholesterol in the MRFIT study (>240 mg/dL), concomitant hypertension (diastolic blood pressure > 90 mm Hg) with no smoking was associated with a 3.5-fold increase in CHD mortality, but for those in the third (200 mg/dL) and fourth (220 mg/dL) quintiles who smoked, CHD mortality increased approximately sixfold. Smoking transformed midlevel risk for CHD mortality to a risk greater than that for a hypercholesterolemic person who did not smoke (94). Data collected from 300 of Brooklyn's most disadvantaged children with truncated families and very young grandparents suggest a greater incidence of CHD at a young age likely to be caused by the concomitant harmful effects of smoking and untreated hypertension (94).

Like alcohol, smoking promotes malnutrition in two ways: first, the diets of smokers are of lower nutritional value than those of nonsmokers, and second, smoking has direct antinutrient effects such as reduced vitamin C levels with passive smoking (95). Steinberg has suggested that decreased intake and increased use of antioxidant nutrients (vitamins C and E and retinoids) accelerate oxidation of low-density-lipoprotein cholesterol and alter the balance between clotting and antithrombotic activity unfavorably (96). However, attempts to prevent degenerative diseases among smokers by providing antioxidant nutrients have had mixed results, as illustrated by one Scandinavian study in which the occurrence of lung cancer increased among carotenoid-supplemented subjects (96).

Illicit Drugs

Marijuana. Marijuana use is fairly widespread, with use by women of childbearing age ranging from 10 to 25% (97). Crack cocaine use is currently an inner-city, African American phenomenon associated with polydrug use as well as sexually transmitted diseases and lack of prenatal care. Bell and Lau give prevalence rates for cocaine use by high school seniors ranging from 2 to 17% (97). Socioeconomic differences in usage patterns for illicit drugs vary according to pressures from peers, law enforcement, educational efforts, and simple experimentation with new drugs. Data on prevalence for illegal drugs are highly suspect, and studies of effects must always be read cautiously.

Cocaine. Cocaine is a powerful sympathomimetic that affects both placental function and the fetus directly throughout pregnancy. Moreover, cocaine, like alcohol, marijuana, amphetamines, and heroin, produces a withdrawal syndrome in exposed children. Polydrug use affects the severity and duration of withdrawal in affected infants (87, 97). Though specific "fetal cocaine" and "fetal marijuana syndromes" have been hypothesized, clear documentation is lacking. Some infants exposed to marijuana show the stigmata of FAS which may reflect a heightened susceptibility to alcohol among marijuana or polydrug users. Infants born to cocaine using mothers have multiple

perinatal complications including growth retardation and CNS bleeding. These children are often developmentally delayed and have seizure disorders. (82, 87, 97). Bell and Lau give prevalence rates for use by high school seniors ranging from 2 to 17% (97).

The principal effects on the fetus of cocaine use by the mother are symmetric growth retardation with reduced head circumference and premature delivery (87, 97, 98). In a recent study of 98 cocaine-exposed infants, Roizen et al. showed a significant developmental delay in these children compared with nonexposed controls, but this delay was predicted by the growth retardation concomitant to premature delivery and living in homes with drug-affected mothers or relatives rather than by cocaine exposure per se (98). Moreover, with respect to postnatal development (99) and growth (100), the social milieu in which cocaine use occurs (99) and concomitant alcohol and tobacco use during pregnancy (100) may be more important than the cocaine use. Again, these findings must be judged cautiously and in an environmental context.

IMPORTANCE OF PUBLIC POLICY: KEEPING NUTRITIOUS FOOD AVAILABLE TO THE POOR

Malnutrition as part of a “poverty syndrome” occurs in some poor families when society accepts the legitimacy of poverty and malnutrition (29). Chronic poverty involves more than lack of income, but mass poverty and malnutrition in society is caused by a nation's economic policy and the politics of entitlement (29, 43, 101). Policies that nurture and nourish children yield remarkable improvements in health and social stability. In the United States, the failure to implement policies supporting poor children and their families raises the question, “In what direction is our society going?”

The prevalence of malnutrition will depend on the depth of poverty to which society allows those with the least income and resources to sink (1). Failed or inadequate public policy predicts the prevalence of consequences of poverty, which include, of course, malnutrition. Which poor families are affected, however, depends on behavioral characteristics. Parents in affected families often lack the skills to nourish and nurture children. To resolve the problem of malnourished children in the United States, resources must be made available to provide nutritious food and to address the multiple interdependent problems faced by poor families. Support for the poorest in society begins with a broad base of support for everyone (29, 43, 101, 102). Otherwise, notes Chamberlin, “for every family whose functioning is improved by some kind of intensive intervention, several more medium-risk families will take their place as their life circumstances change” (102).

In the United States, provision of food stamps, school lunches and breakfasts, and the special program for Women, Infants and Children (WIC) has improved nutritional status both by providing nutritious food and by allowing the purchase of a higher quality diet with the same amount of money budgeted for food, thus effectively reversing Engels' law (46). These supports are often referred to as “welfare,” implying an unearned benefit to the recipient. Actually, these supports benefit children, who in developed societies are not responsible for their own support, and they benefit everyone by creating a healthy population able to learn, work, and earn. They do not create “welfare dependence” since supplemental programs provide essential food to working families and their children.

Contemporary food programs have never been shown to be a detriment to work. Rather, they are an alternative to the bread lines and soup kitchens of a post-Victorian era ([101](#)).

Childhood malnutrition in the context of poverty predicts various endpoints—learning failure, social dysfunction, increased risk for drug use, birth defects, and chronic illness later in life. While it is incorrect to maintain that any form of malnutrition is the solitary cause for recurrent poverty, ignorance, dysfunction, and disease, malnutrition in the context of poverty is a significant contributor to a self-sustaining system—an ecology of learning failure, poverty, and malnutrition ([1](#), [28](#)). These unfortunate outcomes are contingent on continued poverty and are concomitant to malnutrition. Yet, the poor in the United States live in social environments that are harsh and hostile rather than supportive, with substandard schools and an inadequate system for health care ([1](#), [4](#), [5](#), [19](#), [27](#), [40](#), [41](#), [42](#) and [43](#), [102](#)). The converging validity of data from various studies providing both nutritional supplementation and social support ([36](#), [66](#), [66a](#), [75](#), [76](#)) suggests that the rigor of Susser's criteria ([77](#)) should be tempered by the reality of effective interventions.

Eliminating poverty includes provision of food and structures of opportunity within which the poor can adapt and cope. Poor people must be treated as real individuals, not as caricatures of a defective culture. These calls for the investment of human and monetary resources may seem unrealistic, but the political unacceptability of effective policies should not cause us to “turn to politically acceptable formulas which provide no real solutions” ([43](#)).

GENETIC PERSPECTIVE

Geneticists approach the general subject of nutrition and the specific requirement for nutrients with the view that the recommended dietary allowance (RDA) for an essential nutrient is not optimum for all individuals. Rather, individuals in a population have genetically determined variations in their nutrient requirements that extend over a wide range. This concept arose historically from two older scientific disciplines: human biochemical genetics and nutrition science. The former discipline originated with Sir Archibald Garrod's Croonian lectures of 1908. Garrod defined four "inborn errors of metabolism" as blocks in the normal flow of metabolic processes. Biochemical and clinical expression of these metabolic blocks demonstrated patterns of inheritance consistent with Mendel's predictions for transmission of single genes with large effect on the phenotype. Thus arose the concept that genes controlled metabolism and that disease states were created by blocks in this metabolic flow, yielding accumulated precursors and deficient products.

Today, we recognize that "inborn errors" are discontinuous traits resulting from variation in the structure and function of enzymes or protein molecules. The amino acid

sequences of enzymes and their quantity are dictated by genes. The control of enzyme function is predicated by molecular regulation through gene transcription, posttranscriptional processing of RNA, translation, posttranslational modification, and protein turnover. Over 8000 monogenic human disorders are cataloged and available. Of these, about 300 have a defined biochemical basis (1). The extent of normal variation in genes controlling enzyme activity suggests that about 30% of our population is heterozygous for common alleles (2). Within this continuous diversity, mutations produce discontinuous, relatively rare traits that are expressed as disease under normal environmental conditions.

Mutant gene frequencies vary in populations; for example, mitochondrial branched-chain a-ketoacid dehydrogenase (BCKAD) deficiency (maple syrup urine disease) occurs in 1 of approximately every 250,000 newborns worldwide, but occurs in 1 of 176 in an inbred Mennonite population (3). The mutation is one of few that are not private to individual families. The Mennonite mutation is in the E1a gene and changes a tyrosine at position 194 to asparagine (Y302N). In the homozygous state, it produces extreme toxicity due to accumulated branched-chain a-ketoacids (BCKAs) if affected newborns are fed the RDA during rapid growth. However, normal growth and development are expected if dietary isoleucine, leucine, and valine are restricted to 20 to 40% of the RDA during rapid growth in year 1 of life (4, 5).

Considerable human variation occurs in the structure and activity of enzymes involved in the catabolism of essential amino acids, but only a few are so impaired that ingestion of the RDA creates severe disease. Population-based newborn screening and dietary intervention are now applied through public health programs to at least five rare inborn errors for which newborn screening predicts genetic susceptibility to a normal diet (6). By contrast to these relatively rare inborn errors, all humans lack the enzyme that converts L-gulonolactone to ascorbic acid, but scurvy does not occur if sufficient vitamin C is ingested and absorbed (7). Thus, the frequency of genetic susceptibility to a "normal" diet ranges from rare to common and extends to the metabolism of amino acids, carbohydrates, lipids, purines, pyrimidines, minerals, and vitamins.

GENETIC DISORDERS BENEFITED BY NUTRITIONAL SUPPORT

Over 300 genetic disorders have been reported in which toxic manifestations relate to accumulation, deficiency, or overproduction of normally occurring substrates and products of metabolic flow. In many of them, modifications of the dietary supply will alleviate the manifestations. In a large number, however, irreversible damage has already occurred by the time symptoms appear. Optimum management of these disorders depends on identifying affected subjects while they are presymptomatic or before irreversible disease has occurred. Because the disorders are genetic, markers are theoretically present from the moment of conception, and thus the genetic power of prediction and prevention is applicable. In practice, a number of disorders can be detected in the fetus in the 10th to 16th week of gestation by studies on chorionic villus or amniotic fluid cells. Prenatal diagnosis has been pushed forward to the 9th to 12th week of gestation through the use of chorionic villus biopsy (8). Some intrauterine sequelae of the inborn error, such as congenital cataracts in galactosemia, may be prevented by removing lactose from the mother's diet. Other inherited metabolic

alterations are detected postnatally in the presymptomatic infant by analysis of blood, urine, erythrocytes, leukocytes, or cultured skin fibroblasts.

A selective search for presymptomatic genetic disease is often undertaken when there is a family history of inherited disease. Selective screening for inherited disease is also initiated for relatively common symptoms such as failure to thrive in childhood. Early treatment has proved effective for many diseases such as phenylketonuria (PKU), galactosemia, isovaleric acidemia, homocystinuria, maple syrup urine disease (MSUD), argininosuccinic aciduria, and citrullinemia. Irreversible brain damage occurs if treatment is not initiated in PKU before the 3rd week of life. In MSUD, galactosemia, isovaleric acidemia, and disorders of the urea cycle, irreversible damage to the brain may occur within the 1st week of life. To prevent this, population-wide nonselective screening of newborns has been instituted for PKU, MSUD, galactosemia, homocystinuria, and tyrosinemia. Thus, speed in diagnosis and treatment is of the utmost importance in preventing a poor outcome.

In the future, population-based presymptomatic detection will be extended to other disorders. However, before screening is initiated as a public health program, several principles should be fulfilled ([Table 61.1](#)). Knowledge of the pathogenesis, preventability, and availability of therapy must precede initiation of routine screening programs. [Table 61.2](#) lists genetic disorders in which modification of nutrient intake has been employed. Effectiveness in preventing clinical sequelae is experimental in some of the therapies listed.

-
1. The disorder produces a high burden to the affected individual yet is preventable
 2. Methods for screening, retrieval, diagnosis, and management must be practical and available to the population as a whole
 3. Inheritance and pathogenesis of the disease should be understood
 4. Benefit:cost ratio of the program should be greater than one
 5. Patients' rights should be protected (including confidentiality and informed consent)
 6. False-negative laboratory screening results should not occur
 7. False-positive laboratory results should be minimized
-

Table 61.1 Criteria for Nonselective Newborn Screening

Table 61.2 Nutritional Treatment of Genetic Disorders

Although many patients with inherited disorders benefit from nutritional support, each would require a chapter for adequate discussion. Thus, this chapter emphasizes disorders for which population-based screening, retrieval, diagnosis, and nutritional support are available to prevent their irreversible, severe pathologic problems.

GENERAL PRINCIPLES OF GENETIC DISEASE MANAGEMENT

Specific enzymes produced under the direction of individual genes catalyze specific reactions as noted in the following genetic and metabolic sequences. A is converted to D through intermediates B and C using enzymes AB, BC, and CD:

If enzyme CD were genetically impaired, at least six pathophysiologic consequences might occur:

1. Deficiency of product D. For example, in PKU, when phenylalanine is not hydroxylated to form tyrosine, not only is accumulated phenylalanine toxic, but tyrosine becomes an essential nutrient. Tyrosine must be supplemented to maintain proper growth in the dietary management of PKU.
2. Loss of feedback control. If product D normally functions in feedback control of enzyme AB, overproduction of an intermediate product may occur because D is

not present in amounts necessary to regulate production of intermediates B and C. Exemplary of this phenomenon is acute intermittent porphyria, in which heme is deficient and does not exert feedback control on d-aminolevulinic acid (d-ALA) and porphobilinogen syntheses, with consequent excess accumulation and neuropathic sequelae.

3. Accumulation of C, the immediate precursor of the blocked reaction. In MSUD, toxic BCKAs accumulate because they cannot be decarboxylated and transacylated to their coenzyme A–acyl acid derivatives. The consequence in the neonate is severe central nervous system (CNS) depression and apnea, stupor, coma, and death. If the neonate survives, severe mental retardation ensues if the child is not treated by diet restriction within the 1st week of life.
4. Accumulation of A or B, remote precursors of the blocked reaction sequence, CD. If the preceding reactions are freely reversible, a precursor in addition to the one immediately before the block will accumulate. This process is illustrated in MSUD by increased leucine, isoleucine, and valine, which are formed by reamination of the BCKAs α -ketoisocaproic, α -keto- β -methylvaleric, and α -ketoisovaleric acids, respectively.
5. Increased production of alternative products (E) through little-used metabolic pathways. As illustrated in [Figure 61.1](#), when phenylalanine accumulates because of impaired phenylalanine hydroxylase (PAH), phenylpyruvic, phenylacetic, and phenyllactic acids are produced in larger than normal amounts through existing pathways that normally do not function at physiologic concentrations of cellular phenylalanine.

Figure 61.1. Metabolism of aromatic amino acids. The metabolic flow and nutrient interaction in disorders of phenylalanine and tyrosine are diagrammed. *Crosshatched bars* represent impaired enzymes involved in bipterin biosynthesis, phenylketonuria, and tyrosinemia. See text for discussion.

6. Inhibition of alternate pathways by accumulated substrate (i.e., C in CD impairment). For example, neurotransmitter synthesis may be depressed in PKU owing to increased blood phenylalanine that competitively inhibits tyrosine hydroxylase and tryptophan hydroxylase in the CNS. Another example is type I tyrosinemia. The accumulation of succinylacetone inhibits d-ALA dehydratase

([Fig. 61.2](#)) and results in secondary accumulation of d-ALA, attacks of acute porphyria with peripheral neuropathy, hypertension, and bizarre behavior.

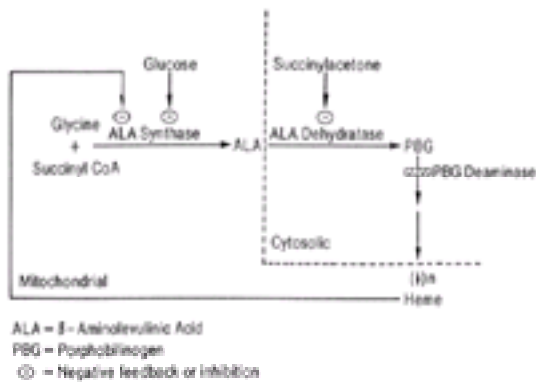

Figure 61.2. Inhibition site in heme biosynthesis of relevance to diagnosis and treatment of tyrosinemia type I. The *hatched bar* schematically represents the partial block in acute intermittent porphyria with resultant overproduction of d-ALA (d-aminolevulinic acid) and PBG (porphobilinogen) with decreased heme biosynthesis. In type I tyrosinemia, succinylacetone is produced and inhibits d-ALA dehydratase with accumulation of d-ALA alone, which is neurotoxic. d-ALA accumulation can be reduced by addition of excess dietary glucose (calories) and by hematin infusions that negatively control d-ALA synthase at levels of both enzyme and gene expression.

Twelve approaches to therapy of inherited metabolic disease are discussed here. The choice of therapy depends on the mechanisms producing disease. Several therapeutic approaches may be tried sequentially or used simultaneously, depending on the acuteness of the disease process.

1. *Enhancing anabolism and depressing catabolism.* This involves the use of high-energy feeds, appropriate amino acid mixtures, and administration of insulin, if needed. Fasting should be prevented. This therapeutic maneuver should be common to all inborn errors involving catabolic pathways.
2. *Correcting the primary imbalance in metabolic relationships.* This correction involves a reduction through dietary restriction of accumulated substrate(s) that are toxic and provision of products that may be deficient. For example, in PAH deficiency, phenylalanine is restricted and tyrosine is supplemented.
3. *Enhancing excretion of accumulated substances that are overproduced.* Treatment of gout with uricosuric agents leads to lower blood uric acid levels by blocking renal reabsorption. The tissue deposits of uric acid salts are then mobilized. A more general use is hydration to enable renal clearance of toxic compounds.
4. *Providing alternative metabolic pathways to decrease accumulated toxic precursors in blocked reaction sequences.* For example, the accumulated

ammonia in enzyme defects of the urea cycle is reduced by removing nitrogen through administration of therapeutic amounts of phenylbutyric or phenylacetic acid to form phenylacetylglutamine from glutamine. Similarly, in isovaleric acidemia, innocuous isovalerylglycine (IVG) is formed from accumulating isovaleric acid (IVA) if supplemental glycine is provided to drive glycine-*N*-transacylase. IVG is excreted in the urine.

5. *Using metabolic inhibitors to lower overproduced products.* For example: allopurinol inhibits xanthine oxidase and decreases overproduction of uric acid in gout, Lovastatin and Compactin suppress hydroxymethylglutaryl-coenzyme A (CoA) reductase and reduce excess cholesterol biosynthesis in familial hypercholesterolemia, and 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) inhibits *p*-OH-phenylpyruvic acid dioxygenase (*p*-OHPPAD) and thus succinylacetone production in type I tyrosinemia.
6. *Supplying products of blocked secondary pathways.* In cystic fibrosis, the exocrine pancreas does not function in a normal manner to produce and secrete digestive enzymes. Administration of these pancreatic enzymes partially corrects this insufficiency.
7. *Stabilizing altered enzyme proteins.* The rate of biologic synthesis and degradation of holoenzymes depends on their structural conformation. In some holoenzymes, saturation by coenzyme increases their biologic half-life and thus overall enzyme activity at the equilibrium produced by mutant proteins. This therapeutic mechanism is exemplified in homocystinuria and MSUD. Pharmacologic intake of vitamin B₆ in homocystinuria or vitamin B₁ in MSUD increases intracellular pyridoxal phosphate or thiamin pyrophosphate and will increase the specific activity of cystathionine b-synthase (CBS) or BCKAD complex, respectively (8, 9).
8. *Replacing deficient coenzymes.* A variety of vitamin-dependent disorders are due to blocks in coenzyme production and are “cured” by lifetime pharmacologic intake of a specific vitamin precursor. This mechanism presumably involves overcoming a partially impaired enzyme reaction by mass action. If reactions are impaired that are required to produce methylcobalamin and/or adenosylcobalamin, homocystinuria or methylmalonic aciduria (or both) will result. Daily intake of milligram quantities of vitamin B₁₂ may cure both disorders (10). In biotinidase deficiency, the coenzyme biotin is not released from its covalently bound state. Reviews of “vitamin-dependency syndromes” have been published (11, 12).
9. *Artificially inducing enzyme production.* If the structural gene or enzyme is intact, but suppressor, enhancer, or promoter elements are not functional, abnormal amounts of enzyme may be produced. It should be possible to “turn on” or “turn off” the structural gene and enable normal enzymatic production to occur. In the acute porphyria of type I tyrosinemia, excessive d-ALA production may be reduced by suppressing transcription of the d-ALA synthase gene with excess glucose and hematin (Fig. 61.2).
10. *Replacing enzymes.* Many attempts to replace deficient enzymes by plasma infusion and microencapsulation have been tried with limited success. Recently the use of polyethylene glycol coating of adenosine deaminase significantly prolonged the biologic half-life of this enzyme in treating severe combined immunodeficiency (13). The engineering of b-glucosidase with a high mannan receptor site enables intravenous use of Ceredase to treat type I Gaucher's disease.

11. *Transplanting organs.* Kidney transplant in Fabry's disease and liver transplant in type I glycogen storage disease benefit systemic metabolism with the return of organ function replacing deficient enzyme activity.
12. *Correcting the underlying defect in DNA so that the body can manufacture its own functionally normal enzymes.* This experimental approach has great possibility for the future. The DNA for many proteins such as adenosine deaminase, hypoxanthine-guanine phosphoribosyl transferase, ornithine transcarbamylase, and the LDL cholesterol receptor has been cloned, and retroviral constructs containing their cDNA transfected into dividing somatic cells from affected individuals. Human gene therapy is currently contemplated for these inborn errors, although several technical problems in gene stability and expression must be solved first. Other molecular approaches such as homologous recombination to correct mutant sequences on endogenous genes are also future possibilities (14).

Nutritional management remains a principal component in treating all of these inherited disorders, and some practical considerations for nutritional support should be considered. Foremost is the need to maintain normal growth, which cannot be achieved without adequate intake of energy and amino acids. Energy requirements are greater than normal when natural protein is restricted and L-amino acids supply protein equivalent (15). L-Amino acids administered in one daily dose are oxidized to a much greater extent than those in the same dose divided and administered throughout the day (16). Nitrogen balance was improved considerably when L-amino acids were ingested in several doses throughout the day with whole protein, rather than in one dose (17). If adequate energy and amino acids cannot be ingested to support normal growth through oral feeds, nasogastric, gastrostomy, or parenteral feeds should be used. Failure to adapt nutrient intake to the individual needs of each patient can result in mental retardation, metabolic crises, neurologic crises, growth failure, and, with some inherited metabolic diseases, death. When specific amino acids or nitrogen requires restriction, total deletion of the toxic nutrient for 1 to 3 days in the presence of excess energy intake is the best approach to initiating therapy. Longer deletion or overrestriction may precipitate deficiency of the amino acid(s) or nitrogen. Because the most limiting nutrient in the diet determines growth rate, overrestriction of an amino acid, nitrogen, or energy will result in further intolerance of the toxic nutrient(s).

Dietary restrictions to correct imbalances in metabolic relationships often require the use of chemically defined or elemental medical foods (18). These medical foods must be accompanied by small amounts of whole natural protein that supply the restricted amino acid(s). Natural foods seldom supply more than 50%, and often much less, of the protein requirements of patients. Nitrogen-free natural foods that provide energy are limited in their range of nutrients. Consequently, care must be taken to provide nutrients often considered to be contaminants because their essentiality has been demonstrated through long-term use of total parenteral nutrition (19). Thus, in addition to nutrients for which an RDA is established, other nutrients must be supplied in adequate amounts. These include the trace minerals chromium and molybdenum; the vitamins biotin and pantothenic acid; choline and inositol; and carnitine when excess acylcarnitines are produced and excreted, as in methylmalonic acidemia or propionic acidemia. Other possible conditionally essential nutrients for patients with PKU have been described (20).

Elemental medical foods consist of small molecules that often provide an osmolality that exceeds the physiologic tolerance of the patient. Abdominal cramping, diarrhea, distention, nausea, and vomiting result from hyperosmolar feeds. Aside from gastrointestinal distress, more-serious consequences can occur such as hypertonic dehydration, hypovolemia, hypernatremia, and death. Osmolalities of selected medical foods intended for inherited diseases of amino acid metabolism have been published (21).

AROMATIC AMINO ACIDS

Inborn errors of the aromatic amino acids were historically the first to respond to nutritional support. Phenylketonuria was discovered in 1933, and the prevention of its resultant mental retardation by dietary intervention is classic. Today, more than 200 different mutations at the PAH gene locus are described (22).

BIOCHEMISTRY

The essential amino acid phenylalanine is used for two major purposes: tissue protein synthesis and hydroxylation to form tyrosine. The hydroxylation reaction requires PAH, O₂, tetrahydrobiopterin, dihydropteridine reductase (DHPR), and NADH plus H⁺ (Fig. 61.1). The normal adult uses only 10% of the RDA for phenylalanine for new protein synthesis, and approximately 90% is hydroxylated to form tyrosine. The growing child uses 60% of the required phenylalanine for new protein synthesis, and 40% is hydroxylated to form tyrosine. Mass spectrometry and stable isotope studies of patients with PKU provide information on other pathways available for phenylalanine metabolism. These alternative pathways, outlined in Figure 61.1, are minor in the metabolism of phenylalanine at 50 μmol concentration in the plasma of normal individuals. However, byproducts become apparent when phenylalanine is not hydroxylated to tyrosine and accumulates to over 500 μmol (22).

Tyrosine is the normal immediate product of phenylalanine and is essential to five pathways (Fig. 61.1), including synthesis of protein, catecholamines, melanin pigment, and thyroid hormones. Tyrosine also provides energy when catabolized through *p*-hydroxyphenylpyruvate to fumarate and acetoacetate. Enzymes required in this latter degradative pathway include tyrosine aminotransferase, *p*-hydroxyphenylpyruvic acid dioxygenase (*p*-OHPPAD), homogentisic acid oxidase, and fumarylacetoacetic acid hydrolase (FAH) (Fig. 61.1).

Phenylketonuria

Phenylketonuria is a group of inherited disorders of phenylalanine metabolism caused by impaired PAH activity. The disease is expressed at 3 to 6 months of age and is characterized by developmental delay, microcephaly, abnormal electroencephalogram, eczema, musty odor, and hyperactivity. If not treated before 3 weeks of age, the metabolic imbalance produces irreversible mental retardation. The defect in metabolism in classic PKU is associated with less than 2% of the activity of normal PAH, and these

“classic” mutations are now defined (23). The enzyme is expressed primarily in liver but not in peripheral blood cells, bone marrow, or cultured cells. Five of the most frequent mutations in a U.S. clinic include I65T, R408W, Y414C, L348V, and IVS10nt546, which account for more than 50% of mutant PAH alleles. Genotypes with R408W and IVS10nt546 result in more severe PAH impairment while Y414C and I65T have relatively mild phenotypes (23). Heterozygous parents for “classic” PKU have 50% enzyme and can be identified by increased ratios of semifasting phenylalanine squared to tyrosine (P^2/T) in vivo (24).

The genetic bases for disorders of PAH followed localization of the PAH gene to chromosome 12q22-q24 and cloning of the gene, which has 90 kilobases (kb), 13 exons, and 12 introns (22). At least 200 different mutations have been identified that cause the “PKU phenotype,” and these involve deletions in coding frames, missense mutations, and intron splice site mutations (22, 23). Ethnic variation occurs in the type and frequency of PAH mutations, a fact that provides clues to migration of populations in history (22). Cloning of this gene and identification of different mutations have assisted in genotyping probands, counseling families, and predicting the amount of dietary phenylalanine that will be required (23). Preventive newborn screening with immediate and lifelong avoidance of excess phenylalanine in the diet continues to be the principal paradigm of therapy despite these advances in molecular genetics.

Other forms of PKU may result from defects in other enzymes involved in the overall reaction. DHPR, an enzyme normally present in many tissues, reduces the quinoid form of dihydrobiopterin to tetrahydrobiopterin (Fig. 61.1). The gene for DHPR is located on chromosome 4p15.1-p16.1. Several other types of PKU result from defects in the synthesis of tetrahydrobiopterin (25) (Fig. 61.1). In addition to functioning as a coenzyme for PAH, tetrahydrobiopterin is also required by tyrosine hydroxylase and tryptophan hydroxylase (26, 27) (Fig. 61.1). Because these enzymes produce essential neurotransmitters, defects in biopterin synthesis are associated with progressive neurologic disease unless tetrahydrobiopterin, L-3,4-dihydroxyphenylalanine (L-DOPA), and serotonin are replaced (26).

Although the precise pathogenesis of mental retardation in classic PKU is not known, accumulation of phenylalanine or its catabolic byproducts, deficiency of tyrosine or its products, or all four circumstances will produce CNS damage if phenylalanine accumulates in plasma above normal concentrations during critical periods of brain development. The pathologic consequence varies with the time in brain development at which the chemical insult occurs. Deficient myelination and abnormalities in brain proteolipids and/or proteins occur in late gestation and during the first 6 to 9 months of life (28). During this period, oligodendroglia migration may also be impaired, resulting in irreversible brain damage later in childhood. Protein synthesis in the brain is also depressed, probably owing to competitive inhibition by high phenylalanine concentrations on blood-brain barrier transport, with consequent imbalance in intraneuronal amino acid concentrations (29). In the mature brain, neurodegeneration (30), behavioral difficulties, and prolonged performance times may result from depressed neurotransmitter synthesis (31, 32). Impairment of these neuropsychologic functions in the mature brain may be reversible when phenylalanine returns toward

normal concentrations in cells and blood (31, 32).

Screening

The disorders of phenylalanine metabolism require identification, diagnosis, and appropriate therapy before clinical expression of the disease is apparent. Nutritional and possibly other therapy should be instituted before the 3rd week of life. Thus a tetrapartite public health program involving screening, retrieval, diagnosis, and treatment must be coordinated and efficient to prevent mental retardation. A screening test using the bacterial inhibition assay (33) detects potential cases in the newborn population. One laboratory can effectively screen 20,000 to 200,000 samples per year using these methods. Although other methods such as fluorometry are more quantitative, the Guthrie test is used worldwide because of its ease of application and low cost. Newborns with blood phenylalanine concentrations above 121 $\mu\text{mol/L}$ (2 mg/dL) on the screening test are restudied. The actions taken in "retrieval" depend on the concentration of blood phenylalanine, days of age, and protein intake at the time of screening.

Protein ingestion may not be required for a positive PKU screen, but quantitative normal concentrations during the first 48 hours of life are needed for comparison (34). Almost all infants with PKU have blood phenylalanine concentrations above normal during the 1st day of life, even before the first feeding if they have "classic" PKU mutations (23, 24). Neonates with PAH gene mutations resulting in less severely impaired PAH may take longer to develop an elevated blood phenylalanine concentration. Some infants with relatively mild elevation of blood phenylalanine have serious neuropathology that is progressive due to a defect in synthesis of tetrahydrobiopterin. Therefore, diagnosis of "positive" newborn screenees should include measurement of urinary tetrahydrobiopterin (BH_4) and erythrocyte DHPR.

Newborn screening in most of the 50 states, in conjunction with aggressive approaches to retrieval and diagnosis, has led to early institution of diet therapy and prevention of mental retardation (34). To be successful, state-mandated screening programs must enable collection and rapid evaluation of specimens while providing an organized, efficient retrieval system of babies whose screening tests yield positive results (34, 35). With the present early infant discharge from the newborn nursery and the increase in breast feeding, lower phenylalanine concentrations of 121 to 242 $\mu\text{mol/L}$ (2 to 4 mg/dL) are considered "positive," and follow-up is initiated (36). Approximately 1 in 10,000 Caucasian newborns in the United States is affected with PKU, whereas 1 in 132,000 newborns in the black population is affected (35). Data in Table 61.3 detail the number of cases of PKU diagnosed since the inception of an exemplary statewide screening program in Georgia. The mean frequency of PKU is based on a population of newborns that is 63% Caucasian.

Disease	Total	Incidence

Table 61.3 Incidence of Inherited Metabolic Diseases in Georgia's Newborn Population

Diagnosis

Patients with initial blood phenylalanine concentrations above 121 $\mu\text{mol/L}$ (>2 mg/dL) should have the test repeated immediately. If the initial or follow-up screening test yields levels above 484 $\mu\text{mol/L}$ (8 mg/dL), plasma amino acids should be quantitated by ion-exchange chromatography with the infant on a known phenylalanine intake from natural protein sources. A precise diagnosis is necessary to establish the mode of therapy.

Differential diagnosis requires several laboratory procedures. These include ion-exchange chromatography to determine plasma phenylalanine, tyrosine, and other amino acid concentrations; genotyping of parents and proband (37); and assays of biopterin and DHPR (26). DNA analysis using restriction fragment length polymorphisms (RFLP) and cDNA probes for the PAH gene help in classifying patients and determining the amount of dietary phenylalanine to prescribe (22, 23). For families with an affected child, prenatal diagnosis is available through direct mutational analysis of fetal cell DNA for known PAH genes, or indirect RFLP analysis of PAH in parents and proband for unknown fetal PAH genes (22, 38). Because PAH is not expressed in cultured amniotic fluid cells and because phenylalanine concentrations do not rise in amniotic fluid until the last trimester, prenatal monitoring was not possible before molecular techniques became available.

Treatment

Patients with plasma phenylalanine concentrations above 250 μmol , plasma tyrosine concentrations below 50 μmol , and normal BH_4 and DHPR require prompt treatment with a phenylalanine-restricted, tyrosine-supplemented diet. The objective of nutritional support of the child with classic PKU is to maintain blood phenylalanine concentrations that will allow optimum growth and brain development by supplying adequate energy, protein, and other nutrients while restricting phenylalanine and supplementing tyrosine

intake.

Although the effects of moderately elevated plasma phenylalanine are not yet known, optimum blood levels should be as close to normal as possible. This objective is met through use of a combination of medical and natural foods. Some investigators have supplemented the phenylalanine-restricted diet with isoleucine, leucine, and valine and have found improvement in behavior and decreased plasma phenylalanine (39). This may be related to inhibition of phenylalanine transport by competition at either the intestinal or blood-brain barrier uptake steps (29). Gene replacement therapy using recombinant viruses containing the PAH gene requires more fundamental research before being of practical use. Recombinant retroviruses containing the cDNA for PAH can introduce a functioning PAH gene into dividing liver cells, but long-term PAH expression is limited (22, 40). These approaches are under study and require not only stable transformation and PAH expression, but also coordinating DHPR and bipterin synthesis to accomplish the overall reaction. Thus, gene therapy is not yet applicable to practical therapy of PKU.

Therapy of the child with bipterin-deficient forms of hyperphenylalaninemia requires administration of tetrahydrobiopterin and use of the phenylalanine-restricted, tyrosine-supplemented diet in combination with L-DOPA and carbidopa (26). Serotonin that is derived from tryptophan may also improve behavior, since tryptophan hydroxylase is also impaired by diminished tetrahydrobiopterin (26, 27, 41).

Initiation of Nutritional Support. Blood phenylalanine concentration at the time of diagnosis may be rapidly lowered by feeding the infant a 20-kcal/oz (67 kcal/dL) low-phenylalanine or phenylalanine-free formula (42). A minimum of 120 kcal/kg/day intake is necessary. Within a mean of 4 days (SD \pm 3), blood phenylalanine concentration should drop to treatment range on a phenylalanine-free formula. Treatment should be initiated in hospitalized infants to enable adequate parental information transfer and to monitor blood amino acids daily. Laboratory results should be available promptly to prevent precipitation of phenylalanine deficiency and to enable rapid replacement of phenylalanine and tyrosine to optimum blood concentrations.

If the infant or child is not hospitalized for initiation of nutritional support or if only weekly blood phenylalanine concentrations are obtained, 48 hours of a phenylalanine-free formula followed by maintenance formula containing adequate phenylalanine from an appropriate source should be prescribed. Blood phenylalanine concentration will fall to treatment range within a mean of 10 days (SD \pm 5) with this approach (42). Blood phenylalanine concentrations should be between 120 and 300 μ mol as soon as possible, but no later than the 3rd week of life.

Chronic Care. Long-term care of the patient with classic PKU dictates that medical and natural foods provide all nutrients in required amounts.

Nutrient Requirements. Table 61.4 outlines the suggested ranges of phenylalanine, tyrosine, protein, energy, and fluid to offer. A formal prescription must be written that is individualized to the specific genotype (23, 43, 44 and 45), growth rate, and consequent needs of each patient. Weekly adjustments in the diet prescription may be necessary,

particularly during the first 6 months of life, based on hunger, growth, development, and laboratory analyses of plasma phenylalanine and tyrosine concentrations. The prescribed phenylalanine should maintain the 3- to 4-h postprandial blood phenylalanine concentration between 60 and 300 μmol (46). Phenylalanine is an essential amino acid (47) and cannot be deleted from the diet without producing death (48). Excess restriction produces growth failure, rashes, bone changes, and mental retardation (48).

Nutrient	Unit	Age						
		3 to 6 months	6 to 12 months	1 to 2 years	2 to 3 years	3 to 11 years	11 to 15 years	15 to 18 years

¹For most essential amino acids, essential fatty acids, vitamins and minerals, requirements are provided in adequate amounts.
²At least 1 mg of iron should be added for each mill of energy provided in the diet.

Table 61.4 Approximate Daily Requirements for Selected Nutrients by Infants, Children, and Young Adults with Selected Inherited Disorders of Amino Acid Metabolism

The infant with classic PKU requires 20 to 50 mg phenylalanine per kilogram body weight for growth, with younger infants requiring the larger amount (49). The phenylalanine requirement declines rapidly between 3 and 6 months of age as growth rates decline. Requirements for phenylalanine in the 6- to 12-month-old patient with classic PKU may fall to 15 mg/kg/day, but they vary considerably (Table 61.4). Frequent monitoring of blood phenylalanine concentration and intake is required to prevent excess intake when growth rate decelerates and to prevent inadequate intake when growth rate is at its peak, as in early infancy and during the prepubertal and pubertal growth spurts and during the later half of gestation.

Tyrosine is an essential amino acid for individuals with PKU. For this reason, plasma tyrosine concentrations must be monitored; if they are low, L-tyrosine supplements are given. Dietary proteins contain, by weight, 5.5% phenylalanine and 4.5% tyrosine, on average. The normal individual hydroxylates some 40 to 90% of phenylalanine to form tyrosine. To supply a normal tyrosine intake to patients with PKU, 10% of protein prescribed should be as tyrosine. Tyrosine supplements alone will not prevent mental retardation in classic PKU (50).

The protein content of the diet for patients with PKU has traditionally been higher than normal. Protein requirements are increased when either an L-amino acid mix or casein hydrolysate is the primary protein source rather than natural protein (51). Thus, recommendations for protein for nutritional support exceed the RDA (52, 53). Mean

protein intake 24% above the 1989 RDA for age was associated with greater phenylalanine tolerance and growth in infants with PKU than was found when mean protein intake was 9% above RDA (54). Recommendations for energy and fluid intake (Table 61.4) are the same as those for normal individuals (52, 55).

Low-Phenylalanine and Phenylalanine-Free Medical Foods. Adequate protein cannot be obtained from natural foods without ingesting excess phenylalanine (natural proteins contain 2.4–9% phenylalanine by weight) (56, 57, 58, 59, 60 and 61). Thus, special medical foods are used to provide protein (62, 63 and 64). Formulations, composition of major nutrients, and sources of these products are given in Table 61.5.

Table 61.5 Formulation, Nutrient Composition, and Sources of Medical Foods for Selected Inborn Errors of Metabolism

Natural Foods. Serving lists are available to simplify the phenylalanine-restricted diet for families and professional persons guiding them (Table 61.6). The lists are similar to diabetic exchange lists in that foods of similar phenylalanine content are grouped together and can be exchanged for one another within a list to vary the diet (63). Portion sizes of foods in each list may be found in reference 63.

Table 61.6 Average Nutrient Content of Servings Lists for Phenylalanine and/or Tyrosine and Protein-Restricted Diets

Diet plans for children with PKU at different ages using different medical foods may be found in [Table 61.7](#) and [Table 61.8](#). For instance, Lofenalac, Phenex-1, PKU 1, or XP Analog could be used to initiate a prescribed diet for a neonate at 55 mg phenylalanine/kg/day ([Table 61.7](#)). By 4 years of age, patients with some genotypes might require as much as 25 mg/kg/day. To allow as many natural foods as possible, Periflex, Phenex-2, Phenyl-Free, or XP Maxamaid are more likely to be the medical food of choice ([Table 61.8](#)), since they contain no phenylalanine ([Table 61.5](#)).

Management Problems. Management problems described for children with PKU occur in other children with inherited disorders of metabolism. Principles described here apply to children with other disorders as well but are not reiterated in other sections.

Maintenance of an adequate intake of protein and energy is important for the infant and child with PKU even though phenylalanine must be restricted. Nutritional support must be aggressive, and if intake fails to meet prescription, a nasogastric or gastrostomy tube should be placed to achieve anabolism. This is extremely important in disorders of branched-chain amino acids (BCAAs) and nitrogen metabolism. Protein is obtained from medical foods; therefore, the amount of medical food offered must be varied to provide the protein needed. Nonprotein sources of energy such as corn syrup, Moducal and Protein-Free Diet Powder (Mead Johnson Nutritionals, Evansville, IN), Polycose Glucose Polymers, Pro-Phree (Ross Products Division, Abbott Laboratories, Columbus, OH), sugar, and pure fats can be added to maintain energy intake and to satisfy the child's hunger without affecting blood phenylalanine concentrations. Natural foods should be prescribed in numbers of servings and introduced at the appropriate ages and in the usual textures as for any child. Children should be given a variety of foods at the appropriate age so that these foods may be included in the diet later in life. In this way, increasing total phenylalanine requirements may be met.

A variety of factors may influence blood phenylalanine concentrations. Those that may elevate the blood phenylalanine concentration include acute infections with concomitant tissue catabolism, excessive or inadequate phenylalanine intake, and inadequate protein or energy intake. Infection affects plasma amino acid concentrations in normal adults (65). Similar increases in blood phenylalanine concentrations occur in febrile, treated patients with PKU. Because of this fact, any infection should be promptly diagnosed and appropriately treated. The best approach to nutritional support during short-term infections is to increase the intake of fluids and carbohydrates through the use of Pedialyte with added Polycose powder; fruit juices; high-carbohydrate, protein-free beverages; and soft drinks that do not contain caffeine.

Excess phenylalanine intake is the most common cause of elevated blood phenylalanine concentration in the older child with PKU. This condition may be due to overprescription, misunderstanding of the diet by the caretaker, or "snitching" of food by the child. Frequent evaluations of blood phenylalanine concentration with accompanying accurate diet records for calculation of intake are used to determine the dietary phenylalanine prescription. Diet records are also useful in determining parental understanding. Misunderstanding of diet requires additional education of parents. One of the most common "misunderstandings" in older children is the total number and size of servings allowed. In extended families living in close proximity, the child may receive three to four times the allowed amount of food from different well-intentioned but uninformed relatives. "Snitching" of food by the child is the most difficult problem to handle. The child should be given sound reasons for avoiding foods not allowed on the diet, and this responsibility should be shifted to the child by 4 to 6 years of age. Appropriate disciplinary action by the parents should also be supported if the patient is unwilling to accept this responsibility. Lifetime nutritional support should be emphasized

to the parents at the onset of therapy, and to both parents and child at recurring intervals.

Phenylalanine deficiency associated with inadequate phenylalanine intake has three specific stages of development (66). The first stage is characterized biochemically by decreased blood and urine phenylalanine. Clinically, the child may appear normal, lethargic, or anorectic and may fail to gain length or weight. In the older child, increases in blood alanine and b-hydroxybutyric and acetoacetic acidemia result from muscle alanine production and b-lipolysis. In the second stage, blood phenylalanine levels increase as a result of muscle protein degradation, but blood tyrosine may be low. BCAA concentrations may increase with decreases in other plasma amino acids. Aminoaciduria appears because of renal tubular malabsorption (67). In this stage, body protein stores are catabolized, energy sources are depleted, and “active” membrane transport functions are impaired (67). Eczema is common. In the third stage of phenylalanine deficiency, blood phenylalanine is below normal, as are other amino acids. Accompanying clinical manifestations include failure to gain weight, failure to gain height, osteopenia, anemia, sparse hair, and finally death if the deficiency is not corrected by supplemental dietary phenylalanine and tyrosine.

Insufficient protein intake results in an inadequate supply of essential amino acids and/or nitrogen for growth. When protein synthesis is decreased, phenylalanine is no longer used for growth and accumulates in the blood. If catabolism occurs because of prolonged lack of nitrogen and/or amino acid intake, blood phenylalanine concentration increases because tissue protein contains some 5.5% phenylalanine. In instances of protein insufficiency, medical food intake should be increased to supply the required nitrogen and/or essential amino acids.

Energy, the first requirement of the body, is necessary for growth. When energy is provided as carbohydrate and fat, and if adequate nitrogen is available, nonessential amino acids may be synthesized from their ketoacid precursors. Furthermore, carbohydrate ingestion leads to insulin secretion, and insulin promotes amino acid transport into the cell and consequent protein synthesis (68, 69). The mechanisms by which insulin regulates amino acid uptake in muscle change with increasing age (69). When energy intake is inadequate, tissue catabolism occurs to meet energy needs. Such catabolism releases phenylalanine, leading to elevated blood phenylalanine concentrations. Sufficient energy must be provided through generous use of nonprotein and low-protein foods to ensure a normal growth rate.

Low blood phenylalanine concentrations (<25 μmol) may lead to depressed appetite (70), decreased growth (71), and, if prolonged, mental retardation (46, 48). Low blood phenylalanine concentrations are often due to inadequate prescription of phenylalanine for the affected child during rapid growth phases. In such cases, the prescription for phenylalanine can be increased by addition of measured amounts of milk and/or solid foods. In some situations, medical food may be diluted to a volume that is too great for the child to consume in the allotted time. The volume must be decreased to the amount the child can ingest. Concentrated medical foods are frequently used without any untoward side effects. They may be mixed as a paste and spoon-fed, even to the young infant. The practice could begin at 3 to 4 months of age or when tongue thrust is no

longer a problem for solid food intake. Extra fluid must then be offered between feedings to maintain appropriate water balance.

Assessment of Nutritional Support. Along with biweekly assessment of growth through measurement of height, weight, and head circumference and evaluation of development by appropriate developmental scales, the adequacy of phenylalanine and tyrosine intake is determined by twice-weekly quantitation of the blood phenylalanine and tyrosine concentrations. The 1st year is the period of most rapid growth and of greatest vulnerability to nutritional insult. Thus, twice-weekly blood tests are suggested during the first 3 months and weekly thereafter until the child is 1 year of age. After 1 year of age, weekly blood tests suffice for monitoring diet. If, however, blood phenylalanine concentrations exceed 300 μmol (5 mg/dL), more frequent determinations should be obtained. When indicated, the prescription for phenylalanine is decreased, and frequent blood tests are obtained until blood phenylalanine concentrations are between 60 and 300 μmol .

For blood tests to be of use in adjusting the prescription, laboratory analyses must be both accurate and prompt. Quantitative methods of phenylalanine determination using automated ion-exchange chromatography and liquid blood are preferable. This method allows evaluation of all amino acids. The microbiologic (Guthrie) method is acceptable for screening, but is nonquantitative and invalid if antibiotics are used. Fluorimetric methods are quantitative and preferred to the Guthrie test to monitor blood phenylalanine (72). If properly instructed, parents may be given responsibility for obtaining the specimens on filter paper or in microcapillary tubes and mailing them to a central laboratory.

A record of food ingested before and during blood sampling for blood phenylalanine measurement is essential and should be kept by the child's caregiver. The correlation between the child's intake of phenylalanine, tyrosine, protein, and energy; the child's clinical status; and the blood phenylalanine and tyrosine concentrations is considered when the diet is altered.

The success of early diet management rests with the parents and depends on their understanding of the disease and their ability to cope with the diet. Later, the child's understanding of the diet and ability to assume responsibility for it are critical. These factors in turn are related to the support the parents and patient receive from various professional members of the genetic team. Roles and functions of some team members have been described (73).

Results of Therapy. Early diagnosis and treatment of infants with PKU with a nutritionally adequate, phenylalanine-restricted, tyrosine-supplemented diet have promoted normal growth and prevented severe mental retardation. A study showed that mean height, weight, and head circumference of 111 children treated from before 120 days of age were the same as those of normal children at 4 years of age (74). Assessment of mental development in these same children at 4 years of age yielded a mean IQ score of 93 on the Stanford Binet Intelligence Scale (75). Delay in treatment and suboptimal control of blood phenylalanine concentration produced lower IQs than projected from parental IQs. More-recent programs with tighter control of plasma

phenylalanine have improved overall outlook for normal IQs (46). Trefz et al. (37) reported that when blood phenylalanine concentration was kept below 360 μmol , there was no difference in mean IQ by genotype of 9-year-old children.

The semisynthetic nature of the phenylalanine-restricted diet has led to questions concerning its adequacy. Mean serum carnitine (total, free, and esters) of 16 treated patients was about one-third that of normal children of similar age (76). Low plasma tyrosine concentrations were found in both treated and untreated patients (77, 78 and 79). Following an overnight fast, concentrations of all essential plasma amino acids were below the lower limit of normal and the concentration of plasma glycine was elevated in patients who ingested two different medical foods (80). The elevated concentration of plasma glycine occurred even in patients receiving a glycine-free medical food (PeriflexR, Scientific Hospital Supplies, Inc., Gaithersburg, MD). Treated patients with PKU often have below-normal concentrations of prealbumin (81, 82). Depressed plasma concentrations of total cholesterol have been reported in treated children and untreated adults with PKU (83, 84 and 85). Lower than normal plasma and erythrocyte docosahexaenoic acid concentrations and higher than normal *n*-6 series fatty acid concentrations have been found in patients undergoing therapy for PKU (86, 87). The significance of these differences is unclear, but they appear to be diet related.

Calculation indicates that intake of major nutrients is adequate (88), compared with the RDAs. Balance studies of calcium, phosphorus, magnesium, and iron in 8 girls, 6 to 8 years of age, on Lofenalac suggested that magnesium may be inadequate to provide for optimal nutrition (89). Studies of chromium, iron, ferritin, and selenium in children with PKU revealed low concentrations (90, 91). Iron deficiency has been reported in significant numbers of children undergoing therapy for PKU despite more than adequate iron intake (92, 93). Low activity of glutathione peroxidase and low plasma selenium have been found in treated children with PKU who were receiving medical foods without added selenium (94, 95 and 96). Potentially life-threatening cardiac dysrhythmia was found in one selenium-deficient treated child with PKU (97). Significantly reduced mitogenesis to optimal concentrations of monoclonal antibody (OKT3) and plant lectin phytohemagglutinin was demonstrated in a group of patients with PKU with reduced serum selenium, compared with a normal group (98). Patients with PKU with low selenium concentrations had elevated concentrations of T4 and rT3, which decreased significantly with selenium supplementation (99). Inadequate intake may be responsible, since patients receiving medical food with adequate added selenium have normal plasma concentrations. Plasma retinol concentrations of infants and children with PKU undergoing treatment are often below those of normal subjects (82). When Lofenalac is the protein source, the intake of vitamin E suffices for normal plasma concentrations despite the high intake of polyunsaturated fatty acids (100). Adequacy of niacin status in children on Lofenalac is questionable because of limited intake of tryptophan and niacin and disturbances in tryptophan metabolism (101).

Bone changes noted radiographically were reported as early as 1956 in treated children with PKU. Bone mineral content of 11 treated children were more than 1 SD below the mean (102). Bone osteocalcin, a calcium-binding protein with a high content of d-carboxyglutamic acid, was considerably below the normal range, and 80% of patients had serum calcium levels below 9.0 mg/dL. The mean of the three most recent serum phenylalanine concentrations correlated negatively with the bone mineral content and

osteocalcin. Hillman et al. (102) suggested that bone abnormalities were related to lack of control of plasma phenylalanine. McMurry et al. (103) found normal bone mineralization in preschool children with PKU in good dietary control. As blood phenylalanine increased in older patients under poorer dietary control, values for bone mineral content, bone width, and bone density were always lower than control values. Trabecular bone mineral content was recently assessed in 11 young adults with PKU who had been treated from early childhood with a diet restricted in complete protein plus added amino acids, minerals, and vitamins. Bone mineral content was significantly lower in patients than in the normal population (104). Amino acid imbalances, inadequate protein intake, and the need for phosphorus to buffer organic acids made from excess dietary phenylalanine could have contributed to bone abnormalities. Mean plasma concentrations of IgA and IgM were significantly lower in patients with PKU undergoing therapy (105) than in normal children.

Diet Discontinuation. Certain clinicians have suggested that the diet might be discontinued at 4, 6, or 12 years of age with no adverse effects (106, 107 and 108). Investigators have questioned this possibility because studies have shown significant differences in performance and intelligence in children (109, 110) and neurologic function in adults who discontinued the diet and those who remained on the diet (30, 111). Severe agoraphobia (112) reversible by a return to the phenylalanine-restricted diet also has been reported in adults. Vitamin B₁₂ deficiency resulting in hematologic changes and neurologic disease occurs in off-diet patients who refuse foods of animal origin but fail to supplement with phenylalanine-free medical foods (113).

In studies using the patient as his or her own control, elevated plasma phenylalanine concentrations prolonged the performance time on neuropsychologic tests of higher integrative function, reduced the mean power frequency of the electroencephalogram (EEG), and decreased urinary dopamine excretion and plasma L-DOPA in older treated patients with PKU (114, 115). A correlation was found between high plasma phenylalanine concentrations, prolonged performance time on the neuropsychologic tests, and decreased urinary dopamine in 10 patients (114). In a study of eight additional patients, statistically significant decreases were found in the mean power frequency of the EEG and in plasma L-DOPA when plasma phenylalanine concentration increased (115). EEG slowing occurred in PKU heterozygotes at concentration changes of blood phenylalanine that are induced by aspartame ingestion (150 μmol) (31). These effects were reversible and correlated in the reverse direction when plasma phenylalanine was reduced. Severe neurologic deterioration occurred in several off-diet PKU patients (30, 111). Reversal of most of the symptoms was possible in a patient who returned to a phenylalanine-restricted, medical food-containing diet (30). Elevated plasma phenylalanine may be concentrated by the blood-brain barrier in neural cells and inhibit L-DOPA and serotonin synthesis by competing for tyrosine and tryptophan hydroxylases (115).

Maternal Phenylketonuria

Pregnant women with PKU who are untreated at conception and during gestation have offspring with intrauterine growth retardation, microcephaly and congenital anomalies, often severe and incompatible with life. Mental retardation is common in offspring of

mothers whose plasma phenylalanine is above 150 μmol (116). The pathogenesis of the fetal damage is uncertain but is believed to be related to elevated maternal blood phenylalanine concentration (117) because phenylalanine is actively transported across the placenta to the fetus (118). Fetal blood phenylalanine concentrations are 1.5 to 2 times those of maternal blood (119). Such elevated fetal plasma phenylalanine concentrations are again concentrated 2- to 4-fold by the fetal blood-brain barrier (120, 121). Intraneuronal phenylalanine concentrations of 600 μmol interfere with brain development by one or more of the several previously described mechanisms, including abnormal oligodendroglial migration and/or myelin and other protein synthesis (122). Thus, it is extremely important to maintain normal plasma phenylalanine concentrations in the reproductive female with PKU before conception and throughout gestation. Offspring of untreated women who survive fail to grow and develop normally. In fact, Kirkman (123) predicted that if the fertility of these women is normal and they are not treated with dietary control of phenylalanine intake, the incidence of PKU-related mental retardation could return to the prescreening level after only one generation.

In 1984 the Collaborative Study of Maternal Phenylketonuria (MPKUCS) was initiated to answer questions related to diet and reproductive outcome in women with PKU (124). Interim results of the MPKUCS support the premise that a phenylalanine-restricted diet and the gestational age at which it is initiated affect reproductive outcome (125). Little is known of the effect of dietary phenylalanine in artificial sweeteners on newborn outcome in the general population.

Nutritional Support of MPKU. Adherence to a phenylalanine-restricted diet by pregnant women is a major problem. These women must adjust to the taste of the phenylalanine-free medical food and be able to withstand the social pressures to eat proscribed foods, such as animal protein. Therefore, the phenylalanine-restricted diet should be initiated at least 3 months before a planned pregnancy by women who have PKU, if they have previously discontinued diet.

The objectives of therapy for pregnant women with PKU are a healthy mother and a normal, healthy newborn. To obtain adequate protein and fat storage in early pregnancy to support last trimester fetal growth, careful attention must be paid to prescribing diet and evaluating nutritional status. Although the blood phenylalanine concentration most likely to yield the best reproductive outcome is unknown (124), one group of investigators suggests that these objectives may be achieved by a phenylalanine-restricted diet that maintains blood phenylalanine concentration between 60 and 180 $\mu\text{mol/L}$ (126). Plasma phenylalanine concentrations below 60 $\mu\text{mol/L}$ may lead to maternal muscle wasting and poor fetal growth. Recommended phenylalanine intake to prescribe for initiating therapy is given in Table 61.9 (127). Other indices of nutritional status should be in the normal range for pregnant women. After initiation of diet with the minimum recommended phenylalanine prescription (Table 61.9), plasma phenylalanine concentration and weight should be monitored twice weekly, if possible, to enhance weight gain and maintain targeted plasma phenylalanine concentration.

Trimester average (range)	Amino acids			Energy ^b (kcal/day)	
	PHE ^a (mg/day)	TYR ^a (mg/day)	Protein ^c (g/day)	Mean	Range
Trimester 1 (0 + 14 weeks gestation)

32 ^d	210 + 1200	1740	37%	2500	2100-3400

^aRecommended range of PHE intake based on 95% of PKU carrier studies

^bEnergy diet with the lowest amount recommended for trimester and age. Targeted monitoring of plasma PHE is essential to prevent deficiency in excess. Modification based on frequent plasma PHE and TYR concentrations, status of PHE, TYR, protein, and energy and maternal weight gain.

^c37% is only metabolizable when supplemented; 37% should be based with full protein, medical proteins, or soup for ingestion. Recommended intake is from NHANES survey (2000)

^dBased on IOM Food and Nutrition Board (1980) Energy requirements for some women may be greater than the upper limit of the average gain in their appropriate weight gain.

Table 61.9 Recommended Phenylalanine (PHE), Tyrosine (TYR), Protein and Energy Intakes for Pregnant Women with PKU

Even after plasma phenylalanine concentration is stabilized in the treatment range, frequent changes in the individualized diet prescription are required as pregnancy progresses, based on concentrations of plasma phenylalanine, tyrosine, and other amino acids and on weight gain. Phenylalanine and tyrosine requirements of each pregnant woman depend on genotype, age, state of health, and trimester of pregnancy (127, 128). About midpregnancy, phenylalanine tolerance increases considerably (127, 128). Specific numbers of servings of low-protein cereals, fruits, fats, and vegetables (Table 61.6) are prescribed by the nutritionist to supply the individual amount of tolerated phenylalanine.

As noted for the child with PKU, the amount of protein prescribed (Table 61.9) exceeds the RDA because of the use of L-amino acids as the primary source of protein equivalent. A phenylalanine-free medical food (Table 61.5) is used to provide most of the protein prescribed and nitrogen-free foods (Free Foods B, Table 61.6), such as pure sugars and pure fats, are used to provide the remaining energy needs. A protocol is available that suggests a step-by-step approach to planning and evaluating nutritional support for the pregnant woman with PKU (63).

Birth measurements of neonates of women with PKU are negatively correlated with maternal plasma phenylalanine concentrations and positively correlated with maternal energy and protein intake and weight gain during pregnancy. The plasma phenylalanine concentration of the pregnant woman with PKU is negatively correlated with total protein intake (128), suggesting that total protein intake should minimally be at the amount recommended in Table 61.9 for better control of plasma phenylalanine.

Appropriate weight gain is related to height and prepregnancy weight and is greater for underweight than for normal-weight women (129). Data in Table 61.10 describe recommended pregnancy weight gain for underweight, normal-weight, and overweight women.

Weight Status ^a	Recommended Weight Gain (kg)	
	1st Trimester	Total
Normal weight	1.6	15.5-16.0
Underweight	2.3	12.5-18.0
Overweight	0.9	7.0-11.5

Data from the Subcommittee on Nutritional Status and Weight Gain During Pregnancy, 1990 (129).

^aWeight status at conception.

Table 61.10 Recommended Weight Gain during Pregnancy for Women with PKU

Two families of fatty acids, linoleic (C18:2, *n*-6) and α -linolenic (C18:3, *n*-3) are essential for humans (130). Linoleic acid should supply about 7% (52) and α -linolenic acid should supply 0.7 to 2.5% of energy in the diet (131), especially during pregnancy.

Women in the MPKUCS who had a good reproductive outcome had a greater fat intake throughout pregnancy than women with a poor outcome (128). Whether the poor outcome was due to inadequate essential fatty acids is not clear. Because most of the medical foods are devoid of, or contain very little, α -linolenic acid (Table 61.5), the fat used to supply 30 to 40% of energy in the diet should be obtained from cooking and salad oils, margarines, salad dressing, and shortenings with either unhydrogenated canola or soybean oil as the first ingredient in the ingredient list (132).

Intakes of iron, zinc, and selenium require monitoring to prevent deficiency. Supplemental iron may be required if maternal plasma ferritin concentration decreases to less than 12 ng/mL. Women with PKU who are on a low-protein diet and do not ingest medical food daily before pregnancy may have many nutrient deficiencies, including protein, iron, selenium, and vitamin B₁₂ (113). Because all of the vitamin B₁₂ and most of the zinc in the diets of Americans are derived from animal protein, pregnant women with PKU are at risk for developing deficiencies of these nutrients if adequate medical food is not ingested.

Phenylalanine-free medical foods that provide prescribed protein for the pregnant woman with PKU also provide the required amounts of vitamins. Therefore, a prenatal vitamin capsule containing vitamins A and D should not be prescribed for women ingesting adequate amounts of phenylalanine-free medical food. In fact, supplementation may provide vitamin A at levels approaching those that are teratogenic (133).

Morning sickness and changes in food preferences that accompany pregnancy may make adherence to the diet difficult for some pregnant women. Healthcare professionals

need to support these patients and work with metabolic nutritionists to improve the palatability and acceptance of the phenylalanine-free medical foods. One option might be to schedule the medical food at times when nausea is less likely to occur. Additional suggestions to help control nausea are available in the *Nutrition Support Protocols* (63).

Monitoring Nutritional Support. Ongoing monitoring of women with PKU involves more than measuring plasma concentrations of phenylalanine and tyrosine. Maternal weight gain, concentrations of plasma amino acids, albumin, ferritin, selenium, and zinc should be assessed on a regular basis. Because pregnant women with PKU are at risk for spontaneous abortion and premature delivery, they should be treated as high-risk patients, even if their blood phenylalanine concentration is in the targeted treatment range. Multiple ultrasound studies, beginning at 16 to 20 weeks' gestation, may be requested to monitor fetal head size and intrauterine growth patterns. Level II ultrasound to scan for heart defects and other malformations may also be ordered.

Tyrosinemias

Several known disorders of tyrosine metabolism (Table 61.11) may be amenable to nutritional support (see Fig. 61.1). Precise biochemical diagnosis is important because disorders such as liver disease, scurvy, and prematurity may produce increases in blood tyrosine that are not due to permanent, specific enzyme defects in tyrosine metabolism.

Designation	Enzyme/Defect	Clinical Features
Hepatorenal tyrosinemia type Ia	Fumarylacetoacetyl hydrolase	Orchitis, renal Fanconi syndrome, acute porphyria, succinylacetone, hepatocellular carcinoma
Hepatorenal tyrosinemia type Ib	Maleylacetoacetate isomerase	Liver failure, Fanconi syndrome, psychomotor retardation (in succinylacetone)
Oculodentary tyrosinemia type II	Hepatic tyrosine aminotransferase	Eye and skin disorders with variable mental retardation
Primary <i>p</i> -OHPPAD deficiency type IIIa	<i>p</i> -OHPPAD	Neurologic abnormalities, mental retardation
Phenylketonuria type IIIb	<i>p</i> -OHPPAD	Metabolic acidosis, microcephaly
Torment neuronal IIc	<i>p</i> -OHPPAD	Premature, possibly lethal
Tyrosinosis IIIc/d	Probably type II	Myasthenia (possibly acute porphyria attack)

^a*p*-OHPPAD is *p*-Oxidophenylpyruvate decarboxylase.

Table 61.11 Inherited Disorders Producing Increased Plasma Tyrosine

Seven clinical forms of hereditary tyrosinemia have been reported (Table 61.11). Type Ia is caused by a primary defect of hepatic FAH with the production of an abnormal metabolite, succinylacetone (134). The gene for FAH has been localized to chromosome 15q23-25 (135). Succinylacetone is formed from the accumulated substrate fumarylacetoacetate (Fig. 61.1). If maleylacetoacetic acid isomerase is functional, succinylacetone is also formed from maleylacetoacetate. Succinylacetone is extremely toxic and is associated with impaired active transport function and disordered hepatic enzymes, including *p*-OHPPAD and d-ALA dehydratase (136). Decreased

activity of both hepatic and erythrocyte d-ALA dehydratase has been reported in these patients and is postulated to be the mechanism for development of acute porphyric-like episodes (Fig. 61.2) (137 and 138). Using the drug NTBC to inhibit *p*-OHPPAD has prevented acute porphyric episodes and decreased rates of progression of cirrhosis and Fanconi syndrome (139).

Tyrosinemia type Ia is characterized by a generalized renal tubular impairment with hypophosphatemic rickets, progressive liver failure producing cirrhosis and hepatic cancer, hypertension, episodic behavioral and peripheral nerve deficiencies, and elevated concentrations of blood phenylalanine and tyrosine, with succinylacetone and d-ALA excretion in urine (140). The most common mutant allele is a splice donor site gain in intron 12 (IVS12G @ A+5). Many other missense and nonsense mutations are known. Reversion of the IVS12 mutation to normal in noncancerous hepatic nodules is described. FAH is expressed in amniotic and chorionic villus cells, and prenatal diagnosis is available by biochemical or molecular techniques (140).

Tyrosinemia type Ib, believed to be due to a deficiency of maleylacetoacetate isomerase, has been reported in one infant (140). Liver failure, renal tubular disease, and progressive psychomotor retardation occurred prior to death at 1 year of age. Succinylacetone did not accumulate. If this is confirmed, the pathophysiology of tyrosinemia type I will require reevaluation.

Tyrosinemia type II is characterized by greatly elevated concentrations of blood and urine tyrosine and increases in urinary phenolic acids, *N*-acetyltyrosine and tyramine. A deficiency of hepatic cytosolic tyrosine aminotransferase (TAT) has been demonstrated (140). Characteristic physical findings include stellate corneal erosions and plaques and bullous lesions of the soles and palms. Persistent keratitis and hyperkeratosis occur on the fingers and palms of the hands and on the soles of the feet. These skin abnormalities respond to restriction of dietary phenylalanine and tyrosine. Intracellular crystallization of tyrosine is thought to cause these inflammatory responses. Mental retardation may occur. The *TAT* gene is located on human chromosome 16q22. Missense, deletions, nonsense, and splice site mutations are known.

Three clinical subsets of type III tyrosinemia result from dysfunctions of *p*-OHPPAD (Fig. 61.1) (Table 61.10). The most severe is type IIIa with no hepatic *p*-OHPPAD. Neurologic abnormalities, including seizures, ataxia, and mental retardation have been reported in untreated patients with type IIIa. Hawkinsinuria (type IIIb) is named for the 2-L-cysteinyl 5-1,4-dihydroxycyclohexenyl-5,1-acetic acid that presumably is formed from an intermediate of impaired *p*-OHPPAD reaction. Metabolic acidosis and failure-to-thrive with “swimming pool”-like odor are described. Tyrosine restriction improves the critical condition.

Type IIIc is “benign” neonatal tyrosinemia, associated with increased plasma and urinary concentrations of tyrosine and its metabolites. It occurs in 0.2 to 10% of neonates (140). Short-term protein restriction to 1.5 to 2.0 g/kg body weight/day has lowered plasma tyrosine concentrations in most patients within 4 weeks of life. Whether added ascorbate will stabilize and increase the activity of *p*-OHPPAD in this disorder is not clear. Persistence of hypertyrosinemia in this disorder may lead to impaired mental

function, and short-term dietary and ascorbate therapy are recommended ([141](#)).

Diagnosis

Differential diagnosis is imperative for institution of appropriate therapy. Quantitation of plasma amino acids by ion-exchange chromatography and mass spectrometry (GC/MS) is a necessary approach to diagnosis. The more severe tyrosinemia type I may not be detected by newborn screening using the bacterial inhibition assay because newborn blood tyrosine may not be above 8 mg/dL. Many newborn screening programs consider 440 $\mu\text{mol/L}$ (8 mg/dL) within normal limits and do not retrieve these babies for further diagnosis. We routinely retest newborns with blood tyrosine levels above 220 $\mu\text{mol/L}$ (4 mg/dL) if no other cause is clinically evident. If blood tyrosine is above 8 mg/dL at 14 days of age, we evaluate renal tubular and hepatic function as well as urine by organic acid analysis for the presence of *p*-hydroxyphenyl acids and succinylacetone. Prenatal diagnosis of type I hereditary tyrosinemia has been made by measurement of succinylacetone in amniotic fluid ([142](#)), by measurement of FAH activity in cultured amniotic fluid cells, and by molecular analyses. Type II tyrosinemia has a marked increase in urinary *p*-OH-phenylacids and blood tyrosine ([143](#)). It increases with increasing age of the infant, whereas type IIIc decreases. Hawkinsinuria is measured by its ninhydrin reaction using ion-exchange chromatography.

Treatment

The objective of nutritional support for the hereditary tyrosinemias is to provide a biochemical environment that allows normal growth and development of intellectual potential. It will prevent pathophysiologic changes only in types II and III. Plasma phenylalanine concentrations should be maintained between 40 and 80 μmol , and plasma tyrosine concentrations between 50 and 150 μmol . Plasma methionine may need to be regulated by dietary means in tyrosinemia type I. We follow plasma methionine as an index of S-adenosylmethionine (SAM) transferase deficiency produced by liver damage and restrict dietary methionine when plasma methionine is elevated.

Nutritional therapy of the hereditary tyrosinemias requires a firm diagnosis because the approaches to therapy between types are different. Phenylalanine and tyrosine restriction is less severe and prognosis is excellent for types II and III. In type I, however, progressive liver and renal failure may occur as well as acute episodes of porphyria. Renal impairment must also be treated in tyrosinemia type I. Generalized renal tubular failure may result in metabolic acidosis, hypophosphatemia, rickets, and hypokalemia unless replacement of bicarbonate, phosphate, 1,25-dihydroxycholecalciferol, and potassium is instituted. Rapid treatment of infections is required to prevent a “catastrophic” catabolic state with overproduction of succinylacetone.

Many of the “porphyric” symptoms are due to overproduction of d-ALA secondary to the inhibitory effect of succinylacetone on d-ALA dehydratase and/or decreased heme biosynthesis ([Fig. 61.2](#)). Parenteral nutrition with 20 to 25% dextrose solutions may control these acute porphyric attacks ([144](#)). Continued or progressive loss of

energy-requiring functions that involve loosely bound heme to heme-protein (plasma membrane transporters, cytochrome P-450) may be due to rapid turnover and insufficient heme biosynthesis (Fig. 61.2). Infusions of hematin have produced transient decreases in d-ALA and have improved acute attacks of intermittent porphyria, but this invasive therapy is not recommended unless NTBC is not available (145, 147). Hepatocellular carcinoma, however, will *not* be prevented and will require liver transplant to prevent metastases (140, 145). The drug NTBC, which inhibits the activity of *p*-OHPPAD (148) in the treatment of tyrosinemia type I, may reduce the need for liver transplants and is an indicated adjunct to diet therapy (149). Patients should be on “protocol.” There is an excellent mouse model (149).

Nutritional Requirements. When one is planning nutritional support for the infant or child with tyrosinemia, a formal prescription that recommends daily amounts of phenylalanine, tyrosine, protein, energy, and fluid should be written. The prescription for phenylalanine and tyrosine is based on blood analyses correlated with intake that indicate the child's requirement and/or tolerance for each amino acid. Data in Table 61.4 describe amounts of phenylalanine, tyrosine, protein, energy, and fluid to offer as beginning therapy.

Because a large portion of phenylalanine is normally hydroxylated to form tyrosine (150), phenylalanine must also be restricted in the diet of patients with tyrosinemia. Phenylalanine requirements appear to be greater for children with tyrosinemia than for children with PKU. In general, the more distal the block is in the catabolic pathway, the more normal the amino acid requirement is. Tyrosine needs of children with tyrosinemia have been inadequately described and will vary with the metabolic state of the child and the accumulation of succinylacetone. If plasma tyrosine is inadequately controlled in NTBC-treated patients, symptoms of tyrosinemia type II occur.

Some investigators suggest that patients with tyrosinemia type I have decreased ability to metabolize methionine, whereas others believe that the elevated plasma methionine concentrations are secondary to liver damage (140). Whatever the cause for hypermethioninemia, some have recommended methionine restriction when blood methionine concentrations are above 40 μmol in the absence of hepatocellular damage. Although the extent of methionine restriction to maintain normal blood methionine concentration is unknown, one recommendation is 50 mg/kg of body weight for a 15-month-old child (151). L-Cysteine supplementation is also recommended for children with tyrosinemia type I, particularly if methionine restriction is implemented (152).

Recommended protein intakes for infants and children with tyrosinemia are given in Table 61.4. Because the primary protein source used for the infant is either an L-amino acid mix or a casein hydrolysate, recommended intake is greater than for the normal infant (51, 52). For tyrosinemia type I, when NTBC is administered, energy needs are similar to those of normal infants (52).

Medical Foods Low in or Free of Phenylalanine and Tyrosine. Adequate protein cannot be obtained from natural foods without ingesting excess phenylalanine and tyrosine (proteins contain by mass 1.4 to 5.8% tyrosine). Thus, special medical foods are used that contain little or no phenylalanine or tyrosine. Several medical foods are

available to provide protein (62, 63 and 64). Formulations, composition of major nutrients, and sources of medical foods are given in [Table 61.5](#).

The methionine content of Low Phe/Tyr Diet Powder; XPHEN, TYR Analog; XPHEN, TYR, Maxamaid; TYR 1, and TYR 2 ([Table 61.5](#)) is too great for use if dietary methionine must be restricted. In such a situation, Tyromex-1 Amino Acid Modified Medical Food with Iron; XPHEN, TYR, MET Analog and XPHEN, TYR, MET Maxamaid ([Table 61.5](#)), which contain no phenylalanine, tyrosine, or methionine, could be used.

Serving Lists. Serving lists are available for the phenylalanine-tyrosine-restricted diet ([Table 61.6](#)) (63). Methionine content is given for each list in the event that methionine restriction is required for type I. Portion sizes of individual foods in each list are given in reference 63.

Initiation of Nutritional Support. The most rapid decline of blood tyrosine concentration at the time of diagnosis may be obtained by feeding a 20 kcal/oz (67 kcal/dL) phenylalanine- and tyrosine-free formula with no added source of phenylalanine and tyrosine. Total energy intake above 120 kcal/kg/day is required to prevent a catabolic phase. Laboratory results of blood phenylalanine and tyrosine should be rapidly available or a deficiency of phenylalanine and tyrosine (153) could be precipitated. Catabolism, either due to inadequate energy intake and/or phenylalanine and tyrosine is particularly undesirable in treating tyrosinemia type I because a catabolic phase with overproduction of succinylacetone will worsen the clinical state. Protein sources containing 20 to 70 mg phenylalanine and 60 to 80 mg tyrosine/kg body weight/day are usually required after 3 to 4 days of total restriction in the newborn period.

Assessment of Nutritional Support. Frequency of assessment is dictated by the type of tyrosinemia and clinical course of the patient. In tyrosinemia type I, vital signs, height, weight, head circumference, neurologic examination, and development are documented weekly for the first 3 months, biweekly for the second 3 months, and monthly between 6 months and 1 year of life. Plasma amino acids are quantitated by ion-exchange chromatography and succinylacetone and *p*-hydroxyphenyl organic acids by GC/MS. Additional laboratory studies include urinary d-ALA, blood and urine assessment of renal losses (HCO_3^- , K^+ , Na^+), and liver status (α -fetoprotein and liver function tests). Clinical status, dietary intake, and laboratory data should be monitored and correlated in managing tyrosinemia type I at intervals indicated previously. Application for inclusion in NTBC trials and for eventual liver transplant should be initiated within the 1st year of life for patients with type I tyrosinemia.

Outcomes of Nutritional Support. Outcomes, to date, have been variable with tyrosinemia type I. Some of this "variation" is caused by the lack of clear diagnostic criteria in the past to delineate the various types of tyrosinemia. Early detection and diagnosis using GC/MS; low-phenylalanine and low-tyrosine, high-carbohydrate diets; hematin infusions; and early replacement of renal tubular losses bring success at early ages in treated tyrosinemia type I. Although NTBC may be the ultimate treatment for tyrosinemia type I, institution of the treatment immediately after birth may be necessary to prevent hepatocellular carcinomas, but there are few data to support outcome in this

regard (139). The low-phenylalanine, low-tyrosine diet has been successful in several patients with tyrosinemia types II and III, with rapid resolution of clinical signs and symptoms (140). Neonatal tyrosinemia requires early but transient protein restriction. The efficacy of oral ascorbate at 50 mg/day is unclear. Controlled outcome data are not yet available.

BRANCHED-CHAIN AMINO ACIDS

Disorders of BCAA metabolism provide an interesting interface between clinical and basic sciences. Using the nutritional model of preventing mental retardation through screening, retrieval, diagnosis, and management of newborns, many rare experiments of nature have become available and have advanced our knowledge concerning nutrition needs and metabolic use of isoleucine, leucine, and valine (154).

Biochemistry

The BCAAs isoleucine, leucine, and valine are essential nutrients. In the newborn, 75% of the amounts ingested is used for protein synthesis. That present in excess of need for synthetic purposes is degraded through many steps to provide energy (Fig. 61.3). The initial step in catabolism is reversible transamination, requiring a specific transaminase and the coenzyme pyridoxal phosphate. The second step is irreversible oxidative decarboxylation, which uses the BCKAD complex. This complex is located in the inner mitochondrial membrane and requires the coenzymes thiamin pyrophosphate, lipoic acid, CoA, and NAD⁺ (154, 155, 156, 157, 158 and 159). Figure 61.3 diagrams this overall reaction, which is impaired in MSUD. At least six proteins are involved: E1a, E1b, E2, E3, a kinase, and phosphatase.

Figure 61.3. Catabolism of branched-chain amino acids. *Crosshatch bars* represent blocks in maple syrup urine disease (branched-chain α -ketoacid dehydrogenase complex) and in isovaleric acidemia (isovaleryl-CoA dehydrogenase). *TPP*, the cofactor thiamin pyrophosphate; (*n*), several catalyzed intermediate steps.

The loci for these genes are E1a at chromosome 19q13.1q13.2; E1b at 6p21-p22; E2 at 1p31; and E3 at 7q31-q32 (154). The BCKAD-specific kinase and phosphatase have not been cloned, nor have chaperonin proteins, which are involved in their mitochondrial assembly process. Almost all mutations in these proteins that produce MSUD are private. The only one common among Mennonites is in the E1a protein and is a conversion of tyrosine to asparagine at amino acid 393 (Y393N).

Relatively little help in managing MSUD has resulted from these advances except for the role of pharmacologic cofactors. When thiamin pyrophosphate saturates its site on E1a, the biologic turnover of BCKAD is decreased. Increasing thiamin ingestion increases intracellular thiamin pyrophosphate (TPP), and the TPP-binding sites on the decarboxylase (E1a) moiety of the BCKAD complex become saturated. When these TPP-binding sites are occupied, the multienzyme complex undergoes a conformational change that makes it more resistant to chymotrypsin and heat degradation. The biologic half-life of the enzyme and overall activity are increased when a new equilibrium of enzyme synthesis and degradation is reached. This model has been tested and is supported by clinical, functional, and structural studies (155, 156, 157, 158, 159 and 160) (Fig. 61.4).

Figure 61.4. Model for stabilization of branched-chain α -ketoacid dehydrogenase by thiamin pyrophosphate. The multienzyme complex branched-chain α -ketoacid dehydrogenase has a configuration that is more stable to degradation when thiamin pyrophosphate (TPP) binding sites on its decarboxylase moiety are occupied. *FAD* and *NAD*, flavin and nicotinamide adenine dinucleotide.

Branched-Chain α -Ketoaciduria (Maple Syrup Urine Disease)

MSUD is a group of inherited disorders of isoleucine, leucine, and valine metabolism (154, 161). These disorders result from several different mutations that impair various components of the multienzyme BCKAD (Fig. 61.3). Although most mutant enzymes are immunologically present, one reported patient had absent branched-chain acyl

transferase (E2) as a cause of thiamin-resistant MSUD (156, 162). An autosomal recessive mode of inheritance was found in all reported cases, supporting nuclear, rather than mitochondrial, origin of these proteins. The cellular mechanisms involved in assembling the products of these nuclear genes into a multienzyme complex in mitochondria are of considerable clinical and fundamental importance and are still unresolved.

Infants with MSUD appear normal at birth and are clinically well until after they eat a protein-containing feed. The most severely impaired enzymes may produce seizures, apnea, and death within 10 days of birth. The disorder is characterized by elevated blood, urine, and cerebrospinal fluid concentrations of the BCKAs, their amino acid precursors, and the pathognomonic allopregnenolone. Progressive neurologic dysfunction and production of fragrant urine with the odor of burnt sugar (caramel) or maple syrup follow. The sweet smell may only be evident in earwax, easily sensed after otoscopic examination. Neurologic impairment in the newborn is manifested by poor sucking, irregular respiration, rigidity alternating with periods of flaccidity, opisthotonos, progressive loss of Moro reflex, and seizures.

Several variants covering a spectrum of impaired mitochondrial BCKAD complexes have been reported. Clinical manifestations are expressed intermittently upon protein loading or with febrile illness in patients with partial enzyme activity between 5 and 20% of normal. Patients with 3 to 30% BCKAD complex activity express an intermediate form of the disease. A thiamin-responsive form with expression similar to the intermediate form has been described (154). Whole-body leucine-1-¹³C oxidation to ¹³CO₂ may be the best method to ascertain total body needs, because peripheral cells may not reflect liver and renal BCKAD function (156, 158).

Untreated patients with classic MSUD (0–2% BCKAD complex activity) who survive beyond early infancy have retarded physical and mental development (4, 5). Early diagnosis and therapy lead to normal growth and development. If death occurs in the first few days of life, few unique abnormalities are seen in the brain. With prolonged survival, deficient myelination is thought to be due to enzymes involved in myelin formation, inhibition of amino acid transport, and inhibition by BCKAs of oxidative phosphorylation (4, 5).

Screening

Because apnea and death may be the first clinical manifestations of the classic disorder, newborn screening, retrieval, and initiation of therapy are urgent, and all four processes must be completed within the 1st week of life. Nonselected screening of the newborn population is currently in progress (in some states) using a bacterial-inhibition assay for blood leucine concentrations (3, 35). Bedside screening in selected children uses the urinary dinitrophenylhydrazine (DNPH) reaction for branched-chain α -ketoaciduria. This reaction can also be used to monitor dietary progress. International newborn screening indicates that the incidence of MSUD is about 1 in 216,000 (163). The incidence in Georgia, where 37% of newborns are black, is approximately 1 per 123,000 live births (Table 61.3). Little information comparing frequencies among ethnic groups is available,

although some inbred communities have a high frequency ([154](#)).

Diagnosis

Any infant with a blood leucine concentration above 4 mg/dL (305 $\mu\text{mol/L}$) on the newborn screening test should be immediately evaluated. Most infants with the classic disease have more than 8 mg/dL (610 $\mu\text{mol/L}$) leucine at 72 hours of age. Diagnosis is confirmed using ion-exchange chromatography to quantitate plasma isoleucine, leucine, valine, and alloisoleucine and GC/MS to identify urinary BCKAs. The extent of enzyme impairment should be determined on cultured cells such as dermal fibroblasts to enable future prenatal diagnosis, since prenatal monitoring is available if the cellular phenotype is confirmed in fibroblasts cultured from the patient's skin ([164](#)). In some families with severely impaired enzyme function, heterozygotes can also be identified from enzymatic assays of cultured dermal fibroblasts ([162](#)). However, total-body leucine oxidation using stable isotopes and the $^{13}\text{CO}_2$ "breath test" is the most reliable diagnostic tool to establish dietary needs, including thiamin responsivity ([156](#), [158](#)). Except in Mennonites, molecular analysis is useful only for research purposes.

Treatment

Although hemodialysis with nitrogen-free dialysate ([165](#), [166](#)) or exchange transfusion ([165](#)) may be required when diagnosis is delayed, if screening, retrieval, and diagnosis are completed within 8 to 10 days of life, these actions are seldom necessary. Because hemodialysis superimposes iatrogenic risk and prolongs a catabolic phase, it is not recommended. BCAA-free orogastric feeding of protein and energy should begin as soon as the diagnosis is made. The objective is to produce anabolism in the infant and thereby prevent accumulation of neurotoxic BCKAs ([167](#)). If orogastric feeding is not acceptable, gastrostomy or a central line for hyperalimentation with dextrose and lipid should be initiated for initial care of classic MSUD during the neonatal period. Except during illness, restricting protein intake to 1.5 g/kg/day may be adequate therapy for those with 20% or more of enzyme activity.

Long-term therapy for MSUD is dietary. The objective of long-term nutritional support in the child with MSUD is to maintain plasma concentrations of BCAAs that will allow maximal development of intellect while supplying adequate energy, protein, and other nutrients for optimal growth. Plasma concentrations of BCAAs (3–4 hours after a meal) should be maintained within the following ranges: isoleucine, 40 to 90 μmol ; leucine, 80 to 200 μmol ; and valine, 200 to 425 μmol . Isoleucine deficiency results in skin lesions that resemble acrodermatitis enteropathica ([168](#), [169](#)). With a deficiency of isoleucine or valine, plasma concentration of leucine remains elevated. With deletion of the BCAAs, plasma isoleucine returns to normal first, followed by valine. If adequate dietary isoleucine and valine are then added to maintain normal plasma concentrations, plasma leucine concentration returns to normal in 5 to 10 days ([170](#)).

The objectives of nutritional support are met by using a combination of medical foods ([Table 61.5](#)) and natural foods ([Table 61.12](#)). Most patients with MSUD who have detectable BCKAD multienzyme complex by immunoassay respond to oral thiamin administration of 100 to 1000 mg daily ([156](#), [158](#), [160](#), [171](#)). In classic MSUD, thiamin is

only an adjunct therapy, and dietary restriction of isoleucine, leucine, and valine is needed. Supraphysiologic amounts of oral thiamin should be added for at least a 3-month trial period because it stabilizes the enzyme complex (Fig. 61.4). Increased residual specific activity of mitochondrial membrane-bound enzymes may require this prolonged period because of the biologic half-life of this subcellular organelle. During this period, decreased sensitivity to dietary BCAAs is usually observed, and more can be added to the diet. Evaluation of total body leucine oxidation before and during thiamin administration gives direct evidence for responsivity (156, 158).

Food List	Isoleucine (mg)	Leucine (mg)	Valine (mg)	Protein (g)	Fat (g)	Energy (kcal)

Table 61.12 Average Nutrient Content of Equivalent Lists for Branched-Chain Amino Acid–Restricted Diets

Nutrient Requirements. Data in Table 61.4 outline the suggested amounts of BCAAs, protein, energy, and fluid to offer the infant or child with MSUD. Because the BCAAs are essential, they cannot be deleted from the diet without producing growth failure and death. In planning nutritional support of the infant or child with MSUD, a formal prescription should be written that includes recommended daily amounts of BCAAs, protein, energy, and fluid. Frequent adjustments in the dietary prescription are necessary. Adjustments are needed daily during the first few weeks and biweekly during the first 6 months of life, based on appetite, growth, development, and laboratory analyses of plasma BCAAs and BCKAs. Because leucine residues are more prominent than isoleucine and valine in most proteins, supplemental L-isoleucine and L-valine as free amino acids may be necessary in the newborn period and beyond to prevent deficiency of these two essential amino acids. However, competition between the free BCAAs at the intestinal cell can cause imbalances in plasma amino acids (172).

Requirements for isoleucine, leucine, and valine vary considerably depending on age, type and extent of enzyme defect, growth rate, and state of health. Younger infants normally have greater requirements per unit body weight than older infants. A rapid decline occurs in requirements for BCAAs between 3 and 6 months of age. Careful monitoring of plasma concentrations and intake of BCAAs is required to prevent excess intake when growth rate declines and to provide adequate intake when growth is

accelerated as in early infancy, during prepuberty and puberty, and during the last half of gestation. There has been one successful pregnancy in an adult with MSUD whose protein requirements were those of a normal adult but fell dramatically after delivery (154).

The recommended protein intake for infants with MSUD (Table 61.4) exceeds that for normal infants and children because the primary protein source consists of L-amino acids (51). Recommended energy intake after the initial acute period is the same as for normal infants and children, but may vary considerably (see Table 61.4) (52). During the neonatal acute period, up to 170 kcal/kg/day may be required (173).

Medical Foods Free of Branched-Chain Amino Acids. Adequate protein cannot be obtained from ordinary foods without ingesting more BCAAs than are required in classic MSUD. The BCAA content of foods as a percentage of protein ranges from approximately 3.5 to 8.5% (56, 57, 58, 59, 60 and 61). Because of the BCAA content of most proteins, medical foods are used that are formulated from L-amino acids free of BCAAs. In the United States, several products are available to provide protein (62, 63 and 64). Formulations, major nutrient composition, and sources of these products are given in Table 61.4.

Equivalent Lists. Equivalent lists of foods are available to provide variety and needed natural protein in the diet (63). The lists are similar to diabetic exchange lists in that foods of similar leucine content are grouped together and may be exchanged for one another within the same list. Average isoleucine, leucine, valine, protein, and energy contents of these lists are given in Table 61.12.

Initiation of Nutritional Support. A rapid decline in plasma isoleucine and valine can be achieved at the time of diagnosis by feeding formula free of BCAAs. However, plasma leucine will continue to increase over the first 4 days of life, even if dietary BCAA restriction is implemented at birth (170). Most patients are not anticipated at birth, and infants whose screening results are positive are treated at 7 to 14 days of life. In our experience, branched-chain ketoacidosis can be averted by high-energy intake with no added BCAAs over a 72-h period if instituted between 8 and 11 days of age. There is an association among the degree of α -ketoisocaproic acid excretion, leucine elevation, and clinical outcome (174). Laboratory results of plasma BCAAs should be rapidly available to prevent the predicted deficiency in isoleucine and valine. When replacement is begun, these two amino acids may be added as free L-amino acids to increase their ratio to leucine in natural protein. High-energy intake of 140 to 170 kcal/kg of body weight during this period prevents catabolism of body protein. If the osmolality of formula permits, protein at 3.0 to 3.5 g/kg should be offered. This regimen will lower the concentrations of BCAAs to near normal ranges. If deficiency of either isoleucine or valine occurs, plasma leucine concentrations will remain elevated as a function of muscle catabolism or decreased protein synthesis.

Sample diets for management of children with MSUD are listed in Table 61.13 and Table 61.14. The leucine required at birth may fall from 70 to 40 mg/kg/day at 2 years. Medical foods designed for MSUD should be used for therapy, but to prevent deficiency of the essential amino acids isoleucine and valine, solutions of these two BCAAs are

added back to the formula. As described in these sample dietary guides, this need persists over this 2-year developmental period.

Assessment of Nutritional Support. Frequency of assessment is dictated by the clinical course and the response of plasma amino acids. Monitoring of therapy should use three combined approaches. Ion-exchange chromatography should be used daily to quantitate plasma amino acid concentrations for approximately 3 weeks after birth; these help determine requirements for the individual BCAAs. Urine can be evaluated at bedside for decline in the DNPH reaction much like Clinitest was used to monitor diabetic ketoacidosis. Quantitation of organic acids by GC/MS can detect decline in

BCKAs and presence of b-lipolysis.

After requirements are established, plasma amino acid concentrations are determined approximately every 2 weeks to ensure that the child has not “outgrown” the prescription. Samples should be obtained at midday before the noon feeding. We have found organic acid analysis of urine to be helpful. BCKAs decrease under optimum dietary conditions. If energy or a specific amino acid is overrestricted, evidence of b-lipolysis (acetoacetic acid, b-OH-butyric acid) is found.

After hospital discharge, daily testing of urine with DNPH by a parent at home screens rapidly for ketoaciduria. As a rule, “preventive” clinical evaluation of the child for cryptogenic infections before overt ketoacidosis occurs is more effective than trying to treat the child after a catabolic phase has produced its attendant ketoacidosis. If the urine DNPH results are positive, a blood sample should be collected on filter paper for leucine assay and the urine should be further analyzed by GC/MS to differentiate “ketonuria” from branched-chain α -ketonuria. A physician should evaluate the child for infection or other causes of ketoacidosis. With a dietary history, a physician's examination, and laboratory analyses, one can usually differentiate among overrestriction, intercurrent infection, or dietary underrestriction as a cause for branched-chain α -ketoaciduria. Weekly quantitation of leucine, isoleucine, and valine and dietary records are useful for chronic management. Every effort should be made to maintain plasma BCAAs in the normal range. Plasma leucine concentrations above 600 μmol are associated with clinically significant α -ketoacidemia and appearance of ataxia (4, 174). Changes suggesting dysmyelination were found in the white matter in the cerebral hemispheres, brainstem, mesencephalon, thalamus, and globus pallidus of patients with chronically elevated concentrations of BCAAs (175).

Episodes of infection can evoke catabolism of tissue protein and increase plasma concentrations of BCAAs. Clinical improvement is rapid if some BCAAs are administered along with an amino acid mix that provides 150 to 200 kcal/kg/day. Parenteral amino acid solutions free of BCAAs have also caused a rapid decline in plasma BCAAs during infection, with concomitant clinical improvement (176).

Outcome of Nutritional Support. Patients diagnosed at 5 days of age or less had IQs (97 ± 13 SD) above those of normal siblings or parents (177). Factors influencing IQ were age at the time of diagnosis, neonatal condition, and long-term metabolic control. Reproductive outcome of a woman with classic MSUD, whose blood BCAAs were controlled by diet, was excellent (178).

The first attempt to manage an 8-month old infant with MSUD used pure amino acids totaling approximately 50 g daily. Oil and sugar were used to yield 1500 kcal/day. Mineral and vitamin mixtures were also provided. Plasma concentrations of BCAAs decreased significantly, and the maple syrup odor disappeared from the urine. During the dietary trial, length and weight increased from the 3rd to the 50th percentile (179).

Nutritional support of a neonate with BCKA was subsequently described (180). Plasma amino acids were measured as a basis for dietary changes. Approximate protein intake ranged from 3.5 to 3.0 g/kg/day between 3 and 8 months of age, respectively. Energy

intake was about 125 kcal/kg/day. At birth, the infant was at the 10th percentile for length and weight; during the 1st year of life, length increased toward the 50th percentile, but weight remained at about the 10th percentile. Anemia, with a hemoglobin of 8.5 g/dL, was present from 1 to 3 months of age. At 55 weeks of age, the patient had a developmental quotient of 97, which is in the normal range (180).

Experience with seven patients with MSUD, three of whom expired, was reported (181). The surviving patients received an L-amino acid mix free of BCAAs to which corn oil (43% of energy), dextrimaltose (45% of energy), minerals, and vitamins were added. Protein and energy intake was not reported. Linear growth of one patient by 1 year of age was considerably below the 10th percentile. Three of the four surviving patients had weights below the 10th percentile; length/height percentiles were not given.

A number of other investigators have reported poor growth in treated children with BCKA (181, 182, 183, 184, 185, 186 and 187). Except for Henstenberg et al. (187), who indicated that mean protein and energy intakes were 78 and 86% of RDA, respectively, few authors reported protein or energy intake. However, intake of both protein and energy by children with MSUD has been reported to be below that of comparably aged normal children (188). Whether failure to thrive is due to the underlying disease or to iatrogenic dietary effects is unclear. Some investigators reported normal growth when adequate protein and energy were fed (156, 158, 179, 180).

Selenium deficiency has been found in treated patients with MSUD (189). B vitamin deficiencies resulting in anemia, angular stomatitis, and skin lesions occurred in one baby when the B vitamin mixture was not added to the diet for 6 weeks (180). Folic acid deficiency was reported in an infant after about 4 months on a synthetic diet (190). Acidosis occurred in an infant treated with an amino acid mix in which several amino acids were provided as the HCl salt (191).

Termination of Nutritional Support. Patients with classic MSUD are unable to terminate diet, even if they respond to thiamin. The occurrence of death in variants with intermittent MSUD suggests the need for some form of ongoing therapy in even these relatively stable patients (154). The BCKAs are relatively acute neurotoxins and probably interfere with oxygen consumption and adenosine triphosphate (ATP) production in the medullary reticular substance of the brain (154).

Isovaleric Acidemia

First described in 1967, isovaleric acidemia was identified by the urinary excretion of IVA (189). Subsequently, a deficiency of isovaleryl-CoA dehydrogenase (IVD) was defined in cultured skin fibroblasts (170). This enzyme is a mitochondrial flavoprotein that uses electron transfer factor (ETF). Although ETF deficiency is also reported, mutations in the apoenzyme are specific for isovaleryl-CoA as substrate. IVD deficiency blocks the catabolism of leucine at the next step after the BCKAD complex (Fig. 61.3). The IVD gene was assigned to chromosome 15q14-q15 (191), and molecular heterogeneity is defined and five classes proposed on the basis of the effects of various mutations on IVD (191, 192). Class I has normal-sized IVD and missense mutations.

Classes II, III, and IV have smaller proteins, and class V has no immunologically detectable IVD ([192a](#)). IVA, 3-hydroxyisovaleric acid (3-OHIVA), and the adduct IVG accumulate in body fluids. Gas-liquid chromatography and mass spectrometry can identify these compounds in body fluids ([161](#)).

The phenotypic abnormalities result from the toxic accumulation of free IVA. An alternate pathway producing IVG using glycine-*N*-acylase reduces the accumulation of the toxic precursors. Thus, clinical differences in phenotype are due to the degree of impaired IVD and epigenetic phenomena such as the degree of alternate detoxification available to this alternative pathway ([161](#), [193](#), [194](#)). Carnityl adducts offer an additional alternate pathway to detoxify free IVA.

Despite molecular advances in understanding the mutations affecting IVD, two disease forms continue to be clinically useful classifications: the acute form and the chronic intermittent form ([161](#)). Patients with the acute form of isovaleric acidemia are generally normal full-term infants at birth. Within the first days of life, poor feeding, tachypnea, vomiting, and a characteristic “sweaty-feet” odor (due to IVA) of the blood and urine are frequently noted. Diarrhea, lethargy, hypotonia, and tremors ([161](#)) may also be found. In some cases, patients do not respond to treatment; they may become cyanotic or comatose, and death often results ([161](#)). The exact cause of death is frequently unknown. Severe metabolic acidosis, hyperammonemia, CNS hemorrhage, cardiac arrest, and sepsis are some probable causes. Infants who are detected early and respond to treatment survive the neonatal period and develop appropriately. If the acute neonatal disease is prevented, they progress into the chronic intermittent type of isovaleric acidemia ([161](#)).

In the chronic intermittent form, babies are normal at birth. During late infancy they may develop episodes of vomiting, acidosis, stupor, and coma. A sweaty-feet odor is usually present, and a transient alopecia is occasionally seen. These episodes may begin as early as 2 weeks of age, and the frequency of attacks seems to decrease with age. Urinary tract and upper respiratory infections frequently trigger these episodes, as do excessive intake of protein and aspirin. Many children affected by the intermittent form prefer fruits and vegetables over meat and milk. The degree of enzyme (IVD) impairment and capacity of the alternate IVG-producing pathway, as well as intake, probably produce these clinically different presentations.

Several patients with either the acute or the chronic form of isovaleric acidemia have had moderate-to-severe hematologic abnormalities, including leukopenia and thrombocytopenia, with pancytopenia being the most common. IVA inhibits granulopoietic progenitor cell proliferation in bone marrow cultures and may account for the neutropenia often seen in isovaleric acidemia ([195](#)). In one instance, transfusion of packed red cells and platelets prevented further complications. Depressed hemoglobin levels were also seen in several patients. Transient alopecia seems to be more common with the chronic intermittent form than with the acute form of the disease and may be nutritionally related ([161](#)). Hyperammonemia (up to 1200 μmol) has also been reported during neonatal crises ([161](#)).

Diagnosis

Because IVG is excreted during both remission and ketotic attacks, measurement of urinary IVG by GC/MS is the best method of diagnosis. Normal 3- to 5-year-old unaffected children have no detectable urinary IVG (<2 mg/day). Affected children of the same age excrete from 40 to 250 mg/day (161). During ketotic episodes, urinary 3-OHIVA, 4-OHIVA, and methylsuccinic acid are excreted in large quantities as well (161).

Diagnosis is confirmed by measuring the impaired ability of skin fibroblasts cultured from affected individuals to oxidize leucine-2-¹⁴C to ¹⁴CO₂ (190, 196). A more complicated assay using mitochondria and 1-¹⁴C-IVA has also been used (197). High-field proton nuclear magnetic resonance is a promising new technique for rapid diagnosis of isovaleric acidemia because it can readily detect IVG in a small sample of urine (198).

Prenatal diagnosis is available by combined organic acid analysis of amniotic fluid and enzyme assay of cultured amniotic fluid cells. A heterozygote for IVD has been detected prenatally (199).

Treatment

During acute ketotic attacks, parenteral fluid therapy and correction of the metabolic acidosis are indicated as adjuncts to high energy intake and L-carnitine and glycine therapy (161). Serum and urine IVA concentrations are monitored during ketotic attacks. GC/MS analysis is the most accurate means of determining serum and urinary IVA (161). A special method of GC/MS allows separate quantitation of the two isomers, IVA and 2-methylbutyric acid (161). Serum IVA ranges from 0.1 to 84 mg/dL (161) depending on the patient's clinical status. A simple and rapid method of determining 4-OHIVA concentrations in the plasma has recently been devised (200); however, elevations of this metabolite lag at least 36 hours behind the maximum plasma level of IVA (200), which limits its use clinically. Monitoring urinary IVG provides a good parameter of nutrition therapy. Titration of IVG with free glycine to a stable optimum is desirable. However, excess glycine over free substrate (IVA) may inhibit IVG production (Fig. 61.5). When leucine restriction is optimal and the patient is stable, about 90 mg/kg/day is optimal. During acute disease, a higher intake (300–600 mg/kg/day) of glycine may be necessary until infection or dietary leucine indiscretions are removed (202).

Figure 61.5. Effect of oral glycine supplement on isovalerylglycine production in stable isovaleric acidemia. Oral glycine supplements indicated on the *abscissa* were administered at weekly intervals to a patient with isovaleric acidemia while she was maintained on a constant leucine-restricted diet. Isovalerylglycine (IVG) and isovaleric acid were quantitated by gas chromatography. Symbols represent the mean of duplicate 24-h urine samples collected over the last 2 days of each interval. Note the increase in IVG production at 50–150 mg/kg/day with increased IVG production at 300 and 600 mg/kg/day of dietary glycine supplement. (Courtesy of Division of Medical Genetics, Emory University, Atlanta, GA).

Nutrient Requirements. A low-protein diet of 1.2 to 1.5 g/kg/day in children under 1 year of age improves clinical symptoms, and many patients restrict protein by choice (161). This represents only 60% of the RDA. Protein restriction alone is therefore not the best mode of therapy because overrestriction of essential BCAA (ILE, VAL) is inevitable if leucine is adequately restricted in natural food.

Leucine restriction and the use of pharmacologic doses of glycine have been reported. In six patients with isovaleric acidemia, glycine therapy resulted in decreased IVA in plasma and urine (161). Urinary IVG simultaneously increased, often two- to threefold (Fig. 61.5). Clinical improvement occurred that was characterized by increased growth, control of acidosis, and resolution of pancytopenia with glycine supplements and protein restriction over a 2-week period.

Glycine used to remove IVA through an alternative pathway is a prototype for nutritional detoxification of accumulated substrates in inborn errors of metabolism (Fig. 61.5) (201, 202). The ubiquitous enzyme glycine-*N*-acylase has a broad range of substrates (Table 61.15) that accumulate in other inborn errors of metabolism and might also be amenable to this approach. The relative amounts of glycine required to optimize removal of IVA (or other substrates for the glycine-*N*-acylase reaction) need careful evaluation and will change with the clinical condition of the patient (202).

Substrate	K_M	V_{max}
	(10^{-4} M)	($\mu\text{mol}/\text{min}/\text{mg protein}$)
Tiglyl-CoA	1.1	33.3
Isovaleryl-CoA	1.8	12.3
Benzoyl-CoA	0.09	10.4
2-Methylbutyryl-CoA	1.1	8.3
3-Methylcrotonyl-CoA	0.14	5.7
Propionyl-CoA	1.8	4.4
Acetyl-CoA	2.1	1.6

Table 61.15 Kinetic Constants for Glycine-*N*-Acylase from Bovine Liver

Some evidence exists for substrate inhibition of the reaction when excess glycine is added under stable conditions (Fig. 61.5). The optimal dose of supplemental glycine was determined for a 9-year-old Caucasian girl with isovaleric acidemia who was well and maintained on a leucine intake of 54 ± 3.6 mg/kg/day. Supplementation with glycine below or above the range of 50 to 150 mg/kg resulted in a 50% decrease in IVG excretion. Urinary IVA excretion was consistent throughout the study. No b-hydroxy-IVA was detected in plasma or urine. The results of this study indicated that (a) the optimal dose of glycine for this patient under these stable clinical and nutritional conditions was 50 to 150 mg/kg, (b) an optimal dose of glycine should be quantitated for specific ages, clinical states, degree of enzyme activity, and leucine intake in the treatment of isovaleric acidemia, and (c) glycine supplements above 300 mg/kg/day increased plasma and urinary concentrations of glycine but resulted in decreased IVG excretion, as if this substrate inhibited glycine-*N*-acylase when concentrations of its cosubstrate, isovaleryl-CoA, were controlled (202).

Systemic carnitine deficiency was demonstrated in several patients with isovaleric acidemia (203). Although plasma levels of carnitine were low in these patients, the acylcarnitine ester—isovaleryl carnitine (IVC)—was increased, especially during illness (203, 204). Relative deficiency of muscle carnitine and use of carnitine as an adduct for IVA are two reasons for treating with extra L-carnitine. The relative therapeutic value of L-carnitine has been compared with that of glycine in the treatment of isovaleric acidemia in a 4.5-year-old black male (204). Administration of glycine plus leucine resulted in excretion of more IVA as IVG than when leucine was administered alone. Leucine plus L-carnitine increased IVC excretion from a pretreatment level of 7 μmol per 24 hours to a posttreatment level of 1470 μmol per 24 hours. Large doses of carnitine are needed, in the range of 100 to 200 mg/kg/day, to accomplish this therapeutic excretion, whereas 100 to 150 mg/kg/day of glycine will suffice. Smaller doses of carnitine supplements are recommended to prevent “deficiency.”

Medical Foods Free of Leucine. Four medical foods free of leucine have been designed specifically for nutritional support of patients with isovaleric acidemia and other

disorders of leucine catabolism. Formulations, major nutrient composition, and sources of these medical foods are given in [Table 61.5](#).

Outcome of Nutritional Support. A male infant with isovaleric acidemia, treated from the neonatal period with a medical food designed for MSUD with added L-isoleucine and L-valine and whole protein to supply essential restricted leucine, had normal growth and development. Height and weight were between the 25th and 50th percentile. Head circumference was at the 50th percentile. On average, the diet supplied 2.5 to 3.0 g protein/kg/day and 100 mg leucine/kg/day. L-Carnitine and glycine were not a part of the dietary regimen ([205](#)).

Growth of a male infant diagnosed prenatally with isovaleric acidemia has been reported. At birth the infant was breast-fed ad libitum, and 250 mg glycine/kg/day was administered. In spite of the low protein intake from human milk and the glycine supplement, the patient became acidotic and began to vomit and hyperventilate at 3 days of age. Breast-feeding was discontinued, and a leucine-free diet providing 125 kcal/kg supplemented with 380 mg glycine/kg/day was begun. His clinical status improved rapidly. Dietary leucine at 45 mg/kg/day with glycine at 250 mg/kg/day and protein at 2.0 g/kg was introduced at 5 days of age. At 2 years of age, the patient was developmentally normal and above the 95th percentile for height and weight. Diet at 2 years of age supplied per kg: 46 mg leucine, 1.7 g protein, and 72 kcal. Only one hospitalization for vomiting and dehydration was required during the 2-year period ([202](#)).

Outcomes in nine patients with isovaleric acidemia managed by protein restriction (1.5–2.0 g/kg in infancy, 0.8–1.5 g/kg thereafter) and 250 mg glycine/kg/day have been reported ([206](#)). Since all patients had secondary carnitine deficiency (total serum carnitine 19 ± 3 $\mu\text{mol/L}$), four of the children were supplemented with 50 mg/kg/day L-carnitine, and in these, serum carnitine returned to normal (51 ± 5 $\mu\text{mol/L}$). Actual height, weight, and head circumference of patients were not reported, although growth velocities were stated to be normal after diet initiation. Developmental quotients or IQ scores of the five subjects in whom diet was initiated during the neonatal period ranged from 49 to 115 ([206](#)).

In a study by one of the authors (PBA), the patient failed to grow normally, most probably because of low energy intake; however, development was normal. Food refusal has been reported in a patient with isovaleric acidemia ([207](#)). Both physiologic and behavioral components to feeding problems were reported. The physiologic component involved altered serotonin metabolism. Any factor such as hyperammonemia or a high-carbohydrate, low-protein diet that stimulates the transport of tryptophan, a precursor of serotonin, into the brain, could lead to anorexia. A low-tryptophan diet was suggested as one alternative to the treatment of anorexia ([208](#)).

Of 11 reported French patients with isovaleric acidemia, 8 were alive after the neonatal period. Leucine restriction and glycine supplementation were used to manage patients. Six of the eight surviving patients have normal development ([209](#)).

SULFUR-CONTAINING AMINO ACIDS

The biochemistry and nutritional requirements for sulfur-containing amino acids have been largely elucidated in humans by studies of inherited blocks in their metabolic pathways.

Biochemistry

Natural protein contains approximately 0.3 to 5.0% methionine. Some dietary methionine is used by the body for tissue protein synthesis, but most is used in the transsulfuration pathway to form adenosylmethionine, adenosylhomocysteine, homocysteine, cystathionine, α -ketobutyrate, cysteine, and their derivatives (Fig. 61.6). The first step in the transsulfuration pathway is synthesis of SAM, a reaction catalyzed by methionine-S-adenosyltransferase (MAT). Impaired MAT results in hypermethioninemia and variable clinical expression from sulfurous breath odor to mental retardation. The hepatic isoform of MAT only is deficient (212). In this reaction, the adenosyl portion of ATP is transferred to methionine. Biologically important compounds that obtain their methyl group from SAM include creatine, choline and phosphatidylcholine, methylated DNA and RNA, and epinephrine. Decarboxylated SAM is the source of the three carbon moieties of spermidine and spermine. S-Adenosylhomocysteine is formed as an intermediary product in this pathway and is hydrolyzed to homocysteine.

Figure 61.6. Metabolic pathways of sulfur amino acids. *Hatched bars* represent impaired reactions in three inherited metabolic disorders resulting in hyperhomocyst[e]inemia.

Homocysteine then has four possible pathways open to it. Homocysteine reacts with serine in the presence of cystathionine b synthase (CBS), found in liver and brain, to form cystathionine (Fig. 61.6). CBS requires pyridoxal phosphate as a coenzyme. Homocysteine can also be remethylated to form methionine through two different enzymatic reactions. In one reaction, the methyl group is derived from betaine and is catalyzed by betaine-homocysteine methyltransferase. The second reaction requires

N^5 -methyltetrahydrofolate as a methyl donor and methylcobalamin ($\text{CH}_3\text{-B}_{12}$) as coenzyme ([Fig. 61.6](#)) and is catalyzed by 5-methyltetrahydrofolate-homocysteine methyltransferase. Finkelstein and Martin used an in vitro system that approximated in vivo conditions in rat liver to measure the simultaneous product formation by the three enzymes that use homocysteine ([210](#)). In this control system, 5-methyltetrahydrofolate-homocysteine methyltransferase, betaine homocysteine methyltransferase, and CBS accounted for 27, 27, and 46%, respectively, of the homocysteine consumed. The fourth pathway open to homocysteine is spontaneous oxidation to homocystine ([Fig. 61.6](#)). This reaction occurs only when homocysteine is present in tissue in abnormal amounts. It is essentially irreversible because the disulfide bond of homocystine is covalent. Homocystine is not further metabolized. CBS metabolizes most homocysteine with high affinity to cystathionine, using serine as cosubstrate and pyridoxal phosphate as coenzyme. Cystathionine is then hydrolyzed to cysteine and α -ketobutyrate. The enzyme cystathionase, which also uses pyridoxal phosphate as coenzyme, is required for this reaction ([Fig. 61.6](#)). A deficiency of cystathionase results in cystathioninuria, which has no pathologic consequence. α -Ketobutyrate is converted to propionyl-CoA, which is carboxylated to methylmalonyl-CoA and isomerized to succinyl-CoA, a Krebs cycle intermediate. L-Cysteine is catabolized to pyruvate, NH_3 , and H_2S .

Homocystinuria

Defects in the function of CBS or 5-methyltetrahydrofolate-homocysteine methyltransferase result in classical homocystinuria. Impaired activity of the latter enzyme may be caused by failure to synthesize methylcobalamin from vitamin B_{12} or by a deficiency in 5,10-methylenetetrahydrofolate reductase, as well as by mutations in the apoenzyme, CBS ([211](#)). Several different defects impair the uptake, transfer, and conversion of dietary vitamin B_{12} to methylcobalamin ([11](#), [212](#), [213](#)).

The most common form of homocystinuria is caused by a deficiency of CBS. The human CBS locus has been mapped to chromosome 21q-22.3 ([214](#)). The gene has been cloned, and over 20 mutations are characterized in expression systems. Although phenotypes vary for the same genotype, some mutations respond to vitamin B_6 (I278T, P145L, A114V) and others do not (G307S) ([215](#)). Severely impaired enzyme function produces accumulation of plasma homocyst(e)ine and methionine and decreased cyst(e)ine in cells and physiologic fluids. If this biochemical circumstance is not treated early in life, skeletal changes, dislocated lenses, intravascular thromboses, osteoporosis, malar flushing, and, in some patients, mental retardation will occur.

The skeletal changes and dislocated lenses are presumably due to a structural defect in collagen formation produced by α -homocystine interaction with aldose groups on collagen ([212](#)). Intravascular thromboses may occur at any age and have been found in coronary, renal, carotid, and intracranial arteries. Some 50% of untreated patients die before 20 years of age, and 95% before 50 years of age ([216](#)). The natural history of homocystinuria due to CBS deficiency has been clarified in a large series of patients ([217](#)). Heterozygosity for some mutations in CBS (and/or in tetrahydrofolate reductase) may predispose patients to development of premature occlusive arterial disease ([218](#)).

Further information on the relationship between total plasma homocyst(e)ine and premature coronary disease is given in [Chapter 34](#).

It is not known to what degree the mental retardation seen in homocystinuria is due to a metabolic sequela, such as a deficiency of cystathionine in myelin formation, or results from multiple small cerebrovascular thromboses. In a series of 84 patients, half were of average intelligence, several were university graduates, and one held a Ph.D. (216). Mental deficiency may occur with severely impaired CBS as a consequence of multiple cerebral-arteriolar obstructions if homocystinemia is not controlled by diet.

Screening

CBS deficiency is inherited as an autosomal recessive disease. Accurate estimates of the incidence for homocystinuria are not available, but newborn screening in 13 countries found 1 in 344,000 infants screened (212). Screening for homocystinuria in Georgia yielded an incidence of approximately 1 per 345,088, with hypermethioninemia occurring in 1 per 44,242 live births ([Table 61.3](#)). Homocystinuria occurs in many ethnic groups, but has a higher frequency in persons of Irish extraction than in other ethnic groups, 1 in 58,000 (212). This finding may be a bias of ascertainment because of the original description of, and continued screening for, this disorder in the Irish population. Vitamin B₆-responsive mutations in CBS are probably not ascertained by neonatal screening for elevated blood methionine.

Selective screening uses the inexpensive urinary nitroprusside reaction. In this reaction, excessive amounts of reduced homocysteine and cysteine form a stable red color with nitroprusside. This selective screening test for sulfur amino acids should be included in the evaluation of any patient with an unknown cause for arterial thrombosis, dislocated lens, marfanoid habitus, or mental retardation. This test is also positive in cystinuria and should be included as a screen for patients with nephrolithiasis.

In a large survey of patients with homocystinuria due to CBS deficiency, only 13% responded to vitamin B₆ (217). Most of these patients were "leaky mutants" who had residual CBS activity and expressed their disease in adolescence or young adulthood rather than early childhood. Response to vitamin B₆ occurs in several mutations with some residual enzyme activity. The mechanism involves stabilizing CBS to biologic degradation (212). The more residual enzyme activity present, the more dramatic the response to vitamin B₆. Hypermethioninemia may not be present in the newborn if CBS activity exceeds 15% of normal. Some patients with CBS deficiency have no activity in the fibroblasts, yet appear to be B₆ responsive (215).

Diagnosis

Positive results in a newborn screen by bacterial inhibition assay for methionine must be followed by assay of plasma amino acids using ion-exchange chromatography because many environmental, as well as genetic, variations cause neonatal hypermethioninemia. With a CBS defect, homocystine, cysteine-homocysteine, and methionine are all

elevated in plasma and increase with increased protein intake ([Fig. 61.6](#)). Demonstration of significantly decreased CBS, folate, CH₃-B₁₂, or homocysteine methyltransferases is necessary to confirm the diagnosis and implement appropriate therapy. Methionine may be elevated in the absence of homocystinemia in liver disease and in specific impairment of SAM. By contrast, in defects of homocysteine remethylation to methionine, methionine is low or normal, whereas homocysteine concentrations are elevated. Hyperhomocysteinemia due to disorders of cobalamin methylation to CH₃-B₁₂ or the two homocysteine methyltransferases will not be detected by nonselective newborn screening for elevated blood methionine. Similarly, B₆-responsive “mild” CBS deficiency is missed by newborn screening. Thus, selective screening using urinary nitroprusside reaction or plasma amino acid analysis is indicated for all children or adults with ectopic lens, unexplained vascular occlusions, marfanoid habitus, and mental delay.

Management of CH₃-B₁₂ deficiency or impaired methyl transfer with homocystinuria does not include methionine-restricted diets. Rather, pharmacologic amounts of vitamin B₁₂, folate, choline, or betaine are added, depending on the primary defect. Liver biopsy specimens, transformed lymphoblasts, or cultured skin fibroblasts express CBS and are used to confirm the most common cause of homocystinuria, and molecular screening and sequencing of the CBS gene are useful in predicting management. Prenatal diagnosis can be provided by direct enzyme assay of amniotic fluid cells or by DNA analysis if the mutations are known ([212](#), [215](#), [217](#)).

Treatment

Objectives of nutritional support in homocystinuria vary according to the age at which diagnosis is made and the specific cause. If homocystinuria is due to CBS deficiency expressed in the newborn, the clinical objectives are (a) to prevent the development of skeletal and ocular abnormalities, (b) to prevent intravascular thromboses, and (c) to ensure normal intellectual development.

Pharmacologic doses of pyridoxine should be tried in all patients with hypermethioninemia and homocystinemia ([217](#), [218](#) and [219](#)). In newborns and early childhood, 25 to 100 mg/day should be tried for 4 weeks before methionine restriction. Older children and adults should be given oral pyridoxine (1 g/day). Pyridoxine's effect on plasma methionine and homocystine concentrations is monitored weekly on a “constant” protein intake. Because enzyme stabilization is the most common mechanism of vitamin responsiveness, weeks may be required for a biochemical response to occur. If the plasma methionine and homocysteine concentrations are reduced, the amount of pyridoxine should be gradually lowered until the minimum dose required to maintain biochemical normality is reached. Doses of 25 to 750 mg/day have been required for some patients ([219](#)). Excess vitamin B₆ for prolonged periods may cause peripheral neuropathy ([220](#)) and liver injury ([221](#)); consequently, if vitamin B₆ is not helpful, it should be discontinued. Betaine supplements (6 g/day) will help maintain postprandial plasma homocysteine concentrations in the near-normal range in vitamin

B₆-responsive individuals ([222](#)).

Patients who do not respond completely to pyridoxine require a methionine-restricted diet supplemented with L-cysteine. L-Cysteine becomes an essential amino acid in homocystinuria ([Fig. 61.6](#)). If plasma folate concentrations are below normal owing to excess use in remethylating homocysteine to methionine, folate should be added as a supplement.

Nutrient Requirements. In prescribing and implementing nutritional care plans for infants and children with homocystinuria due to CBS deficiency, one must consider energy, protein, methionine, cysteine, folate, vitamins B₆ and B₁₂, betaine, and fluid needs. Younger infants have a greater methionine requirement per kilogram of body weight than older infants. Suggested daily methionine intakes range from 35 mg/kg in the young infant to 5 mg/kg in the 15- to 19-year-old patient. Suggested beginning energy, protein, methionine, and fluid intakes for infants and children of different ages are given in [Table 61.4](#). If the medical food mixture provides more than 24 kcal/oz, extra fluid should be offered between feedings to prevent dehydration.

Calcium cystinate, a soluble form of L-cysteine, should supplement the methionine-restricted diet at all ages. The young infant should be offered 300 mg/kg body weight. This amount may be decreased to 200 mg/kg at 6 months of age and 100 mg/kg at 3 years of age and thereafter. The calcium cystinate should be mixed with the chemically defined methionine-free medical food to provide even distribution throughout the day. Older children can sprinkle it in applesauce or other low-protein solids.

Methionine-Free Medical Foods. Several medical foods have been developed as protein sources for patients with homocystinuria ([62](#), [63](#) and [64](#)). Formulations, composition of major nutrients, and sources of these products are given in [Table 61.5](#).

Serving Lists. Methionine may be provided for the young infant by addition of specified amounts of proprietary infant formula to the methionine-free medical foods. As growth and development proceed, solid foods should be added at the usual ages. The methionine requirement is small, and most foods contain moderate amounts in relation to requirement ([56](#), [57](#), [58](#), [59](#), [60](#) and [61](#)). Because of this, the amount of solid food that can be ingested is small. To provide variety to the methionine-restricted diet, serving lists have been prepared ([63](#)). Average methionine, cystine, protein, and energy contents of these lists are given in [Table 61.16](#).

Food List	Methionine mg/l	Cystine mg/l	Protein g/l	Fat g/l	Energy kcal
Breads/cereals	20	20	1.2	0	55

Table 61.18 Diet Guide for Homocystinuria (4 years of age): Weight 17 kg

Assessment of Nutritional Support. Following introduction of diet and stabilization, plasma methionine and cysteine concentrations should be monitored twice weekly until the patient is 3 months of age. Weekly monitoring is suggested until 6 months of age and twice monthly thereafter if blood methionine levels are stable. After a dietary change, plasma methionine and cysteine should be measured after 3 days have elapsed. A 3-day record prior to each blood sample is necessary to evaluate plasma methionine and cysteine. Plasma methionine should be maintained between 15 and 30 μM in fasting plasma. Little or no homocystine should be present in blood and urine. Growth and development as well as clinical evaluation of the pulses, skeletal growth and development, and ocular lenses are routinely assessed.

Results of Nutritional Support. In a retrospective study of 629 patients with CBS deficiency, methionine restriction initiated neonatally prevented mental retardation, decreased the frequency of lens dislocation, and reduced the incidence of seizures (217). Pyridoxine treatment of late-detected vitamin B₆-responsive patients decreased the rate of thromboembolic events (217). Weight and height in a girl with homocystinuria treated from the 9th day of life was at the 90th percentile (223). Hispanic male twins born at 38 weeks gestation with homocystinuria grew well during the entire 1st year of life while on nutrition support. Protein intake of these two patients averaged 3.7 g/kg/day during the first 6 months of life and 2.6 g/kg/day during the second 6 months. Energy intake averaged 131 kcal/kg during the first 6 months and 100 kcal/kg during the second 6 months (224).

Cysteine deficiency manifested as abnormally low plasma cysteine concentrations, elevated plasma methionine, and weight loss in a 3-year-old male with homocystinuria who received 32 mg/kg/day of L-cysteine was reported (225). The Hispanic twins referred to above received 58 to 118 mg cysteine/kg/day, which resulted in plasma cysteine concentrations of 19 to 30 $\mu\text{mol/L}$ (224). Up to 150 mg L-cysteine/kg/day may be required to maintain normal plasma cysteine concentrations (226).

Elevated plasma copper and ceruloplasmin concentrations were found in 15 patients

with homocystinuria, compared with values found in age- and gender-matched normal controls. No relationship to plasma homocysteine could be found (227). The twins mentioned above had elevated serum copper concentrations of 151 and 144 µg/dL at about 13 months of age. Low plasma selenium concentration (about 15 µmol/L) and erythrocyte glutathione peroxidase activity (about 3 U/g Hgb) were found in a child with homocystinuria treated with a medical food free of selenium (228). Administration of 50 µg selenium (in selenium-enriched yeast) every other day was required to maintain normal indices of selenium status. The twins mentioned above ingested, on average, 26 µg selenium (as sodium selenite) daily throughout the 1st year of life (224). Serum selenium concentrations ranged between 60 and 72 µg/L, very similar to values reported for normal human milk-fed babies (229).

Vitamin A absorption tests were carried out in eight untreated patients with homocystinuria by measuring the elevation in serum after administration of vitamin A alcohol (retinol). The explanation proposed for the resulting subnormal serum vitamin A elevation was that retinol was oxidized by -SH groups excreted into the gut (230). Of the eight plasma retinol values obtained on the twins studied, one was below 20 µg/dL and five were between 20 and 30 µg/dL. According to parental report, vitamin A intake was always more than adequate (1.20–5.58 times RDA for age). Serum transthyretin concentrations were all below 20 mg/dL (marginal), and two of the four values obtained were below 15 mg/dL (deficient) (224).

Fasting serum folate concentrations in eight untreated patients with homocystinuria were found to be abnormally low (4 ng/mL, compared with 8 ng/mL in control subjects). Two of these subjects were treated with 20 mg/day folate, which led to a decrease in urinary homocysteine excretion (231). Severe folate deficiency was found in an untreated infant with homocystinuria who was receiving diluted boiled cow's milk for an episode of gastroenteritis. Excessive use of 5-methyltetrahydrofolate in the remethylation of homocysteine to form methionine is proposed as a reason for folate deficiency in untreated patients (232). The twins in our study had adequate hemoglobin concentrations after 4 months of age, and mean corpuscular volume was normal (224).

Termination of Nutritional Support. Most clinicians who treat individuals with homocystinuria believe that patients should be kept on the diet indefinitely. Termination of diet after growth is achieved may lead to thromboembolisms and ciliary muscle laxity with lens dislocation. When initiation or maintenance of nutritional support is not possible, acetylsalicylic acid (1 g/day) and dipyridamole (100 mg/day) increase platelet survival time and decrease thrombotic events (233). Vitamin B₆ in pharmacologic doses should be continued.

Reproductive Performance

Fewer conceptions are reported for both men and women who do not respond to vitamin B₆ than for those who do. Offspring of male patients do not suffer excess losses and are generally reported to be normal. A study showed that higher rates of fetal loss occurred in presumptive heterozygous fetuses carried by CBS-deficient mothers than occurred in normal women (217). Whether hypermethioninemia, homocysteinemia, or other metabolic variations in methionine metabolism are teratogenic is as yet unclear,

but a teratogenic mechanism as defined for “maternal PKU” is possible. Also “folate”-responsive neural tube defects may involve hyperhomocyst(e)inemia as a pathophysiologic mechanism.

Carrier State. Heterozygotes for CBS deficiency may be at risk for premature vascular occlusion (222). The physician's duty to diagnose, inform, and treat extended family members of probands with CBS deficiency awaits further definition of this risk and outcomes of intervention (see [Chapter 34](#)) (224).

AMMONIA

Nutritional management of disorders involving ammonia fixation and urea production uses traditional rules for treating inborn errors of metabolism. Three essential rules are restricting the toxic precursor, adding deficient product, and encouraging alternative pathways for nitrogen excretion. Furthermore, an anabolic state should be maintained to promote growth and prevent catabolism of lean body mass. Study of the biologic variation imparted on ammonia fixation and the urea cycle by heritable mutations in these biochemical reactions has greatly increased our understanding of the normal physiology, biochemistry, and molecular biology of human nitrogen metabolism (234).

Biochemistry

Central dogma holds that ammonia is converted to urea in the liver through the Krebs-Henseleit cycle ([Fig. 61.7](#)) and excreted in the urine. The first three enzymes of the cycle and *N*-acetylglutamate synthetase are mitochondrial. *N*-Acetylglutamate synthetase catalyzes the conversion of acetyl-CoA plus glutamate to *N*-acetylglutamate, an essential cofactor for carbamylphosphate synthetase. Carbamylphosphate synthetase I catalyzes the conversion of ammonia, ATP, and bicarbonate to carbamylphosphate. Ornithine transcarbamylase (OTC) uses carbamylphosphate and ornithine as cosubstrates to form citrulline, which is exported from mitochondria to the cytoplasm, where cytosolic reactions are linked to those three mitochondrial functions. Citrulline and aspartate form argininosuccinic acid, a reaction catalyzed by argininosuccinic acid synthetase. Fumarate is cleaved from argininosuccinic acid by argininosuccinic acid lyase, yielding arginine. Urea is then formed by the action of arginase, regenerating cytosolic ornithine, which is transported back into the mitochondria to react with OTC.

Figure 61.7. Inborn errors in the urea cycle and nutritional approaches to their management. Ammonia fixation and urea production are metabolically cycled with inherited blocks producing hyperammonemia indicated by *hatched bars*. Important nitrogen molecules and their biochemical origins are outlined in *boxes*. Mitochondrial enzymes in urea synthesis are carbamylphosphate synthetase, *N*-acetylglutamate synthetase, and ornithine transcarbamylase. Use of benzoate, phenylacetate, and phenylbutyrate is indicated to provide alternate pathways for nitrogen excretion. Dietary arginine is added to provide urea cycle substrate distal to genetically impaired reactions. Restriction of dietary protein and addition of dietary energy to prevent protein catabolism are also indicated.

Urea Cycle Enzyme Deficiencies

Disorders of the urea cycle are a group of inherited defects in these six enzymes that produce urea ([Fig. 61.7](#)) ([234](#)). With the exception of OTC deficiency, all have an autosomal recessive mode of inheritance. OTC deficiency is inherited as an X-linked dominant trait that is usually lethal in males ([234](#)). Many of the genes for these enzymes have been localized to the human genome, cloned, and had mutations defined. *OTC*, a 73-kb gene containing 10 exons, is located on Xp21.1. Over 20 mutations have been defined with some genotype/phenotype relationships. For example, the generation of stop codons from R109X and R109Q results in no residual liver enzyme and severe neonatal presentation. By contrast, the R129 to histidine mutation also present in the spf-ash mouse model of OTC deficiency has a milder phenotype and residual liver enzyme activity ([235](#)). Carbamylphosphate synthetase is located on 2p, argininosuccinic acid synthetase on 9q34, argininosuccinic acid lyase on 7q11, and arginase on 6q23. All are primarily expressed in liver, and all of these genes have defined mutations in their respective disorders ([Table 61.19](#)) ([234](#), [235](#), [236](#), [237](#), [238](#), [239](#), [240](#), [241](#), [242](#), [243](#), [244](#), [245](#), [246](#) and [247](#)). Argininosuccinic acid synthetase has several pseudogenes that confound DNA analysis ([234](#), [243](#)). In OTC deficiency, defects in the protein include disordered mitochondrial uptake and immunologically absent protein in this organelle ([235](#)). Arginase has two genes with differential expression in liver and erythrocytes. In addition to these defects in ureagenesis, a seventh cause of hyperammonemia is the HHH syndrome (hyperammonemia, homocitrullinemia, hyperornithinemia), which is caused by defective mitochondrial uptake of ornithine ([247](#)).

Gene	Chromosomal Location	cDNA	Gene Size/Exons	Tissue Distribution
Mitochondria				
Carbamylphosphate synthetase	2p	52	Unknown	Liver, intestine, kidney (fetal)
N-Acetylglutamate synthetase	Unknown	Unknown	Unknown	Liver, intestine, kidney (fetal), spleen
Orotidine transcarbamoylase	2p34-35	1.08	73 kb/10	Liver, intestine, kidney (fetal)

Argininosuccinate synthetase	9q34 (many pseudogenes)	1.6	62 kb/14	Liver, kidney, fibroblasts, brain (fetal)
Argininosuccinate lyase	Tranq11.2	2.0	35 kb/16	Liver, kidney, brain, fibroblasts
Arginase	9q21	1.55	11.5 kb/8	Liver, erythrocytes, kidney, lens, brain (fetal)

Table 61.19 Chromosomal Location, Gene Location, Gene Size, Number of Exons, and Tissue Distribution of Genes for Urea Cycle Enzymes

Hyperammonemia is a biochemical manifestation of all disorders of the urea cycle. Other biochemical characteristics of each defect follow: carbamylphosphate synthetase I defect causes decreased plasma citrulline; OTC deficiency results in orotic aciduria and X-linked patterns of transmission; argininosuccinate synthetase deficiency is associated with increased plasma citrulline accompanied by orotic aciduria; argininosuccinate lyase deficiency causes increased argininosuccinate in plasma and urine; and arginase deficiency has increased arginine in plasma and urine. Clinical features in the newborn suggesting urea cycle defects occur with protein ingestion. In increasing order of severity, these defects include poor feeding, vomiting, lethargy, hypotonia, stupor, bleeding diatheses, convulsions, coma, shock, and death. Mental retardation occurs in survivors of these disastrous newborn episodes, but successful control of hyperammonemia in the newborn may prevent this sequela.

Clinical Phenotypes

Hyperammonemia and its clinical sequelae of vomiting, lethargy, and coma relate to excessive protein intake or catabolism and are observed in all the defects. However, biochemical and phenotypic manifestations differ in the individual enzyme deficiencies. In argininosuccinate (ASA) lyase deficiency, a specific hair abnormality, trichorrhexis nodosa, is evident ([Fig. 61.8](#)). This condition is related to arginine deficiency and the relatively high arginine content of normal hair protein. Hair reverts to normal with arginine supplementation ([Fig. 61.8](#)). Adult siblings with ASA lyase deficiency may have little-to-no clinical manifestations despite identical mutations. In patients with defects of the first four enzymes, arginine deficiency has also been associated with progressive degeneration of the CNS, and a peculiar rash with control of hyperammonemia through protein restriction alone ([236](#), [237](#)).

Figure 61.8. Effect of arginine on hair growth in argininosuccinic aciduria. A 6-year-old boy with hyperammonemia, trichorrhexis nodosa, and developmental delay was diagnosed with argininosuccinic aciduria. **A.** Before diet therapy he had diffuse, brittle hair. **B.** Six months later, while receiving 350 mg/kg/day arginine, he had luxuriant blond hair and his first haircut. (Courtesy of P. Fernhoff, Division of Medical Genetics, Emory University, Atlanta, GA).

Each enzyme defect has a spectrum of clinical manifestations ranging from death in the newborn period to cyclical vomiting and migraine in adolescence. For example, the typical male with OTC deficiency has less than 5% activity and dies in the neonatal period. A surviving male child with the “late-onset” form of OTC deficiency has immunologically present OTC with decreased affinity for ornithine, a shift of pH optimum, and 25% of normal activity under physiologic conditions ([238](#)). Mutational analyses of the *OTC* gene has differentiated “neonatal” from late-onset phenotypes ([234](#), [235](#)).

Enzymatic evidence for genetic heterogeneity comes from kinetic studies in fibroblasts of patients with argininosuccinic acid synthetase deficiency. Early biochemical studies showed that enzymes from patients with citrullinemia all exhibited decreased binding of citrulline and/or aspartate, but the residual argininosuccinic acid synthetase had a distinct and different curve of activity in each patient ([239](#)). Analyses of RNA in citrullinemic patients revealed heterogeneity, and over 20 different mutations are now defined ([234](#), [240](#), [243](#)).

Expression of the Heterozygous State for OTC Deficiency

The female heterozygote of OTC deficiency may have mild protein intolerance manifested clinically by migraine in adults and by cyclic vomiting with intermittent hyperammonemia in children ([248](#)). When protein or ammonium chloride loads were administered to 15 children with migraine and cyclic vomiting, 9 had abnormally high baseline plasma ammonium levels; the tests produced marked hyperammonemia in 8 and 6 developed migraine symptoms. Enzyme assay in seven girls with cyclical vomiting showed three with deficient OTC activity ([248](#)). Heterozygous females with

OTC deficiency may be asymptomatic or as severely affected as hemizygous males (249).

Screening

Nonselected screening of all newborns for urea cycle disorders was routinely conducted in Massachusetts using a bacterial auxotroph that required arginine (250). Nine of 700,000 newborns were found to be homozygous-affected or heterozygous for ASA lyase deficiency (250). Selective screening tests for disorders of the urea cycle are available (251, 252). One method for selective screening for hyperammonemia in the newborn nursery requires drops of blood, can be performed at the bedside, and gives results in 15 minutes (253). This method can be readily adopted in offices and hospitals for selective screening. Its lack of use in this country is related to cost and demand.

The true incidence of urea cycle defects is not known because population-based screening has not been conducted, and many undiagnosed deaths may be caused by these disorders. The overall incidence is underestimated at 1 in 25,000 live births (254).

Diagnosis

Hyperammonemia in association with other characteristic biochemical and clinical findings is diagnostic of specific disorders in the urea cycle (234). The enzyme defect can be inferred from the metabolites (in addition to ammonia) that accumulate in blood and urine: orotic acid in the urine in OTC deficiency; and citrulline, argininosuccinic acid, and arginine in the plasma and urine in argininosuccinate synthetase, ASA lyase, and arginase deficiencies, respectively. Carbamylphosphate synthetase or the rare *N*-acetylglutamate synthetase deficiency is suggested by exclusion of these four enzymopathies and requires liver biopsy with enzyme analyses for diagnosis. Hyperammonemia can also be caused by acute or chronic liver diseases, galactosemia, neonatal Niemann-Pick type IC, tyrosinemia, hereditary fructose intolerance, Reye's syndrome, asparaginase treatment, propionic acidemia, hyperlysinemia, hyperornithinemia, isovaleric acidemia, methylmalonic aciduria, long-term use of parenteral amino acids, and a wide range of infectious agents in infancy. Definitive diagnosis depends on clinical acumen followed by appropriate laboratory studies. A suggested algorithm for differential diagnosis of urea cycle enzyme defects is given in Figure 61.9. A suspected urea cycle enzyme defect is a medical emergency and requires immediate intervention.

Figure 61.9. Algorithm for differential diagnosis of urea cycle disorders.

Treatment

The treatment of inherited urea cycle enzymopathies can be divided into short- and long-term therapy and depends on the specific diagnosis.

Short-Term Therapy. We prefer to begin orogastric perfusion with high energy intake (150 kcal/kg/day) but no protein. Pro-Phree or Protein-Free Diet Powder is useful for this approach (see [Table 61.5](#)). L-Arginine (350–500 mg/kg/day) should be added to this formulation. Sodium benzoate (300 mg/kg/day) can successfully reduce acute hyperammonemia in the neonatal period. Phenylbutyric acid or phenylacetic acid (500 mg/kg/day) is also given to form phenylacetylglutamine, which is excreted in the urine, eliminating from the body two nitrogen atoms per molecule ([Fig. 61.7](#)) (257). Addresses and telephone numbers of suppliers of these compounds are given in [Table 61.20](#). Urinary potassium loss is enhanced by excretion of hippurate and phenylacetylglutamine. Consequently, plasma potassium concentrations should be monitored, and supplements given if needed.

Product	Supplier
Medications	
Sodium benzoate plus sodium hippurate (Benzoate-Hippurate)	Chemical Dynamics, Inc. 7-30710 Valley Street Rock Hill, S.C. 29733 08110 884-4100
Sodium phenylacetate powder and sodium hippurate powder (Phenylacetate-Hippurate)	Pharmacia & Upjohn, Inc. 2325 Rockledge Avenue Kalamazoo, MI 49001 80054 524-2000
Nutritional Supplements	
L-Arginine powder** 100% protein solution (10% strength)	Arginine 100%, 100 RWD Pharm, Inc., 5000 Mountain View, P.O. Box 1000 Tomball, TX 77375 713 260-1100
L-Arginine powder and sodium chloride solution (10% strength)	Pharmacia & Upjohn, Inc. 2325 Rockledge Avenue Kalamazoo, MI 49001 80054 524-2000
L-Arginine 100% (10% strength) solution for intravenous use	Pharmacia & Upjohn, Inc. 2325 Rockledge Avenue Kalamazoo, MI 49001 80054 524-2000
L-Citrulline powder*	Citric Acid, Inc. 1100 South Main Street Springfield, MA 01102 413 772-4444

Table 61.20 Suppliers of Medications and Nutritional Supplements Required for

Treatment of Urea Cycle Disorders

Hemodialysis may be useful in the presence of coma in reducing plasma ammonium levels (255). Peritoneal dialysis for 7 days in a male neonate with OTC deficiency removed 50 times more ammonia than a single exchange transfusion did (256). However, peritoneal dialysis includes risks such as *Candida* peritonitis and continued catabolism. If dialysis is used, parenteral L-arginine and Ucephan (McGaw) should begin as well.

A priority of newborn therapy is to “force” the neonate into an anabolic phase with energy feedings. Peripheral venous hyperalimentation with 10 to 20% glucose and lipid (2–4 g/kg) may be necessary if gavage is not tolerated. As gavage feedings are increased, peripheral alimentation should be decreased. After 4 days of “no-protein,” high-energy, arginine- and benzoate-supplemented feedings, blood ammonia levels should revert to near normal. Cautious addition of 1.0 to 1.5 g/kg/day of protein is then necessary.

Long-Term Therapy. The objectives of therapy in a child with a defect of the urea cycle are to maintain plasma concentrations of ammonia as near normal as possible, and to supply protein and other essential amino acids and nutrients that will allow maximal intellectual development and optimal growth. Four major approaches are used in treating individuals with urea cycle defects (Fig. 61.7): (a) reducing precursors of ammonia (protein intake), (b) correcting arginine deficiency, (c) enhancing alternate mechanisms of waste nitrogen loss, and (d) accelerating renal excretion of accumulated intermediates (234, 257).

Methods used to reduce ammonia precursors include protein restriction, prevention of body protein catabolism, and use of essential and “semiessential” amino acids. Any time intake of protein or essential amino acids is severely restricted, precursors for synthesis of carnitine (lysine, methionine), glutathione (cysteine, glutamate), and taurine (cysteine) may be limiting. Restricted methionine intake may result in a decrease in the available pool of labile methyl groups required for synthesis of important metabolic compounds.

L-Arginine supplementation is required in all of the urea cycle enzyme defects except arginase deficiency. To maintain normal or slightly elevated plasma arginine concentrations, 100 to 500 mg/kg of body weight daily is used (258). L-Arginine can then produce ornithine for ammonia fixation and drive the cycle to citrulline and argininosuccinate (Fig. 61.7). These two amino acids are poorly absorbed by the kidney and allow nitrogen loss. Acceleration of renal excretion of accumulated intermediates in the impaired cycle is sought. Arginine supplementation increases citrulline and argininosuccinic acid excretion in argininosuccinic acid synthetase and ASA lyase deficiency, respectively (234, 258).

Waste nitrogen urinary loss can be enhanced by the use of sodium benzoate, phenylacetate, or phenylbutyrate (259) (Fig. 61.7). Glycine conjugates with benzoate via

glycine-*N*-acylase, which leads to excretion of a nearly stoichiometric quantity of nitrogen as hippurate (Fig. 61.7). Toxicity is low on 200 to 500 mg/kg/day. Folate must be administered to provide a source of one-carbon fragments for synthesis of glycine from serine to prevent glycine depletion (260). Pyridoxine is necessary for transamination. Phenylbutyrate and phenylacetate increase urinary nitrogen excretion as phenylacetylglutamine (258, 259) (Fig. 61.7). The suggested dose is 500 mg/kg body weight. This efficient alternative pathway removes two molecules of nitrogen per molecule of phenylacetylglutamine and requires monitoring of protein intake to prevent deficiency. Excess use of these nitrogen-binding drugs can lead to nitrogen deficiency and poor growth.

Catabolism during a febrile illness or because of poor appetite may lead to life-threatening elevations in blood ammonia. In addition to prompt diagnosis and treatment of the infection, decreased protein intake (0 g for 1–2 days), increased energy intake, and peritoneal dialysis may all be required. Gastrostomy feedings may be required to ensure adequate intake and prevent inadequate growth or catabolism.

In planning nutritional support of the infant or child with a defect of a urea cycle enzyme, a formal prescription for the day should be written that includes recommended amounts of protein, energy, fluid, L-arginine, and drugs that enhance nitrogen loss. The prescription for protein should be based on the specific diagnosis, degree of impaired urea cycle, and blood ammonia concentrations and correlated with various parameters of growth, including rates of height and weight increase, and hair, nails, teeth, and skin changes.

Protein intakes suggested in Table 61.21 are based on amounts required to cover obligatory nitrogen losses and growth needs (261) of infants and children fed an excellent protein source such as egg or milk. Intakes may need to be increased if the child fails to grow adequately on the recommended intake or if sodium benzoate, phenylacetate, or phenylbutyrate is administered. Renal capacity to excrete excess acidity as NH⁴⁺ is modulated by the amount of protein ingested (262). Overrestriction of protein may lead to catabolism and impaired renal activity to excrete NH⁴⁺. Tryptophan intake should be at the minimal requirement for growth to prevent excess serotonin synthesis that suppresses appetite (207, 208).

Age	Nutrients

^aNot used with arginase deficiency.

^bProtein intake may need to be increased if sodium benzoate, sodium phenylacetate, or sodium phenylbutyrate is prescribed.

Table 61.21 Recommended Daily Nutrient Intakes (Ranges) for Infants, Children, and Adults with Urea Cycle Disorders

Energy intakes recommended in [Table 61.21](#) are somewhat higher than those for normal infants and children to provide ketoacid precursors from carbohydrate for synthesis of nonessential amino acids and to prevent protein degradation. Carbohydrate should not provide more than 50% of the energy because of frequently elevated plasma triacylglycerol concentrations.

In any situation in which protein-restricted diets are fed, L-carnitine supplements may be necessary. Recommended amounts of supplemental L-carnitine are 50 to 100 mg/kg/day. L-Carnitine supplements are reported to lower blood ammonium concentrations ([263](#), [264](#)). Citrate deficiency has been reported in patients with ASA lyase deficiency, and supplementation was recommended ([265](#), [266](#)).

Medical Foods for Urea Cycle Disorders. Nutritional support of urea cycle disorders requires restricting nitrogen intake, which is best accomplished by providing about one-half to two-thirds the prescribed protein in the form of essential amino acids only. Formulation, composition, and sources of medical foods for urea cycle enzyme defects are given in [Table 61.5](#). Cyclinex-1 and Cyclinex-2 contain 25 mg of L-carnitine per gram of protein ([63](#)).

Serving Lists. Serving lists of natural foods are available to simplify protein-restricted diets for professionals and for families ([Table 61.6](#)).

Assessment of Nutritional Support. Frequency of assessment is, in part, dictated by the clinical course of the patient. Blood ammonia concentrations should be monitored routinely and maintained below 50 μM . Plasma concentrations of amino acids should be monitored and maintained in the normal range. Plasma albumin and globulin concentrations are indices of protein status and should be evaluated frequently. Plasma transthyretin and retinol-binding protein have shorter half-lives than albumin and can provide information on protein status at an earlier stage in deficiency than albumin can. Caretakers should provide dietary diaries and records of health status in tandem with blood for ammonia and plasma amino acid determinations. Growth and development should be routinely assessed. If evidence of protein deficiency occurs or growth is not maintained, increased protein intake is necessary.

Results of Nutritional Support. Results of therapy in infants with complete or near-complete enzyme deficiencies have been less than optimal, with delayed death and below-normal development. If the serious brain swelling and coma are prevented in the neonatal period or if onset of disease expression is delayed, physical growth and mental development are more nearly normal with nutritional and pharmacologic support ([234](#)). If diagnosis is anticipated and treatment is begun during the neonatal period in

affected siblings with citrullinemia or argininosuccinic acidemia, relatively normal outcome is observed even with severe enzyme defects (267).

GALACTOSE

Biochemistry

Because lactose is the principal carbohydrate and energy source for infants and young children, galactose maintains a central metabolic role in human nutrition. Lactose is hydrolyzed in the intestine by lactase to glucose and galactose, and 0.5 to 1.0 mg galactose/kg/min is produced (268). Galactose is converted to glucose-1-P and energy through the Leloir pathway. This occurs primarily in the liver, where galactose becomes glucose through three enzymatic steps (Fig. 61.10). First, galactose is phosphorylated to galactose-1-phosphate (Gal-1-P) by galactokinase. The rate-limiting and evolutionarily conserved step is the transfer of the uridyl moiety from uridine diphosphate (UDP)-glucose to UDP-galactose (UDP-Gal) with the consumption of Gal-1-P and release of free glucose-1-phosphate. This complex bimolecular, two-substrate catalytic reaction is catalyzed by Gal-1-P uridyltransferase (GALT) (Fig. 61.10). UDP-gal can be converted back to UDP-glucose through a reversible reaction to UDP-Gal-4-epimerase (Fig. 61.10). The glucose thus formed can be used for glycogen synthesis or phosphorylated to glucose-1-phosphate for further energy production. UDP-Gal is an important precursor for galactated membrane proteins and glycolipids.

Figure 61.10. Metabolic blocks in galactose metabolism that lead to galactosemia. Genetic disorders of catalyzed reactions are indicated by *hatched bars*.

Galactosemia

Galactosemia may occur because of deficient functioning of any of three enzymes: galactokinase, GALT, or UDP-Gal-4-epimerase (269) (Fig. 61.10). Patients with galactokinase deficiency have only cataracts, but also produce galactitol and galactonic

acid through alternate pathways ([Fig. 61.10](#)). Galactokinase deficiency does not produce the acute hepatotoxic manifestations or the accumulation of Gal-1-P seen with GALT deficiency. Several variants with different degrees of function and structure have been described for mutant GALT ([275](#)). This gene locus is on chromosome 9p ([270](#), [271](#) and [272](#)). The cDNA and gene for GALT have been accurately sequenced, and many different mutations identified ([272](#), [273](#), [274](#), [275](#), [276](#) and [277](#)).

Galactosemia due to deficiency of GALT leads to accumulation of Gal-1-P, which may act as a phosphate sink, reducing intracellular phosphate for high-energy phosphate bonds. Thus, ATP, GTP (guanosine triphosphate), and CTP (cytidine triphosphate) levels are reduced. Gal-1-P may also inhibit galactation of phospholipids and phosphoproteins by competitive inhibition. Several other hypotheses for the pathophysiology of GALT deficiency include UPD-gal deficiency, galactose excess with galactation of membrane proteins, and galactitol accumulation with deleterious effects on intracellular osmolality ([278](#), [279](#) and [280](#)). Many or all of these postulated pathologic processes are probably involved.

Clinical symptoms of the GALT defect appear early in infancy. About 10% of infants with GALT deficiency are born with cataracts. Acute hepatotoxicity may appear with the start of milk feeding. Prolonged neonatal jaundice at 4 to 10 days of age is common. Hyperbilirubinemia and hyperammonemia may be exacerbated by toxic injury to liver cells by delayed maturation of glucuronyl transferase ([281](#)), mild hemolysis, and bleeding. Bleeding diatheses, *Escherichia coli* sepsis, and shock are catastrophic events that occur during the neonatal period. Therefore, rapid screening, retrieval, diagnosis, and treatment are essential for population-based newborn screening programs if the clinical sequelae of neonatal galactosemia are to be prevented. Other relatively minor symptoms occur. Anemia from various causes is present in about 40% of untreated patients. Lethargy, hypotonia, food refusal, vomiting, and diarrhea are also common symptoms in infancy.

Retarded mental and physical growth occur in most of the untreated patients who survive ([282](#)). The pathophysiology of galactosemia remains unclear, but early diet clearly prevents neonatal sepsis, shock, and bleeding. Whether intrauterine effects of accumulated galactose or deficiency of UDP-gal ([286](#)) causes the pathology remains for further study. Cataracts occur in about 45% of untreated children and are thought to result from formation and accumulation of galactitol in the lens of the eye, which is impermeable to efflux. Galactitol creates an osmotic gradient that allows glutathione to efflux and results in decreased concentrations of lens glutathione. When glutathione concentrations are decreased, glutathione peroxidase is inactivated, and hydrogen peroxide accumulates to toxic levels. Hydrogen peroxide denatures lens protein, producing lenticular cataracts ([269](#), [281](#)). Hepatomegaly occurs in nearly all cases of GALT deficiency, and cirrhosis develops in untreated patients. Liver damage results in decreased synthesis of liver coagulants and albumin, and a decrease in a wide range of liver functions. Because of decreased albumin synthesis and proteinuria, ascites and generalized edema occur in about 36% of untreated patients ([281](#)). The albumin synthesized by untreated patients with galactosemia contains large amounts of galactose, whereas albumin of normal individuals is free of galactose ([287](#)). Untreated or poorly controlled patients are extremely susceptible to infection with gram-negative organisms. Immunoincompetence is probably a direct result of inhibition by Gal-1-P of

immune protein synthesis by lymphocytes and inactivation of leukocyte phagocytosis. Galactose and its accumulated metabolites are toxic to the glomeruli and tubules of the kidney. Additionally, active tubular transport is impaired because of deficient ATP, producing generalized aminoaciduria and loss of phosphate, potassium, and bicarbonate. On rare occasions, hypoglycemia occurs. Causes include defective hepatic gluconeogenesis, the inability to convert glycogen to glucose because of inhibition of phosphorylase kinase by Gal-1-P, and hyperinsulinemia that may result from galactose stimulation of pancreatic b cells and decreased hepatic extraction of insulin (281).

Despite early diagnosis and removal of galactose during the neonatal period, some patients with classic (G/G) galactosemia have long-term poor outcomes, including infertility in females, growth failure, dyspraxic speech, ataxia, and mental retardation (282, 283). This has been called the “enigma” of galactosemia (269, 278). This enigmatic outcome may be of intrauterine origin and has been associated with more-severe mutations in GALT. For example, the Q188R mutation in exon 6 is prevalent among Caucasians and more prevalent among classic galactosemia patients with two or more of the above chronic deficits (277, 278). By contrast, the S135L mutation in exon 5 of the GALT gene is associated with good outcomes in patients treated from birth, is prevalent in black patients, and has differential expression in different organs (284). Other variant mutations, such as the Duarte variant (N314D), when associated with G alleles such as E203K may return structural integrity and function to the dimeric GALT protein function and produce a “good” clinical outcome (273, 275, 276). Over 57 mutations have been defined to date in patients with galactosemia (Table 61.22).

Table 61.22 Sequence Changes in the Human GALT Gene found in Patients with Galactosemia

Screening

GALT deficiency of clinical importance to the neonate is found in approximately 1:8000 births (Table 61.3). Based on 1.7 million newborns screened in Georgia, about 1:40,000

have classic (G/G) galactosemia while about 1:10,000 have variant forms. The most common screening method used is the Beutler fluorescent test for galactosemia (288). This procedure consists of incubating dried blood on filter paper disks with a mixture of uridine diphosphoglucose (UDPG), galactose-1-P, and NADP. Erythrocytes from normal individuals containing GALT and phosphoglucomutase produce glucose-1-phosphate, glucose-6-phosphate, and fluorescent NADPH through the linked reaction of glucose-6-phosphate dehydrogenase. If heat has inactivated this reaction (e.g., in summer), glucose-1-phosphate is added to differentiate between heat inactivation of GALT and GALT deficiency (true galactosemia).

Positive screening results occur with classic (G/G) GALT deficiency and with variants of GALT that are thermolabile such as the Duarte/galactosemia compound heterozygote. Confirmation of positive Beutler screening test results requires the use of erythrocyte hemolysates for quantitative enzyme activity determinations and quantitation of erythrocyte galactose and Gal-1-P content. A combined analysis of the GALT biochemical phenotype and molecular genotype is important for diagnosis, therapy, prognosis, and genetic counseling (275, 277).

Diagnosis

Patients with positive Beutler test results should have all lactose removed from their diets immediately while enzyme diagnosis and family workup proceed. Fresh, sterile heparinized blood should be sent to a central laboratory experienced in enzyme analyte and molecular analyses. Both patient and parents should be evaluated by the center for biochemical phenotype and molecular genotype. Diagnosis of galactosemia is accomplished through measurement of activity of GALT in erythrocytes, erythrocyte Gal-1-P content, and molecular analysis of the GALT gene for prevalent mutations. No activity occurs in individuals homozygous for the classic disease (G/G), whereas heterozygotes (G/N) have approximately one-half normal activity. Since the Q188R allele occurs in 70% of Caucasians with G/G galactosemia, it is easy to identify (277, 278). The Duarte allele (N314D) has a characteristic isozyme pattern when erythrocytes are studied by isoelectric focusing for the GALT enzyme. The need for therapy in patients with an activity of 25% or less of GALT, as in compound heterozygotes for Duarte/galactosemia alleles, has not been established. However, galactose should be restricted in early life for patients with any mutant genotype if erythrocyte Gal-1-P is more than 2 mg/dL or urinary galactitol exceeds 5 mmol/mol creatinine.

GALT is expressed in cultured amniotic fluid cells and chorionic villi. Thus, GALT deficiency can be detected prenatally by both direct enzyme assay and DNA analysis if the mutations are known. Amniotic fluid of a fetus with galactosemia has recently been found to have an elevated concentration of galactitol. Assessment of the galactitol content of amniotic fluid by GC/MS provides an ancillary method for prenatal diagnosis and may perhaps be related to enigmatic outcome (289).

Treatment

Objectives of therapy in galactosemia are to ameliorate or prevent symptoms while providing adequate energy and nutrients for normal growth and development. Treatment should begin as early in life as possible and consists of removal of all sources of lactose and galactose from the diet of patients with no enzyme activity. Patients with GALT activity above 5 to 10% of normal may tolerate small amounts of galactose found in muscle meats, fruits, and vegetables.

Nutrient Requirements. Energy and nutrient requirements of infants and children with well-controlled galactosemia are the same as those for normal individuals of the same age, gender, and physical activity level. Whether above-normal energy and protein intakes prevent the linear growth retardation seen in poorly controlled children is not known.

Formulas. Human milk contains 6 to 8% lactose; cow's milk, 3 to 4% lactose; and many proprietary infant formulas, 7% lactose. These milks must be replaced by a formula free of bioavailable galactose (Isomil Soy Formula with Iron, Ross Products Division, or Prosobee, Mead Johnson Nutritionals).

Formulas containing soy protein isolate have about 14 mg galactose/L in the form of raffinose and stachyose, oligosaccharides that contain galactose. At one time it was thought that these oligosaccharides yielded free galactose on hydrolysis in the intestine. It is now believed that the human intestine has no enzymes to hydrolyze these oligosaccharides (290). Thus, they may be safely used for feeding infants and children with galactosemia. RCF (Ross Products Division) and Next Step Soy Formula (Mead Johnson Nutritionals) may be used by children and adults who require a galactose-free formula. Casein hydrolysates such as Alimentum, Nutramigen, and Pregestimil (Mead Johnson Nutritionals) have been treated to remove lactose but may still contain small amounts of galactose. Data in [Table 61.23](#) describe foods allowed in, and excluded from, the galactose-restricted diet.

Table 61.23 Galactose-Restricted Diet

Free Galactose in the Diet. Milk and milk products are well-known sources of lactose and casein. Less well known is that different forms of casein and cheeses contain galactose in various amounts ([291](#), [292](#) and [293](#)). Based on studies by botanists and plant physiologists that began in the early 1950s, it is clear that cereals, fruits, legumes, nuts, seeds, tubers, and vegetables contain galactose. But many believe that the galactose in these foods is in linkages resistant to human digestive enzymes. Many fruits and vegetables, however, contain free (soluble) galactose in amounts ranging from less than 0.5 mg/100 g to 35.4 mg/100 g fresh weight ([294](#)). Ten of 12 baby foods had detectable amounts of free galactose, with applesauce and squash containing the largest amounts ([295](#)). Galactose has also been found in fermented cocoa beans ([296](#)).

Oral loads of raffinose and stachyose have been administered to one patient with GALT deficiency ([290](#)). No changes were observed in erythrocyte Gal-1-P, the analyte used to monitor dietary compliance. Soybean formula was fed to a 14 year old with GALT deficiency, and an insignificant change in Gal-1-P was found ([297](#)). These observations led clinicians to suggest that legumes could be used freely in the diets of patients with GALT deficiency, although explicit warning of the possible release of absorbable free galactose in the small intestine by bacteria when the patient had diarrhea had been given ([290](#)). Ingestion of legumes over a 5-year period led to a 21 to 100% increase in erythrocyte Gal-1-P in four patients with GALT deficiency, while of four patients who did not receive legumes, three had decreases in Gal-1-P of 17, 19, and 23%, and one patient had an increase of 37% ([298](#)). Chickpea flour contains 110 mg free galactose per 100 g flour ([299](#)). Free galactose in six types of cooked legumes ranged from 42 to 444 mg/100 g dry beans ([300](#)). Many legumes (dried beans and peas), cereals, fruits, nuts, seeds, and vegetables have not yet been analyzed for free galactose. Until such analyses are conducted, we will not know the extent of free galactose in foods.

Bound Galactose in Food and Drugs. Bound galactose is present in lactose, arabinogalactans I and II, feruloylated galactose, galactan, glycolipids, galactinol, galactopinitols, and rhamnogalacturonans I and II ([300](#)). Lactose is found in milk and dairy products and as an extender in many over-the-counter and prescription drugs ([301](#)). Hash-browned potatoes and some other prepared foods contain added lactose, and some chefs sprinkle meat with lactose before frying for faster and better browning ([300](#), [302](#)). Calcium lactobionate, the active ingredient in Neocalglucon, a liquid calcium supplement, is a substrate of b-galactosidases ([303](#)) and yields free galactose.

Organ meats such as brain, kidney, liver, pancreas, and spleen contain galactosylcerebrosides, gangliosides, and lactosyl sulfatide. These compounds are constantly turned over in living organisms. In patients with GALT deficiency, the free galactose liberated is metabolized to Gal-1-P or other metabolites such as galactitol ([304](#)). Glycoproteins found in muscle meats contribute significant amounts of galactose

to the diet (305).

Enzymes That Degrade Compounds Containing Bound Galactose.

α -Galactosidases, enzymes that digest carbohydrates with galactose in α -linkages, are found in human tissues and are probably responsible for the degradation of human galactosylcerebrosides, galactosylsulfatides, and gangliosides. α -Galactosidases also appear to be distributed in many plant tissues (306). Bean-O is an α -galactosidase isolated from *Aspergillus niger* and marketed by AkPharma, Inc., as a food enzyme that reduces gas formation from many vegetables. α -Galactosidases can hydrolyze the terminal galactose attached to digalactosyldiacylglycerol yielding galactose and monogalactosyldiacylglycerol (307).

β -Galactosidases are found in many foods, including apples and pears, peppers, tomatoes, and cocoa beans (308, 309, 310, 311 and 312). The human intestine also contains β -galactosidases (313). The β -galactosidases in the human intestine digest lactose, but also have heterogenous activity on compounds with galactose in β -1,4 linkages (313). β -Galactosidase preparations from *E. coli* release galactose from ferulic acid and from monogalactosyldiacylglycerols (307, 314).

Results of Nutritional Support. Treatment of patients with GALT deficiency, although life saving, may not result in complete freedom from the sequelae of the disorder. Infants diagnosed and treated early who maintain excellent dietary control have better intellectual function than those who have poor control or are diagnosed late (282). Control is defined on the basis of erythrocyte Gal-1-P concentrations and is considered excellent if consistently below 2 mg/dL (315). However, even with deletion of all known galactose-containing foods, children frequently have a higher Gal-1-P and a lower IQ than their normal siblings (316). Patients may have difficulty with language, abstract thinking, visual perception, ovarian failure, and cataracts, despite good dietary control (315, 316, 317, 318 and 319). These clinical deficits may be related to intrauterine damage from intrauterine accumulation of Gal-1-P or galactitol and/or maternal galactose transported into the vulnerable fetus. Embryonic membranes are constantly synthesized and degraded and require galactose and UDP-Gal. Galactose (i.e., milk) restriction in at-risk pregnant females is generally advised (320) although little change in outcome has been observed (282). This may be because many fruits, vegetables, and legumes contain free galactose, making restriction of all exogenous galactose impossible (300).

The recent observation that UDP-Gal is partially deficient in erythrocytes of patients with galactosemia offered another potential reason for poor outcome despite adequate lactose restriction (321). These findings have not been confirmed by others and uridine supplements have not been helpful in therapy (322, 324). Thus, other pathophysiological mechanisms or intrauterine development remain problematic.

Bone mineralization of both female and male patients with galactosemia was below that of normal age-, gender-, and ethnicity-matched subjects (325). Bone mineralization was positively correlated with calcium intake and in females was improved in those women who received estrogen (325).

A recently described mouse “knockout” for GALT has no acute hepatotoxicity or apparent ovarian failure. The mouse model differs from humans in having no aldose reductase and thus in not overproducing galactitol ([Fig. 61.10](#)). Thus, a pathological effect of polyol production and treatment using aldose reductase inhibitors is of considerable research interest for future therapeutic intervention ([326](#), [327](#)).

Assessment of Nutritional Support. Evaluation of growth, development, lens, liver function, erythrocyte Gal-1-P concentrations, and urinary galactitol excretion are necessary to determine adequacy of dietary intervention. Use of galactosylated hemoglobin A₁ as an index of dietary control has been suggested, but it is less sensitive and is an indirect test ([328](#)).

Diet Termination. Although some investigators have recommended liberalizing the galactose-restricted diet at 12 to 13 years of age, this is not warranted, because the potentially damaging effects of accumulated galactitol and Gal-1-P in the lens, liver, kidney, and brain remain. Females with galactosemia must continue treatment with galactose exclusion to reduce possible in utero damage to their future offspring ([329](#)). Diet termination is not recommended.

β -Oxidation, which results in sequential cleavage of two-carbon units from fatty acids, is an important source of energy for the body during fasting and metabolic stress. Free fatty acids released into the blood via catabolism of fat stores or from dietary sources are metabolized in two intracellular compartments: the peroxisomes and the mitochondria. Peroxisomes (sometimes referred to as microbodies) are subcellular organelles bounded by a single lipid bilayer membrane (1). They are ubiquitously distributed in tissues but are particularly abundant in liver and kidney (2). Most peroxisomal proteins are synthesized in the cytosol in their final form, although several are made in a precursor form that requires posttranslational proteolytic processing. All peroxisomal proteins are encoded in the nuclear genome and transported to the organelle posttranslationally. This process involves at least three mechanisms (3, 4). The most common is the presence of a serine-lysine-leucine amino acid motif at the carboxy terminus of the protein, which serves as a targeting signal to direct the protein to peroxisomes. A second mechanism uses an amino terminus–targeting signal. The third entails an internal amino acid motif.

Mitochondria are more complex structures than peroxisomes and are bounded by two lipid bilayer membranes (the inner and outer mitochondrial membranes). The intermembrane space constitutes a distinct compartment within the mitochondrion, while the space bounded by the inner mitochondrial membrane is known as the matrix. Mitochondria are unique organelles in animals in that they contain their own genetic information. The mitochondrial genome is composed of a circular DNA molecule encoding several protein subunits that constitute part of the electron transfer chain complexes as well as genes for specific tRNA and ribosomal RNA molecules necessary

for mitochondrial protein translation.

Human sperm cells are nearly devoid of mitochondria, while human oocytes contain numerous mitochondria. Genes on the mitochondrial chromosome therefore are inherited strictly from the mother by both sexes and can be passed on to subsequent generations only by females. This leads to the characteristic pattern of maternal inheritance seen in disorders associated with defects in the mitochondrial genome. Most proteins found in the mitochondria, however, are nuclear encoded and thus are inherited in a standard mendelian fashion. In general, they are synthesized in a larger precursor form containing information in an amino-terminal signal peptide necessary for targeting the proteins to the mitochondria (5, 6, 7, 8, 9 and 10). These signal sequences are usually removed after the protein is imported into the mitochondrion. More than one targeting signal may be necessary to direct the imported protein to the correct mitochondrial space or membrane. Peroxisomes and mitochondria arise by division of previously existing organelles and are randomly distributed to daughter cells upon cellular division.

Mitochondrial fatty acid oxidation is predominantly responsible for the oxidation of fatty acids of carbon length 20 or less, while the peroxisomal pathway is physiologically more relevant for longer-chain fats. Mitochondrial β -oxidation is a complex process involving transport of activated acyl-CoA moieties into the mitochondria and sequential removal of 2-carbon acetyl-CoA units (11) (Fig. 62.1). These in turn are used as fuel for the tricarboxylic acid cycle or production of ketone bodies (Fig. 62.2). The end result is generation of reducing equivalents that are funneled into the electron transport chain and ultimately lead to production of ATP. Ketones derived from hepatic fat metabolism can be used as an auxiliary fuel by most tissues, including the brain. At least 25 enzymes and specific transport proteins are responsible for carrying out the steps of mitochondrial fatty acid metabolism, some of which have only recently been recognized (Fig. 62.1 and Table 62.1). Of these, defects in at least 15 have been shown to cause disease in humans. The first of these disorders was identified only 20 years ago (12, 13), and most have been identified in the past 10 years.

Enzymes	Proven Clinical Disorder
Fatty acid activation	
Acyl-CoA synthetase	No
Carnitine cycle	
Plasma membrane carnitine transporter	Yes
CPT I	Yes
Carnitine:acylcarnitine translocase	Yes
CPT II	Yes
Mitochondrial β-oxidation spiral	
Very long chain acyl-CoA dehydrogenase (membrane)	Yes
LCAD (matrix)	No
MCAD	Yes
SCAD	Yes
Bifunctional protein	
Long chain 3-oxoacyl-CoA hydratase	Yes (isolated)
Long chain 3-ketoacyl-CoA thiolase	Yes
Crotonase (short-chain 3-oxoacyl-CoA hydratase)	No
SCHAD	Possible
Short-chain 3-ketoacyl-CoA thiolase	Possible
Enzymes of β-oxidation of unsaturated fats	
Long chain Δ^2 , Δ^3 -enoyl-CoA isomerase	No
Short-chain Δ^2 , Δ^3 -enoyl-CoA isomerase	No
2,4-Dienoyl-CoA reductase	Possible
Enzymes of ketone body production	
3-HMG-CoA synthase	
3-HMG-CoA lyase	
3-hydroxybutyryl-CoA dehydrogenase	

Table 62.1 Enzymes Involved in Mitochondrial Fatty Acid Oxidation

Fatty acid oxidation in peroxisomes uses a different set of enzymes (14, 15) (Fig. 62.3) and Table 62.2. While this system functions optimally for fats of carbon chain lengths between 12 and 16, its role in oxidation of fats longer than 20 carbons may be physiologically more relevant, since these molecules are not good substrates for the mitochondrial enzymes of β-oxidation. Activation of fatty acids to fatty acyl-CoAs is probably coincident with transport into peroxisomes (16). Following a series of enzymatic steps that shorten the acyl-CoA moiety in 2-carbon-unit increments to a minimum of 6 carbons, reaction products can be exported from the peroxisome as acylcarnitines. They are also available for use in intraperoxisomal anabolic pathways

such as cholesterol synthesis. β -oxidation in peroxisomes involves fewer enzymes than in mitochondria (perhaps as few as five), and defects in all of them have been identified as causes of human disease. However, abnormalities of peroxisomal biogenesis leading to multiple enzymatic deficiencies are much more common in humans.

ENZYMES OF β -OXIDATION

Mitochondria

Free fatty acids are transported through the blood after intestinal absorption or mobilization from endogenous stores by the use of albumin as a carrier protein or in the form of triacylglycerols in lipoprotein complexes (17). Transport of free fatty acids intracellularly and through the cytoplasm is probably accomplished by a specific

transport process; however, the mechanism is not well characterized ([18](#), [19](#)). Before undergoing β -oxidation, free fatty acids must be activated to their corresponding acyl-CoA thioesters. Long-chain-specific acyl-CoA synthetases can be found in various subcellular locations but are thought to arise from a single gene product ([20](#)). Short- and medium-chain carboxylic acids directly enter the mitochondrial matrix, where they are activated. In contrast, long-chain fats are activated in the cytoplasm and require active transport into mitochondria. Transport of long-chain acyl-CoAs requires at least two enzymes, a transporter protein, and carnitine as an intermediate carrier molecule. Carnitine is itself transported intracellularly by a specific transporter protein ([21](#), [22](#)). Two carnitine transporters have been described, one specific to liver and a second with a more ubiquitous distribution, including kidney, muscle, and fibroblasts ([23](#)). Long-chain acyl-CoAs are conjugated to carnitine by carnitine palmitoyl transferase I (CPT I) ([17](#), [24](#)). This enzyme is located on the inner aspect of the outer mitochondrial membrane. Tissue-specific isoforms of this enzyme probably exist. Long-chain acylcarnitines are then passed to carnitine palmitoyl transferase II (CPT II) in the inner mitochondrial membrane by a translocase ([25](#)).

Once present in the mitochondrial matrix, acyl-CoAs of all chain lengths undergo a series of enzymatic reactions which results in release of the 2-carbon-unit acetyl-CoA and a new acyl-CoA molecule that is two carbons shorter. The first step in this cycle is dehydrogenation of the acyl-CoA to 2-enoyl-CoA. This reaction is catalyzed by a family of related enzymes, the acyl-CoA dehydrogenases (ACDs) ([26](#), [27](#), [28](#) and [29](#)). Four different members of this family are active in β -oxidation: very long-, long-, medium-, and short-chain acyl-CoA dehydrogenases (VLCAD, LCAD, MCAD, and SCAD, respectively), which differ in their chain-length specificity. The ACDs differ from most other dehydrogenases because they use electron-transfer flavoprotein (ETF) as a final electron acceptor and thus can channel electrons directly into the ubiquinone pool of the electron transport machinery by way of ETF dehydrogenase. The ACDs are homotetramers that are synthesized in a larger precursor form in the cytoplasm from nuclear-encoded transcripts and transported into mitochondria. Once inside the mitochondrial matrix, the leader peptide is removed by a specific protease, and the mature subunits assemble into the active homotetramer. One molecule of flavin adenine dinucleotide (FAD) is noncovalently attached to each ACD subunit. cDNAs for each of these proteins have been cloned, and sequence analysis shows that they are approximately 30 to 35% conserved, suggesting evolution from a common primordial gene ([29](#), [30](#), [31](#) and [32](#)).

2-Enoyl-CoAs produced by the ACDs are hydrated to 3-hydroxy-acyl-CoAs. These in turn undergo 2,3 dehydrogenation to 2-ketoacyl-CoAs, followed by cleavage of the thioester bond. This releases acetyl-CoA and completes one turn of the β -oxidation cycle. The exact mechanism of these steps varies for substrates of differing chain length. A trifunctional protein (TF) has recently been identified that has 2-enoyl-CoA hydratase, 3-hydroxy-acyl-CoA dehydrogenase, and 3-acyl-CoA ketothiolase activities for longer-chain acyl-CoA substrates ([33](#), [34](#), [35](#) and [36](#)). This complex is an octamer consisting of 4 a and 4 b subunits. LCHAD activity resides on the a subunit along with that of 3-enoyl-CoA hydratase, while the b subunit contains the 3-ketoacyl-CoA thiolase activity. In contrast, individual proteins that catalyze these reactions for shorter-chain substrates have been identified and purified, each with a single activity ([37](#)). There is, however, considerable overlap in the substrate specificity of these enzymes, and

additional enzymes with yet different substrate optima have been postulated to exist for some of these steps (38). Enzymes catalyzing several additional sets of reactions are necessary for complete oxidation of unsaturated fatty acyl-CoA molecules.

Ketone bodies are produced exclusively in the liver from acetyl-CoA generated by β -oxidation (Fig. 62.2). HMG-CoA synthase forms 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) from acetoacetyl-CoA and acetyl-CoA. Acetyl-CoA and acetoacetate are then produced by cleavage of HMG-CoA by HMG-CoA lyase. Finally, acetoacetate is reduced to D-3-hydroxybutyrate by D-3-hydroxybutyrate dehydrogenase within mitochondria.

Several alternative metabolic pathways become important when mitochondrial β -oxidation is impaired. Peroxisomal β -oxidation allows continued metabolism of longer-chain fats, while ω -oxidation in the cytosol (which proceeds from the opposite end of the fatty acid) results in production of the characteristic dicarboxylic acids often present in these disorders. In addition, deacylation of acyl-CoA by cytosolic thioesters, and conjugation of acyl-CoAs to glycine and carnitine, become important mechanisms of CoA scavenging and detoxification, respectively.

Peroxisomes

Activation of fatty acids with chain lengths between 12 and 24 carbons and import into the peroxisomes is probably accomplished concomitantly by an acyl-CoA synthetase (16). A second enzyme with activities toward longer-chain substrates may exist (39, 40). The actual β -oxidation cycle in peroxisomes differs from that in mitochondria in a number of important ways (14, 41). The first step of the cycle in the peroxisomal matrix is oxidation by palmitoyl-CoA oxidase, leading to production of an enoyl-CoA (42). This enzyme transfers electrons directly to molecular oxygen, producing hydrogen peroxide, and may be, evolutionarily, distantly related to the mitochondrial acyl-CoA dehydrogenases. Additional oxidases can perform similar reactions using 2-methyl branched-chain acyl-CoAs and CoA intermediates of bile acids as substrates. The second and third steps of the β -oxidation cycle are carried out by a trifunctional protein complex containing enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase activities associated with the inner aspect of the peroxisomal membrane (43, 44). A peroxisomal-specific 3-ketoacyl-CoA thiolase catalyzes the final step of the cycle, producing acetyl-CoA and regenerating an acyl-CoA (45). Carnitine acyltransferases likely facilitate removal of acetyl-CoA and acyl-CoAs from peroxisomes for subsequent metabolism in mitochondria or elsewhere (46, 47 and 48). Additional enzymes involved in the metabolism of unsaturated long chain fats in peroxisomes include organelle-specific 2,4-dienoyl-CoA reductase, 3/2 enoyl-CoA isomerase, 2-enoyl-CoA hydratase, 2,5 enoyl-CoA reductase, and 3,5/2,4-dienoyl-CoA isomerase.

DEFECTS OF FATTY ACID METABOLISM

Mitochondria

Defects of Carnitine Biochemistry

Deficiencies of several steps of carnitine biochemistry and acylcarnitine transport into mitochondria have been described. These include defects of the specific plasma membrane carnitine-transporter proteins, CPT I and II, and the carnitine-acyl-carnitine translocase. Deficiency of the plasma membrane carnitine transporter represents a true primary carnitine deficiency (23). Carnitine is freely filtered by the kidney and must be reabsorbed from the proximal tubules to preserve plasma levels. Because the transporter for carnitine is deficient in kidney as well as other tissues in this defect, carnitine cannot be reabsorbed. This leads to a carnitine deficiency in end organs and impaired long-chain fatty acid metabolism.

Patients with carnitine-transporter deficiency can present with severe hypoglycemia and dilated cardiomyopathy in infancy or childhood. Alternatively, they may show onset of hypertrophic cardiomyopathy, progressive muscle weakness, and muscle lipid storage in the first year of life. A mixed picture of these findings has also been seen. Fetal hydrops secondary to this disorder has been reported (49, 50). Plasma carnitine levels are extremely low or undetectable in these children, and a dramatic rise is seen upon supplementation with pharmacologic doses of carnitine (100 mg/kg body weight). Patients' symptoms also show dramatic resolution with therapy. Outcome for these children is likely to be good if diagnosis is prompt and therapy is instituted.

CPT I deficiency is a rare disorder characterized by the onset in infancy of episodic hypoketotic hypoglycemia and multiorgan system failure (51). Less than a dozen cases have been reported. Muscle symptoms are not present. In one case, an apparently healthy girl aged 2 years 9 months developed hepatomegaly and coma following a viral illness and died (52). Organic aciduria is not prominent in this disorder, but hyperammonemia may be present. Plasma carnitine levels are normal or elevated, with a high free fraction. Elevated levels of creatine kinase were seen in sibs from one family. Analysis of samples from patients with CPT I deficiency has revealed normal CPT I levels in muscle, but low activity in other tissues including liver (51, 53). Patients with an isolated deficiency of muscle CPT I have not been reported. Patients thus far have not responded well to therapy with carnitine.

Deficiency of the carnitine-acyl-carnitine translocase has recently been reported (54, 55 and 56). Patients presented in the newborn period with severe hypoketotic hypoglycemia and cardiac arrhythmias and/or hypertrophy. All have had a grossly elevated acylcarnitine:free carnitine ratio, while dicarboxylic aciduria was reported in one. One child died at 36 months of age following a prolonged course of progressive muscle weakness (54). He had episodes of coma associated with intercurrent illness and fasting which left him profoundly weak for 2 to 3 weeks following recovery. Another patient died at 8 days of age of a pulmonary hemorrhage, probably secondary to liver failure (55). Mild hyperammonemia was present in both cases. Organic aciduria was not prominent. Two sibs died at age 2 months of liver failure, after presentation at age 2 days (56). Carnitine supplementation did not appear to improve clinical symptoms in either patient.

CPT II deficiency is the most common of this group of disorders. It classically presents in late childhood or early adulthood as episodes of recurrent exercise- or stress-induced myoglobinuria (57), which can be severe enough to occasionally lead to acute renal failure. Patients are typically well between episodes. There is no tendency to develop hypoglycemia. Weakness and muscle pain are common. The characteristic diagnostic finding in these patients is a low total plasma carnitine level with increased acylcarnitine fraction and no dicarboxylic aciduria. Long-chain acylcarnitines may in fact be elevated (58). A more severe variant of CPT II deficiency similar in symptoms to CPT I deficiency has recently been reported (58, 59). These patients presented with neonatal hypoglycemia, hepatomegaly, and cardiomyopathy. A severe reduction in CPT II activity was found in all tissues tested, including liver, heart, muscle, and fibroblasts, while CPT I activity was normal. This decrease in enzyme activity was in the same range as that seen with the later-onset form of the disease. Plasma carnitine was not increased. Mutations in the cDNA for CPT II have been described, and expression studies of mutant CPT II alleles suggest that the level of residual function of the mutant enzyme may determine the clinical phenotype (59, 60 and 61). A common mutation has been reported to account for half of mutant alleles in the late-onset form of the disease. Carnitine supplementation has not been of benefit in the severe form of CPT II deficiency (62).

Defects of ACDs

Deficiencies of VLCAD, LCAD, and SCAD have been described in relatively few patients. VLCAD deficiency has only recently been recognized. The first patient presented with ventricular fibrillation and respiratory arrest at 2 days of age and exhibited massive dicarboxylic aciduria (63). Plasma glucose and ammonia levels were not reported. She was treated with a low-lipid diet and carnitine supplementation. Despite the dramatic neonatal presentation, she recovered and is reported well at 2 years of age, without muscle or cardiac abnormalities. The patient's older sib died suddenly at 2 days of age and showed hepatic steatosis at necropsy. It is now clear that VLCAD deficiency is commonly, but not invariably, associated with early-onset cardiac and skeletal myopathy (64). One patient with onset of recurrent exercise-induced myoglobinuria in adolescence has been described (65). Hypoketotic hypoglycemia, hyperammonemia, and hepatocellular failure have been reported, and 3-hydroxy-dicarboxylic acids or saturated dicarboxylic acids may be present in the urine (63, 66). Cloning of the gene for VLCAD has allowed identification of a variety of genetic defects, but no common mutations have been found (32, 67, 68, 69 and 70).

Putative LCAD deficiency has been reported, but all patients originally categorized as LCAD deficient subsequently were proven to have a deficiency of VLCAD instead (71, 72 and 73). Thus, there are no known patients with bona fide LCAD deficiency.

A number of patients with SCAD deficiency have been described (74, 75, 76, 77 and 78). Clinical findings have included episodes of intermittent metabolic acidosis, neonatal hyperammonemic coma, neonatal acidosis with hyperreflexia, and infantile-onset lipid-storage myopathy with failure to thrive and hypotonia. Hypoglycemia has not been reported in this disorder. The characteristic metabolites of ethylmalonic and

methylsuccinic acids seen in SCAD deficiency have also been described in individuals who appear to have normal SCAD activity in fibroblasts. It has been suggested that a relatively common variant of SCAD may predispose to excess production of these metabolites, but the role of this in disease remains unclear (79).

In the past several years, MCAD deficiency has emerged as one of the most common inborn errors of metabolism in certain populations. The most frequent presentation is one of intermittent hypoketotic hypoglycemia with onset in the second year of life (clinical features reviewed in [11]). Mild hyperammonemia and coma may or may not be present. These findings often lead to inappropriate diagnosis of Reye syndrome. The patient is usually well between episodes. Dicarboxylic aciduria is extensive during times of illness, but can be undetectable by routine means when the patient is well. Similarly, micro- and macrovesicular steatosis present during acute illness may resolve between acute episodes. Most patients who have subsequently been shown to have died of MCAD deficiency have survived an initial episode. Thus, recurrent Reye syndrome-like episodes especially should trigger suspicion of this disorder. Sudden death in a previously healthy child has been described in numerous cases of MCAD deficiency. In the appropriate age range, such deaths are often misascribed to “sudden infant death syndrome” (SIDS). Autopsy usually reveals the characteristic micro- and macrovesicular steatosis and should suggest the diagnosis. Finally, completely asymptomatic individuals have been identified in the course of family studies of patients. The diagnosis of MCAD deficiency in asymptomatic individuals has been made possible in the past several years by dramatic advances in laboratory techniques based on identification of alternate metabolites that accumulate in various bodily fluids (80, 81).

Remarkable progress has been made in recent years in our understanding of the molecular mechanisms responsible for MCAD deficiency. Following cloning of the cDNA for MCAD, several groups simultaneously reported that a single common mutant allele was responsible for up to 90% of mutant alleles in patients with this disorder (82). Substitution of a G for an A residue at position 985 results in replacement of a lysine by a glutamic acid residue, leading to production of an unstable protein (83). Furthermore, screening of newborn blood samples has revealed that the carrier frequency for this disorder is quite high in some populations. Allele frequencies for the A to G⁹⁸⁵ mutation range from 1 in 40 in northern European populations to less than 1 in 100 in Asian and some southern European populations. In the United States, a carrier frequency for all mutations of 1 in 60 has been estimated for Caucasians (84). This translates into a predicted disease frequency of 1 in 15,000. MCAD deficiency has not yet been diagnosed in an African American. The public health issues surrounding a disease of potentially such high frequency have been vigorously debated. The predicted incidence of MCAD deficiency on the basis of these studies is similar to, or greater than, that for phenylketonuria (PKU), a disorder screened for in all 50 states in the United States. Thus, some groups feel strongly that newborn screening for MCAD deficiency is warranted.

Deficiency of Other β -Oxidation Enzymes

Patients with a deficiency of long-chain 3-hydroxy acyl-CoA dehydrogenase (LCHAD) have tended to fall into two clinical subclasses (85, 86, 87, 88, 89 and 90). One group

presented primarily with symptoms of cardiomyopathy, myopathy, and hypoglycemia. Peripheral neuropathy with or without pigmentary retinopathy and recurrent myoglobinuria may be present (38, 91, 92). These patients are deficient in all three enzymatic activities of the trifunctional protein. The other group has shown a picture of severe hepatocellular disease. Considerable overlap in these groups has been described, however, and LCHAD deficiency has also been reported in patients with recurrent Reye syndrome–like symptoms and in sudden infant death. Defects in the α subunit appear to destabilize trifunctional protein, resulting in the multiple enzymatic deficiencies seen in some patients (93, 94 and 95). A common G to C mutation at nucleotide position 1528 accounts for approximately 80% of mutant alleles thus far identified in this gene (94). Heterozygosity for trifunctional protein α subunit deficiency has recently been implicated as a potential risk factor in the development of fatty liver of pregnancy or “hemolysis, elevated liver enzymes, low platelet” (HELLP) syndrome (96, 97). Mutations in the β subunit of trifunctional protein have been less well characterized but can also destabilize trifunctional protein (95). The reason for the clinical heterogeneity in this disorder remains to be elucidated (98).

Three patients have been reported with a deficiency of short-chain 3-hydroxy acyl-CoA dehydrogenase (SCHAD) (99, 100). The first was a 16-year-old previously healthy girl who developed episodic myoglobinuria at age 13 years. At age 16 years she developed a flulike illness with generalized weakness, hypoketotic hypoglycemia, and lethargy. She subsequently died of a cardiac arrhythmia. Dicarboxylic and 3-hydroxydicarboxylic aciduria were present acutely. An older brother died at age 8 years of encephalopathy after a 6-year history of intermittent episodes of irritability, ataxia, and mild mental retardation. The 16-year-old girl had 35% of normal SCHAD activity in muscle, compared with controls, but activity for long-chain substrates was preserved. A second patient exhibited episodic vomiting, dehydration, and hyperammonemia beginning at age 13 months (100). Urine findings during acute episodes included elevated 3-hydroxybutyrate and acetoacetate levels along with dicarboxylic acids and 3-hydroxydicarboxylic acids of chain length C6 to C14. Urinary carnitine was increased and was mostly conjugated. A final patient displayed a complex clinical picture complicated by a concurrent chromosomal abnormality but with biochemical findings similar to those of the second patient. Only the last patient exhibited hypoglycemia. SCHAD activity in isolated mitochondria from the latter two patients was reduced to about 5% of normal (100).

Three patients have recently been described with developmental delay and muscle weakness; one of them, who died of a Reye-like illness, had urine metabolite findings suggesting a defect in 3-ketoacyl-CoA dehydrogenase (101). Definitive enzyme testing has not been performed. An isolated defect of 3-enoyl-CoA hydratase deficiency has not been reported.

One patient has been reported to have a potential defect in the enzyme 2,4-dienoyl-CoA reductase (102). This patient presented in the newborn period with persistent hypotonia. She was found to have elevated lysine and decreased carnitine levels in plasma. 2-*trans*,4-*cis*-Decadienoylcarnitine was identified in plasma and urine, and reduced activity of 2,4-dienoyl-CoA reductase was found in liver and muscle. The patient died at 4 months of age of respiratory acidosis. Confirmation of the clinical significance of these

biochemical abnormalities awaits identification of additional patients.

Multiple Acyl-CoA Dehydrogenation Disorder (MAD)

Abnormalities of ETF or ETF dehydrogenase deficiency lead to an in vivo deficiency of all dehydrogenases that use ETF as an electron acceptor (103). This includes the ACDs discussed above, as well as isovaleryl-CoA dehydrogenase, 2-methylbutyryl-CoA dehydrogenase, glutaryl-CoA dehydrogenase, dimethylglycine dehydrogenase, and sarcosine dehydrogenase, enzymes involved in the intermediate metabolism of branched-chain amino acids, tryptophan, lysine, and choline. Intermediate compounds accumulate related to blockages in all of these pathways. Because glutaric acid is present in the urine of some patients, this disorder is frequently referred to as glutaric aciduria type II (GA II) to distinguish it from a primary deficiency of glutaryl-CoA dehydrogenase (GA I).

Clinical manifestations of MAD are extremely heterogeneous. A neonatal form can be seen with severe hypotonia, dysmorphic features, and cystic kidneys. These infants also exhibit metabolic acidosis and hypoglycemia. Milder variants are common, with nonspecific neurologic signs, myopathy, fasting hypoketotic hypoglycemia, and/or intermittent acidosis. In some patients, only fasting hypoketotic hypoglycemia and/or intermittent acidosis is seen. In these patients, the organic acid profile in times of illness is usually dominated by ethylmalonic (EMA) and adipic acids, leading to the alternate name of EMA-adipic aciduria for this disorder.

Analysis of fibroblasts from patients with MAD has revealed defects in both protein subunits of ETF and in ETF dehydrogenase (104). Cell lines with and without immunologically cross-reactive material have been described. cDNAs for both subunits of ETF and ETF dehydrogenase have been cloned, and direct mutational analysis has revealed a variety of defects in patients. Thus far, correlation of the mutation with severity of clinical symptoms has not been possible.

Riboflavin-Responsive Defects of Fatty Acid Metabolism

Riboflavin is the precursor to FAD, an essential cofactor for the ACDs, ETF, and ETF dehydrogenase. Several sets of patients with biochemical abnormalities suggesting β -oxidation defects have responded with clinical improvement to pharmacologic doses of riboflavin (100–200 mg/kg/day). One group clinically resembles patients with multiple dehydrogenase deficiency and appears to represent a variant of ETF or ETF dehydrogenase with an as yet undefined defect in interaction with FAD. Increasing intramitochondrial concentrations of FAD by administration of riboflavin apparently allows enough cofactor binding to restore activity. A second set of patients shows a picture of late-onset lipid-storage myopathy and muscle weakness with some level of hepatic dysfunction. These patients also appear to respond to therapy with riboflavin, but their defect remains undefined. Marked clinical heterogeneity within each group has been documented.

Deficiencies of Ketone Body Production

HMG-CoA synthase deficiency has been reported in a child with fasting hypoketotic hypoglycemia. Deficiency of HMG-CoA lyase, which is also active in the metabolism of leucine, presents with hypoketotic hypoglycemia with hyperammonemia and acidosis (105). Identification of hydroxymethylglutaric acid in the urine is diagnostic.

Peroxisomes

Defects of Peroxisomal Biogenesis

Deficiencies of single peroxisomal enzymes exist for a number of the steps of peroxisomal β -oxidation (Table 62.2). Defects of peroxisomal biogenesis with a resulting failure to import all or a subset of matrix enzymes are far more common, however. Absence or significant reduction in the number of peroxisomes occurs in four disorders historically considered distinct: Zellweger syndrome, neonatal adrenoleukodystrophy, infantile Refsum disease, and pipecolic acidemia (1, 106). It is now clear that these are related disorders that form a spectrum of clinical severity from the early lethal phenotype seen in Zellweger syndrome to the later-onset symptoms of infantile Refsum disease and pipecolic acidemia.

Zellweger syndrome was the first disorder of peroxisomal biogenesis to be identified (107). Classic findings include characteristic dysmorphic facial features and other malformations accompanied by severe neurologic dysfunction with hypotonia, seizures, and ultimate deterioration. Liver function is abnormal, as is that of the gastrointestinal tract, leading to failure to thrive. Neuronal heterotopia and renal cortical cysts are seen pathologically. Proximal limb shortening may be present. Death usually occurs within the first few months of life. Peroxisomes are completely absent in all tissues examined, and the enzymatic functions associated with peroxisomes are similarly absent or mislocalized to the cytosolic compartment. This results in severe impairment of cholesterol synthesis, bile acid metabolism, β -oxidation of very long chain fats and branched-chain fats, ether phospholipid synthesis, and phytanic acid and pipecolic acid metabolism.

Neonatal adrenoleukodystrophy and infantile Refsum disease can manifest in the first 6 months of life with a presentation resembling that of Zellweger syndrome, but with slightly later onset of symptoms (108, 109). These disorders, along with pipecolic acidemia, can also appear in early childhood (less than 3 years of age) with findings of psychomotor retardation (108, 109), ophthalmologic abnormalities, and other neurologic deficits, including neurosensory impairment and nystagmus. Biochemical findings in patients with neonatal adrenoleukodystrophy, infantile Refsum disease, and pipecolic acidemia resemble those of Zellweger syndrome but may be more subtle.

Understanding of the molecular basis for deficient peroxisomal biogenesis in this group of disorders is evolving rapidly. Complementation analysis of fibroblasts from these patients reveals that at least 10 separate genes are affected (110). Three of these have

been identified as a protein import receptor, a peroxisomal assembly factor, and a 70-kd peroxisomal membrane protein, with the latter defect found in the largest group of patients ([111](#), [112](#), [113](#) and [114](#)). Some of the complementation groups are rare and so far identified only in patients with the Zellweger phenotype, but this is likely to be an ascertainment bias ([110](#)). Patients in the remaining complementation groups may exhibit any of the clinical phenotypes.

Disorders of Single Enzymes

X-linked adrenoleukodystrophy is the most common disorder involving peroxisomal β -oxidation, affecting 1/20,000 males ([15](#)). Biochemical studies originally characterized an impaired ability to activate fatty acids to their acyl-CoA esters and suggested that this was a disorder of an acyl-CoA synthetase. Recent molecular data, however, have identified defects in an ATP-binding transporter located in the peroxisomal membrane as responsible ([115](#)). Why this defect affects the activity of acyl-CoA synthetase remains to be elucidated. Regardless, patients show a severely impaired ability to metabolize very long chain fatty acids in the peroxisomes. Several clinical phenotypes have been associated with defects at this locus ([115](#), [116](#), [117](#), [118](#), [119](#) and [120](#)). Classical cerebral childhood adrenoleukodystrophy is the most common of these and accounts for 50% of cases. Boys are usually well until the second half of the first decade of life, when progressive quadriplegia, blindness, and dementia develop. Death generally occurs within 5 years of onset of symptoms. In 30% of individuals, a later-onset disorder designated adrenomyeloneuropathy is seen in which male patients experience progressive spastic paraparesis with peripheral neuropathy beginning in the second or third decade of life. Up to 30% of females who are carriers of X-linked adrenoleukodystrophy show a similar picture beginning at about age 30 years. Finally, some males with a defect in this gene show only adrenal insufficiency (which also accompanies almost 90% of adrenoleukodystrophy and adrenomyeloneuropathy). There may be great clinical heterogeneity within families.

The remaining defects in peroxisomal β -oxidation are relatively rare, with only a handful of reported cases each. Acyl-CoA oxidase deficiency is characterized by early-onset seizures, psychomotor retardation, and neurologic degeneration similar to neonatal adrenoleukodystrophy and is often referred to as “pseudo-neonatal adrenoleukodystrophy” ([121](#)). Dysmorphic features are not seen. Hepatic peroxisomes are present and an isolated elevation of very long chain fatty acids is found in blood and urine. Peroxisomal trifunctional protein deficiency also presents similarly to neonatal adrenal leukodystrophy, but with accumulation of trihydroxycoprostanic acid in addition to very long chain fatty acids ([122](#), [123](#), [124](#) and [125](#)). Dysmorphic features may be present. Several patients with clinical and pathologic features identical to those of Zellweger syndrome have been described who have abundant hepatic peroxisomes and an isolated defect of the peroxisomal 3-ketoacyl-CoA thiolase ([126](#), [127](#)). This entity has been referred to as “pseudo-Zellweger syndrome.” Very long chain fatty acids, pipercolic acid, and bile acid intermediates are all elevated in these patients.

Classic Refsum disease due to deficiency of phytanic acid oxidase is not a defect of peroxisomal β -oxidation per se but deserves mention because of the confusing nomenclature. Clinical findings include retinitis pigmentosa, cerebellar ataxia, and

peripheral neuropathy, with onset of symptoms varying from childhood to the fifth decade of life (128). There is no mental retardation, dysmorphic features, or hepatomegaly. This disorder is characterized by accumulation of phytanic acid in blood and tissues, while measures of other peroxisomal enzyme functions are normal.

DIAGNOSIS OF DEFECTS OF FATTY ACID METABOLISM

Mitochondria

Diagnosis of defects of mitochondrial fatty acid metabolism requires a high level of suspicion in the appropriate clinical settings (Table 62.3). This is crucial because, in many instances, the biochemical abnormalities that might suggest a defect of β -oxidation often resolve along with clinical symptoms. Thus, individuals with unexplained hypoglycemia, acidosis, hyperammonemia, myopathy with or without recurrent myoglobinuria, or progressive neuropathy should be considered candidates for one of these disorders. All cases of Reye syndrome, patients with Reye syndrome–like symptoms, “SIDS,” or unexplained sudden or near death in childhood should be evaluated for a defect in fat metabolism.

Hypoketotic hypoglycemia with fasting or stress
Reye syndrome (especially recurrent)
Hypotonia and/or muscle weakness
Peripheral neuropathy
Coma
Sudden death in infancy or childhood
Cardiomyopathy
Unexplained metabolic acidosis \pm hyperammonemia
Hyperuricemia
Recurrent myoglobinuria
Elevated serum creatine kinase
Dicarboxylic aciduria
Carnitine deficiency

Table 62.3 Findings Suggestive of a Defect in Mitochondrial β -Oxidation

When an individual presents with such a clinical picture, it is critical to obtain blood and urine samples acutely for appropriate analysis, since biochemical findings may disappear when the patient is well. Because routine organic acid analysis is often normal when patients are not in an acute crisis, these patients should be more extensively evaluated if a diagnosis is not immediately obvious. This is best done in a referral center by a specialist trained in the evaluation of these patients. Plasma free and total carnitine levels can often suggest whether a deficiency is primary or secondary (Table 62.4). Laboratory clues to the diagnosis of one of these disorders include dicarboxylic or 3-hydroxydicarboxylic aciduria, hypoglycemia in the face of little or no ketosis, mild lactic acidosis, and mild hyperammonemia. Hyperuricacidemia is a useful sign if present but is nonspecific. Myoglobin in blood or urine and elevated plasma

creatine kinase levels can be seen when muscle involvement is present. Highly sensitive techniques, using mass spectrometry, can detect minute quantities of intermediates specific for certain fatty acid oxidation disorders. These intermediates are often not detectable by routine organic acid analysis (80, 81). All patients with a suspected defect in fatty acid metabolism should receive an echocardiogram because of the high incidence of cardiomyopathy in many of these disorders. A fasting test with or without a subsequent challenge test with medium- or long-chain triglycerides may induce excretion of a diagnostic metabolite but should only be undertaken in a hospital setting by someone experienced in performing such tests. A medium-chain triglyceride loading test must only be performed *after* specifically excluding the diagnosis of MCAD deficiency, as catastrophic consequences can result in patients with MCAD deficiency. Direct DNA mutational analysis is readily available for the common A to G⁹⁸⁵ mutation responsible for MCAD deficiency (82). Specific enzyme analysis can be performed for many of these defects on cultured fibroblasts and/or liver or skeletal muscle. Newborn screening for MCAD deficiency has been suggested but remains controversial (129, 130).

Enzyme Defect	Total Carnitine	Free Carnitine	Free/Total Carnitine
Carnitine Transporter	Very Low	Low	Normal
CPT I	Normal or high	High	High
Translocase and CPT II	Low	Very low	Low
VLCAD, LCAD, MCAD, SCAD, LCHAD, SCHAD, ETF and ETFdehydrogenase and 2,4-dienoyl-CoA reductase	Low	Low	Normal or low

Table 62.4 Plasma Carnitine Levels in Defects of b-Oxidation

Peroxisomes

Diagnosis of defects of peroxisomal b-oxidation is more straightforward than that of mitochondrial defects since clinical symptoms and biochemical abnormalities are not intermittent. Clinical findings suggesting a defect of peroxisomal biogenesis or an isolated defect in b-oxidation are summarized in Table 62.5. These diagnoses should be considered in the setting of unexplained seizures and/or developmental delay, especially if accompanied by hypotonia. Screening plasma and/or urine for very long chain fatty acids, pipercolic acid, phytanic acid, and pristanic acid will identify most patients. Additional investigations can include quantitation of bile acid and cholesterol synthesis intermediates, red blood cell membrane plasmalogen level, and presence or absence of peroxisomes in cultured skin fibroblasts. Finally, specific enzyme analysis on cultured skin fibroblasts as well as complementation analysis can be performed to

identify the precise nature of the defect in a patient. Molecular mutational analysis remains largely a research tool.

Seizures
Hypotonia
Dysmorphic features
Large fontanelle
High forehead
Epicanthal folds
Malformed ears
Inverted nipples
Rhizomelic chondrodysplasia
Hepatomegaly and/or hepatic failure
Renal cysts
Neurologic and/or intellectual degeneration
Ophthalmologic abnormalities
Peripheral neuropathy
Optic atrophy
Cataracts
Retinopathy
Hearing impairment
Failure to thrive

Table 62.5 Findings Suggestive of a Defect in Peroxisomal β -Oxidation

GENETICS OF DEFECTS OF FATTY ACID METABOLISM

All of the defects of mitochondrial fatty acid metabolism identified thus far and all of the peroxisomal disorders except X-linked adrenoleukodystrophy are inherited in an autosomal recessive fashion. The recurrence risk for subsequent sibs is therefore 25%. X-linked adreno-leukodystrophy is inherited as an X-linked trait. Affected males are hemizygous for one abnormal gene, while carrier women are heterozygous for one normal and one mutant allele. Thus, carrier women face a 50% risk of having an affected male or carrier female with each pregnancy. There may be great clinical heterogeneity within families, and individuals with the severe childhood onset and less severe myeloneuropathy forms may be present in the same family. To explain this, it has been proposed that one or more additional autosomal genes modulate the clinical severity of this disorder.

SUDDEN INFANT DEATH AND DEFECTS OF FATTY ACID METABOLISM

The role of mitochondrial β -oxidation defects in SIDS bears special mention. Precision is required when discussing SIDS. Since the definition of SIDS includes normal autopsy findings, many patients with defects of β -oxidation will be eliminated from this population by careful microscopic study of muscle, heart, and liver. Unfortunately, not all deaths reported as SIDS receive the same level of scrutiny, and thus cases of β -oxidation disorders may still be represented. In addition, some disorders of β -oxidation can clearly present with minimal or no tissue changes, making postmortem diagnosis far more difficult. An early claim that 15 to 17% of cases of SIDS are caused by defects of β -oxidation has been tempered by additional data, but it is likely that approximately 1 to

3% of unexplained sudden deaths in infancy and childhood are related to such disorders ([131](#), [132](#) and [133](#)). Because of this high frequency and because of the lack of reliable autopsy findings, all children who die suddenly from unexplained causes (whether or not they are infants) should be evaluated for possible metabolic defects, including disorders of β -oxidation.

Postmortem examination should include analysis of blood, urine, or aqueous humor for organic acids and acylglycines and/or acylcarnitines. Tissue samples of liver, skeletal muscle, and heart should be rapidly frozen and stored at -70°C for future enzymatic analysis, and a skin fibroblast culture should be started when possible. Only such an intense effort to determine a diagnosis in these cases will permit accurate counseling for the family regarding recurrence risks and identification of asymptomatic siblings. It has been suggested that newborn screening for MCAD deficiency could reduce the incidence of SIDS, but this remains to be substantiated ([129](#), [130](#)).

TREATMENT OF DEFECTS OF FATTY ACID METABOLISM

Mitochondria

The mainstay for therapy of defects of mitochondrial β -oxidation is avoidance of fasting. By not allowing patients with these disorders to become dependent on β -oxidation for energy needs, accumulation of intermediate metabolites and development of symptoms can be minimized. Thus, during periods of wellness, fat consumption should ideally be restricted to the ADA minimum nutritional requirements for age. This may be difficult to achieve in practice, and a goal of 25% of calories by fat may be more realistic.

Increased caloric intake may be necessary during intercurrent illness because of increased metabolic demands on the body. This can be met via oral or nasogastric tube (NG) administration of an appropriate formula or by intravenous (IV) infusion of glucose (8–10 mg/kg/min) if oral intake is inadequate. Orally administered corn starch (1.5–2.0 g/kg/dose) has been used as an alternative glucose source in some patients with long-chain fat metabolism defects to reduce dependence on NG or IV calories.

Substitution of medium-chain triglycerides for complete dietary fats in patients with defects in long-chain fat metabolism has been reported to be of value, as fats in this preparation can bypass the metabolic block. Carnitine at a dose of 100 mg/kg can completely reverse the symptoms of carnitine-transporter deficiency and may be necessary to replete carnitine levels that are secondarily lowered in other patients.

The concept of carnitine as a completely benign therapy has been called into question for patients with β -oxidation defects ([134](#), [135](#)). Theoretically, promoting entry of long-chain fats into mitochondria, the physiologic role of carnitine, may be counterproductive in patients unable to subsequently metabolize those substances. Adverse effects of such therapy have been reported ([134](#)). In addition, few controlled studies are available regarding the efficacy of carnitine therapy in defects of fatty acid metabolism other than primary deficiencies. Finally, carnitine may interfere with production of acylglycines in some instances and actually decrease the total amount of

excreted metabolites ([80](#), [135](#)).

Conjugation of acyl-CoAs with glycine occurs via a specific enzymatic reaction and represents a major route for excretion of excess acyl-CoAs as well as other organic acids. Glycine therapy (300 mg/kg/day) has been advocated for patients with multiple dehydrogenase deficiency and has been shown to increase metabolite excretion in these and other patients ([136](#)). Concern over toxicity has tempered its use, however. Riboflavin (200 mg/kg/day) may be useful in some patients with multiple acyl-CoA dehydrogenase deficiency and riboflavin metabolism defects.

Peroxisomes

Treatment of patients with defects in peroxisomal β -oxidation has been problematic and, in recent years, controversial. Therapy for X-linked adrenoleukodystrophy has received the most attention. Several inhibitors of very long chain fatty acid synthesis have been used in an attempt to control excess accumulation of very long chain fats in patients. These include oleic acid, glycerol trioleate, and glycerol trierucate. The most extensive therapeutic trial to date used a diet that provided 10% of calories as fat, with less than 10 to 15 mg of C26:0 fatty acid per day ([137](#)). In addition, 1.7 g/kg body weight/day of glycerol trioleate oil and 0.3 g/kg body weight/day were also given, along with 10 to 15 mL safflower oil and 2 g fish oil (to avoid a deficiency of essential fatty acids). Using this regimen, very long chain fatty acid levels were normalized in patients with either adrenoleukodystrophy or adrenomyeloneuropathy, but little or no clinical improvement could be documented ([137](#)). It is still not known whether presymptomatic treatment will prevent or delay appearance of symptoms, but this now seems the best possible alternative for patients with this deficiency. Liver transplant has been used in this disorder with mixed results. Therapy of the other single-enzyme defects of peroxisomal β -oxidation has not been reported.

Treatment of the disorders of peroxisomal biogenesis has been problematic because of the multisystemic disease and the numerous metabolic pathways affected in these individuals. In addition to reduction of very long chain fatty acid intake, patients may benefit from reduction of phytanic acid intake (10 mg/day) as in adult Refsum disease ([128](#)). Dairy products, ruminant fats, and ruminant meats are the prime dietary sources of phytanic acid. Green vegetables, originally excluded from the diet, are no longer believed to contribute significantly to the physiologic phytanic acid load. Unfortunately, limited information is available on many food items. Since it is difficult to reduce dietary intake below 10 to 20 mg/day, it may be necessary to supplement with an artificial liquid formula. Benefits in uncontrolled studies have been reported for supplementation of patients with oral formulations of ether lipids, cholic (100 mg/day) and deoxycholic acids (100 mg/day), and docosahexenoic acid (250 mg/day), but large-scale controlled studies are necessary for rigorous evaluation of the efficacy of these treatments ([138](#), [139](#) and [140](#)). Regardless, based on experience with X-linked adrenoleukodystrophy, these therapies are likely to be helpful (if at all) only when begun presymptomatically, and perhaps only in the milder disorders of peroxisomal biogenesis.

DEFINITION

Use of the Triceps Skinfold and Body Mass Index

Because weight and height change throughout childhood, the cutoff points of any measure used to define obesity must be age and gender dependent. The ideal anthropometric measure of fatness is one that correlates reasonably well with fat as a percentage of body weight. Among children and adolescents, weight for height, body mass index, and triceps skinfold demonstrate comparable correlation coefficients with fat as a percentage of body weight, measured by underwater weighing (1). Despite the similarity of the correlation coefficients, variants of weight for height and triceps skinfold thickness probably capture different aspects of body fat. Although the triceps skinfold thickness provides a direct measure of fat, it only does so at one location in the body. Furthermore, because body fat redistributes at adolescence to a more central distribution, the triceps skinfold thickness may decrease even as body fat increases. Weight and height measures do not measure fatness directly, but use of an index such as body mass index (BMI; wt/ht^2) may remove the covariance of weight and height and thereby provide a more direct measure of the effect of increased fat on weight.

In adolescents, a convenient algorithm (2) exists to screen patients for obesity (Fig. 63.1). The algorithm begins with a BMI in excess of the 95th percentile for age and gender, using tables derived from representative surveys of the U.S. population (3) (see also Appendix Table III-A-18-b-1 and Table III-A-18-b-2), or a BMI of 30.0 or above. If the BMI exceeds the 95th percentile for age or gender or if it is greater than 30 BMI units, an in-depth medical assessment is warranted. The details of the medical assessment are considered below. The same algorithm could reasonably be applied to screen younger children. In both adolescents and young children, selection of the 95th percentile as a screening tool reduces the sensitivity of the measure but increases its specificity (4). This approach therefore minimizes the likelihood that obesity will be overdiagnosed and thus lead to excessive concern about weight when no significant problem exists.

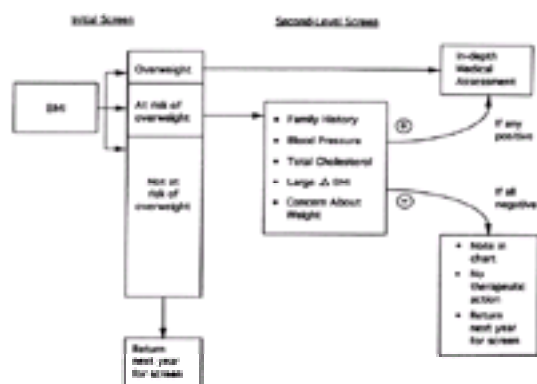

Figure 63.1. A convenient algorithm (2) exists to screen patients for obesity. The algorithm begins with a BMI in excess of the 95th percentile for age and gender, using tables derived from representative surveys of the U.S. population (3), or a BMI \geq 30.0. If the BMI exceeds the 95th percentile for age or gender or if it is greater than 30 BMI units, an in-depth medical assessment is warranted.

Changes in Body Fat and Fat Distribution with Age

The BMI and triceps skinfold do not change synchronously with age. In females after the first year of life, the triceps skinfold thickness remains stable, then begins to increase in early adolescence (5). Female adolescence is characterized by an increase in body fat from a mean of 17% of body weight to 25% of body weight. In males, changes in fatness are somewhat more complex. The triceps skinfold decreases at approximately 4 years of age, increases immediately before puberty, and subsequently decreases during the adolescent growth spurt. Male adolescence is characterized by a decline in body fat from a mean of 18% of body weight to 11% of body weight.

Changes in BMI with age are similar for both genders. BMI rises between birth and 9

months of age and subsequently declines to a nadir at approximately 4 to 5 years of age (6). Thereafter, BMI rises through adolescence. The point at which BMI begins to increase after the nadir is known as the period of adiposity rebound.

The pattern of fat distribution also changes with age and differs for males and females. In both genders during adolescence, body fat redistributes from peripheral to central sites (7, 8). In girls, more fat is deposited in the gluteal regions than in the abdomen. In males, fat tends to be deposited more centrally.

Changes in adipocyte numbers tend to parallel the changes in body fatness that occur from early childhood. Adipocyte replication occurs as body fat increases, regardless of whether the increase in body fat is normal or excessive (9, 10). Adipocyte size increases in early infancy. However, after early infancy, adipocyte size remains relatively constant until puberty, when another small increase occurs. The factors that control the regionalization of body fat and adipocyte replication throughout childhood remain unclear.

EPIDEMIOLOGY

Prevalence

Both triceps skinfold and BMI data suggest that the prevalence of obesity among children and adolescents in the United States has increased rapidly over the last 30 years. Based on the use of a triceps skinfold greater than the 85th percentile among children and adolescents studied in the National Health Examination Surveys (NHES; 1963–1970), the prevalence of obesity appeared to increase by 54% in children aged 6 to 11 years by the time the second National Health and Nutrition Examination Survey (NHANES II) was conducted in 1980 (11). Over roughly the same time period, the prevalence of obesity among adolescents aged 12 to 17 years had increased by 30%. Increases in the prevalence of superobesity, defined as a triceps skinfold above the 95th percentile, increased even more rapidly over the same time period. More-recent data, collected between 1980 and 1990, when the NHANES II and NHANES III examinations were completed, and based on an age- and gender-specific BMI above the 85th percentile in the NHES (12), demonstrated that the prevalence of obesity increased by 12% in boys and 44% in girls aged 6 to 11 years. In male and female adolescents aged 12 to 17 years, the prevalence of overweight increased by 45 and 37%, respectively. Increases in more severe obesity, defined by the authors as a BMI above the 95th percentile, ranged from 37 to 137%. These estimates suggest that one in five children and adolescents in the United States is now overweight. Furthermore, both the triceps skinfold data, which provide direct measures of fat, and the BMI data indicate that the prevalence of severe obesity has increased more rapidly than more modest degrees of excess fatness.

The reasons for the changes in prevalence have not been carefully examined. Although dietary fat intake in the population has declined (13), increased quantities of food are consumed outside of the home. The fat and caloric content of foods consumed outside the home remains unclear and may contribute to caloric imbalance. Likewise, although Neilsen estimates of time spent viewing television by children have not changed

substantially over the last 20 years (14), the Nielsen estimates may be biased because only half of those families invited to participate do so (14). More-recent data from the National Longitudinal Survey of Youth suggest that children and adolescents currently watch more than 1 hour more of television per day than they did before 1963–1970 (15). Approximately 30% of children watch 5 or more hours of television daily. Nonetheless, the relative contributions of diet and inactivity to the increases in prevalence of obesity remain unclear.

Critical Periods for Onset of Childhood Obesity

A critical period for development of obesity is defined as a developmental stage in which physiologic alterations increase the later prevalence of obesity (16). Fetal life, the period of adiposity rebound, and adolescence appear to be critical periods for onset of obesity in children and adolescents. Several groups appear at risk for development of obesity or its complications as a consequence of intrauterine developments. Low-birth-weight infants appear to have an increased risk of hypertension and cardiovascular disease as adults (17). However, it is not clear that adults born with low birth weights have an increased prevalence of obesity in adulthood, although visceral fat may be increased (18). The best evidence that fetal life constitutes a critical period for development of obesity derives from studies of infants of diabetic mothers. These infants are fatter at birth than infants whose mothers are not diabetic. By 1 year of age, the differences in fatness at birth are no longer present (19). However, by 5 to 6 years of age, children of mothers diabetic during pregnancy have an increased prevalence of obesity that persists through 18 years of age (20).

The second critical period in childhood is the period of adiposity rebound. Children with early adiposity rebound appear at increased risk for development of obesity that persists into adulthood (21, 22).

Adolescence, particularly in girls, represents a third critical period in childhood for development of obesity. Longitudinal data suggest that the risk of persistence of adolescent obesity into adulthood is threefold greater in adolescent girls than in boys (23). Furthermore, obesity in adolescence carries an increased risk of all-cause and cardiovascular mortality in adult males and cardiovascular morbidity in both male and female adults that appears independent of adult weight (24).

Regardless of the age of onset, fatness appears increasingly canalized with age (25, 26). Furthermore, estimates suggest that 30 to 80% of overweight children remain overweight as adults (27). Adults who were overweight during childhood may account for a disproportionate percentage of morbidly obese adults (28).

The mechanisms that act to entrain obesity and its complications at these periods remain unclear. The relationship between early fetal undernutrition and morbidity may be mediated by fetal adaptations to stress, such as hypercortisolism (29). Whether fetal undernutrition also leads to increased body fat or enhances the likelihood of comorbidities of obesity remains unclear. The increase in body fatness that occurs in infants of diabetic mothers may entrain either the number of fat cells, the central regulation of fatness by the hypothalamic-pituitary-adrenal axis, or adipocyte factors

concerned with regulation of body fat. Factors that regulate body fatness during the period of adiposity rebound remain less certain. Adiposity rebound may represent the period when the genetic predisposition to obesity may be expressed. Conversely, the period of adiposity rebound may represent the first important period in life when social forces that affect activity and diet begin to operate. Entrainment of these behaviors could have a disproportionate effect on the onset and persistence of later obesity. As indicated above, adolescence represents a period when major changes in body fat and fat distribution occur in both genders. Excessive increases in body fat during female adolescence appear to increase the risk that increased body fat will persist. In males, the risks of adult disease that adolescent obesity entrains may reflect the central redistribution of fat that occurs in adolescence (7, 8).

Role of the Physical Environment

Childhood obesity has been associated with a variety of variables within the physical environment, including season, region, and population density (30). Obesity among children and adolescents is also more prevalent in winter and spring than in summer and fall. Childhood obesity is more prevalent in the northeastern United States, followed in descending order by the Midwest, South, and West. Within each region, obesity is more prevalent in densely settled urban areas than in areas with lower population densities.

The mechanisms that account for the variations induced by season, region, and population density remain unclear. However, regional and seasonal differences in diet and activity represent likely candidates. Other cultural factors such as differences in the amount of clothing worn and its consequent effect on the perception of body appearance represent reasonable hypotheses. In highly urbanized areas, reduced access to exercise facilities or heightened concern about safety may reduce the opportunity for activity.

Role of the Behavioral Environment

Family Environment

A variety of familial and behavioral variables have also been associated with childhood obesity. Children whose parents are obese have an increased risk of obesity (5). Obesity is most prevalent among single children and less prevalent among children from large families (31).

The role of socioeconomic class in the genesis of childhood obesity remains unclear. Although an early study demonstrated an inverse relationship of obesity to socioeconomic class (32), other studies have shown either a direct (33) or no significant relationship (34). Several sources of data suggest that obesity may represent a determinant rather than a consequence of socioeconomic class in young adults (35, 36). The effect of social class on the prevalence of obesity has not been examined in more recent representative surveys of the U.S. population.

Children who are the victims of parental neglect (37) and those who suffer from increased psychosocial problems (38, 39) also appear at increased risk for development of obesity.

Diet

Energy balance can be expressed as $TEE = RMR + TEF + ACT$, where TEE is total daily energy expenditure, RMR is resting metabolic rate, TEF is the thermic effect of food, and ACT is the energy spent on activity. Obesity occurs when energy intake exceeds energy expenditure. The only two discretionary components of the energy balance relationship are food intake and energy spent on activity.

The absence of a clear relationship of dietary intake to development of obesity in children derives from the difficulties inherent in accurately measuring dietary intake. For example, overweight children rarely gain more than 5 extra kilograms per year. Assuming that all excess weight is fat, that the cost of synthesis of adipose tissue is minimal, and that a kilogram of adipose tissue contains 150 to 200 g of water (40, 41), the daily caloric excess necessary to produce a gain of 5 kg of adipose tissue annually approximates a caloric imbalance of 100 kcal/day (Table 63.1).

Adipose tissue = 20% H₂O
1 g fat = 9 kcal/g
1 kg adipose = 800 g fat = 7200 kcal
5 kg adipose tissue = 36,000 kcal/365 days = 98 kcal/day

Table 63.1 Caloric Excess Necessary to Gain 5 kg of Adipose Tissue per Year

Comparisons of reported dietary intake with energy expenditure measured by the doubly labeled water method emphasize the difficulties inherent in accurate measurement of the minor caloric imbalances necessary to generate obesity. For example, careful dietary records collected from normal-weight and overweight adolescents underestimated measured energy expenditure by 20% and 40%, respectively (42). Although younger children may provide more-accurate estimates of food intake (43, 44), dietary records still cannot provide the valid caloric intakes necessary to establish the source of caloric imbalance that generates excess weight gain. However, dietary records may help identify foods that are the appropriate target of

therapy or eating patterns that could be modified to reduce caloric intake for the individual patient.

Because dietary records to establish caloric intake are inaccurate, studies of patterns of eating or food consumption may be a more fruitful approach to the examination of the role of diet in the genesis of childhood obesity. Such studies have not been done. The increased caloric density of fat and the possibility that individual differences in fat oxidation account for a differential susceptibility to weight gain (45, 46) suggest that reduced dietary fat intake is an appropriate target for preventive efforts.

Activity

As indicated above, energy expenditure includes the energy spent on resting or basal metabolic rate, the thermic effect of a meal, and the energy spent on activity. Although an initial report demonstrated that maternal obesity appeared related to reduced energy expenditure in infants (47), subsequent studies have failed to reveal any significant differences in energy expenditure between infants born of normal and overweight mothers (48). Furthermore, total energy expenditure at 12 weeks of life failed to predict changes in body fat that had occurred by 9 months and 2 years of age (49).

Studies of resting metabolic rate conducted in obese and nonobese children (50) and adolescents (51) have consistently shown an elevated resting metabolic rate in the obese subjects, even after normalization for fat-free mass. Although the thermic effects of food were lower in obese than in nonobese children, no differences were observed after weight reduction (52). Furthermore, no significant differences have been observed between obese and nonobese adolescents (53).

Reduced energy spent on activity could also increase susceptibility to obesity in children and adolescents. For example, vigorous physical activity declines markedly in girls during adolescence and may increase the risk of obesity onset during this period (54, 55). As indicated in [Table 63.2](#), doubly labeled water studies indicated that the energy spent on activity, calculated from TEE measured with doubly labeled water and resting metabolic rate, gradually increases throughout childhood (56, 57, 58 and 59). If reduced energy spent on physical activity represented a risk factor for development of obesity, the incidence of obesity should be inversely related to the energy spent on physical activity. However, the increases with age in the energy spent on activity suggest that alterations in activity do not adequately account for the increased risk of obesity that accompanies either the period of adiposity rebound or adolescence. Nonetheless, reductions in the energy spent on metabolic rate, the thermic effects of food, or activity could predispose individuals or subgroups to an increased risk for development of obesity.

Age Group	(reference)	Males	Females
5 years	(56)	1.36 (13)	1.40 (17)
9-12 years	(58)	1.61 (23)	1.53 (15)
12-18 years	(51)	1.79 (20)	1.69 (28)
Adults	(57)		1.70 (23)

Table 63.2 Mean (SD) Energy Costs of Activity (TEE/RMR) in Humans of Different Ages (Determined by the Doubly Labeled Water Method)

Inactivity

The decreased activity in adolescents (54, 55) and adults (60) in the United States has focused attention on inactivity as a potential cause of obesity. Activity within populations, measured by time of participation in activities, may have an effect on the prevalence of obesity that is independent of the effect of inactivity, measured by television time (61). If inactivity was the reciprocal of activity, the effects of activity and inactivity on the prevalence of obesity would not be independent. These data also suggest that inactivity may be better understood as sedentary behavior rather than as function of energy expenditure.

The principal sedentary behavior in the United States is television viewing. Current estimates suggest that approximately one-third of children in the United States view more than 5 hours of television per day (15). Television viewing occupies more time on an annual basis than any other behavior except sleep. Television viewing has been linked with a variety of adverse health outcomes (14), including obesity (15, 62). Furthermore, the relationship between television viewing and obesity may be causal (62). Television viewing is associated with reduced activity, although metabolic rate may not be lower than when children engage in other sedentary activities such as reading (63). Television viewing is also associated with increased food intake, and the foods consumed are those advertised on television (64).

Several sources of data are consistent with the view that the covariation of inactivity with other behaviors may contribute to the adverse effects of inactivity on obesity. For example, although television viewing is a sedentary activity, television viewing has been significantly associated with increased fat intake (63). Furthermore, recent studies in adolescents (65, 66) demonstrated significant relationships between inactivity and other adverse health practices, such as smoking, consumption of less healthy foods, or increased fat intake.

CLINICAL EFFECTS

Syndromes Associated with Childhood Obesity

[Table 63.3](#) includes most of the clinical syndromes associated with childhood and adolescent obesity ([67](#)). Even in specialty clinics that deal with childhood obesity, syndromes associated with obesity are rare. Most syndromes associated with obesity are readily identified by physical examination because of short stature, dysmorphic features, or ocular anomalies.

Alstrom-Hallgren syndrome
Carpenter syndrome
Cohen syndrome
Cushing syndrome
Growth hormone deficiency
Hyperinsulinemia
Hypothalamic dysfunction or tumor
Hypothyroidism
Laurence-Moon-Biedl syndrome
Polycystic ovary disease
Prader-Labhart-Willi syndrome
Pseudohypoparathyroidism
Turner syndrome

Table 63.3 Clinical Syndromes Associated with Childhood Obesity

Because childhood obesity is generally accompanied by an increase in linear growth ([68](#)), short stature in association with obesity should prompt a careful search for other characteristics associated with potential clinical syndromes. Additional features common to more than one syndrome include ocular (Alstrom-Hallgren syndrome [[69](#)], Bardet-Biedl syndrome [[70](#)], pseudohypoparathyroidism), hand (Carpenter syndrome, Cohen syndrome, Bardet-Biedl syndrome, Prader-Labhart-Willi syndrome [[71](#), [72](#)], pseudohypoparathyroidism), or menstrual abnormalities (Cushing's syndrome [[73](#)], hypothalamic dysfunction [[74](#)], Bardet-Biedl syndrome, polycystic ovary disease [[75](#)], Prader-Labhart-Willi syndrome, Turner's syndrome).

Consequences of Obesity in Childhood

Although many of the consequences of childhood obesity resemble those in adults, they occur less frequently. Several are unique to childhood-onset obesity. Among the most prevalent consequences of obesity in children is the discrimination that overweight children suffer at the hands of their peers. Young children learn to associate obesity with other undesirable characteristics. For example, children as young as 6 years of age consistently rank obese children as less desirable candidates as friends than children

with any other handicap (76). As children grow older, discrimination becomes more institutionalized. Among adolescents, college acceptance rates for obese girls are lower than those for nonobese girls with comparable academic credentials (77). As adults, girls overweight in late adolescence and early adulthood complete fewer years of education, marry significantly less frequently, and have lower family incomes and increased rates of poverty (35).

Orthopaedic problems unique to childhood occur more frequently among the obese. Slipped capital femoral epiphysis occurs among children with a prevalence of approximately 3/100,000 persons per year (78), but most children with this problem are obese (79). The disease probably reflects the susceptibility of the epiphysis of the femoral head to the increased stress of weight bearing. The disease may present only with hip pain or a limp. Blount's disease (80), or bowed tibia with a consequent deformity of the medial aspect of the proximal tibial metaphysis, occurs with increased frequency among obese children. Blount's disease reflects the effects of increased weight bearing on cartilaginous bone, with compensatory overgrowth of the tibia. Surgery may be necessary to correct the deformity. Minor injuries, such as ankle sprains, may resolve more slowly or become chronic in overweight children and adolescents and may account for persistent extremity pain.

Although the cardiovascular consequences of obesity occur less frequently than they do in adults, the precursors of adult disease are present in childhood. Acanthosis nigricans, an increased pigmentation of the skin of the neck and axillae, may be a consequence of the increased friction between skinfolds but may also indicate abnormal glucose tolerance and hyperinsulinemia (81). However, frank non-insulin-dependent diabetes mellitus is rare in children and adolescents in the absence of a strong family history of diabetes. Hyperlipidemia is frequent among obese children. Furthermore, the lipoprotein pattern is characterized by elevated levels of low-density lipoproteins and decreased levels of high-density lipoproteins (82, 83).

Hepatic abnormalities occur in a sizable fraction of overweight children. These abnormalities generally consist of modest elevations of liver enzymes and may reflect hepatic steatosis (84). In severely obese patients, hepatic steatosis may progress to cirrhosis. Weight loss can normalize the abnormal levels of liver enzymes. As in adults, obesity may also be associated with cholecystitis (85). A more common cause of abdominal pain is gastroesophageal reflux caused by the increased intra-abdominal pressure of visceral or subcutaneous abdominal fat.

The two most serious and urgent complications of childhood and adolescent obesity are sleep apnea (86) and pseudotumor cerebri. Severe sleep apnea invariably occurs in association with snoring, and parents may describe the apneic episodes. Long apneic episodes are associated with hypoxia and may trigger a fatal cardiac arrhythmia. Up to 50% of children with pseudotumor may be obese (87), although the role that obesity plays in the pathophysiology of pseudotumor remains unclear. Compression of the optic nerve may produce visual field cuts. Rapid weight reduction is essential for both problems.

Clinical Assessment

Few causes or consequences of obesity occur in the absence of signs or symptoms. Therefore, a careful history and physical examination are crucial to exclude underlying associated syndromes or to identify complications of obesity.

History

A careful history of the age of onset of obesity may help identify underlying risk factors that may predispose to the persistence of the disease. Such factors include gestational diabetes in the mother or onset of obesity at the time of adiposity rebound. Questions regarding discrimination in school represent a useful mechanism to engage the child's or adolescent's interest and participation in the therapeutic process. A family history of severe obesity or associated hypertension, diabetes, or cardiovascular morbidity heightens concern about future comorbidities in the pediatric patient and helps establish the level of family concern regarding the medical complications of obesity.

Although the dietary history cannot be used to establish the level of caloric intake, a 24-hour recall and a brief series of quantitative questions about the consumption of juice, milk, soft drinks, fast food, and high-caloric-density snacks such as candy bars, chips, cookies, ice cream, or frozen yogurt may identify specific foods that can be permanently altered or eliminated from the diet. Questions about time spent outdoors, participation in vigorous activities, and time spent viewing television are essential to establish the level of activity and identify potential approaches to reduce inactivity or increase vigorous activity.

The review of systems should include questions that address the principal morbidities outlined above. Headaches or visual changes may indicate the presence of pseudotumor cerebri or the rare hypothalamic tumor. Snoring in association with daytime somnolence suggests the possibility of sleep apnea. Dyspnea on exertion provides a functional measure of activity and the restriction on activity imposed by obesity. Abdominal pain may be functional and may result from school avoidance, but it may also indicate the presence of gastroesophageal reflux or cholecystitis. Irregular periods or amenorrhea may indicate polycystic ovary disease. Hip pain or a limp suggests imminent or acute slipped capital femoral epiphysis.

Physical Examination

The physical examination should begin with a careful plot of height and weight on a growth chart to establish the severity of obesity. Measurement of the triceps skinfold thickness will help establish whether the excess weight represents body fat or increased frame size. Measurement of the waist and hip circumferences provides a crude estimate of visceral fat distribution. Determination of blood pressure with an appropriate-size cuff and the use of age-appropriate standards is essential.

Short stature or dysmorphic features should prompt careful exclusion of one of the

syndromes associated with childhood obesity. The presence of acanthosis nigricans or the violaceous striae that characterize Cushing's syndrome can be noted on inspection of the skin. A careful funduscopic examination should be performed to exclude papilledema suggestive of increased intracranial pressure. Enlarged tonsils may contribute to sleep apnea. If a tonsillectomy is warranted, careful postoperative care is essential, because obese children are at high risk for postoperative obstruction from the peripharyngeal swelling that follows a tonsillectomy. Abdominal tenderness may reflect cholecystitis or cholelithiasis. Limited range of motion of the legs at the hip may be the only indication of slipped capital femoral epiphysis. In younger children, bowed extremities require radiologic examination to exclude the possibility of early Blount disease.

Laboratory Assessment

Serum cholesterol levels to exclude the possibility of hyperlipidemia, liver enzyme levels to identify hepatic steatosis, and a urinalysis to exclude glucosuria should be done routinely. Abnormal liver function tests in a child with a history of abdominal pain or a family history of gall bladder disease require an ultrasound examination of the abdomen to exclude cholelithiasis. Fasting glucose and insulin levels may help clarify the risk of diabetes mellitus in a child or adolescent with acanthosis nigricans. A history consistent with sleep apnea warrants a sleep study to determine the frequency and severity of apneic episodes. Sex hormones, luteinizing hormone, and follicular stimulating hormone may be helpful adjunct measures in girls with signs or symptoms of polycystic ovary disease. Additional laboratory studies that are not suggested by concerns identified during the history or physical examination are rarely helpful.

TREATMENT

Family involvement in the treatment of childhood and adolescent obesity is crucial ([88](#), [89](#)) because the pediatric patient is rarely responsible for the purchase, preparation, or serving of food. Such involvement is implicit in the description of the therapeutic approaches that follow.

Regardless of the severity of obesity, the first consideration for any overweight individual is weight maintenance. For some children, such as those who are 120% of their ideal weight, weight maintenance for 1 year may be the only step necessary to achieve ideal weight for height. However, aggressive therapy must be considered from the outset for the morbidly obese adolescent who is 200% of ideal weight. Although dietary therapy is necessary to achieve weight reduction, increased levels of activity may be essential to achieve weight maintenance after weight loss has been accomplished.

Education

Education of the obese child or adolescent rarely proves successful as an isolated intervention in treatment of childhood obesity. However, several principles are useful in the treatment of children and families. Use of the Food Guide Pyramid to guide food

choices may help to reduce dietary fat intake (90). Furthermore, use of labels to establish fat and caloric content will help families purchase lower fat and calorie options.

Dietary Modification

Reduced caloric intake must remain the cornerstone of weight reduction therapy, because it is easier to achieve a caloric deficit by reduced food intake than by increased activity. As indicated above, the most useful function of a dietary history is to identify foods that can be altered or eliminated.

Low-Fat Diets

Reductions in dietary fat represent the first step in modification of dietary intake. According to the current recommendation of the American Academy of Pediatrics, dietary fat intakes should approximate 30% of calories for children over the age of 2 years. Several caveats accompany this recommendation. First, although no comparable studies in children have been done, reductions in dietary fat in the absence of reduced caloric intake may only achieve modest weight reduction in adults (91). Although anecdotal reports suggest that excessive concerns about the effects of dietary fat have led to growth failure in young children (92), concerns about the effect of caloric restriction on the growth of the population become moot in obese children where the potential for minor adverse effects of diet are exceeded by the risks of persistent obesity.

A second alternative for children and young adolescents is the “Stop-light Diet” (93). This approach classifies foods as green, yellow, and red, according to whether the food can be consumed freely, with caution, or only on rare occasions. The stop-light diet has been used repeatedly and effectively in weight-reduction studies of 8- to 12-year-old children.

The manner in which dietary modifications are introduced may be as important as the dietary modification itself. For example, children appear to respond better when the emphasis is on foods that families *can* eat, rather than on foods that are restricted (89). This observation is consistent with the finding that children and adolescents for whom specific diets were recommended did poorly in comparison to children and adolescents for whom recommended diets were less specific (94). Both observations suggest that the results of therapy are likely better when more control of the choices remain in the hands of children and their families.

Use of Restrictive Diets

Severely obese adolescents whose weight is 180% or more in excess of ideal, or children or adolescents with a major complication of excess body weight, may require more aggressive dietary interventions such as the protein-modified fast. The protein-modified fast should be used cautiously in patients with renal or cardiac disease; however, it may be highly beneficial in patients with liver disease that results from hepatic steatosis. Before the diet is started, it is essential to determine whether the

candidate for the diet is capable of weight maintenance. If weight maintenance is impossible before the diet is started, the patient is more likely to relapse after the diet is discontinued.

The protein-modified fast consists of a carbohydrate-free diet that contains 2.0 to 2.5 g protein/kg ideal body weight/day provided as meat or other high-quality protein, supplemented with 30 mEq KCl, 800 mg Ca, and a multivitamin with minerals daily (67, 95). Vegetables low in carbohydrate may be consumed ad libitum. Fluid intake should be maintained at a level of 48 oz of noncaloric fluids daily. Ketosis appears within 48 to 72 hours of the initiation of the diet and can be used to monitor dietary adherence. After the diet is started, it should be continued for several months. Weight losses are most rapid in the first 2 weeks of the diet and thereafter average 0.5 to 1.0 kg/week. Patients should be seen frequently during the diet to monitor adherence, identify potentially adverse effects of the diet, and provide ongoing family support. Blood counts, liver function tests, and amylase and albumin levels should be monitored monthly. At the termination of the diet, carbohydrates should be reintroduced gradually over several weeks.

Complications of the protein-modified fast include malaise during the transition to ketosis, orthostatic hypotension, and diarrhea or constipation. Although gall bladder disease may occur in association with fat-free diets, this complication is rare in children and adolescents following the protein-modified fast, probably because the fat contained in a meat-based diet may cause gall bladder contractions and thereby reduce biliary sludging. Nonetheless, if a patient develops abdominal pain with weight reduction, an ultrasound of the abdomen is essential to exclude cholelithiasis or pancreatitis.

Alterations in Activity

Increased Activity

Increased activity may have several benefits during weight reduction. In adults, increased activity may block the adaptive decrease in metabolic rate that occurs in response to a hypocaloric diet, perhaps by a reduction in the loss of fat-free mass (96, 97). Second, increased activity in association with a low-calorie diet may increase the rate of weight loss. Finally, increased levels of activity may increase the likelihood of weight maintenance after weight loss is achieved. Reasonable recommendations for activity are those proposed by the International Consensus Conference on Physical Activity Guidelines for Adolescents, which suggest that adolescents should participate in three or more sessions per week of moderate to vigorous activity that last 20 minutes or more (98). However, recommendations for vigorous activity are not appropriate for massively obese adolescents who may achieve maximal energy expenditure with walking. For this group, simple increases in activity should be the goal.

Increased activity among obese preadolescents increases total energy expenditure and is not apparently counterbalanced by reduced activity in other areas (99). As in adults (100), losses of fat are likely to depend on the individual's capacity for fat oxidation, the intensity of exercise, and the quantity of fat in the diet.

How increases in activity are accomplished may contribute to the long-term success of the intervention. For example, lifestyle activities chosen by the child may accomplish more sustained rates of weight reduction than structured exercise programs that provide fewer choices (101), perhaps because children are more likely to participate in an activity that they choose. Furthermore, when children make a choice, they may feel more responsible for the decision to change (102).

Reduced Inactivity

As indicated above, both increased activity and reduced inactivity may have beneficial effects on weight changes in the population. The long-term effects of increased activity and reduced inactivity on weight reduction have only recently been carefully examined (102). When the effect on weight of increased activity was compared with that of reduced activity, 4-month and 1-year weight losses were significantly greater for the group reinforced for reductions in inactivity than in the group that was reinforced for increased activity. Furthermore, attitudes toward high-intensity activity were more positive among children who were reinforced for decreased sedentary activity than among children reinforced for increased activity. These data suggest again that efforts to reduce inactivity under circumstances in which children choose the alternative activity are more effective than when children are reinforced for the activity itself. Further trials of the effects of reductions in inactivity are essential.

Behavior Modification

Behavior modification is not an additional therapeutic endeavor but rather the mechanism by which changes in diet and activity are effected. As indicated above and in repeated studies by Epstein and his colleagues (88), parental involvement in weight reduction programs aimed at children is essential.

The major components of behavior modification are contracting, self-monitoring, and social reinforcement and modeling (88). Contracting provides reinforcement to promote adherence to the weight reduction regimen or incentives for weight loss. Self-monitoring involves careful daily observation of diet and activity. Social reinforcement and modeling involves teaching children and parents how to model behaviors related to diet and activity for other family members. The capacity to make free choices between alternatives appears highly beneficial to adherence and should be central in the design of weight reduction programs for children and adolescents.

Other therapies aimed at the modification of family behaviors, such as family therapy, have not been studied as intensively. One reason is that interventions such as family therapy are not as readily quantified. Likewise, because studies of behavior modification have focused most intensively on children less than 12 years of age, the effectiveness of this intervention in other age groups has not been established.

Alternative Therapies

Therapies for morbid obesity in adolescents, as in adults, are associated with a high relapse rate. For example, virtually all patients studied as inpatients in a variety of studies of hypocaloric diets regained their weight after discharge from the study. Furthermore, substantial numbers of patients may not be able to initiate hypocaloric diets or may be so incapacitated by their weight that movement is impossible. For these patients, more aggressive therapies such as pharmacotherapy or gastric bypass surgery may be warranted. Unfortunately, experience with these therapies in adolescents is limited.

Pharmacotherapy

Few trials of pharmacotherapy in adolescents have been reported. Although combined trials of phenteramine and fenfluramine have been performed ([103](#)) or are under way in adults, few comparable data exist for adolescents. Therefore, at present, pharmacotherapy must be reserved for morbidly obese adolescents but only after other, more conservative, approaches, including the protein-modified fast, have been exhausted.

Only one report has considered the effects of *d,l*-fenfluramine on overweight children and adolescents. In a trial that compared 30 or 60 mg of *d,l*-fenfluramine in 11- to 17-year-old patients with a placebo-treated group ([104](#)), mean weight loss at 6 months was 3.3 BMI units, and at 12 months was 5.1 BMI units for the treated group. These losses approximate 8.25 and 12.75 kg, respectively. Although side effects appeared minor, use of pharmacotherapy should be reserved for morbidly obese adolescents in whom all more conservative therapies have failed, until trials involving larger numbers of patients are available. Furthermore, adolescents and their physicians must retain realistic expectations regarding the response to therapy. Pharmacotherapy will probably not achieve the massive weight reduction necessary for the morbidly obese patient to achieve ideal body weight.

Surgery

Gastric bypass surgery or vertically banded gastroplasty must be considered therapy of last resort for the morbidly obese adolescent who has failed all other conventional therapies. Only two reports have been published regarding the use of surgery to treat obesity in this age group ([105](#), [106](#)). These studies suggest that mean weight losses are in excess of 40 kg, depending on the type of operation and gender of the patient. These results may underestimate the effects of surgery, because weight gains in some of the operative patients would have continued unabated without intervention. Surgery is probably not warranted for patients with Prader-Labhart-Willi syndrome, many of whom promptly regain the weight that they lose. Acute complications of surgery include leaks at the anastomosis and wound infections. Long-term complications include anemia. Nonetheless, weight losses have been sustained in almost all patients for over 7 years.

Outcome

Childhood- and adolescent-onset obesity appears to account for approximately 30% of obesity present in adult women. Furthermore, in both males and females, obesity in adolescents appears associated with a risk of adult morbidity and mortality that seems independent of the effect of adolescent weight on adult weight. These observations suggest that effective treatment of obese children and adolescents may exert a substantial effect on the morbidity and mortality of adult obesity.

Children also appear more responsive to weight reduction therapies than adults. For example, Epstein et al. (88) have shown that the long-term effects of a family-based program of diet and activity promoted by behavior modification could still be demonstrated 10 years after the program was introduced. These results indicate that children should be targeted for an increased proportion of the resources and efforts aimed at weight control in the U.S. population.

The generalized deficiency of all nutrients, i.e., protein-energy malnutrition, is by far the most common nutritional deficiency in the world today. Although this condition is rare in developed countries, it occurs in a number of infants and/or children with the underlying medical problems discussed below. Thus, it is helpful to consider the special nutrient needs and nutritional management of these children within the framework of protein-energy malnutrition as encountered in many underdeveloped parts of the world.

Protein-energy malnutrition results from a lack, in varying proportions, of protein and energy. It is seen most frequently in infants and young children and may occur in epidemic (famine-related) or endemic (disease-related) forms. Whether the cause is primary (e.g., insufficient food supply) or secondary (e.g., poor absorption, increased excretion, increased requirements), the physico chemical pattern of the tissues, defensive capacity to environmental aggressors, and efficiency and ability for work are affected adversely. Moreover, the condition is associated with a high mortality rate.

Protein-energy malnutrition includes two distinct syndromes, marasmus and kwashiorkor, as well as a mixed syndrome, often termed *marasmic kwashiorkor*. *Marasmus* refers to the state of chronic total undernutrition (i.e., a deficiency of both protein and energy). It results in growth failure as well as gradual emaciation and inanition. *Kwashiorkor*, derived from the Ga language of Ghana, was used initially to refer to the protein deficiency of weanling infants, i.e., “the disease that the first child gets when the second is on the way” (1). Clinically, it is characterized by signs of protein deficiency, including edema and ascites, as well as growth failure.

Both conditions occur in varying degrees in the groups of pediatric patients discussed below. Mild and moderate forms of both distinct syndromes are subclinical and characterized only by growth failure and possibly some retardation of mental development. Whether or not these latter consequences are permanent is a matter of debate; on balance, it appears that most can be ameliorated with appropriate treatment (2).

CYSTIC FIBROSIS AND OTHER CHRONIC PULMONARY DISEASES

Cystic fibrosis is characterized by progressive deterioration of pulmonary and pancreatic function. The former may increase nutrient requirements somewhat, but probably its greatest nutritional impact is an adverse effect on intake, particularly during acute exacerbations and in older children with severe pulmonary disease. Pancreatic insufficiency severely limits the absorption of fat, a major energy source of most diets. Thus, the cause of malnutrition in infants and children with this disease can be both primary (i.e., inadequate nutrient intake) and secondary (i.e., fecal losses of protein and, particularly, fat). The latter cause usually can be controlled with appropriate pancreatic enzyme replacement.

Traditionally, a high-protein, low-fat diet has been advocated for patients with cystic fibrosis. However, with appropriate pancreatic enzyme replacement, most patients can maintain a reasonable nutritional status with a “normal” diet. Younger patients usually have very good appetites, but with advanced pulmonary disease, appetite usually decreases. Many patients with advanced disease take in far less protein and especially energy than is recommended. From time to time, the theoretical possibility of essential fatty acid deficiency secondary to poor fat absorption is mentioned. However, unless the intake of essential fatty acids is quite low, this is rarely a significant problem.

There is some concern that malnutrition may hasten deterioration of pulmonary function, but there is no definitive proof that this is the case. Nonetheless, acute improvement of nutritional status improves muscle strength (3). Thus, attempts either to improve nutritional status or to prevent even minimal deterioration of nutritional status are warranted.

In recent years, high-fat formulas have been advocated for patients with chronic pulmonary disease. The rationale, supported adequately by fact, is that oxidation of fat produces less carbon dioxide than oxidation of carbohydrate and, hence, a high-fat intake imposes less stress on the already compromised pulmonary system. This obviously is an important consideration in patients who require mechanical ventilation or who have severely compromised pulmonary function. One product based on this principle (Pulmocare, Ross Laboratories) is available for patients with pulmonary disease. Although designed for adults, the product is used in pediatric patients; however, its sodium content is quite high.

CONGENITAL HEART DISEASE

Chronic protein-energy malnutrition, manifested chiefly by growth failure, is also a common finding in infants with congenital heart disease, particularly those with conditions associated with congestive heart failure. Although not studied extensively, the nutrient needs of patients with heart disease do not appear to be much greater, if at all, than those of infants or children without heart disease. Rather, in most patients, the cause of the accompanying malnutrition can be traced to inadequate intake. In some patients, this is a result simply of poor appetite; in others, it appears to be due to excessive tiring during feeding. In addition, fluid and sodium intakes frequently are restricted as a part of treatment and use of diuretics is common. Either practice, of course, may limit growth, even if intake of protein and energy is adequate.

The most common form of nutritional therapy for infants with congenital heart disease is use of a high-nutrient-density formula, which reduces the volume that must be ingested. Tube feeding via either a nasogastric or gastrostomy tube is frequently necessary, particularly in infants whose disease is sufficiently severe to cause excessive tiring during feeding. In general, if sufficient nutrients are delivered, most such patients will grow at a reasonably "normal" rate.

GASTROINTESTINAL DISORDERS

Malnutrition is endemic among infants and children with gastrointestinal disorders. The cause is usually loss of nutrients secondary to the specific derangement in gastrointestinal function, either diarrhea or vomiting. However, both diarrhea and vomiting are frequently "treated" by withholding all nutrients except water and electrolytes. This practice, of course, contributes to development of malnutrition.

Acute Diarrhea

Acute diarrhea caused by most common organisms rarely persists for more than 4 to 5 days. During this time, the major goal of therapy is to maintain a normal state of hydration. This can be accomplished with use of oral rehydration solutions and/or special formulas ([Table 64.1](#)). Hospitalization and intravenous fluid therapy may be necessary, particularly if fever and/or vomiting accompany the diarrhea.

Organism	Infant	Infant/Child	Child/Adolescent	Adolescent	Adult
Shigella	4-8g	2-8g	2-8g	2-8g	2-8g

Table 64.1. Nutrient requirements for children with acute diarrhea. Adapted from: American Academy of Pediatrics. (1997). Pediatric nutrition assessment. Washington, DC: American Academy of Pediatrics.

Table 64.1 Composition (amount/100 kcal) of Special Formulas for Infants with Deranged Intestinal Function

What to feed and whether to feed the child with acute diarrhea have been subjects of considerable controversy for many years, and both remain unresolved. In general, stool output is greater in the patient who is fed, but this does not mean necessarily that feeding should be proscribed. Most patients can ingest at least some nutrients; however, the nature of this intake must be selected carefully, taking into account the probable etiology of the diarrhea. The approach followed by the authors is outlined below; other approaches, of course, may be equally successful.

In general, the etiology of most cases of acute diarrhea is either bacterial or viral. Thus, a stool culture to detect the specific pathogen is indicated. In most developed countries, the recognized enteropathogenic bacteria (*Salmonella*, *Shigella*, and enteropathogenic *Escherichia coli*) are infrequent causes of diarrhea. Rather, most acute bacterial diarrheas are caused by one of the many toxicogenic strains of most gram-negative organisms. Thus, a routine stool culture, unless it suggests a predominant organism, usually is not helpful. On the other hand, since the pathogenesis of toxicogenic bacterial diarrhea (i.e., a secretory diarrhea resulting from stimulation of the adenylate cyclase system, as occurs in cholera [4]) differs from that of viral diarrhea (i.e., an osmotic diarrhea secondary to inhibition of glucose transport as described for rotavirus [5]), testing the stool for pH and reducing substances can be very helpful. In general, a low pH (<6.0) and the presence of reducing substances suggest a viral etiology. The stool must be tested, of course, following a period of adequate intake of a reducing sugar (e.g., a 5% glucose solution or a rehydration solution); in addition, the water content of the stool rather than any solid matter should be tested.

If the etiology of the diarrhea appears to be viral, a carbohydrate-free formula (Table 64.1) is usually well tolerated. However, such formulas result in ketosis and sometimes hypoglycemia; thus, some carbohydrate intake is necessary. In the hospitalized child, this can be provided intravenously. Most who do not require hospitalization usually tolerate at least some sugar intake by the enteral route. In general, 0.5 g of glucose or sucrose per ounce of formula, provided intake is adequate but not excessive, is well tolerated and prevents ketosis and/or hypoglycemia. If this preparation is tolerated, the amount of carbohydrate can be increased daily or every other day as tolerance for carbohydrate increases. Once full carbohydrate content (i.e., approximately 2 g/oz) is tolerated, the patient usually can be switched to a carbohydrate-containing formula.

If the etiology of the diarrhea is a toxicogenic bacterium, feeding usually does not affect the volume of stool output. In many cases, in fact, a glucose-electrolyte solution appears to decrease the volume of stool output. In such patients, therefore, decisions concerning feeding must be based on clinical experience.

The tendency to avoid feeding lactose to infants with diarrhea, regardless of etiology,

probably is unnecessary. If stool pH is normal when the child is first seen and reducing substances are not present, lactase deficiency is an unlikely contributor to the diarrhea.

If the acute episode of diarrhea does not resolve in the usual 4 to 5 days, as happens in a small number of patients, nutritional therapy management becomes a much more important consideration. While most infants can tolerate a 4- to 5-day period with little or no nutritional intake, few can tolerate more than 2 weeks without becoming malnourished and developing secondary intestinal changes due to both persistent diarrhea and malnutrition. Such infants are much more likely to develop secondary deficiencies of mucosal hydrolases (e.g., lactase deficiency and, less commonly, sucrase deficiency) and also monosaccharide intolerance. Managing these infants without hospitalization is much more difficult. Choice of formula, again, must be made on the basis of the suspected or culture-proven cause of the diarrhea; in addition, the much greater likelihood of secondary mucosal hydrolase deficiencies must be taken into account. If small volumes of a particular formula are reasonably well tolerated, it frequently is possible to deliver enough to meet nutritional needs by a continuous infusion technique (6). This usually requires hospitalization of small infants.

Many other congenital and/or acquired forms of chronic diarrhea (e.g., abetalipoproteinemia, celiac disease), if not managed appropriately, frequently result in the same secondary changes in mucosal function. Nutritional management, in general, is similar to that described above and must be coordinated with the usual medical management of these conditions. Although diet is a major aspect of the therapy of most chronic diarrheas, a detailed discussion of this aspect of therapy is beyond the scope of this chapter.

Vomiting

Most acute episodes of vomiting are of short duration and present few nutritional problems. However, chronic vomiting accompanies a number of conditions. The most common of these conditions intrinsic to the gastrointestinal tract is gastroesophageal reflux. To some extent, this condition is physiologic in infancy; however, it assumes pathologic significance if it results in failure to thrive and/or recurrent pulmonary aspiration.

In the early stages, nutritional management of this condition includes maintaining the patient in an upright position during and immediately following feeding and reassuring the parents that the persistent vomiting is causing no harm so long as the infant is gaining weight normally and is not having respiratory symptoms. If either growth failure or a decrease in weight-for-height develops despite optimal medical management, remedial nutritional therapy is indicated (i.e., feedings delivered continuously into the duodenum or jejunum to minimize the risk of further reflux). Many patients require corrective surgery.

Short Bowel Syndrome

Functionally, short bowel syndrome can be considered in the same way as chronic diarrhea. In this condition, alterations of gastrointestinal motility, secretion, digestion,

and absorption are secondary to massive small intestinal loss rather than bacterial and/or viral invasion and the secondary effects of these organisms and malnutrition. In general, the severity of the short bowel syndrome is related inversely to the length of the remaining intestinal segment; however, loss of the ileocecal valve, which acts as a physiologic sphincter to slow transit time and prevent backwash ileitis, also increases severity (7). Specific symptoms also result from removal of specific segments of intestine. Since disaccharidase activity is greater in jejunal cells and since cholecystokinin and other intestinal hormones are secreted by jejunal sites, removal of the jejunum results in more-severe carbohydrate malabsorption and, perhaps, decreased biliary and pancreatic secretion as well as deranged motility. Ileal loss, on the other hand, results in loss of both bile salt uptake and absorption of vitamin B₁₂. In general, the ileum's potential for adaptation appears to be superior to that of the jejunum. Thus, loss of jejunum usually is better tolerated than loss of the ileum.

The early phase of the short bowel syndrome immediately after massive resection usually is associated with massive fluid and electrolyte losses, making effective enteral alimentation impossible. Thus, during both this phase and the early part of the intermediate phase, most nutrient requirements must be provided parenterally. As the remaining small bowel gradually adapts, enteral intake usually can be advanced, but this must proceed slowly. In general, continuous feeding via either an indwelling nasogastric or gastrostomy tube is better tolerated during this phase than bolus feeding. In addition, elemental formulas ([Table 64.1](#)) are generally better tolerated than nonelemental formulas.

Eventually, maximum adaptation is achieved, and more complex proteins and carbohydrates can be introduced. Even during this final phase, however, frequent small feedings may be necessary. During all phases, pharmacologic manipulations (e.g., cholestyramine to chelate bile acids; loperamide and/or paregoric to slow transit time; antibiotics to eradicate significant bacterial overgrowth) may provide symptomatic as well as physiologic improvement. (See [Chapter 68](#).)

GENERAL APPROACH TO NUTRITIONAL THERAPY

Accurate determination of nutritional status obviously is the first step in all types of nutritional therapy. However, assessing the nutritional status of infants is difficult (8), in part because malnutrition is not precisely defined and in part because the earliest changes of malnutrition are subtle adaptations that tend to ameliorate the effects of malnutrition. Nonetheless, some objective evaluation of nutritional status should be applied to every child who is a potential candidate for nutritional therapy. If for no other reason, this evaluation provides a baseline for monitoring the results of therapy. Physical growth charts, height and weight velocity curves, and other anthropometric data are given in Appendix [Table III-A-14-b-1](#), [Table III-A-14-b-2](#), [Table III-A-14-c-1-a](#), [Table III-A-14-c-1-b](#), [Table III-A-14-c-2-a](#), [Table III-A-14-c-2-b](#), [Table III-A-14-d-1-a](#), [Table III-A-14-d-1-b](#), [Table III-A-14-d-2-a](#), [Table III-A-14-d-2-b](#), [Table III-A-14-e-1](#), [Table III-A-14-e-2](#), [Table III-A-14-f-1](#), [Table III-A-14-f-2](#) and [Table III-A-14-g-1](#), [Table III-A-14-g-2](#).

Many anthropometric and biochemical assessment techniques are available (see

[Chapter 54](#)); their specific advantages, disadvantages, and limitations have been discussed extensively ([8](#)). In general, no single test or combination of tests is ideal. Indeed, clinical judgment based upon knowledge of the disease process and the status of the body's nutritional reserves appears to be as reliable as any of the commonly used “objective” tests ([9](#)). In the authors' experience, assessment of weight in relation to height (length) is one of the most useful indices of nutritional status. A child who falls below the 10th percentile on this standard curve, regardless of either weight for age or height (length) for age, can be assumed to be malnourished and in need of nutritional therapy.

The situation of the child whose weight is appropriate for height (length) but whose weight and height are low for age (i.e., the stunted child) is more problematic ([10](#)). There is no convincing evidence that such a child is malnourished and in need of aggressive nutritional intervention. On the other hand, an attempt to permit the child to achieve his or her growth potential is warranted. This usually requires both a nutritional history and a more extensive medical evaluation, including evaluation of endocrinologic status (see also [Chapter 59](#)).

In general, the approach advocated for nutritional management of the low-birth-weight (LBW) infant ([Chapter 51](#)) is equally applicable to any malnourished infant or child—indeed, any infant or child with an underlying condition predisposing to malnutrition. Initially, particularly in less severely affected individuals, attempts should be made to increase nutrient intake by conventional means. If this approach is unsuccessful, one of several commercially available supplements can be used. However, these often replace usual food intake and thus may not result in the desired increased total intake. Moreover, most of the products currently available were designed for adults and are not optimal for pediatric patients. One exception is Pediasure ([Table 64.1](#)).

If conventional foods are not tolerated, use of special formulas or supplements and perhaps delivery by tube, either as a bolus or continuously, are the next steps ([Chapter 100](#)). The choice of both formula and method of delivery, of course, must be dictated by the patient's underlying condition. Tube feedings can be given throughout the day or only during part of the day (e.g., at night), depending upon the patient's age, condition, and nutritional status. If the patient's condition (e.g., pulmonary disease) makes an indwelling nasal tube inadvisable, a gastrostomy tube, inserted percutaneously or surgically, should be considered. If gastrointestinal tolerance of even elemental formulas is severely limited, parenteral nutrients can be used, either as the sole source of nutrition or as a supplement to tolerated enteral nutrient combinations.

PARENTERAL NUTRITION

The now widespread use of parenteral nutrition (see [Chapter 101](#)) is usually considered one of the major contributing factors to the current low mortality of infants born with surgically correctable lesions of the gastrointestinal tract (e.g., omphalocele, gastroschisis, intestinal atresias) as well as those with short bowel syndrome and intractable diarrhea ([11](#)). Although the role of parenteral nutrient delivery in decreasing the mortality and morbidity of other groups of pediatric patients (e.g., LBW infants) is

less clear, the technique is used in a wide variety of pediatric patients. Moreover, despite the many hazards of the technique, most agree that the obvious anabolism that can be achieved with parenteral delivery of nutrients is preferable to the inevitable continuation of catabolism if delivery of adequate nutrients by other routes is impossible. This is particularly true if careful attention is paid to every aspect of the technique, thereby minimizing its hazards and maximizing its benefits.

Route of Administration

Parenteral nutrients can be infused by either central vein or peripheral vein. An energy intake of 70 to 80 kcal/kg/day can be provided consistently and safely by the peripheral venous route, but for obvious reasons, the duration of this type of delivery is limited. Much greater intakes (100 to 120 kcal/kg/day) can be delivered for a longer period by the central venous route. Acceptable intakes of all other nutrients are possible by either route.

Although the advantages and disadvantages of these two routes of delivery are frequently discussed, both are efficacious when used in the appropriate circumstances. In general, the time that parenteral nutrients are likely to be required and the nutrient needs of the patient should determine which route is chosen. If parenteral nutrients are likely to be required for more than approximately 10 days, central venous delivery usually is preferable.

In LBW infants, the infusate frequently is delivered by umbilical vessel catheters. Although this route of delivery is convenient, it cannot be recommended without reservation. The flow characteristics of the umbilical vessels do not permit sufficient dilution of a concentrated nutrient infusate to circumvent intimal damage. Also, the incidence of thrombosis with umbilical catheters is quite high, malposition of these catheters can result in severe consequences, and the incidence of sepsis appears to be greater when nutrients are delivered by umbilical vessels than when delivered by either central or peripheral vein.

The Nutrient Infusate

The nutrient infusate should include amino acids as well as sufficient energy (glucose and lipid), electrolytes, minerals, and vitamins. Suitable infusates for both central vein and peripheral vein delivery are shown in [Table 64.2](#). While these are acceptable for most infants and children, modification may be required to reflect the specific needs of individual patients.

Component	Amount/kg/day
Amino acids	2.5 g–4.0 g
Energy	60–120 kcal
Glucose ^a	15–30 g
Lipid ^b	0.5–3.0 g
Electrolytes and minerals	
Sodium (as chloride)	2–4 mEq
Potassium (as phosphate and chloride) ^c	2–4 mEq
Calcium (as gluconate)	1.5–2.0 mmol
Magnesium (as sulfate)	0.25 mEq
Phosphorus (as potassium phosphate) ^d	1.5 mmol
Trace minerals	See Table 64.4
Vitamins	See Table 64.5
Volume	100–150 mL

^aFor peripheral vein infusion, glucose concentration should not exceed 10–12.5%.

^bLipid must be infused separately (see text).

^cPotassium, as phosphate, should be limited to 2.5 mEq/kg/day (approximately 1.7 mmol phosphate) unless chemical monitoring suggests need for more phosphate; if only additional potassium is required, it should be provided as the chloride salt.

Table 64.2 Composition of Suitable Parenteral Nutrition Infusate(s)

Several crystalline amino acid mixtures are available ([Table 64.3](#)); all contain most essential amino acids (exceptions are cystine and tyrosine, which are either unstable or insoluble in aqueous solution) and varying amounts of nonessential amino acids. An amino acid intake of 2.5 to 4.0 g/kg/day is recommended. Higher intakes, although tolerated by most infants, are more likely to result in elevated plasma amino acid concentrations and azotemia. Some advocate amino acid intakes below 2.5 g/kg/day for the LBW infant, particularly during the first few days of therapy when nonprotein energy intake is low (due to glucose and lipid intolerance). Recent studies suggest that there is no reason to advocate this practice, even if concomitant energy intake is quite low ([12](#)).

Amino Acid	Aminosol ^a	Aminosol-P ^b	Trovanol-P ^c	Neosol ^d	Pedialyte-P ^e	Trojanol ^f

Table 64.3 Amino Acid Content (mg/2.5 g) of Commercially Available Amino Acid Mixtures

Glucose is the preferred nonlipid parenteral energy source; however, the ability of some infants to metabolize it is limited. Many infants, particularly during the early period of

parenteral nutrition, develop hyperglycemia and osmotic diuresis with concomitant urinary loss of electrolytes when the amount of glucose infused exceeds tolerance. Careful, continuous administration of small doses of insulin appears to alleviate glucose intolerance in LBW infants, thereby permitting administration of much greater glucose intakes ([13](#)). Whether this practice is desirable remains to be determined.

Most LBW infants tolerate 5 to 7% solutions of dextrose (3.5–5.0 mg/kg/min, or 18–25 kcal/kg/day) if volume is limited to 100 mL/kg/day, even during the first few days of life; thus, in very small and/or unstable infants, it is wise to begin parenteral nutrition with these lower glucose intakes and increase the intake as the infant's tolerance for glucose improves. In older, more stable infants, an initial glucose intake of 15 g/kg/day (about 50 kcal/kg/day) is usually well tolerated and can be delivered easily by the peripheral route without exceeding a glucose concentration of 10%. With central venous delivery, much greater intakes (i.e., 25–30 g/kg/day, or 85–102 kcal/kg/day) are eventually tolerated. Even in the most stable patients, however, these higher intakes should be achieved gradually with daily increments of no more than 5 g/kg/day. In all patients, glucose tolerance should be closely monitored as glucose intake is being increased (see below). Once achieved, the higher intakes usually are well tolerated so long as the patient's condition remains stable.

Electrolyte requirements vary from patient to patient; thus, the amounts suggested in [Table 64.2](#) should not be interpreted as absolute requirements. Adjustments are often necessary and should be made on the basis of close monitoring (see below).

The amounts of calcium and phosphorus required for optimal skeletal mineralization (i.e., 100–120 and 60–75 mg/kg/day, respectively) in the “normally growing” LBW infant often cannot be incorporated into the parenteral nutrition infusate because of the chemical incompatibility of calcium and phosphate. (See also [Table 101.7](#) and text in [Chapter 101](#) concerning avoidance of coprecipitation of these two ions.) In general, the amounts suggested in [Table 64.2](#) are compatible and cause no problems over the short term. However, if parenteral nutrition is required for weeks to months, skeletal mineralization may be inadequate, particularly that of the LBW infant.

Addition of trace minerals to the infusate is recommended if exclusive parenteral nutrition is likely to exceed 7 to 10 days. Suggested intakes ([14](#)) are given in [Table 64.4](#). Many advocate including zinc and copper from the outset. Issues related to the recommended doses of trace elements and commercially available multitrace element solutions for infants and children are discussed in [Chapter 101](#).

Trace Minerals ^a	Preterm Infants	Term Infants and Children ^b
Zinc (µg)	400	250 (5000)
Copper (µg)	20	20 (300)
Selenium(µg)	2.0	2.0 (30)
Chromium(µg)	0.2	0.2 (5)
Manganese (µg)	1.0	1.0 (50)
Molybdenum (µg)	0.25	0.25 (5)
Iodide (µg)	1.0	1.0 (1)
Iron ^c		

^aThe American Society for Clinical Nutrition Committee on Clinical Practice Issues (14).

^bParenteral nutrients are used as a supplement for tolerated enteral feeds or as sole source of nutrients for 4 weeks; only zinc and, perhaps, copper are needed.

^cMaximum recommended intake per day is shown in parentheses.

^dIron dextran (1-2 mg/L) has been used safely in adults, but reported experience in children, particularly infants, is limited. Estimated requirements, based on the assumption that 10% of the recommended enteral intake is absorbed, are 100 and 200 µg/kg/day, respectively, for the term and preterm infant.

Table 64.4 Recommended Parenteral Intakes (amount/kg/day) of Trace Minerals^a

Parenteral vitamin requirements are not known with certainty. Obviously, the usual recommended dietary allowances (RDAs) may not apply with parenteral administration. Recommended parenteral intakes are given in [Table 64.5 \(14\)](#). Currently, however, a multivitamin preparation that provides the recommended intakes of all vitamins for underweight premature infants is not available. Intakes provided by the most commonly used U.S. pediatric multivitamin mixture, which is deemed suitable for children aged 1 to 11 years, are also shown in [Table 64.5](#). (See also [Table 101.11](#) and [Table 101.12](#) for European pediatric formulas.)

Vitamins	Preterm Infants ^a (Amount/kg/day)	Term Infants and Children ^b (Amount/Day)
A (µg)	500	700
E (mg)	2.8	7
K (µg)	80	200
D ₃ (µg)	4 (160 IU)	10
Ascorbic acid (mg)	25	80
Thiamin (mg)	0.35	1.2
Riboflavin (mg)	0.15	1.4
Pyridoxine (C) (mg)	0.18	1.0
Niacin (mg)	6.8	17

^aThe American Society for Clinical Nutrition Committee on Clinical Practice Issues (14).

^bTotal daily dose should not exceed that recommended for term infants and children. A dose of 2 mL of reconstituted MVI-Pediatric (Amour Pharmaceutical Co., Chicago, IL) provides the following intakes (amount/kg/day): vitamin A, 280 mg; vitamin E, 2.8 µg; vitamin K, 80 µg; vitamin D₃, 4 µg (160 IU); ascorbic acid, 32 mg; thiamin, 0.48 mg; riboflavin, 0.16 mg; pyridoxine, 0.8 mg; niacin, 6.8 mg; pantothenate, 2.0 mg; biotin, 6.0 µg; folate, 56 µg; vitamin B₁₂, 0.4 µg.

^cTrace amounts are provided by a vial of reconstituted MVI-Pediatric.

Table 64.5 Suggested Parenteral Intakes of Vitamins^a

Use of Parenteral Lipid Emulsions

Infants who receive fat-free parenteral nutrition, particularly LBW infants and nutritionally

depleted infants, develop classic essential fatty acid (EFA) deficiency (i.e., an elevated triene:tetraene ratio) very quickly (i.e., days) when growth and/or regrowth is initiated (15). Thus, it is desirable to use lipid emulsions to prevent this deficiency, which is detectable biochemically (eicosatrienoic acid:arachidonic acid > 0.25) before clinical signs appear. Parenteral lipid emulsions are also a useful source of energy. Emulsions of either soybean oil (Intralipid, Kabi-Vitrum; Travamulsion, Travenol Laboratories; Liposyn III, Abbott Laboratories) or a mixture of safflower and soybean oils (Liposyn II, Abbott Laboratories) are available in both 10 and 20% concentrations (see Table 101.5 for the composition of such formulations). A dose of only 0.5 g/kg/day of soybean oil emulsion prevents classic EFA deficiency; since the linoleic acid content of the emulsion of soy and safflower oils is even greater, a smaller dose may suffice. The linolenic acid content of the latter emulsion is somewhat lower but is probably adequate.

All infants, including LBW infants, usually tolerate the small dose of parenteral lipid emulsion necessary to prevent EFA deficiency. However, the ability of an individual infant to tolerate a larger dose is quite variable. In general, the ability to metabolize intravenous fat emulsions is related directly to maturity (16), but the stressed and/or malnourished patient (i.e., the small-for-gestational-age LBW infant and the nutritionally depleted older child) also may have difficulty metabolizing these preparations (17).

Doses of fat emulsion in excess of the infant's ability to metabolize it results in accumulation of triglyceride in the bloodstream. This in turn may decrease pulmonary diffusion capacity, presumably secondary to accumulation of small lipid droplets within the pulmonary capillaries (18). It also results in recruitment of the reticuloendothelial system for lipid clearance and, hence, lipid accumulation in these cells (19). This lipid accumulation is a likely explanation for the impaired host defense mechanisms reported in patients receiving lipid emulsions (20). Metabolism of the infused lipid increases serum concentrations of free fatty acids, which compete with bilirubin and other substances for binding to albumin (21). Thus, administration of large doses of lipid emulsion may be hazardous for infants with pulmonary disease, infection, and/or hyperbilirubinemia.

Considering the difficulties of monitoring serum concentrations of both triglyceride and free fatty acids, it probably is wise to limit the dose of lipid emulsion given to patients who are likely to be intolerant to 0.5 to 1.0 g/kg/day. Most other patients usually tolerate a dose of 3 g/kg/day or more, but even in these patients, it is wise to begin with a smaller dose (e.g., 1–1.5 g/kg/day) and increase the dose slowly. In LBW infants, administration of lipid emulsion should be initiated with a relatively low dose (0.5 g/kg/day) and increased gradually to a maximum of 3 g/kg/day. In all patients, the emulsion should be infused continuously throughout the day.

The 20% soybean oil emulsion appears to be cleared more rapidly than the 10% emulsion and thus is less likely to cause hypertriglyceridemia (22). Hyperphospholipidemia and hypercholesterolemia, both of which occur routinely in patients receiving the 10% soybean emulsion, do not occur with use of the 20% emulsion (22), presumably because of the lower phospholipid:triglyceride ratio of the 20% emulsion.

Since the size of the lipid particles of the emulsions (0.4–0.5 microns) exceeds the pore size of an effective filter (0.22 microns), filters cannot be used for infusion of fat emulsions. In the author's opinion, the emulsions should not be mixed directly with other components of the infusate. This practice, which appears to be relatively common, may not destroy the emulsion but it certainly inhibits detection of chemical incompatibilities within the complicated infusate (e.g., precipitation of calcium phosphate). The potential hazards of the latter possibility are compounded, of course, by the fact that filters cannot be used.

Complications of TPN

Despite its obvious nutritional efficacy, total parenteral nutrition (TPN) is associated with a number of complications, both catheter (or infusion) related and metabolic. At the time of central vein catheter insertion, pneumothorax, hemothorax, injury to an artery, and/or hematoma may occur. Thrombosis, dislodgment, perforation, infusion leaks (pericardial, pleural, mediastinal), and infections have been reported during use of central vein catheters. The most common infusion-related problem is infection. Phlebitis and soft tissue sloughing are the most frequent complications of peripheral vein infusions. All these complications can be controlled, but it is difficult to prevent them entirely. Careful attention to care of the central catheter, including frequent dressing changes, is particularly important for controlling infection. Careful frequent observation of the infusion site is necessary to prevent infiltration of infusates delivered by peripheral vein and to ensure proper long-term function of central vein catheters.

Metabolic complications result either from either the limited metabolic capacity of the patient for the various components of the nutrient infusate or from the infusate itself. The metabolic complications most commonly observed and their probable causes are listed in [Table 64.6](#). One of the more troublesome of these is the occurrence of abnormal plasma amino acid patterns with use of many of the currently available amino acid mixtures ([23](#)). Cyst(e)ine and tyrosine, both thought to be essential amino acids for the newborn and perhaps for all patients receiving parenteral nutrients, are unstable and/or only sparingly soluble; hence, none of the currently marketed mixtures contains appreciable amounts of these amino acids ([Table 64.3](#)). Furthermore, all result in very low plasma cyst(e)ine and tyrosine concentrations ([23](#)). Many available mixtures also have large amounts of only a few nonessential amino acids (e.g., glycine) rather than a mixture of all nonessential amino acids ([Table 64.3](#)); thus, extremely high plasma concentrations of the amino acid(s) present in excess are commonly seen.

Complication	Probable Etiology
Disorders related to metabolic capacity of patient	
Hyperglycemia	Excessive intake (either excessive concentration or infusion rate); Change in metabolic state (e.g., infection, surgical stress)
Hypoglycemia	Sudden cessation of infusion
Aspartemia	Excessive nitrogen intake
Electrolyte disorders	Excessive or inadequate intake
Kidney disorders	Excessive or inadequate intake
Vitamin disorders	Excessive or inadequate intake
Essential fatty acid deficiency	Failure to provide essential fatty acids
Hyperlipidemia	Excessive intake; change in metabolic state (e.g., stress, sepsis)
Disorders related to infusate components	
Metabolic acidosis	Use of hydrochloride salts of amino acids (e.g., tyrosine)
Hyperammonemia	Inadequate arginine intake
Abnormal plasma aminoacids	Amino acid pattern of nitrogen source
Hepatic disorders	Unknown; suggested etiologies include prematurity, malnutrition, sepsis, inadequate stimulation of bile flow, toxic effects of amino acids, specific amino acid deficiency, excessive amino acid and/or carbohydrate intake, nonspecific response to lack of feeding
Bone disease	Inadequate calcium and/or phosphorus intake and gestures, other unknown reasons

Table 64.6 Metabolic Complications of Total Parenteral Nutrition and Their Probable Etiology

Whether these abnormal plasma amino acid patterns are hazardous, or even undesirable, is not known. However, considering the well-known relationship between abnormally high plasma amino acid concentrations and mental retardation in infants with inborn errors of metabolism (e.g., phenylketonuria) as well as the relationship between inadequate intake of a specific amino acid and a low plasma concentration of that amino acid, normalization of plasma amino acid patterns seems warranted. Some of the newer amino acid mixtures (e.g., TrophAmine, Kendall-McGaw Laboratories, Inc.) accomplish this to a large extent (24).

Although some metabolic complications are unavoidable, many can be controlled by careful monitoring and appropriate adjustment of the infusate. A suggested monitoring schedule is given in Table 64.7. The monitoring required to ensure safe and efficacious use of lipid emulsions is the most problematic. The most common practice, inspecting the plasma for turbidity, may not reliably detect elevated plasma triglyceride and free fatty acid concentrations (25), which requires chemical determinations that are usually not practical. A reasonable compromise is to observe the plasma frequently (at least 3 times a day) for evidence of lipid accumulation (primarily triglyceride) and measure triglyceride and free fatty acids less frequently. Careful monitoring is particularly important when the lipid dose is being increased, when the infant is unstable, and when a change in the infant's condition occurs. If the plasma becomes turbid, the rate of infusion should be decreased or the infusion stopped completely until the turbidity clears. Usually, infusion can then be resumed at a lower rate. Once the desired dose of intravenous fat is achieved, serum turbidity should be checked once a day (unless the patient becomes unstable) and actual determinations of serum triglyceride and free fatty acid concentrations should be made weekly. The development of cholelithiasis is discussed in Chapter 101.

Variables to be Monitored	Suggested Frequency (per week) ^a	
	Initial Period ^b	Later Period ^c
Growth variables		
Weight	7	7
Length	1	1
Head circumference	1	1
Metabolic variables		
Plasma electrolytes	3-4	2
Plasma calcium, magnesium, phosphorus	2	1
Blood acid base status	3-4	1
Blood urea nitrogen	2	1
Plasma albumin	1	1
Liver function studies	1	1
Serum lipids ^d		2
Hemoglobin	2	2
Urinary glucose	2-6/day	2/day
Variables for detection of infection		
Clinical observations (activity, temperature, etc.)	Daily	Daily
WBC count	As indicated	As indicated
Cultures	As indicated	As indicated

^aInitial period is the time during which the desired energy intake is being achieved or the limits of metabolic instability.

^bFive times

Table 64.7 Suggested Monitoring Schedule During Total Parenteral Nutrition

Weaning Infants from TPN

In most infants, administration of parenteral nutrients need not interfere with introducing enteral feedings as soon as they are likely to be tolerated. Once started, the volume of enteral feedings can be advanced as tolerated by the infant, and the volume of the parenteral nutrition infusate decreased. During the period of combined enteral and parenteral nutrition, care should be taken to ensure that nutrient requirements are met as nearly as possible and that tolerance for both fluids and nutrients is not exceeded. This requires careful attention to the total (parenteral *plus* enteral) intake and frequent downward adjustment of the parenteral intake as enteral intake increases.

Home Parenteral Nutrition

Today, most patients who require parenteral nutrients for a long period of time leave the hospital and receive this therapy at home. Considering the many difficulties of in-hospital parenteral nutrition (see above), the potential problems of TPN at home seem formidable. Nonetheless, both patients who can tolerate some enteral intake and patients who can tolerate only parenteral nutrients have been treated successfully at home for several months to years. In many cases, sufficient nutrients can be administered during only a portion of the day, allowing the older patient to pursue reasonably normal daytime activities and the younger patient (and his or her parents) to sleep with little danger of accidental disconnection of the infusion system. Small portable infusion pumps are available such that the necessary apparatus can be enclosed in vests, backpacks, etc., allowing even the patient who requires constant infusion of parenteral nutrients to pursue a reasonably normal life. Obviously, home parenteral nutrition is more likely to be successful for the older child, adolescent, or adult. However, with careful patient selection, young infants can also be managed quite successfully at home.

The Broviac catheter, which can be used for several months, frequently years, is usually used for home parenteral nutrition. Standard nutrient infusates are obtained from the

hospital pharmacy or from a number of commercial concerns and stored in a small home refrigerator. Catheter care is managed by the patient or by a family member after careful training prior to discharge.

All the usual metabolic and catheter-related complications of parenteral nutrition can occur at home as well as in the hospital. However, patients who can be managed successfully with home parenteral nutrition usually have reached the point at which requirements are reasonably stable. Thus, less frequent monitoring is sufficient. Nonetheless, successful home parenteral nutrition, particularly for the young pediatric patient, requires frequent outpatient visits as well as frequent telephone contact. Some commercial home parenteral nutrition services include frequent home visits by a nurse.

Overall, administration of parenteral nutrients at home has been much more successful than initially envisioned. Certainly, the practice improves the quality of life for patients who require long-term parenteral nutrition. However, the purpose of parenteral nutrition is to provide the necessary nutrients transiently while the compromised gastrointestinal function necessitating use of parenteral nutrition recovers. Some patients, of course, may never be able to survive without parenteral nutrition, but attempts to increase enteral intake must continue. In the authors' experience, this is not always the case; rather, discharge from the hospital often is viewed as the goal of therapy, and once achieved, attempts to increase tolerance of enteral intake slow or stop. This attitude should not become more common.

HISTORY

The term *malabsorption* is frequently used broadly to include intraluminal processes that primarily involve maldigestion, dysfunction at the mucosal level, which alters transport or absorption per se, as well as postabsorptive handling of nutrients. From a nutritional point of view, the end result of malabsorption resulting from maldigestion tends to be more specific in that only one or a few nutrients may be affected, while mucosal disease usually involves generalized malabsorption.

Malabsorption may be implicated in the patient who presents with growth failure, delayed sexual maturation, weight loss, clinical evidence of specific nutrient deficiencies, or bloating and flatulence. Gastrointestinal symptoms may range from frequent passage of large volumes of watery diarrhea, usually associated with carbohydrate malabsorption, to steatorrhea consisting of less-frequent bulky, oily, foul-smelling stool, more commonly seen with fat malabsorption. However, it is not uncommon for gastrointestinal symptoms to be absent or minimal. Other signs and symptoms that can result from malabsorption include fatigue, malaise, anemia, edema, easy bruising, bleeding, muscle weakness, hyporeflexia, bone pain, pathologic fractures, altered taste sensation, poor wound healing, cramps, paresthesias, tetany, and numbness. Although these features are not specific to malabsorption and none is pathognomonic of gastrointestinal dysfunction, malabsorption should enter the differential diagnostic considerations when they are present. A careful history and physical examination should be used to guide an efficient laboratory evaluation of malabsorption ([Table 65.1](#)).

Malabsorbed Nutrient	Clinical Manifestations	Laboratory Tests
Fat	Pale, bulky greasy malodorous stool; diarrhea without odor or gas	Fecal fat
Protein	Edema, muscle atrophy	Fecal nitrogen \pm 1 antitrypsin, and albumin
Carbohydrate	Watery diarrhea, flatulence, abdominal distention	Breath H ₂ , excretion
Vitamin B ₁₂	Macrocytic anemia, neurologic sequelae	MCV, Schilling test, serum B ₁₂
Folic acid	Macrocytic anemia	MCV, serum and RBC folate
Complex vitamins	Angular cheilosis, perleche glossitis, acrodermatitis	
Iron	Microcytic anemia, perleche glossitis, koilonychia	MCV, serum ferritin, serum iron
Magnesium	Paresthesias, tetany	Serum magnesium
Calcium and vitamin D	Paresthesias, tetany, bone pain or fractures positive Chvostek's and Trousseau's signs, muscle cramps	Serum calcium and phosphate, plasma vitamin D, serum alkaline phosphatase
Vitamin K	Right iliofemoral, follicular hyperkeratosis	Prothrombin time
Vitamin E	Decreased deep tendon reflexes	Serum tocopherol
Vitamin K	Easy bruising, hemorrhage	Prothrombin time/PT
Fluid, electrolytes	Tachycardia, hypotension, dry mouth	Electrolyte panel, creatinine, BUN
Bile salts	Watery diarrhea

Table 65.1 Symptoms and Laboratory Evaluation of Nutrient Malabsorption

Medical

In an adult, a history of growth failure or childhood diarrhea may suggest a chronic or latent process, such as celiac sprue. Previous surgical procedures, especially gastric and intestinal resections, may be important in the etiology of malabsorption. Gastric operations often alter the ability to take in sufficient calories, to regulate stomach emptying and/or small bowel transit or to absorb specific nutrients, such as iron and calcium. Intestinal resection, even when restricted, can selectively alter nutrient absorption (i.e., vitamin B₁₂ and bile salts with ileal resection) and when extensive can cause generalized malabsorption because of decreased mucosal surface area. Bacterial overgrowth of the small bowel may be the consequence of surgical resections as a result of decreased gastric acid production or of creation of a blind loop. Prior abdominal or pelvic radiation therapy can contribute to significant nutritional compromise as a result of radiation enteritis and dysmotility from desmoplastic reactions of the serosal surface of the bowel or fibrotic changes in the muscularis.

Recent onset of diarrhea in conjunction with weight loss may indicate the onset of malabsorption. Diarrhea, abdominal discomfort, and distention following a meal may indicate malabsorption-type diarrhea, and the association with the meal differentiates this diarrhea from secretory-type diarrhea.

Associated nongastrointestinal symptoms often help determine the diagnosis of malabsorption syndromes. Rheumatologic symptoms including Raynaud's phenomenon and arthralgias may suggest scleroderma, inflammatory bowel disease, or Whipple's disease. Evidence of extensive vascular disease frequently accompanies mesenteric ischemia. The presence of endocrine diseases, such as hyperthyroidism, diabetes mellitus, and hypoparathyroidism, can suggest that malabsorption may result from these disorders. Pulmonary disease in children with steatorrhea may point to a diagnosis of cystic fibrosis.

Medication history often explains malabsorption of certain nutrients. For example,

cholestyramine binds bile salts, decreasing solubilization of fat and fat-soluble vitamins. Similarly, a history of alcohol abuse may contribute to chronic liver disease or pancreatic insufficiency, both of which may cause fat malabsorption. Other social factors, including homosexual practices and intravenous drug abuse, which predispose to HIV infection and *Giardia lamblia*, may provide clues to causes of malabsorption.

Diet

Diet histories, when accurate and comprehensive, may be helpful in detecting one of the common reasons for growth failure and weight loss, namely inadequate intake. This may result from anorexia related to the underlying disease or to psychosocial issues such as depression, stress, or eating disorders. Additionally, a variety of other factors lead to poor intake. Often, pain curtails food intake. Occasionally, one learns that health professionals and well-meaning acquaintances have instituted programs that unnecessarily restrict the diet. A careful history of diet that reveals a poor intake may prevent an uncomfortable, expensive, and time-consuming evaluation of presumed malabsorption.

Family

Several malabsorptive disorders are characterized by a positive family history. These include inflammatory bowel diseases, celiac sprue, and lactase deficiency. Lack of a positive family history, however, does not exclude these diagnoses. A history in family members of various nongastrointestinal disease states often associated with malabsorption may be helpful in arriving at an ultimate diagnosis.

PHYSICAL EXAMINATION

In severe or prolonged malabsorption, wasting of muscle mass (particularly noticed in the temporal and gluteal regions) and of subcutaneous fat stores is common. When there is marked hypoalbuminemia, peripheral edema or even anasarca can be found. On abdominal examination, distention, visible peristalsis, and borborygmi are sometimes present. Abdominal tenderness is not usually present except in inflammatory conditions. Other stigmata of malnutrition that are discussed in elsewhere ([Chapter 30](#), [Chapter 54](#) and [Chapter 55](#)) may suggest specific nutrient deficiencies.

LABORATORY ASSESSMENT

Laboratory tests used to diagnose malabsorptive disorders can be broadly divided into categories. The initial tests are typically those considered screening tests, primarily general hematology and chemistry studies. This initial battery of tests may be helpful in directing subsequent assessment. A second group of tests is diagnostic or suggestive of generalized mucosal failure. The next series of studies is used to determine specific dysfunction of luminal digestion or specialized absorption mechanisms. Based on a knowledge of absorption ([Chapter 39](#)), it should be possible to do a systematic, direct, and economical laboratory workup. The choice and order of laboratory tests, however, is not universally agreed upon and may be modified by availability and expertise at any

given institution. The rationale, general procedures, and interpretation of a number of biochemical and laboratory tests are presented in [Chapter 57](#).

Initial Testing

The complete blood count, particularly hemoglobin or hematocrit, mean corpuscular volume, and RDW (red cell distribution width) (see [Chapter 88](#)) in conjunction with a peripheral blood smear may suggest iron deficiency (microcytosis and hypochromasia), macrocytosis related to vitamin B₁₂ or folate deficiency, or possibly a combination of these suggested by an elevated RDW. Iron deficiency is most commonly encountered in blood loss but can occur from malabsorption, especially after gastric resection and occasionally as the sole manifestation of celiac sprue. Vitamin B₁₂ malabsorption occurs after gastric resection, distal ileal resection, bacterial overgrowth, extensive ileal Crohn's disease, and in cases of prolonged pancreatic insufficiency. Folate deficiency is found in proximal mucosal disease, such as celiac sprue or tropical sprue. Based on the findings of the blood count and smear, follow-up tests including measurements of ferritin ([1](#)), red blood cell and serum folate or vitamin B₁₂ levels may be indicated. A Schilling test can then be used to determine which of several abnormalities is responsible for vitamin B₁₂ deficiency ([Table 65.2](#)).

Cause of Deficiency	Free B ₁₂	B ₁₂ -F	Antibiotics	Pancreatic
Normal	Normal	-	-	-
Pernicious anemia (lack of intrinsic factor)	Abnormal	Corrected	-	-
Bacterial overgrowth syndrome	Abnormal	Abnormal	Corrected	-
Pancreatic insufficiency	Abnormal	Abnormal	Abnormal	Corrected
Ileal disease or resection	Abnormal	Abnormal	Abnormal	Abnormal

Table 65.2 Diagnosis of Vitamin B₁₂ Deficiency with the Schilling Test

Serum albumin is commonly regarded as helpful in assessing malabsorption and nutritional status, but albumin levels are also affected by sepsis, trauma, liver disease, and inflammation ([2](#)). Hypoalbuminemia in gastrointestinal disease commonly indicates protein-losing gastroenteropathies rather than malabsorption ([3](#)). Hypoproteinemia is unusual at the initial diagnosis of malabsorption on the basis of mucosal disease or pancreatic insufficiency. In pancreatic insufficiency, low lipase levels causing steatorrhea and wasting markedly antedate (by 5 years on average) clinically significant decreased protease production and resultant protein maldigestion ([4](#)). Albumin levels are useful, however, in interpreting levels of minerals, since many minerals are albumin

bound, and low levels are to be expected in hypoalbuminemic patients.

While a common cause of a decreased serum calcium is a low albumin level, a clinically significant decrease in the calcium level may also result from decreased calcium absorption. (In most cases, bone resorption induced by parathyroid hormone (PTH) compensates for low calcium absorption and normalizes the serum calcium level. Still, hypocalcemia can be seen secondary to calcium malabsorption.) Calcium malabsorption may be the result of poor absorption of vitamin D or of binding of calcium with unabsorbed fats to form unabsorbable soaps. A serum 1,25-dihydroxycholecalciferol level is helpful in determining whether a low calcium level (in the presence of a normal albumin) is based on malabsorption of fat-soluble vitamins. Hypomagnesemia is commonly found in short bowel syndrome, as well as occasionally in Crohn's disease and celiac sprue ([Chapter 9](#)). Decreased serum zinc levels are most commonly observed in patients with enterocutaneous fistulae where losses of zinc are high ([Chapter 11](#)).

An increased prothrombin time resulting from vitamin K deficiency in conjunction with evidence of vitamin D deficiency suggests fat malabsorption, which is often accompanied by fat-soluble vitamin malabsorption. Decreased levels of vitamin A and E may be found in this setting as well.

Tests of Mucosal Dysfunction

Gut mucosal failure resulting in weight loss, diarrhea, and generalized nutritional deficiencies may occur in such disorders as celiac sprue, Crohn's disease, Whipple's disease, radiation enteritis, mesenteric ischemia, and intestinal resection. While various mechanisms are involved in these disorders, the overall result tends to be generalized nutritional deficiencies.

Serum carotene is frequently intended as a screening tool for mucosal failure. The test, however, is quite insensitive, and apart from mucosal disease and fat malabsorption, low concentrations can be found in patients with poor dietary intake of carotene and with liver disease. Normal levels of carotene may help to exclude mucosal disease as a cause of malabsorption.

The D-xylose test is also used to screen noninvasively for malabsorption and to distinguish mucosal from intraluminal disease. Urinary excretion of less than 4 g of D-xylose in 5 hours is found in more than 90% of patients with celiac sprue, while a small percentage of those with pancreatic dysfunction and no mucosal disease have decreased excretion ([5](#)). False-negative results can occur in mucosal disease limited to the distal small bowel or with mild proximal disease. False-positive results are found in myxedema, in vomiting, with ascites, following gastric surgery when rapid transit decreases absorption, in bacterial overgrowth syndrome, and during treatment with aspirin, neomycin, glipizide, and indomethacin. Incomplete urine collection and renal insufficiency also cause false-positive results. In this case, serum levels obtained 1 hour after the test dose or a 5-h breath test ([6](#)) can be measured to circumvent these problems (see [Chapter 57](#) for methodology).

In general the “gold standard” diagnostic tests are structural studies for mucosal disorders. In the case of short bowel syndrome, the history of resection, details of residual small bowel length, and anatomy (proximal vs. distal) provide sufficient evidence to determine whether the malabsorption is consistent with the degree of resection ([Chapter 68](#)). When details of resection are unavailable, x-ray studies of the small intestine may help determine the length of remaining small bowel ([Fig. 65.1](#)). In cases of Crohn's disease or ischemia, the small bowel x-ray is helpful in determining the diagnosis, as well as the extent of disease. Enteroclysis (a specified barium study of the small bowel, which provides a detailed picture of the ischemia) may be preferred to standard x-ray, since it avoids or delays flocculation of barium, allows better distention of the lumen, and provides a better assessment of the folds of Kerkring to provide more accurate diagnosis ([7](#)). Specialized radiologic examinations, such as angiography or Doppler ultrasonography for the diagnosis of mesenteric insufficiency and lymphangiography for the identification of intestinal lymphangiectasia, are essential to establish some diagnoses.

Figure 65.1. Short bowel syndrome. A small bowel follow-through x-ray demonstrates a short small bowel and a marked dilatation of the residual duodenum and jejunum. The jejunum is anastomosed to the distal colon.

Another structural test that is often helpful in diagnosing suspected mucosal disease is the small bowel biopsy. The biopsy can be diagnostic in diseases such as amyloidosis, mastocytosis, or Whipple's disease ([Fig. 65.2](#)). In other diseases, including bacterial overgrowth, celiac sprue ([Fig. 65.3](#)), or radiation enteritis, the findings are suggestive but not diagnostic. For a diagnosis of celiac sprue based solely on biopsy results, the classic mucosal changes of absence of villi, elongation of crypts, and lymphocytic infiltration of the epithelium and lamina propria must be demonstrated, with subsequent resolution during 6 to 12 months of a strict gluten-free diet. The purist also insists on withholding the diagnosis until a biopsy following gluten rechallenge of the effectively treated patient again reveals villous damage. This is most important in children, in whom infectious gastroenteritis can mimic celiac sprue. The biopsy results can be

supplemented with noninvasive antibody studies to confirm celiac sprue, particularly in adults and in those who are not IgA deficient. IgA endomysial antibody immunofluorescence in this setting has excellent sensitivity and specificity (approaching 100%), while IgA antigliadin is somewhat less sensitive and specific (82–83%) (8). An unequivocal response to a strict gluten-free diet also provides supporting evidence to confirm the diagnosis of celiac sprue.

Figure 65.2. Whipple's disease, small bowel resection. The lamina propria contains numerous macrophages with abundant eosinophilic cytoplasm, resulting in thickened and mildly blunted villi. While *Mycobacterium avium-intracellulare* could show similar changes, special stains for mycobacteria were negative, and polymerase chain reaction (PCR) was positive for Whipple's bacilli (*Tropheryma whippelii*). The dilated lymphatic spaces are also characteristic of Whipple's disease. (H&E, $\times 40$). (Courtesy of KP Batts, MD.)

Figure 65.3. Celiac sprue, small bowel biopsy. The total villous atrophy, crypt hyperplasia, and relatively squat, cuboidal surface epithelium all indicate mucosal injury. The prominent intraepithelial lymphocytosis as well as similar inflammatory infiltrate in the lamina propria suggests celiac sprue. (H&E, $\times 140$). (Courtesy of KP Batts, MD.)

While mechanisms of fat absorption involve both luminal and mucosal steps, tests indicating the presence of excess fat in stool can be extremely helpful in diagnosing mucosal dysfunction, since fat malabsorption is a feature of most mucosal diseases. Microscopic examination of a single sample of feces using Sudan red stain is favored by some as a key screening test (9). However, it is only reliable when there is moderate or severe steatorrhea. The “gold standard” test for fat malabsorption remains the 48- or 72-h quantitative fecal fat determination, which expresses results as the coefficient of fat absorption

$$\text{[Dietary fat intake – fecal fat excreted]/Dietary fat intake} \times 100$$

While normal fecal fat levels are quoted as up to 7% of intake, it has been shown recently that with diarrhea induced in healthy subjects, up to 14% of intake can appear in stool subjected to rapid gut transit (10). Although fraught with problems of incomplete collection and unpopularity among patients and laboratory personnel, this test not only offers a coefficient of fat absorption but also gives data concerning the amount of stool excreted and the amount of water in the stool. These advantages of the fecal fat determination make it superior to triolein breath tests and Sudan staining (11).

Tests of Luminal Dysfunction

Bacterial overgrowth syndrome results from surgical creation of blind loops, achlorhydria from gastric atrophy, surgical intervention, or prolonged treatment with acid inhibitors. The effect of bacterial overgrowth on nutritional status is related to bacterial deconjugation of bile salts, utilization of vitamin B₁₂ by the bacteria, and mucosal damage causing disaccharidase destruction, protein-losing enteropathy, altered intestinal transport, and secretion of water and electrolytes (Fig. 65.4). The results are malabsorption of fats, fat-soluble vitamins, vitamin B₁₂, and carbohydrates (12). The medical history, constellation of symptoms, and results of screening blood tests may be highly suggestive of this diagnosis, which should prompt one to order a small-bowel aspirate for quantitative aerobic and anaerobic cultures. Cultures of duodenal and jejunal aspirates yield bacterial numbers exceeding the normal level of 10⁵ cfu/mL, but specific pathogenic organisms are usually not identified. Alternatively, noninvasive tests have been developed for bacterial overgrowth, with the ¹⁴C-xylose breath test offering specificity and sensitivity similar to those of cultures, albeit at the expense of exposure to low doses of radionuclide (13). A subsequent barium x-ray study often identifies the etiology of bacterial overgrowth. Effective treatment with antibiotics, usually on a cyclic basis, confirms this diagnosis as the cause of malabsorption.

Figure 65.4. The pathogenesis of malabsorption in bacterial overgrowth syndrome.

Giardia lamblia infestation results in weight loss in up to 65% of cases. If stool examinations for ova and parasites are negative, examination of a duodenal aspirate or a biopsy specimen can be helpful in making this diagnosis (14).

In AIDS, particularly, infectious causes for malabsorption are quite common. Stool and jejunal fluid cultures and examinations for ova and parasites, as well as jejunal and colonic mucosal cultures and histology, are helpful in identifying organisms involved (15).

Pancreatic insufficiency is manifest years after chronic pancreatitis occurs, owing to the large reserve of pancreatic enzymes. Steatorrhea does not occur until lipase levels are less than 10% of normal (16). The tests that are considered the “gold standard” for diagnosis are those that directly measure stimulated pancreatic exocrine function. These tests use intravenous cholecystikinin and/or secretin and a duodenal tube to collect pancreatic juice for measurement of lipase and trypsin and/or bicarbonate. This test is highly sensitive and specific (96 and 93%, respectively) but is invasive, costly (~\$600) and of limited availability (16). Tubeless assays such as the fecal chymotrypsin, bentiromide, and pancreolauryl tests tend to be abnormal when intestinal malabsorption is present. In many patients, a very high level of fecal fat and the presence of pancreatic calcification detected on abdominal x-ray or by computerized axial tomography (CAT scan) are highly suggestive of pancreatic insufficiency, and a successful trial of adequate enzyme replacement may suffice for diagnosis in such cases (Fig. 65.5). However, pancreatic malignancy can also present with pancreatic insufficiency, so ultrasound, CAT scan, or ERCP may be necessary to exclude the diagnosis in some cases.

Figure 65.5. An algorithm for the evaluation of steatorrhea. (Modified from Riley SA, Turnberg LA. Maldigestion and malabsorption. In: Sleisenger MH, Fordtran JS, Scharschmidt BF, Feldman M, eds. *Gastrointestinal disease pathophysiology/diagnosis/management*. Philadelphia: WB Saunders, 1993;1009–27, with permission.)

Isolated disaccharidase deficiency presents with watery diarrhea, distention, and flatulence. For patients who have symptoms clearly associated with milk ingestion, especially in those whose ethnic origin and family history are consistent with the diagnosis, a trial of lactose withdrawal with relapse on rechallenge may suffice for a diagnosis of lactase deficiency. In those whose symptoms are more subtle and less clearly associated with specific foods, hydrogen breath tests performed with various disaccharides often clarify the diagnosis of disaccharidase deficiency.

CELLULAR AND STRUCTURAL CHARACTERISTICS OF THE ORAL TISSUES

Distinctive characteristics of oral tissues may render them particularly sensitive to nutritional extremes. For example, the inability of enamel to remodel coupled with the high cellular turnover rate of oral mucosa and the rates of alveolar bone growth and saliva production make oral tissues a unique indicator of physiologic perturbations.

In the same vein, nutrition and oral health and disease transcend the relationship

between fermentable carbohydrates and dental caries. The oral cavity is the site of chronic disease (e.g., caries, periodontal disease(s), AIDS, nutritional anemias, herpes, salivary gland disorders, osteoporosis, cancer), congenital anomalies (e.g., cleft lip and palate), and environmentally induced birth defects (e.g., fetal alcohol syndrome), which could relate to nutritional status. Nutrients interact with physiologic systems in the oral cavity, such as cell replication, cell repair, and immune response mechanisms, in such a manner as to increase or decrease the risk of disease. Thus, the oral tissues constitute a major site of interactions between nutritional factors and the physiologic systems, a relationship that makes oral health no less vulnerable to the effect of nutrition than general health. In this regard, the oral tissues and fluids mirror subtle changes in nutritional status and are often the first visible site to exhibit signs of nutritional disorders. Thus, nutritional disorders affect the oral tissues and fluids both directly and indirectly.

Most importantly, the linkages between oral disease and systemic health are frequently being clarified and scientifically validated, with some startling and profound observations. Within the last 5 years, clear linkages have been established between periodontal diseases and cardiovascular disease, diabetes, bronchitis, stroke, and low birth weight. The infectious nature of the oral diseases approximately doubles the risk of stroke (1) and cardiac disease (2), as well as increasing the risk for a low-birth-weight infant (3). Since the inherent nature of the infectious oral diseases dictates that the host have an adequate functional immune and cellular repair system and unequivocal data link nutrient intake and these host defense mechanisms, the relationships between oral health, systemic health, and nutrition require careful attention by physicians, dentists, dental hygienists, nurses, and virtually all healthcare providers.

To better appreciate these complex relationships, one must understand the structure and function of the craniofacial-oral-dental complex. Teeth, specialized structures vital for the initial processing of food, are composed of three mineralized tissues—enamel, dentin, and cementum—that encase the highly vascular dental pulp, or “nerve.” These relationships can be seen in the schematic cross section of a tooth in [Figure 66.1](#). The teeth are retained in their bony sockets by means of a fibrous structure termed the *periodontal membrane or ligament*. Influences that affect the integrity of this structure and bone surrounding the socket result in periodontal disease that may progress sufficiently to cause loosening and loss of the teeth (4).

Figure 66.1. Schematic illustration of teeth in contact with the alveolar bone.

Each tooth develops from a tooth bud or germ located in the jaws. The bud consists of an epithelial component that arises as an invagination from the surface and produces enamel. The mesenchymal component consists of the dental papilla, which produces the tooth pulp and dentin, and the dental follicle, which produces the cementum and periodontal ligament once the tooth has formed. [Table 66.1](#) details the chronology of the human dentition. Primary teeth begin forming about 6 weeks in utero, when cells in the primitive oral cavity differentiate to form the dental lamina, which is the site of tooth bud development. Formation of the crown of the tooth begins with secretion of a dentin matrix containing collagen fibrils. Mineral ions then enter the matrix to form small crystals on or between the collagen fibrils. Enamel formation begins as soon as the first dentin layer has been laid down. This mineralization process constitutes the maturation of enamel and continues after all the matrix is formed. As can be seen in [Table 66.1](#), the mineralization process begins as early as 4 months in utero and continues into late adolescence. After the tooth erupts into the oral cavity, it continues to incorporate minerals (including fluoride) into its structure from saliva, food, and drinking fluids (5).

Tooth	Hard Tissue Formation Begins	Amount of Enamel Formed at Birth	Enamel Completed	Eruption	Root Completed
Primary dentition					
Maxillary					
Central incisor	4 months in utero	Two-thirds	12 months	7.5 months	1.5 years
Lateral incisor	4.5 months in utero	Two-thirds	21 months	8 months	2 years
Canine	6 months in utero	One-third	6 months	16 months	2.5 years
First molar	6 months in utero	One-third	11 months	16 months	2.5 years
Second molar	6 months in utero	One-third	11 months	16 months	2 years
Mandibular					
Central incisor	4.5 months in utero	Two-thirds	21 months	8 months	1.5 years
Lateral incisor	4.5 months in utero	Two-thirds	21 months	7 months	1.5 years
Canine	6 months in utero	One-third	6 months	16 months	2.5 years
First molar	6 months in utero	One-third	11 months	16 months	2.5 years
Second molar	6 months in utero	One-third	11 months	16 months	2 years
Permanent dentition					
Maxillary					
Central incisor	3-4 months	---	4-6 years	7-8 years	12 years
Lateral incisor	10-12 months	---	4-6 years	8-9 years	11 years
Canine	4-6 months	---	11-12 years	11-12 years	13-14 years
First premolar	1.5-2.5 years	---	6-7 years	10-11 years	12-13 years
Second premolar	3-4.5 years	---	6-7 years	10-12 years	12-14 years
First molar	4-6 years	Two-thirds + trace	12-13 years	11-12 years	14-15 years
Second molar	7-9 years	---	12-13 years	12-13 years	14-16 years
Mandibular					
Central incisor	3-4 months	---	4-6 years	6-7 years	10 years
Lateral incisor	3-4 months	---	4-6 years	7-8 years	10 years
Canine	4-6 months	---	6-7 years	8-10 years	12-14 years
First premolar	1.5-2.5 years	---	6-7 years	10-11 years	12-13 years
Second premolar	2.5-3.5 years	---	6-7 years	11-12 years	13-14 years
First molar	4-6 years	Two-thirds + trace	12-13 years	11-12 years	14-15 years
Second molar	7-9 years	---	12-13 years	12-13 years	14-16 years

Table 66.1 Chronology of Development of the Human Dentition

The life history of a tooth may be divided into three main eras: (a) the period when its crown is forming and mineralizing in the jaw, (b) the period of maturation when the tooth is erupting into the oral cavity and its root or roots are forming, and (c) the maintenance period while it is functioning in the oral cavity (4). During the preruptive period, the developing enamel and dentin are subject to nutritional deficiencies or imbalances in the same manner as any other developing tissues. Indeed, nutrient deficiencies can affect either the secretory or the maturation stage of enamel formation. For example, hypoplastic lesions in the enamel reflect disturbances affecting the secretory process,

whereas hypomineralized defects reflect interference with the maturation process. These are systemic effects of nutrient imbalances. Of course, both hypoplasia and hypocalcification can be induced by other environmental stresses, such as febrile episodes, genetic defects, and toxic chemicals. Following eruption into the oral cavity, the enamel is bathed in saliva and is exposed to oral microorganisms and their byproducts as well as food, so nutritional deficiencies or excesses and dietary habits may affect teeth in a totally different or more local manner (5).

At least three striking differences exist between the mineralized tissues of the teeth and the other tissues of the body. First, enamel contains no capillary or lymphatic vessels to act as transport systems; however, the intimate relationships between the organic and inorganic components of enamel suggest that pathways in the enamel exist for diffusion of ions and small molecules from saliva and possibly from blood. Although the dentin likewise contains no formed vascular elements, it is more readily permeable to extracellular fluids from the blood because dentinal tubules traverse the dentin. Interchange between elements in the enamel takes place through the bathing of its external surface with saliva. In contrast, interchange in the dentin occurs by reason of the ions present in the blood supply to the pulp or periodontal membrane (4).

Second, owing to the absence of cells, mineralized dental tissues do not have a microscopically or chemically detectable ability to repair improperly formed or mineralized areas, and the tooth cannot repair itself after a portion has been destroyed by tooth decay or mechanical injury. An exception is the remineralization of slightly demineralized, superficial areas of the enamel where the organic matrix and surface integrity are still intact, commonly referred to as “white spots.” In addition, the odontoblasts, which persist throughout life on the pulpal surface of the dentin, form secondary dentin in response to chemical stimuli from an advancing carious lesion in an effort to wall off the noxious influence. Lack of ability to repair dental tissues is in direct contrast to bone, with its continual turnover and ability to remodel (4).

Third, unlike other tissues, the mineralized tissues of teeth have a partial change of environment midway in their life. When the tooth begins to emerge into the oral cavity, the vascular supply to the enamel organ is severed, and the enamel surface comes in contact with a complex mixture of saliva, microorganisms, food debris, and epithelial remnants. Thus, instead of a pure systemic environment, the erupted tooth has, in addition, an oral or external environment. As a consequence, the enamel and cementum surfaces on which carious lesions are initiated by microbial action are largely outside the influences of humoral immune systems, so immune relationships with the caries process are primarily limited to those in saliva (4).

The development and maintenance of the soft tissues and bone that support the teeth are also subject to nutritional defects. The periodontium, as seen in [Figure 66.1](#), comprises the gingiva; the periodontal ligament (peridental membrane), which joins the root cementum to the alveolar bone; the root cementum, a specialized, mineralized tissue similar to bone, which covers the root of the tooth; and the alveolar bone, which forms and supports the tooth sockets. Alveolar bone grows in response to dental eruption, is modified by dental changes, and resorbs when teeth are lost. The finite space between the tooth and the gingiva, known as the gingival sulcus, is lined by a

nonkeratinized epithelium. In addition, dental plaque, one of the primary agents responsible for initiating both dental caries and gingivitis, contains a high concentration of bacteria, which, in the gingival sulcus, are juxtaposed with a “naked” epithelium. Thus, bacteria and their byproducts or antigens can permeate the gingival epithelium and precipitate a classic inflammatory response that denotes periodontal disease(s). In fact, an intact immune system, which is highly dependent on nutritional status, is vital to maintain periodontal health. Another unique characteristic of the oral soft tissues is their rapid turnover rates; thus, continued optimum levels of nutrients are necessary to promote oral health and to prevent disease. Indeed, the diversity of hard and soft tissues that comprise the oral structures and the distinctive nutritional needs of each contribute to the uniqueness of the mouth as an external reflection of past and present nutritional problems (6).

ROLE OF NUTRITION IN CRANIOFACIAL AND ORAL TISSUE DEVELOPMENT

Many severe and even moderate nutritional deficits can result in defective tooth development. The most commonly studied nutrients and conditions that have affected tooth integrity, enamel solubility, and salivary flow and composition in animal models include protein/calorie malnutrition, ascorbic acid, vitamin A, vitamin D, calcium/phosphorus, iron, zinc, and fluoride. Only protein/calorie malnutrition, deficiencies of vitamin A, ascorbic acid, vitamin D, and iodine, and fluoride excess have been demonstrated to affect the human dentition (Table 66.2).

Nutrient	Effect on Tissue	Effect on Caries	Human Data
Protein/calorie malnutrition	Tooth eruption delayed Tooth size Enamel solubility decreased Salivary gland dysfunction	Yes	Yes
Vitamin A	Epithelial tissue development Tooth morphogenesis dysfunction Osteoblast differentiation Thymal hypoplasia	Yes	Yes
Vitamin D/hypophosphatemia	Lowered plasma calcium Hypomineralized (hypoplastic) enamel Tooth integrity compromised	Yes	Yes
Ascorbic acid	Delayed eruption patterns Dental pulp atrophy Osteoblast degeneration Abnormal dentin	No	No
Fluoride	Stability of enamel crystal enamel formation Enamel demineralization Dentin remineralization Mottled enamel lesions	Yes	Yes
Vitamin C	Enamel formation Tooth eruption Delayed tooth eruption Abnormal growth patterns	Yes	Yes
Iron	Hypoplasia? Tooth growth Tooth integrity? Salivary gland dysfunction	Yes	No

Table 66.2 Effects of Nutrient Deficiencies on Tooth Development

Characteristically, enamel hypoplastic defects and hypomineralization have been the hallmarks of under- or overnutrition during tooth development. For example, Sweeney et al. noted that 73% of Guatemalan children with third-degree malnutrition and 43% of children with second-degree malnutrition had hypoplasia of enamel formed prior to the diagnosis of malnutrition (7). Data on 45 malnourished children in a marginal population

(8) supported Sweeney's findings.

Vitamin A deficiency has been implicated as a critical factor because it frequently accompanies protein/calorie malnutrition and is known to affect epithelial tissue development, tooth morphogenesis, and odontoblast differentiation (9). Protracted vitamin A deficiency during tooth development results in atrophy of the enamel organ, metaplasia of the ameloblasts, and defective apposition and calcification of dentin (6). The interference with calcification is expressed clinically by enamel hypoplasia (10). Additionally, vitamin A excess during the first trimester of pregnancy (as in individuals taking retinoic acid analogues to treat cystic acne) can result in severe craniofacial and oral clefts and limb defects (11).

Vitamin D, calcium, and phosphorus deficiencies all significantly affect tooth development and resistance to the caries challenge. Vitamin D deficiency appears to exert its metabolic effect through lowering plasma calcium levels; it has been difficult to localize vitamin D metabolites in target tooth and bone cells (12). Leaver demonstrated that extreme calcium and phosphorus deficiencies may result in hypomineralization of developing teeth (13). The deficit must be severe enough to reduce plasma levels of calcium and phosphorus, which suggests that this mechanism is unlikely to occur in humans because of the highly effective homeostatic mechanisms that mobilize calcium from the skeleton to maintain normal plasma calcium levels. Bawden postulates that vitamin D hypovitaminosis may be more important in considering hypomineralization due to inadequate calcium transport into developing dental tissues (14). Vitamin D deficiency also affects tooth structure and delays their eruption patterns (15).

In childhood vitamin D deficiency, the teeth are characterized microscopically by a widened layer of predentin, by the presence of interglobular dentin, and by interference with enamel formation (hypoplastic defects) (16). Young children with rickets have delayed eruption of the deciduous teeth, and the sequence of eruption is altered (6). The permanent incisors, cuspids, and first molars are usually affected because their development coincides with the age at which rickets is most common (6). Vitamin D-resistant rickets results in more frequent and severe tooth defects than with primary rickets, including large pulps with developmental "exposures" of the pulp.

Vitamin C deficiency also affects tooth development and eruption. Deciduous and permanent teeth of scorbutic infants contain minute pulpal hemorrhages attributable to vitamin C deficiency. In older vitamin C-deficient children, the dental pulp undergoes hyperemia, edema, necrosis, and aberrant calcification, and the dentin shows odontoblastic degeneration and irregular formation (17). The relationship of vitamin C deficiency to dental caries is poorly defined, however. Indeed, although it is likely that the primary mechanism of vitamin C deficiency-induced tooth, gingival, and bone disease involves disruption of collagen biosynthesis, no study has clearly demonstrated the relationship between scurvy and dental caries (18).

In areas where goiter is endemic, children born to mothers with severe iodine deficiency display marked mental and physical growth retardation. Eruption of both primary and secondary teeth is often greatly delayed and precluded. Malocclusion is relatively

common because of the altered patterns of craniofacial growth and development (6).

Perhaps the most intriguing and important data on nutritional status during development and oral disease come from observations on malnutrition and dental caries. Several studies demonstrated delayed tooth eruption, compromised tooth integrity (especially enamel surface solubility), and increased dental caries in animals and in chronically malnourished children (19, 20). Studies in Lima, Peru, demonstrated significant delays in tooth eruption and exfoliation in three groups of malnourished children; such delays were associated with, and appeared to be the direct cause of, a significant temporal delay in caries development in the primary teeth (21). These data support previous studies on malnourished children in India and Guatemala (22, 23).

Clearly, the development of teeth and salivary glands is intimately associated with the nutrient supply. Teeth subjected to nutritional insult during critical stages of development show a diminished ability to withstand caries and thus are at a higher risk. In many studies, impaired salivary function accompanied the morphologic changes in teeth, which may be a primary factor in the subsequent increase in caries susceptibility (24). These data also explain the positive association between socioeconomic status and the prevalence of dental caries in deciduous but not permanent teeth (20). Nutritional injuries early in life may affect tooth formation and may result in increased caries susceptibility, whereas chronic malnutrition is associated with delayed tooth emergence and a shift in the curve for caries prevalence versus age (20). Thus, to understand any cross-sectional survey on caries prevalence, the nutritional history must be taken into account.

On a broader scale, 7% of babies born in the United States each year have some mental or physical defect evident at birth or later (25). Prominent among these defects are structural, functional, or biochemical abnormalities involving the craniofacial complex. The most common of these malformations are cleft lip and cleft palate, affecting 1 out of 600 white infants; the incidence is higher among Asians, Native Americans, and Eskimos and lower among blacks (25). One out of 1600 babies born alive suffers from craniofacial anomalies other than cleft lip or palate, including jaw deformities, defects in ossification, malformed or missing teeth, facial asymmetries, and defects that are a component of other syndromes, such as fetal alcohol syndrome (25). Fetal alcohol syndrome consists primarily of small size for gestational age, dysmorphism (especially of the face and eyes, heart, joints, and internal genitalia), and mental deficiency. Of particular interest are the facial aberrant growth patterns, which include a low nasal bridge, short palpebral fissures, indistinct philtrum of the lip, thin upper lip, short nose, small midface, epicanthic folds, and small head circumference (26).

In addition, certain other craniofacial orodental disorders such as craniosynostosis, hemifacial microsomia, anodontia, amelogenesis imperfecta, dentinogenesis imperfecta, osteogenesis imperfecta, chondrodystrophies, and juvenile periodontitis represent major challenges to human oral health (27). Neural tube defects, among the most common birth defects with a rate of occurrence of 1 to 2 per 1000 births, have been linked to folate deficiency, range in severity, and can result in incomplete formation of cranial bones (28). Many of these malformations and disorders have a genetic basis or an

environmental cause. Certain nutrients given in excess, especially early in pregnancy (e.g., retinoic acid and other lipophilic molecules such as vitamins K and E), induce craniofacial orodental malformations. As stated above, therapeutic doses of 13-*cis* retinoic acid administered during the first trimester of pregnancy to treat cystic acne have resulted in significant craniofacial orodental malformations. The molecular mechanisms during these genetic-environmental interactions are not precisely known but are believed to interfere with developmental processes by reducing the number of cells required for normal morphogenesis of the head, face, jaws, skeleton, and neural tube, among others (28).

A small proportion of craniofacial malformities can be traced to specific genetic or chromosomal disorders, and others result from environmental factors, such as malnutrition, maternal disease, exposure to drugs, and obstetric problems. Most investigators believe, however, that craniofacial malformations have a multifactorial basis, in which particular genes alter the ability of the developing fetus to adapt to environmental factors (25). Indeed, evidence from studies of identical twins clearly establishes the role of environmental and genetic factors in cases of isolated cleft lip or cleft palate (25).

The regulatory genes and gene products functioning as transcriptional factors for the bronchial arches that give rise to the midface and lower face are being discovered, and their interactions with nutrients (e.g., retinoic acid via its specific receptors) are critical to craniofacial orodental morphogenesis (29). A superfamily of genes is now considered to interact with nutrients during instructive stages of craniofacial development in the mammalian embryo (i.e., about 19 to 26 days of gestation in the human). Endogenous retinoic acid appears to function as a developmental organizer during limb development and limb regeneration. Excess exogenous retinoic acid produces significant craniofacial malformations associated with clefting, dental development, hemifacial microsomia, spina bifida, eye defects, and limb morphogenesis (30). The function of endogenous retinoic acid in craniofacial development and how excess levels of retinoic acid might produce congenital malformations are central questions in this area (28, 31) (see also [Chapter 17](#) and [Chapter 18](#) on the roles of vitamins A and D on differentiation and morphogenesis). A striking illustration of the need to understand the effects of nutrition on birth defects is the recent demonstration that folate supplements provided near the time of conception significantly reduced the recurrence of neural tube defects among high-risk individuals in the United Kingdom (32). Similar data relate folic acid or multivitamins in congenital craniofacial malformations such as cleft lip and/or cleft palate (28, 33).

Dietary advice following thorough diagnostic endeavors can materially benefit expectant mothers, lactating women, and infants. Proper oral tissue development clearly depends on adequate nutrition. When dietary advice is provided during such critical development times, it is appropriate to consult with other professionals, including physicians, dietitians, and nutritionists, to ensure reasonable and substantive therapy. Most important, appropriate dietary counseling, particularly with reference to critical developmental times, and intake of essential nutrients, can ensure optimal oral health. Clearly, this knowledge base has profound implications for the continuing advancement of nutrition in the education of professionals and in integrating dentistry more closely with medicine. In this manner, dental/oral healthcare professionals can provide critical

points of entry into the healthcare delivery system for at-risk patients.

NUTRITION AND DENTAL CARIES

Dental caries is a preventable infectious disease of the oral cavity and a major cause of tooth loss in children and adults in the United States. Caries has declined among children, however. A measure of the level of dental caries in a population is the decayed-missing-filled-surfaces (DMFS) rate, which is the number of permanent tooth surfaces (out of a possible 128 surfaces on 32 teeth) that are decayed, missing, or filled. An oral examination was included in the Third National Health and Nutrition Examination Survey (NHANES III) conducted between 1988 and 1991. Among U.S. children aged 5 to 17 examined, over half (54.7%) had a caries-free permanent dentition; however, the mean DMFS was 2.5 (34). In the 1979 to 1980 NIDR survey, 37% of school children examined had no caries in their permanent teeth, and the mean DMFS was 4.77. However, dental decay increases with age; by 15 years of age, about two-thirds of U.S. teens had experienced caries in their permanent dentition (Fig. 66.2). Cavitation occurs most frequently on the occlusal or chewing surface of the tooth. Decay on the smooth surfaces of teeth has declined since 1980, and interproximal caries (between the teeth) is nearly eradicated in the younger age groups.

Figure 66.2. Percentage of U.S. children and adolescents caries free, by age and ethnicity. (From National Center for Health Statistics. Plan and operation of the third National Health and Nutrition Examination Survey, 1988–94. DHHS publ. no. (PHS) 94-1308, series 1, no. 322. Hyattsville, MD: National Center for Health Statistics, 1994.)

Caries was also common in the primary teeth. Although more than 60% of those under 9 years of age had a caries-free deciduous dentition, an average of 3.1 primary tooth surfaces were decayed or filled (34). Mexican American children had the highest mean number of decayed-filled primary tooth surfaces (4.8). About 31% of children aged 6 to 8 years had untreated decay in their primary or permanent teeth (35). The prevalence of unfilled tooth surfaces was greater among low-income, Mexican American, and

non-Hispanic black children and teens.

Based on data collected in the NHANES III survey, 93.8% of dentate adults have treated or untreated coronal caries. The average number of decayed and filled coronal tooth surfaces for adults aged 25 to 34 was 16.5 and climbed to 73.1 in adults 65 to 74.9 (36). The rate of edentulousness continues to decline. In the 1988 to 1991 survey, 26% of adults 65 to 69 years of age were edentulous, compared with 32% of adults in the 1985 to 1986 NIDR adult survey (37). Many adults have had fluoride exposure part of their lives; as a result, teeth are being retained longer.

The decline in caries prevalence does not imply that caries is no longer a public health problem; it is the most common disease of childhood and remains one of, if not the most, prevalent disease(s) in the world. Even the most optimistic data indicate that nearly 50% of children still have the disease. However, most of the caries in the permanent dentition are found in a small number of children; in those aged 5 to 17 years, 80% of the caries were seen in 25% of the children (34). Thus, the target group for intervention (including dietary intervention) has shifted to individuals at high risk, such as those of lower socioeconomic status, immigrants to the United States from developing countries, developmentally disabled individuals, persons undergoing head and neck radiation, and individuals with compromised host defenses because of complicating medical and pharmacy regimens that affect the oral tissues.

For many years, dental caries was thought to be irreversible. Recently it was determined that caries is a dynamic process with three phases: (a) demineralization, (b) equilibrium, and (c) remineralization of tooth enamel. With frequent fermentable carbohydrate exposure and poor oral hygiene, incipient lesions may develop rapidly. In the early stage of tooth decay, the process can be reversed. When no bacterial fermentation is occurring, calcium, phosphorus, and fluoride released from the tooth enamel can be redeposited to remineralize the tooth. A clinical cavity (caries) is the final stage in the disease process. The average time for progression of incipient caries to a carious lesion in children is about 18 ± 6 months.

Etiology of Dental Caries

The direct relationship between diet and dental caries is clearly established. Dental caries results from the interaction of four factors in the mouth: (a) cariogenic plaque bacteria, (b) fermentable substrate, (c) host and tooth factors including fluoride and other minerals, and (d) saliva (38) (Fig. 66.3). These factors must be present simultaneously in the oral cavity for a long enough time to interact.

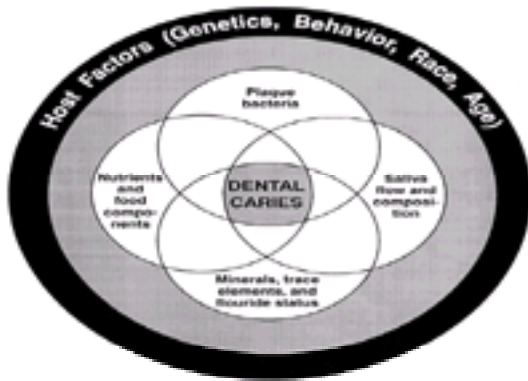

Figure 66.3. Major factors that interact in the dental caries process. (Adapted, with permission, from Navia JM. *Am J Clin Nutr* 1994;59:719S–27S.)

Dental plaque is a sticky gelatinous mass composed of gram-positive bacteria, extracellular polysaccharides, proteins of salivary and dietary origins, and lipids. Without effective oral hygiene, plaque may cover all surfaces of the teeth. When foods are ingested, plaque bacteria metabolize the carbohydrate component, sugars and starches, to form organic acids—lactic, butyric, acetic, formic, and propionic—on the surfaces of the teeth. This fermentation begins within minutes and may continue for hours. These acids lower the pH of plaque and can dissolve tooth structure. Demineralization of enamel is thought to occur between pH 5.3 and 5.7. Stephan proposed using a pH of 5.5 as the “critical pH” in measuring the cariogenicity of a food (39). Frequent intake of carbohydrates that depress the plaque pH below 5.5 can cause repeated acid attacks. When substrate is exhausted, acid production stops and the plaque pH returns to a resting state. Changes in plaque pH have been used to estimate the cariogenicity of foods and snacks.

Dental caries is one of the most common bacterial diseases in humans. In 1960, Fitzgerald and Keyes demonstrated that dental caries was an infectious disease in animals (40). When germ-free animals were fed a high-sucrose diet, no caries developed. When sucrose-fed animals were inoculated with mutans streptococci or exposed to infected animals, they developed smooth-surface and fissure caries. The cariogenicity of *Streptococcus mutans* in humans has been established by monitoring the levels of the organism in the fissures of teeth until they become carious. The number of *S. mutans* increases at sites where caries is diagnosed; caries-free tooth surfaces have low levels of *S. mutans*. Elevated numbers of mutans streptococci are found in children, teens, and adults with high rates of dental caries. Six genetically distinct species of mutans streptococci are now recognized (41). *S. mutans* (serotype C) has been identified as the principal organism responsible for the initial destruction of enamel and the underlying dentin in North American populations. The ability to survive and metabolize carbohydrate in the low-oxygen, acidic environment of dental plaque is a unique property of *S. mutans*. In addition to streptococci, species of actinomyces and

lactobacilli are linked to dental caries.

Human clinical trials to measure the effect of dietary habits on the development of caries or to confirm the findings of epidemiologic studies are considered unethical and are prohibited today. Thus, rats, hamsters, and monkeys have been widely used in caries research and for testing foods for cariogenicity. Rats have been used most extensively because the etiologic agents are essentially the same as in man (42). Caries can be produced within a few weeks in rats, whereas it takes 6 to 18 months for caries to develop in monkeys or humans. Although tooth morphology and saliva composition differ, lesions develop in the pits, fissures, smooth surfaces, and roots of rodents' teeth. As in humans, *S. mutans* are the critical cariogenic microbes, but fermentable carbohydrate must be present for caries to occur. In animal studies, essential nutrition can be provided by gastric intubation to bypass the oral cavity or given orally as animal chow or a gelled nutrient supplement. Poor growth and high mortality have occurred in animals undergoing gastric intubation, however, so this technique is less common than provision of an oral noncariogenic diet.

A programmed feeding machine is used so that the caloric intake, quantity, and frequency of intake of foods tested for cariogenicity can be monitored (43). A measured amount of food can be given to the animals up to 17 times during the day. At approximately 35 days, the animals are sacrificed and the teeth are scored for carious lesions. By using the feeding machine, researchers have shown that caries activity is linked to the quantity and frequency of fermentable carbohydrate intake (42). The results of animal trials cannot be extrapolated directly to humans, but they support a probable role of carbohydrates in human caries.

Role of Carbohydrates in Dental Caries

Epidemiologic surveys, extensive animal experiments, and early controlled human studies all link sugars to the development of dental caries. When refined sugar was introduced into the diets of primitive populations such as Eskimos, Tahitians, and Bushmen, their caries prevalence increased dramatically. As the per capita consumption of sucrose increased in England and the United States in the last 100 years, the prevalence of caries rose. Caries rates fell when sugar was rationed in Europe during World War II but increased again when sugar rationing ended (44). Sreebny showed that the average DMFT index in 12-year-old children in 47 countries was highly correlated with the amount of sugar available per capita daily (45). Populations with low sugar intakes had low caries scores; children who had high sugar consumption developed high rates of caries. In the United States today, total sugars minus lactose constitute 20% of children's total caloric intake (46). Most dietary sugars are added to manufactured foods rather than being added to foods by the consumer at home. The relationship between sugar intake and caries is stronger today in developing countries than in developed countries, where fluoride exposure, regular oral hygiene, and professional care have weakened this relationship (47).

In rodents, monkeys, and humans, the presence of sucrose in the mouth increases the volume and rate of plaque formation. Sucrose has a unique role in permitting bacteria to colonize on the teeth. When high concentrations of sucrose are present, *S. mutans* can

produce extracellular polysaccharides, glucans, which form an organic matrix on the tooth. These insoluble, sticky polymers permit bacterial colonies to adhere to the tooth. In addition to glucans, *S. mutans* produces intracellular polysaccharides (primarily fructans) from sucrose, which are stored and used in glycolysis when dietary carbohydrates are unavailable. [Figure 66.4](#) depicts the relationship of nutritive and nonnutritive sweeteners to the caries process and microbial metabolism. The critical concentration of carbohydrate in a food that will cause caries in man is unknown; however, foods with 15% sugars by weight are considered high-sugar foods. In animals, caries scores increase as the sugar content increases ([48](#)). The Hopewood House Study showed that children eating diets containing complex carbohydrates but few refined sugars had low caries increments ([49](#)). The relationship of sugar intake to caries increment was examined in a longitudinal study of school children in England where the fluoride level in drinking water was low; the highest significant correlation was between grams of sugar eaten daily and caries experience ([50](#)). The weak correlations found between food habits and caries increment can be attributed to several factors: a low level of caries in all children, a high intake of sugary foods by all children, and widespread use of topical fluorides.

Figure 66.4. Relationship of nutritive and nonnutritive sweeteners to oral microbial metabolism and dental caries. (Adapted from Alfano MC. Food Technol 1980;34:70–4.)

The other mono- and disaccharides (glucose, fructose, maltose, and lactose) found in fruits, dairy products, and processed foods are also readily used by oral microorganisms. These sugars diffuse rapidly through dental plaque to become available for bacterial fermentation. Within a few minutes of ingestion, fructose and glucose cause falls in plaque pH similar to those with sucrose; thus, they are considered as cariogenic as sucrose.

When eaten with meals, fresh fruits have low cariogenic potential. This is attributed to the high water content and the presence of citric acid, which stimulates saliva secretion. Fresh fruits vary in sucrose content from 10 to 15% by weight in apples, bananas, and some grapes; 7 to 8% in citrus fruits; to 2% in berries, cherries, and pears. However,

orchard workers who ate large quantities of apples and grapes daily showed a high caries rate (51). Highly acidic foods may prevent bacterial fermentation but cause enamel erosion.

Sugars in solution have been considered less harmful to teeth than solid sweets because beverages clear the mouth quickly. In the 1940s, however, Stephan showed that a 10% glucose rinse lowered the plaque pH below 5.5 (39). The total sugar content in carbonated beverages, fruit drinks, and fruit juices is about 10%, and sport drinks contain about 4.4% total sugars. Based on sugar content, acidity and changes in plaque pH after rinsing with these beverages, all of them appear to have similar cariogenic potential (52). Analysis of dental data from 1971 to 1974 (NHANES I study) showed that frequent between-meal intake of sweetened beverages was associated with increased caries (53). Teenagers and young adults who drank sugar-sweetened soft drinks three or more times between meals daily, increased their odds of having a high DMFT score by 179%. Since then, food manufacturers have replaced some of the sucrose in beverages with high-fructose corn syrup, saccharin, or aspartame. Whether beverages formulated with high-fructose corn syrup are less cariogenic is unknown. Substitution of sport drinks or ion drinks for carbonated beverages or fruit drinks was associated with decalcification of Japanese children's teeth (54). Most of these drinks have a pH below 4. Slowly drinking sugar-sweetened tea or coffee can also dissolve enamel. Use of sugar-based liquid oral medication may affect the oral health of chronically sick children. English children taking long-term liquid oral medicine had significantly more caries of deciduous anterior teeth than their siblings (55).

Extensive studies of the sugar alcohols show that they result in limited acid production by plaque bacteria. Plaque bacteria can ferment sorbitol and mannitol but too slowly to induce dental caries in most people. If sorbitol-sweetened products are used frequently, some evidence suggests that bacterial adaptation may occur (56). After several weeks of regular sorbitol mouth rinses, increased acid production was measured in adults given additional sorbitol. However, acid production may be clinically significant only in xerostomic patients who are at high risk of developing caries if they use sorbitol-mannitol-sweetened gums and candies regularly to relieve the symptoms of dry mouth. Xerostomic patients should be cautioned about the cariogenic potential of these products (57).

Xylitol, a five-carbon sugar alcohol, has been used in Canada and Europe to replace sucrose in candies, gum, and medicines. In the United States, it is approved by the Food and Drug Administration (FDA) for use in special dietary products. Ingestion of solutions of xylitol does not lower plaque pH because oral bacteria lack the enzymes to ferment xylitol to organic acids. A 2-year clinical trial in Finland showed that young adults eating foods sweetened solely with xylitol developed no new caries, whereas groups ingesting fructose and sucrose developed caries (58). Later studies confirmed that xylitol was noncariogenic. Xylitol, however, is not widely used because it is costly to produce.

Saccharin, found in beverages, dietetic foods, and dentifrices and as a table sweetener for diabetics, inhibits tooth decay in rats. Low caries scores and low recoveries of *S. mutans* resulted when rats were challenged with a cariogenic diet supplemented with

saccharin (59). The effects of saccharin on human oral bacteria have not been reported. Aspartame does not support the growth of *S. mutans*, acid production in the mouth, or plaque formation. Frequent rinsing with aspartame was no more cariogenic in rats than distilled water (60). Because soft drinks are a popular cariogenic snack, the use of aspartame in these beverages is safer for teeth.

Frequent use of chewing gum sweetened with xylitol or xylitol/sorbitol mixtures significantly reduces dental plaque as well as plaque and saliva levels of *S. mutans* (61). The Turku chewing gum study showed that those chewing four sticks of xylitol gum daily had 80% less dental decay than subjects chewing sucrose-sweetened gum (62). Gum chewing stimulates salivary flow and pushes saliva into the interproximal area where salivary buffers can neutralize bacterial acids. Chewing also removes food particles from plaque and soft tissues. The net result is that the stimulation of salivary flow caused by the physical act of chewing, coupled with the helpful effects of a noncaloric sweetener, can benefit dental health by “neutralizing” the plaque bacteria's acid response to fermentable carbohydrate-containing foods.

The effect of starch-containing foods on teeth depends on their form, whether the starch is raw or cooked, and whether sucrose is present. Raw starches found in vegetables have low cariogenicity in animals. Vegetables lacking sugars do not cause intraoral acid production or demineralization of enamel in man. Adults with hereditary fructose intolerance are a unique study group who consistently avoid fruits, table sugar, and refined starches containing sucrose because they cause nausea, but these persons eat wheat, rice, potatoes, and root vegetables. An examination of the caries status of these young adults showed that 15 of 27 adults examined were caries free, and the remainder had low DMFT scores. Siblings without the inborn error of metabolism had a higher caries prevalence, similar to that of the general population (63).

Because starch is a large molecule, it cannot diffuse through dental plaque. However, when cereal grains are refined in the production of breads or crackers and are cooked, they are more easily hydrolyzed by salivary and plaque amylases. Fermentation of the resulting sugar, maltose, yields acids that demineralize enamel rapidly. Mixtures of starches and sugars in ready-to-eat breakfast cereals, bread, pastries, and many convenience foods are often retained longer in the interproximal plaque than high-sugar foods. This may make heated sugar-starch combinations more cariogenic than sugar alone (64, 65). Foods previously thought to be of low cariogenicity—breads, muffins, crackers, chips—are no longer considered safe for teeth, especially when they are eaten between meals, because they are retained and can serve as substrate for plaque microbial fermentation.

Other Factors Affecting Cariogenicity

Sugar and starches are not the only factors that determine the cariogenic potential of a food. Frequency of intake, physical consistency, and position of a food in the meal are also important. In rats, the intervals between eating snacks or meals profoundly affect the number of *S. mutans* in plaque and the number of cavities formed. Few caries develop in rats fed a cariogenic diet two or three times a day. As the frequency of sugar and starch exposure increases, however, the caries risk increases. In the 1950s, the

classic human intervention trial, the Vipeholm study, was conducted in Sweden (66). Institutionalized adults were fed an adequate diet and supplemented with either retentive sweets (chocolate, toffee, and caramels) between meals or nonsticky, sweet foods at meal time. Subjects provided up to ten times the sucrose at meals did not experience a significant increase in caries relative to the control subjects. However, the group receiving between-meal sweets developed more caries than subjects receiving sugar at mealtimes. Similarly, analysis of the NHANES I data obtained in a cross-sectional survey revealed that individuals with high DMFT scores consumed table sugars, syrups, sugary desserts, and snacks more frequently than persons with low DMFT scores (67). In a 3-year longitudinal study of 11- to 15-year-old Michigan children living in nonfluoridated areas, teens who developed two or more carious lesions derived more calories from snack carbohydrates and high-sugar foods than children with low caries increments (68). In rat experiments, granola cereal, french fries, bananas, cupcakes, and raisins had a cariogenic potential equal to or greater than that of sucrose (64).

The sequence of eating foods in a meal affects the magnitude of a drop in plaque pH. If a piece of aged cheese is eaten after an acidogenic food such as canned pears in syrup, the plaque pH rises above the danger zone immediately (69). Sugared coffee elicits a rapid drop in pH, but it will rise if followed by an unsweetened food. Sugared coffee at the end of a meal, however, will cause a prolonged drop in plaque pH. Placing acidogenic items between other foods lessens the risk of demineralization.

Saliva and protective components in foods modify the effect of fermentable carbohydrates on the teeth (70). The importance of saliva in caries prevention is perhaps best demonstrated by the rampant caries that develop in xerostomic patients. Saliva flow is stimulated by chewing, by citric acid in fruits, and by sugars. The composition of saliva is also influenced by dietary components.

Four protective mechanisms of saliva are important in caries prevention. First, saliva prevents bacterial aggregation on the tooth surface and speeds clearance of food particles and sugars from the mouth. Second, proteins, bicarbonates, and phosphates in saliva dilute and neutralize plaque acids. Third, immunoglobulins present in saliva protect the teeth by depressing bacterial activity. Finally, calcium, phosphate, and fluoride ions in saliva promote the remineralization of tooth enamel.

Food components can have two protective effects on tooth enamel. Some foods decrease the solubility of enamel (demineralization); others stimulate salivary secretion or remineralization of tooth enamel. Substances that make the enamel less soluble include fluoride in tea, an unidentified factor in cocoa, phytate, oxalate, and proteins in milk. Citric acid found in citrus fruits stimulates saliva production and thereby increases the amount of bicarbonate and phosphate buffers in the mouth.

Much research has been done on the effects of cheese on plaque pH. Over 21 aged cheeses have been identified that do not cause the plaque pH to fall (71). The protective properties of these cheeses are attributed to their texture (which increases the salivary secretion rate) and their protein, calcium, and phosphorus content (which neutralizes plaque acids). Cheese seems to prevent demineralization and promote remineralization

(72). A “protective pH rise factor” has been hypothesized, but none has been identified.

Measuring the Cariogenic Potential of Human Food

Plaque acidogenicity is considered a valid indirect measure of the cariogenic potential of foods in humans. The results of three indirect types of tests (73), taken together, on a variety of commonly consumed foods reveal that the foods with high cariogenic potential are those with high fermentable carbohydrate content, eaten frequently, that adhere to the teeth. Tests also demonstrated that the following foods cause the pH at interproximal sites to fall below pH 5.5, implying that if they are ingested frequently, the risk of caries will substantially increase: dried fruits, breads, cereals, cookies, snack crackers, and potato chips (74). Generally, the more processing a food undergoes, the greater its cariogenicity. Foods that are noncariogenic (i.e., do not drop the plaque pH below 5.5) include some vegetables, meats, fish, aged cheeses, and nuts. These tests are useful predictors of cariogenicity, but additional factors determine if caries actually develop, including host susceptibility, virulence of the oral bacteria, how frequently a food is eaten, the sequence in which foods are eaten in a meal, and the interaction between foods eaten concurrently.

In addition to the continuing concern regarding food cariogenicity and caries prevalence and experience in the so-called normal population, two other specific groups have been targeted as high-risk groups, primarily because of eating and social behavioral patterns: the infant/toddler, at risk of early childhood caries, and the elderly, at risk of developing root surface caries.

Root Caries

Dietary factors are also important in the initiation and progression of root caries. When gingival tissues recede, the root surfaces of teeth are exposed to the oral environment. Because roots lack the protective enamel layer, they are highly susceptible to dental caries. Root caries lesions are primarily a disease of older adults. In the NHANES III survey, root surface lesions were found in 54% of males and 41% of females 65 to 74 years of age. The mean number of decayed and filled root surfaces for 65 to 74 year olds was 2.2 (75). About 60% of the lesions had been restored. Older adults at greatest risk of developing root caries include persons with coronal caries, gingival recession, low saliva flow, low fluoride exposure, and frequent intake of fermentable carbohydrates.

High levels of *S. mutans* are found in adults with root caries (76). Examination of ancient skulls and dentition of members of primitive societies revealed that root caries was more common than coronal caries. Because these groups consumed starches but not refined sugars, complex carbohydrates are implicated in the development of root caries. Adults who have periodontitis or have had periodontal surgery resulting in exposed root surfaces frequently develop root caries if their intake of fermentable carbohydrates is high (77). A high sugar intake is positively associated with root caries, and a high cheese intake is negatively associated with root caries (78, 79). In a cross-sectional study of healthy, free-living elderly persons, high daily intake of semisolid and sticky, slowly dissolving fermentable foods such as ice cream, gelatin, hard candies, and

antacids was positively correlated with root caries (80).

In a 2-year longitudinal study of elderly Bostonians, subjects in the highest quintile for root caries had significantly higher intakes of sweetened liquids, solid fermentable carbohydrates, and starches than subjects who were free of root caries (81). Adults who were free of root caries ate 50% more cheese and 25% more milk than persons with caries. Because root caries develop more rapidly than coronal caries, preventive measures are critical. Nutritional counseling, home oral care, and fluoride therapy should be provided to older adults with gingival recession. Thus, the dietary etiology of root caries seems to be similar to that of coronal caries. Both the amount and frequency of fermentable carbohydrates are important.

Early Childhood Caries

Severe tooth decay in infants and toddlers is a preventable disease associated with inappropriate feeding practices. Early childhood caries, often referred to as nursing caries or baby bottle tooth decay, occurs between 1 and 3 years of age, develops rapidly, and can cause severe dental pain and infection. The prevalence of early childhood caries in the United States is estimated to be between 1 and 12%. However, much higher prevalence rates have been reported among Hispanic, Southeast Asian, innercity, and American Indian/Alaska Native children (>50%) (82).

Children with nursing caries are at greater risk of developing additional caries in the primary and permanent teeth than children who are caries free (83). Initially, the smooth surfaces of the four primary maxillary incisor teeth are involved; later, decalcification of the maxillary and mandibular molars and canines occurs (84). The tongue protects the lower anterior four incisors. First white spot lesions develop on the gingival third of the maxillary front teeth; this stage often goes undetected by parents. Within 6 months, these lesions may progress to a dull white band of demineralization rapidly developing along the gum line of the upper incisors. If the disease advances further, a brown or black collar encircles the necks of the teeth. The four maxillary incisors may be completely destroyed so that only brownish root stumps remain. When nursing caries progresses to the development of abscesses, the abscesses may affect the underlying developing permanent dentition. Restoration of severe caries is expensive and emotionally traumatic for parents and children. The young child must often be treated under general anesthesia. Loss of incisors alters the arch dimension, affects appearance and speech, and may have a psychologic impact on the child.

Nursing caries results from the interaction of pathogenic oral microorganisms, fermentable carbohydrates, and susceptible teeth. *S. mutans* is not part of the indigenous flora of the oral cavity at birth. When the deciduous teeth erupt at about 6 months of age, bacterial colonies begin to form in the mouth. *S. mutans* is believed to be transmitted to infants by caregivers. If mothers have high levels of *S. mutans*, their infants are at greater risk of having elevated levels of these cariogenic organisms in their plaque (85). As discussed above, early malnutrition may increase a tooth's susceptibility to caries.

Early decay of the primary dentition may result from use of a nursing bottle at naptime

and/or bedtime that contains milk, fruit juice, or another sweetened solution. Sweetened liquids pool around the teeth of a child who habitually falls asleep with a bottle in the mouth, leading to demineralization of the enamel. The same pattern of dental decay may result from ad libitum breast-feeding (86). Breast-fed infants with rampant decay have reportedly been allowed to sleep with the mother and remain on the breast for long periods of time. During sleep, diminished flow rates greatly reduce the protective action of saliva. Severity of the disease is linked to the number of decay-causing bacteria present in the oral cavity, the number of feedings per day, and the duration of bottle or breast-feeding.

To prevent early childhood caries, education must occur before the child's primary teeth erupt. All caregivers—parents, grandparents, and daycare workers—must be counseled about the recommended feeding practices with the baby bottle. Nap or nighttime bottle feeding in bed should be discouraged. If a bedtime bottle is offered, the only safe liquid is water. Parents should be encouraged to offer juices from a cup after 6 months of age. Allowing breast-fed infants to sleep with the nipple in the mouth during the night should be avoided after the first primary tooth begins to erupt. Infants should be removed from the breast when they fall asleep. Children should be weaned from the bottle by 12 months of age. Information about nursing caries should be provided in dental offices, pediatric clinics, WIC (Women, Infants, and Children) clinics, birthing centers, and Head Start programs. One-on-one counseling with caretakers of infants and communitywide education programs have been successful in reducing BBTD among southwestern American Indian children (87). The American Academy of Pediatric Dentistry recommends that infants visit a dentist within 6 months after the first tooth erupts in the mouth.

FLUORIDE

The decline in coronal caries in industrialized countries in the past 30 years is attributed primarily to the widespread use of fluorides. This mineral is universally present in nature; trace amounts are found in soils, water, plants, and foodstuffs. Currently, the primary sources of fluoride for humans are community water supplies, foods, beverages, dentifrices, and other dental products. The ionic fluoride ingested in water has a systemic effect prior to tooth eruption and a topical effect after eruption. Dietary fluoride supplements are prescribed for children when fluoride is lacking in the water supply. Professionally applied topical applications of fluoride in higher concentrations are used to protect erupted teeth and are not swallowed. The preventive benefits of fluoride depend upon the concentration of fluoride used, whether it is given systemically or topically, and the type of agent used, whether in water, tablet, drops, a rinse, or a gel. The caries preventive properties of systemic and topical fluoride are additive. Fluoride is more effective in preventing smooth surface caries than occlusal caries.

Mechanisms of Action

Although the cariostatic properties of fluoride are widely recognized, the mechanisms of action of fluoride in the oral environment are not fully understood. At least three mechanisms of action are recognized (88). First, fluoride ions replace some of the hydroxyl groups of the hydroxyapatite in developing teeth to form fluoridated

hydroxyapatite. This increases the stability of the enamel crystals because fluoridated hydroxyapatite is less soluble in organic acids than hydroxyapatite. Fluoride uptake by calcified tissues is extremely high (90%) in infancy but decreases with age. Second, low concentrations of fluoride in the saliva can decrease the rate of demineralization and enhance remineralization of early carious lesions. When enamel is partially demineralized by organic acids, calcium, phosphate, and fluoride from the tooth can diffuse back into the surface layers of enamel and accelerate recrystallization. Third, fluoride has direct effects on the acidogenic plaque bacteria. In higher concentrations, fluoride inhibits growth of *S. mutans* found in dental plaque, and in low concentrations, it inhibits bacterial enzymes, reducing acid production from catabolism of fermentable carbohydrates.

Water Fluoridation

Fluoridation of community water supplies is the most effective method of providing fluoride to large populations. Through extensive epidemiologic studies of naturally fluoridated communities in the United States in the 1930s, the protective properties of fluoride in the prevention of dental caries were fully recognized (89). In 21 U.S. cities, an inverse relationship was shown between caries prevalence in children and the fluoride content of the drinking at an optimal range (Fig. 66.5).

Figure 66.5. Relationship between caries prevalence and fluoride content of drinking water in 21 cities. (With permission from Newbrun E. Fluorides and dental caries. 3rd ed. Springfield, IL: Charles C Thomas, 1986.)

In 1945, Grand Rapids, Michigan, became the first city in the world to fluoridate its drinking water. Between 1950 and 1980, clinical studies conducted in 20 countries showed that adding fluoride to community water supplies reduced caries by 40 to 50% in primary teeth and by 50 to 60% in permanent teeth (90). Recent comparisons of caries in U.S. children who had always lived in optimally fluoridated communities with children never exposed to fluoridated drinking water revealed 25% lower DMFS scores in the fluoridated group (91). The decline in caries prevalence among children living in

communities with nonfluoridated water is attributed to intake of foods and beverages processed with fluoridated water, use of fluoride-containing dentifrices, and use of topical fluorides in the dental office and at home. Adults also benefit from consumption of fluoridated water. The prevalence of coronal and root caries seems to be 20 to 30% lower in adults living in optimally fluoridated communities than in adults residing in cities with lower levels of fluoride in the water supply (92).

According to the United States Public Health Service, the desirable fluoride concentration for dental caries prevention is about 1 part per million (0.7–1.2 ppm, based on climactic temperature). By 1990, 42 of the 50 largest cities in the United States had fluoridated their water supplies. In 1992, in the United States, approximately 144 million people, or 62% of the population on public water supplies, drink water with fluoride levels of 0.7 ppm or higher (93). This includes 9 million people who drink water with natural fluoride at optimal levels. Continuous exposure to fluoride is desirable. In communities where water fluoridation has been interrupted or eliminated, a significant increase in dental caries has been observed (92).

Water fluoridation is the most cost-effective method of preventing tooth decay in the United States. The current average cost for delivering fluoride in the drinking water is less than a dollar per person per year. Even though scientists, health professionals, and the courts generally agree that community water fluoridation is safe, effective, economical, and legally valid, some members of the public remain confused about fluoride's safety. Opponents to fluoridation have attempted to link it to AIDS, Alzheimer's disease, and cancer, but they have provided no scientific evidence to support their claims. Over 50 epidemiologic studies have demonstrated no association between water fluoride and the risk of cancer. In addition, animal studies have failed to establish a relationship between fluoride and cancer (88). Water fluoridation cannot be taken for granted. Health professionals—nutritionists, physicians, dentists, pharmacists, nurses, and public health specialists—have a responsibility to educate patients and the public about the health and economic benefits of fluoridation.

Dietary Supplementation

Children living in cities and rural areas with suboptimal water fluoridation can receive the caries-preventive benefits of fluoride by taking a prescribed fluoride supplement. Children given fluoride drops or tablets daily from 6 months of age through the early teenage years show a low prevalence of caries. The level of dietary supplementation is determined by the age of the child and the concentration of fluoride in the water supply. Well water should be tested for fluoride concentration by the local water district or the county or state health department. [Table 66.3](#) presents the levels of daily fluoride supplementation recommended by the American Dental Association (ADA) Council on Scientific Affairs and the American Academy of Pediatrics. No fluoride supplementation is recommended in areas where the drinking water contains 0.6 ppm fluoride or more. For those consuming water with less than 0.30 ppm fluoride, 1 mg of fluoride is not recommended until age 6. The upper limit of fluoride intake appears to be 0.05 mg/kg body weight. Future dosage schedules may be based on body weight rather than age.

Age	Concentration of Fluoride in Drinking Water (ppm)		
	Less than 0.3	0.3 to 0.6	More than 0.6
6 months to 3 years	0.25 mg	0	0
3 to 6 years	0.50 mg	0.25 mg	0
6 to 16 years	1.00 mg	0.50 mg	0

^appm = parts per million; 2.2 mg sodium fluoride contains 1 mg fluoride.

Table 66.3 Supplemental Fluoride Dosage Schedule (mg/day^a) According to Fluoride Concentration of Drinking Water

Liquid fluoride supplements (drops) are recommended for infants and young children. Fluoride drops or tablets alone are as effective as fluoride-vitamin supplements. A list of accepted fluoride supplements is published regularly by the ADA Council on Scientific Affairs (94). Fluoride-vitamin supplements are not recommended by the ADA because when vitamins are discontinued, fluoride use may cease. Few healthy, full-term, formula-fed infants require a vitamin-mineral supplement. The fluoride present when commercial formula is diluted with fluoridated water is 95 to 100% available. If infant formula is prepared with nonfluoridated water, however, fluoride drops should be prescribed. The fluoride concentration of breast milk and cow's milk is very low (0.1 ppm).

For older children, fluoride tablets are available in the following doses: 0.25 mg F, 0.5 mg F, or 1 mg F. Tablets are formulated with neutral sodium fluoride or acidulated phosphate fluoride (APF). The caries preventive effects of neutral fluoride tablets is similar to that of APF tablets. Chewable fluoride tablets seem to have both topical and systemic benefits. Patients should be instructed to allow the tablet to dissolve by chewing before swallowing. Administering the appropriate dosage of fluoride preparations should be carefully explained to parents, because excess fluoride may lead to dental fluorosis.

Other countries have incorporated fluoride into the food supply by fluoridating salt, milk, flour, or sugar. If community water fluoridation is impractical, these foods appear to be possible vehicles for fluoride. Unfortunately, individual intake of these foods varies widely, so formulating a dosage regimen is difficult.

Primary tooth development begins before birth; therefore, the efficacy of prenatal fluoride supplementation is of interest. During pregnancy, fluoride diffuses across the placental barrier and is incorporated into fetal bones and teeth. Fluoride concentration in fetal blood appears to be about 25% of that in maternal blood (95). Although prenatal supplements are considered safe for mother and fetus, the benefits of supplementation

in reducing caries are unproven. Dental caries rates of children whose mothers received fluoride supplements during pregnancy and children whose mothers did not, did not differ significantly at 3 and 5 years of age (96). Both groups lived in cities without fluoridation of the water supply.

Dental Fluorosis

Fluorosis is characterized by white opaque flecks, white or brown staining, or in severe cases, pitting of the tooth enamel. Because the crowns of all permanent teeth are forming between birth and 14 years of age, the effects of excess systemic fluoride are limited to this age group. The most critical time for developing fluorosis appears to be the first or second year of life when maturation of upper anterior permanent teeth enamel occurs and the daily fluoride ingestion exceeds 2 ppm (97). Fewer than 2% of school children in the 1986 to 1987 NIDR survey had moderate-to-severe fluorosis (98). An increase in the prevalence of mild/very mild dental fluorosis is observed more often in fluoridated than nonfluoridated communities (Fig. 66.6). This is primarily a cosmetic problem and does not increase the teeth's susceptibility to caries. Fluorosis is not considered a public health problem in North America today.

Figure 66.6. Prevalence of dental caries and dental fluorosis in relation to fluoride in drinking water. (From Department of Health and Human Services, Public Health Service Review of Fluoride Benefits and Risks. Report of the Ad Hoc Subcommittee on Fluoride of the Committee to Coordinate Environmental Health and Related Programs. Washington, DC: U.S. Government Printing Office, 1991.)

Exposure to multiple sources of fluoride increases a child's risk of developing fluorosis (99, 100). More than two-thirds of the fluorosis cases can be explained by inappropriate use of fluoride supplements and use of more than the recommended amount of toothpaste (99). If a child receiving optimal amounts of fluoride from dietary sources or fluoridated water swallows large amounts of dentifrice, fluorosis can occur. Nearly all U.S. toothpastes contain fluoride that is readily absorbed when ingested. Toothpaste is generally swallowed rather than expectorated by children under 6 years of age.

Therefore, parents should dispense a pea-sized amount of toothpaste for young children to prevent excess fluoride intake.

Substantial amounts of fluoride can be introduced into the infant's diet through food processing. In the 1970s, it was discovered that infant formulas contained variable and often high levels of fluoride. To reduce the risk of infants receiving too much fluoride, beginning in 1979, infant formula manufacturers voluntarily reduced the amount of fluoride in formulas. Soy-based formulas appear to have higher fluoride levels than milk-based formulas because the soy products contain components that bind fluoride. Ready-to-feed infant fruit juices, tea, fish, dried seafood products, and chicken products can contain high levels of fluoride. Continued monitoring of the fluoride content of a "market basket" of infant and toddler foods in the United States is needed to ensure that fluoride intake remains within safe limits. When the pathogenesis of enamel fluorosis is better understood, the appropriateness of the current fluoride supplementation schedule can be determined.

EFFECT OF NUTRITION ON ORAL SOFT TISSUES

Nutrient Deficiencies

The oral mucosa is particularly susceptible to physiologic or anatomic changes resulting from nutritional deficit or toxicity. Since the turnover rate of oral mucosal cells is relatively rapid (gingival sulcular epithelial cells have a turnover rate of 3 to 7 days), sufficient nutrients must be available at the appropriate times and in the correct concentration for DNA replication, protein synthesis, and cell and tissue maturation to occur. The oral epithelium acts as an effective barrier against invasion of toxic substances, particularly antigens derived from oral microbes, into the underlying collagenous connective tissue. Inadequate nutrition can cause the oral epithelia to either break down or be compromised, thus increasing the tissue's susceptibility to infectious disease.

For these reasons, the oral cavity is one of the first regions of the body to exhibit clinical signs of malnutrition. Virtually every classic nutritional deficiency or toxicity, including scurvy, beriberi, and pellagra, has signs and symptoms in the oral cavity and surrounding structures. The lips, tongue, oral mucosa, and gingiva may all reflect nutritional aberrations long before they are apparent elsewhere in the body. [Table 66.4](#) summarizes the oral signs and symptoms of nutritional aberrations. Nutritionally induced oral changes may include anatomic lesions, color changes, functional changes (e.g., burning mouth and tongue), textural changes, and inflammation of the lips, oral mucosa, corners of the mouth, tongue, and gingiva (6).

Table 66.4 Oral Signs and Symptoms of Nutritional Aberrations

For example, the dorsum of the tongue may undergo changes in size or color, and taste changes may result from atrophy or hypertrophy of tongue papillae. Longstanding nutrient deficiencies may lead to atrophy of the papillae and denudation of the dorsum. A bright red, painful tongue and swelling of the oral mucosa may be early symptoms of pernicious anemia due to a lack of vitamin B₁₂. Inflammation, a burning sensation, and tenderness of the tongue or palate may be caused by a deficiency of vitamin B complex, protein, or iron. Burning mouth syndrome has been associated with vitamin B-complex deficiencies (101), and vitamin B-complex supplementation resolved the symptoms in 85% of subjects. A bright red, inflamed mucosa from a vitamin B-complex deficiency may be seen in long-term alcoholics. The mucosa may become pale in anemias induced by deficiency of iron, folic acid, or vitamin B₁₂. Atrophy of the filiform papillae of the tongue (glossitis) is a sign of malnutrition usually resulting from multiple nutritional deficiencies. A highly significant positive correlation between papillary health and plasma vitamin E status provides some indication that vitamin E may be a marker nutrient for papillary health (102).

In ascorbic acid deficiency, the classic oral signs of scurvy are first seen in the oral cavity, including red, swollen interdental papillae that bleed readily and inflamed, swollen marginal and attached gingiva. Although no longer a public health problem, ascorbic acid deficiency still occurs in isolated cases, usually as a result of total elimination of vitamin C sources from the diet. Most epidemiologic studies have not supported a direct relationship between periodontal disease and ascorbic acid status. However, one study did show a weak association between periodontal disease and ascorbic acid deficiency in an elderly population (103). Consumption of ascorbic acid in excess of recommended allowances has not been shown to be associated with increased periodontal health (104).

No clinical sign is of significance by itself, however, because several etiologic factors usually contribute to a differential diagnosis. For example, inflammation or cracking of the lips may be due to allergies, licking of the lips, or drooling, as well as to nutritional aberrations. Angular cheilosis can result not only from vitamin deficiencies, but also

when overclosure of the jaw by denture wearers allows the skin folds at the corners of the mouth to provide a moist area for bacterial or fungal infections to develop. The painful oral lesions that result from nutrient deficiency can alter a patient's food selection and oral hygiene behavior, thus increasing the risk of oral and systemic diseases.

Nutrient Excesses

Nutrient excesses can also affect the oral cavity. Vitamin A toxicity can impair proper development of the oral mucosal epithelium and result in a variety of oral changes including delayed wound healing (105). Clinical effects reported in a patient taking 200,000 IU/day of vitamin A for over 6 months included gingival erosions and ulcerations, bleeding, swelling, loss of keratinization, and color changes in the oral cavity along with desquamation of the lips and dry mouth. Two months after withdrawal of the supplementation, all clinical manifestations had disappeared (106).

Rebound scurvy is a condition in which scurvy develops as an adaptation result of fast withdrawal after chronic high intake levels of vitamin C in animals (107). Its existence in human populations has been questioned (108), but some supportive evidence (109) has been reported clinically in patients who abruptly terminated megadosing on vitamin C. The resulting scurvy is first manifested in the oral cavity and diagnosed by the dental professional.

Periodontal Disease

Periodontal disease is a general term describing bacterial infection of either the gingiva (that part of the oral mucosa that covers the root and the apical portion of the crown) or both the gingival and the attachment apparatus (ligamentous attachment of the tooth to the surrounding alveolar bone). If the infection is confined to the gingival unit, the resulting disease is called *gingivitis*. If the infection involves destruction of the tissue attaching tooth to bone, the disease is termed *periodontitis*. The two diseases are not a continuum of the same process, but are in fact two separate diseases, each associated with different plaque flora. The etiology of gingivitis is relatively simple, that of periodontitis is extremely complex. Though bacterial plaque is the major etiologic agent in both conditions, other local and systemic factors, many unidentified, play a large role as well.

Most forms of periodontitis result in a slow loss of attachment of the tooth from the surrounding alveolar bone. Although most individuals have some mild periodontal disease, severe periodontal destruction is confined to approximately 24% of the adult population (110).

The reaction of the periodontal tissues to microbial antigens and byproducts is a classic chronic inflammatory-immune response like that observed in infectious diseases in general. Optimal functioning of the host's cellular and humoral immune system and the phagocytic system, as well as the integrity of the oral mucosa (particularly the gingival sulcular epithelium), is important for maintenance of periodontal health and prevention

of periodontal disease.

Evidence directly linking diet and nutritional factors to periodontitis is somewhat controversial (111). In both the animal model and man, numerous longitudinal studies have attempted to associate either nutritional deficiency or supplementation with gingivitis. The few well-controlled animal and human longitudinal studies demonstrated associations between deficiencies of ascorbate and folate and severity of gingivitis (112, 113 and 114). However, an increase in gingivitis does not necessarily mean an increase in susceptibility to periodontitis, the destructive disease that compromises tooth support.

Epidemiologic studies have attempted to link periodontitis directly to nutrition by looking at the degree of periodontal destruction in societies where malnutrition is pervasive or by attempting to relate intake of specific nutrients to the degree of periodontal destruction in well-nourished societies (115, 116). In general, there was more periodontal destruction in malnourished populations than in well-nourished societies. The role of nutrition as a contributing factor is unclear, however, since these malnourished populations consistently demonstrate poor oral hygiene as well. Massive pathogenic plaque accumulation would lead to greater loss of attachment without the possible effects of malnutrition. When the periodontal destruction measured resulted from previous disease, an attempt to correlate this with present nutritional intake is problematic.

Although little evidence links nutritional aberrations directly to periodontal disease, nutritional status has been associated with level of immune response, phagocytic activity, and mucosal integrity, all of which affect the periodontal condition (117, 118).

Nutrition may thus contribute to the pathogenesis of destructive periodontal disease. Rational assumptions for testing can be made by extrapolating data about the importance of various aspects of the host's defense mechanism to the pathogenesis of the disease and further extrapolating known relationships between nutrition and these defense mechanisms. For example, patients with deficiencies of polymorphonuclear neutrophil leukocytes (PMNs) have increased susceptibility to destructive periodontal disease (119). Thus, although little direct evidence of the interrelationships of nutrition and PMN function and periodontitis exists, chronic deficiencies of ascorbate and iron are associated with impaired PMN function, and these deficiencies could contribute to an altered host response to plaque pathogens, making the affected individual more susceptible to periodontitis.

Likewise, several animal and human studies have demonstrated a positive correlation between deficits of ascorbic acid, iron, folate, and zinc and increased permeability or diminished integrity of the gingival sulcular epithelium (an important host defense mechanism) (112, 120). Zinc deficiency in rats resulted in parakeratotic and hyperplastic buccal epithelium due to decreased keratinolytic enzyme activity (121). Dietary vitamin E supplementation accelerated gingival wound healing in albino rats and decreased alveolar bone loss in rice rats (122, 123).

A study comparing fruit farmers and grain farmers showed that periodontal pockets 4 mm and deeper occurred less frequently in workers who ate large amounts of different

fruits and were the least frequent in those consuming citrus fruits (124). Malnutrition almost always has a synergistic interaction with infection. Since periodontitis is an infection, one could hypothesize that malnutrition would render the host more susceptible to destructive periodontal disease. This susceptibility to infection may be even more pronounced in the periodontium because these tissues are constantly exposed to toxic and antigenic challenges from the omnipresent bacterial plaque and thus are in a state of continuous repair.

New evidence from human aging studies gives more credence to these hypotheses (125). Periodontal diseases increase with aging, and the immune response declines in old age in both humans and animals (although older persons are less homogeneous in immune responses than younger persons). As immune function declines, the incidence of infections, cancers, and immune complex diseases increases. Nutritional deficiencies result in impaired immune response. Even children and young adults consistently show an adverse impact of nutritional deficiencies on cell-mediated immunity, complement system, secretory IgA response, and phagocyte function (125, 126). In a group of elderly with no systemic disease, those with clinical, hematologic, and biochemical evidence of nutritional deficiency also showed reduced immune function. When given appropriate nutrition guidance and supplements, immune function improved. When elders (even those with adequate diets) were given physiologic doses of vitamins and trace elements, immune response increased, and the incidence of infections decreased. The nutrients significantly correlated with improved immune response were zinc, vitamin E, folic acid, vitamin B₆ and b-carotene (117, 118, 125).

Some evidence indicates that periodontal tissues may be susceptible to end-organ deficiencies (127). In other words, although systemic levels of a specific nutrient measured biochemically in serum may be within normal limits, increased challenges at a local site may be such that levels normally considered adequate are unable to maintain optimal health at the local site. Such end-organ deficiencies have been reported in other organ systems (128).

Alveolar Bone Health, Osteoporosis, and Dentate Status

One of the more dramatic clinical signs of severe periodontal disease is resorption of alveolar bone, which ultimately results in tooth loss. The literature has long speculated that calcium deficiency is a major etiologic factor in periodontitis and that periodontal disease may foreshadow systemic metabolic bone disorders (129, 130) that then lead to tooth loss. Well-designed studies to determine whether individuals with destructive periodontal disease have any greater disposition to metabolic bone disorders or whether calcium deficiency predisposes the periodontium to destructive disease are only now emerging (131).

The alveolar process (crest of the maxilla and mandible) is composed primarily of trabecular bone. Histologically, it is the same type of bone found in the distal radius, neck of the femur, and vertebrae. When negative calcium balance occurs in the body, calcium is more easily mobilized from skeletal sites consisting of trabecular than cortical bone. Thus, the alveolar bone provides a potential labile source of calcium to meet other tissue needs. Since the alveolar process is thought to undergo resorption prior to other

bones; change in the alveolar process may be used for early diagnosis of osteoporosis.

In females, a high correlation has been shown between dental bone mass and total bone mass. Women with low bone density have fewer teeth. Women with severe residual ridge resorption have osteopenia on the iliac crest, and those with severe postmenopausal osteoporosis are three times more likely to be edentulous than normal controls (132).

Approximately 32% of U.S. women and men aged 65 to 69 are edentulous (110), and tooth loss may reflect osteoporotic loss of alveolar bone. A study of 329 healthy postmenopausal women (133) showed that systemic bone loss may be associated with tooth loss. An inverse relationship was shown between bone mineral density and number of existing teeth, with women who got dentures after the age of 40 having the lowest bone mineral density. In another study, mandibular bone density in edentulous subjects showed significant correlations with bone density elsewhere in the body, especially in the hip (134). In a study of 208 postmenopausal women, those with osteoporosis were more likely to have dentures by age 60 than those without osteoporosis (135). Conversely, postmenopausal estrogen use, which protects against osteoporosis, has been associated with decreased tooth loss (136).

In another study, both mandibular bone mass and the number of teeth were strong predictors of osteoporosis (although not predictors of other periodontal indicators such as mean pocket depth or recession) (137). This study is consistent with previous observations that severe alveolar resorption was related to low bone density of the radius of edentulous subjects (137).

Mandibular bone mass correlated with total body calcium and bone mass of the radius and vertebrae in dentate and edentulous postmenopausal women with osteoporosis (130), with the highest correlation between total body and mandibular bone mass. Thus, the mandible seems to reflect the mineral status of the entire skeleton. Calcium intake in postmenopausal osteoporotic women was also correlated with mandibular density, supporting the hypothesis that low calcium intake may contribute to reduced bone density (137). Thus, the oral healthcare professional must carefully assess an individual's mandibular bone density, which can result in early diagnosis or detection of osteoporosis.

Dentate Status

Resorption of the alveolar process is a widespread problem among patients with dentures. Remodeling of the alveolar bone occurs in response to occlusal forces associated with chewing. With the loss of teeth, the alveolar bone is no longer required for tooth support; as a consequence, bone resorption is accelerated, and bone height is diminished. Bone loss is greatest during the first 6 months following tooth extractions. The reduction in residual ridge height is more pronounced in women than in men; and resorption is greater in the mandible than in the maxilla. Severe mandibular resorption makes it difficult to construct a mandibular denture with good stability and retention. Low calcium intake may compound bone loss in denture wearers. In a small group of edentulous adults, those with the greatest loss of vertical height had lower calcium

intakes (138). Calcium supplementation for new denture wearers may help maintain calcium balance and may slow the rate of alveolar resorption. Positive calcium balance may be especially important to help preserve the integrity of the residual ridges of edentulous postmenopausal women.

Although an intact dentition is not absolutely essential to maintain nutritional health, loss of teeth or of the supporting periodontium can affect food selection and subsequent nutritional status. Periodontal disease with its associated tissue soreness, tooth sensitivity, bone resorption, and tooth mobility can lead to a preference for soft foods of low nutritional value and avoidance of foods requiring chewing. The same may be true for those with severe dental caries and those with dentures.

The number of missing teeth can affect masticatory efficiency and consequent food selection (139). The biting force and the ability to chew food to a particle size that can be swallowed is reduced in partially edentulous (fewer than 10–13 teeth per side of the mouth) or fully edentulous individuals (140). The average denture wearer's chewing ability is thought to be only about 20% that of the dentate adult (141).

Dentate status has also been associated with quality of nutrient intake (142, 143). In one study, individuals with one or two complete (upper and lower) dentures had a 20% decline in the nutrient quality of their diets compared with individuals with partial dentures or their own teeth (144, 145). Another study showed that edentulous participants ate fewer vegetables, less fiber and carotene, and more cholesterol, saturated fat, and calories than did participants with 25 teeth or more (146). Edentulousness has also been associated with gastrointestinal disorders (147), and among the frail elderly, poor oral health is associated with the involuntary weight loss resulting from protein-calorie malnutrition (148). Totally edentulous individuals seem to increase caloric intake after dentures are inserted and they adjust to the new prosthesis (149). The condition of existing teeth can also affect diet. Large carious lesions and considerable loss of periodontal attachment resulting in mobile teeth leads to a preference for soft foods of lower nutrient density and avoidance of hard or fibrous foods that require chewing.

Dentures can also affect taste and swallowing ability, especially if they are maxillary (upper) dentures. The denture covers the upper palate where some taste buds are located and thus can blunt normal taste sensitivity. An upper denture can also impede swallowing. When the upper palate is covered, it is difficult for the tongue to determine the location of food in the mouth. As a result, dentures are said to be the major cause of choking in adults (150).

The dentally impaired can maintain good nutrition by continuing to choose nutritious foods of more chewable consistency, by eating more slowly, by chewing longer, and by cooking foods and/or cutting them into bite-sized pieces.

Food-Related Injury

Thermal or mechanical injury can result from drinking hot beverages, chewing ice cubes, or puncturing oral tissues and cause tooth or mouth pain. This, in turn, may alter

an individual's food selection behavior. Fortunately, the oral tissues turn over more rapidly than other body tissues, possibly as an adaptation to just such insults. As a result, tissue repair is fairly rapid and should not cause long-term dietary problems. Tooth sensitivity is often associated with gingival recession, which is common in middle-aged and older adults. Other causes of sensitivity include toothbrush abrasion, caries, and the side effects of periodontal treatment. Tooth sensitivity sometimes can be corrected by use of over-the-counter desensitizing products.

Failure to Thrive in Children

Oral conditions are often overlooked as contributing factors to eating problems or failure to thrive (FTT) in children. Sore teeth and gums may lead a child to avoid chewing or eating. The foods they will or can eat may not provide adequate calories or nutritional value to meet their growth needs ([151](#)). If caregivers are not alerted to look for oral problems, or if the children are not receiving regular dental care, the oral implications may be missed.

Oral Surgery

In general oral surgical situations, food consumption is impaired for a relatively short period of time, and the risk of nutritional deficiency is low, except in those already at nutritional risk. A soft or liquid diet and multivitamin supplementation may be recommended. For the patient who has a wired jaw, however, eating may be totally impaired for long periods of time, and nutritional status can suffer unless appropriate dietary guidelines are provided. Often patients prefer purees of normal foods to commercial liquid supplements. Diet suggestions *must* be provided that allow these individuals to meet their caloric needs via liquid food sources alone ([152](#)).

Oral Infections and Immune Deficiency Diseases

Oral infections such as herpes simplex and oral candidiasis can result in painful oral lesions that impair the desire and ability to eat. Usually, palliative oral care and appropriate food choices (bland, easily masticated) effectively help maintain nutritional status. However, when these conditions are longstanding (e.g., in HIV-AIDS), nutritional status can be undermined, thus contributing to further virulence of the disease.

The oral cavity is a principal site of lesions associated with human immunodeficiency virus (HIV) infection, which are often painful and drastically limit the intake of nutrients at a time when nutrition is essential. These lesions include HIV-associated gingivitis and periodontitis, oral candidiasis, recurrent herpes simplex infection, xerostomia, and Kaposi's sarcoma. Curative or palliative therapy for these lesions is relatively successful in allowing normal ingestion of nutrients. Excellent reviews on the management of these lesions are available ([153](#), [154](#)). The occurrence of many of these lesions can be drastically curtailed or their severity reduced by the use of prophylactic regimens. Unfortunately, oral manifestations of HIV are often ignored until they reach crisis proportion and contribute to the anorexia-cachexia syndrome common to cancer

patients.

Crohn's disease may have oral manifestations such as ulcers, lip fissures, angular cheilitis, polypoid lesions, perioral erythema, and gingival bleeding in addition to weight loss and diarrhea. Pyostomatitis vegetans is a rare eruption of the oral mucosa that is characterized by small yellow pustules and is considered a marker for inflammatory bowel disease. In one study, oral zinc supplementation caused regression of the pyostomatitis vegetans leading to the conclusion that this oral lesion may be caused by zinc deficiency secondary to malabsorption ([155](#)).

Oral and Pharyngeal Cancers

In 1996 it was estimated that 8260 Americans would die from oral cancers. Oral cancer was projected to comprise 2% ([29,490](#)) of all 1996 estimated new cancer cases in the United States ([155a](#)). The 5-year relative survival rate for persons with oral cancers is 52%, among the lowest survival rates of the major cancers. Most of these malignant neoplasms are squamous cell carcinomas. Tobacco use and heavy alcohol consumption are considered the primary causative agents of oral cancers ([155b](#)), and a variety of consumables such as charcoal-grilled and salt-preserved foods have been implicated as well ([156](#)).

Recent evidence is mounting that several foods and food factors protect against oral carcinomas. The protective effect of liberal fruit and vegetable consumption has been the most consistent finding ([157](#)). Antioxidant nutrients, b-carotene, and vitamin E have shown oral chemopreventive effects in animal models, epidemiologic surveys ([158](#)), intervention trials to reverse premalignancies ([159](#), [160](#) and [161](#)), and prevention of malignancies in high-risk persons. In a case-controlled cohort study of 25,802 adults, serum levels of all individual carotenoids, especially b-carotene, were lower in subjects who developed oral and pharyngeal cancer, and the risks of malignancy decreased with increasing serum level of each carotenoid. Those in the highest tertile of total carotenoids had one-third lower cancer risk than those in the lowest tertile ([158](#)). In a study of cigarette smokers in the United States, b-carotene supplementation at 30 mg/day for 6 months resulted in complete or partial remission of precancerous lesions in 71% of participants ([162](#)). A study by Toma had a 44% response rate with 90 mg b-carotene daily for 6 months ([159](#)). A 60% response rate was reported in a group given 24 mg/day of b-carotene, 1000 mg/day of vitamin C, and 800 mg/day of vitamin E ([163](#)).

In laboratory and animal studies, both b-carotene and vitamin E can inhibit oral carcinogenesis and cause clinical regression of oral leukoplakia ([160](#)), which is a precursor to oral cancer. However, methodological difficulties have resulted in less definitive results in humans to date ([164](#), [165](#)).

Radiation therapy for head and neck cancers causes several conditions that can adversely affect systemic nutrition ([166](#), [166a](#)). If not treated prior to irradiation, chronic pulpal and periodontal infections can become acute because of radiation-associated changes and can lead to osteoradionecrosis. These lesions are extremely painful and difficult to treat and can impair systemic nutrition for months. Radiation therapy can also lead to oral mucositis with complications similar to those previously described for the

chemotherapeutic patient. In addition, if the radiation beam passes through the major salivary glands, fibrosis of the gland occurs, with all the resultant problems associated with xerostomia. If the salivary glands are not the primary foci of irradiation, lead shields can be individually fabricated for the patient to protect the glands from unnecessary irradiation. If the radiation beam is aimed through the muscles of mastication, fibrosis of the musculature may occur. This fibrosis results in limitation of mandibular movement, called trismus, which usually becomes evident 3 to 6 months after irradiation. Trismus makes it difficult for patients to consume a normal diet. Though it will not stop fibrosis of the musculature, physiotherapy, such as range-of-motion and isometric exercises starting prior to the onset of the fibrosis, can decrease the extent of mandibular immobility ([167](#)).

Some of the same oral lesions associated with HIV infections are also seen in cancer patients undergoing chemotherapy. The antimetabolic activity of these drugs often induces a mucositis (see also [Chapter 82](#)), rendering the tissues more susceptible to physical trauma from sharp tooth edges and hard bits of food. Ulceration, secondary infection, and painful stomatitis may result. Generally, the more intense the cytotoxic therapy, the more common the oral complications. Proper prophylactic therapy prior to chemotherapy can prevent or minimize many lesions and result in fewer problems in ingesting required nutrients ([168](#)).

Surveys show that between 60 and 64% of head and neck cancer patients are nutritionally compromised at the time of initial diagnosis ([169](#)). The amount of weight loss prior to surgery is a good predictor of the risk of developing postoperative complications. Depending on the procedure, food intake may be severely compromised after surgery, and it should be closely monitored throughout treatment. The least invasive method of providing essential nutrients to maintain weight should be used. Blended foods given by mouth are tolerated by some patients. If adequate calories cannot be obtained orally, tube or parenteral feeding must be provided (see also [Chapter 100](#) and [Chapter 101](#)); however, oral feeding should resume as soon as possible in oral cancer patients ([170](#)).

Since oral and pharyngeal cancers are very prevalent, carry extremely high morbidity and mortality rates, and are highly detectable, all healthcare providers should work closely to identify early those patients with signs and symptoms of cancer. Appropriate and timely therapy is essential to increase survival from this very detectable and often visible cancer.

Effects of Saliva on Oral Health and Nutrition

Saliva is a primary factor in both the function and maintenance of the oral cavity. In addition to being important in speech and deglutition, certain antimicrobial and nonantimicrobial systems in saliva protect both the hard and soft tissues of the mouth. Cessation or severe decrease of salivary flow from such causes as surgical removal of salivary glands, radiation therapy, and Sjögren's syndrome can lead to microbial infection of the oral cavity, rampant caries, and loss of taste acuity, as well as inability to lubricate, masticate, and swallow food. All these conditions have a profound effect on food selection and thus on systemic nutrition. In fact, significant deficiencies of fiber,

vitamin B₆, iron, calcium and zinc were found in xerostomic older adults (171). Comfort in wearing dentures depends on lubrication of the soft tissues by saliva. Patients with oral dryness retain their dentures poorly and may develop ulcerations at denture borders that make mastication difficult and painful.

It was once believed that the aging process brought with it a “natural” reduction of salivary flow, but in fact, salivary flow in healthy individuals does not decrease due to age (172). Nearly 50% of elderly subjects are taking medications that diminish salivary flow; however, though salivary flow is decreased in these individuals, it generally still does not interfere with either deglutition or maintenance of hard and soft tissues (173). Nonetheless, these patients often feel as if their mouths are dry and frequently use hard candies or gum to stimulate salivary flow throughout the day. Because most candies and gum contain fermentable carbohydrates, the constant exposure may promote root caries and altered food intake because of discomfort or loss of integrity of the dentition. Patients taking xerostomia-producing drugs should be counseled about side effects and should be advised to use candies and gums containing relatively nonfermentable sugar alcohols such as sorbitol, mannitol, or xylitol. Table 66.5 lists xerostomia-inducing drugs by class. The use of artificial saliva, though not a panacea, may benefit some of these patients. To prevent rampant caries in such individuals, aggressive home care emphasizing effective oral hygiene and daily fluoride application is usually recommended.

Analgesics	Antiinflammatory agents
Anticholinergics	Antiparkinson agents
Antidepressants	Antipsychotic agents
Antihypertensive agents	Decongestants
Systemic antihistamines/decongestants	Diuretics
Systemic bronchodilators	Gastrointestinal agents

Adapted from Levy SM, Baker KA, Semla TP, et al. *Gerodentics* 1988;4:121.

Table 66.5 Xerostomia-Inducing Drugs by Class

Acid Reflux Disorders (Gastroesophageal Reflux and Bulimia)

Both gastric reflux and self-induced vomiting observed in eating disorders (see also Chapter 93) commonly irritate oral tissues and destroy dental enamel (174). The extent of oral tissue damage depends on the frequency of the purging and cariogenicity of the diet. Because they are often the first healthcare providers to see these patients, dentists may make an early diagnosis of eating disorders. Some symptoms that may cause these patients to seek dental treatment are sensitivity to hot and cold temperatures or

air, dental pain, and concern about the appearance of their teeth.

The most obvious clinical symptom of bulimia nervosa is loss of tooth enamel and dentin on the lingual and incisal surfaces of anterior teeth and occlusal surfaces of posterior teeth. Enamel erosion is primarily caused by chronic regurgitation of the acidic contents of the stomach. Erosion may also result from frequent intake of fruit juices high in citric acid, sucking on chewable vitamin C tablets, disulfiram (Antabuse) therapy for alcoholism, or exposure to industrial acids. Contact and thermal hypersensitivity occurs when the dentin is exposed. The acidic oral environment irritates the oral mucosa, including the gingiva, palate, and pharynx. With repeated vomiting, esophageal tears may develop. The lips may become cracked, and fissures may develop at the corners of the mouth. Enlargement of the parotid glands, which are painful to palpation, may occur 2 to 6 days after vomiting. Patients with eating disorders have lower resting salivary flow rates than normal adults, which may result in xerostomia ([175](#), [176](#)).

Dental treatment must be coordinated with the primary healthcare provider. Definitive restorative treatment cannot occur until the vomiting behavior is under control. Temporary restorations are placed on eroded tooth surfaces to prevent further loss of enamel and to prevent hypersensitivity. The patient is encouraged to practice meticulous oral hygiene. Patients are cautioned against brushing immediately after vomiting, to prevent further erosion of dental enamel. Instead, a sodium bicarbonate or magnesium hydroxide rinse is recommended to neutralize acid in the mouth. Neutral pH sodium fluoride rinses (0.5%) or home application of stannous fluoride gels (0.4%) in custom trays will prevent dental erosion and enhance remineralization of teeth ([177](#)). Patients should be counseled to limit fruit juices with high citric acid content and to avoid sticky, sweet foods between meals. Foods of low cariogenicity—nuts, seeds, cheese and vegetables—are desirable snacks. If dry mouth is a problem, chewing paraffin wax, sugarless chewing gum, or sugar-free lemon drops may stimulate saliva flow.

The Aging Patient

In the past three decades, the population of individuals age 65 and up has increased by 85.8%, and the population over age 85 increased by 225% ([178](#)). The aging process involves a host of changes that can affect and be affected by the oral condition. Dental problems are considered a primary contributor to malnutrition in the elderly ([148](#)). Sore or missing teeth make it difficult to consume a normal diet. When an individual is edentulous or has ill-fitting dentures, diet quality often suffers ([145](#)), and the soft consistency of manageable foods can lead to constipation. With age, the sense of smell declines ([179](#)), often leading to increased use of cariogenic foods. It was formerly believed, on the basis of threshold studies, that advancing age produced taste loss as well, which could also contribute to decreased nutrient intake. However, these elevations in threshold are relatively small and have fewer clinical effects. The hypogeusia observed in some elderly individuals is possibly associated with specific disorders leading to taste loss, rather than being a normal component of the aging process ([180](#)). Xerostomia is common because of multiple drug use and often results in root caries. Nearly 50% of those aged 75 and older take two or more medications daily ([181](#)), and one-third to one-half of older adults may experience xerostomia ([182](#)). With between 68% of those 65 to 69 years old and 51% of those over 80 being at least

partially dentate, dental caries remains a potential problem. Root caries affects over 60% of dentate individuals, and the caries rate increases with age (183). Periodontal disease is also a problem for older adults, with approximately one-third showing evidence of severe periodontitis (183). Oral cancer is also more common with age, almost tripling between the 55- to 64-year-old group and those aged 85 or older. Tooth loss, pain, malpositioning, loss of vertical dimension, joint dysfunction, and dental prostheses can all impair mastication. In addition, social interactions surrounding eating, and subsequent nutrition can be impaired by mobile or fractured teeth and the condition and/or retention of dental prostheses (181).

Since the elderly are at particular risk of nutritional and oral problems, all health professionals are encouraged to broaden the scope of their routine screening beyond their own discipline. To accomplish this, the Nutrition Screening Initiative (a collaborative project between the American Academy of Family Physicians, the American Dietetic Association, and the National Council on the Aging) has developed simple screening questionnaires based on the major contributors to nutritional risk for use by health professionals in screening the elderly (184). There are screening forms for medical problems, drug interactions, psychosocial factors, nutrition, and oral health. When used consistently, all healthcare providers, including nutritionists and dental professionals, will be able to screen for a variety of factors contributing to nutritional risk and refer to the appropriate provider for further care.

Diabetes and Oral Health

The diabetic condition increases the risk and severity of periodontal disease. In both type I and type II diabetes mellitus, physiologic changes result in a decrease in overall resistance. Increased oral infections and *Candida albicans* are common (181). Severe periodontal problems and tooth loss are often associated with poorly controlled diabetes. In one recent study, tooth loss was significantly associated with non-insulin-dependent diabetes and obesity in adults. Functionally edentulous subjects (<6 teeth) were found to be at significantly greater risk for NIDDM than those who were partially edentulous (7–25 teeth) or dentate. Since obesity was also significantly associated with greater risk for NIDDM, this appeared to confound the relationship between functional edentulism and NIDDM (185). When diabetes is poorly controlled, frequent use of hard candies may counteract bouts of hypoglycemia. This habit, combined with the xerostomia common to diabetes, can lead to rampant dental caries.

With proper management techniques, oral health can be maintained despite the diabetes. A regimen of controlled diet, conscientious and effective oral hygiene, and topical fluoride when indicated, can maintain oral health integrity throughout life (186, 187).

SUMMARY: IMPLICATIONS FOR THE FUTURE

Observations made in recent years suggest that diet and nutrition are intimately linked to general and oral tissue health promotion and disease prevention (188). The oral condition can have a major influence on diet and ultimate nutritional status. Conversely, food choices can affect oral tissues directly and indirectly. Research findings linking

systemic nutritional factors and oral conditions in humans are expanding rapidly, complementing the traditional relationships between local dietary factors and dentition.

The discovery that people can change their eating behavior as a consequence of aggressive health promotion and disease prevention programs and that better, more sensitive measures of nutritional status exist, will have a major impact on our understanding of nutrient–oral tissue relationships and subsequent dietary intervention programs. The key role of the oral healthcare professional identifying patients at risk for systemic nutrition-related disease is essential in providing early entry into the healthcare system. In this regard, *Healthy People 2000* places nutrition and oral health in the appropriate context, articulating that lifestyle and systemic health are associated with oral health, and setting goals for achieving better oral health outcomes. The impact of nutrition on dental education and clinical practice will be profound, provided appropriate academic programs are implemented to train investigators and clinicians in nutrition and oral health science. The consequences will be nothing short of integrating dental medicine more closely into the health-care delivery system and improving public health and welfare.

MOUTH, PHARYNX, AND ESOPHAGUS

The digestive process is initiated by placing food in the mouth. Chewing and salivary secretion result in formation of a food bolus, a rounded, lubricated mass suitable for swallowing (Fig. 67.1). Movement of the bolus from the mouth to the pharynx initiates the process of swallowing. The presence of the bolus in the pharynx activates glossopharyngeal and vagal fibers connected to the swallowing center in the brainstem (1). The swallowing center coordinates initiation of swallowing, opening the upper esophageal sphincter, peristalsis in the upper esophagus, and momentary cessation of breathing. The presence of food in the mouth also activates neural pathways that result in salivary secretion, gastric acid secretion, pancreatic secretion, contraction of the gallbladder, and relaxation of the sphincter of Oddi. Thus, although the mouth and pharynx have little direct role in digestion and absorption of nutrients, neurally mediated events initiated by the presence of food in the mouth and pharynx are important in coordinating the initial phases of the integrated response of the entire gastrointestinal (GI) tract to a meal.

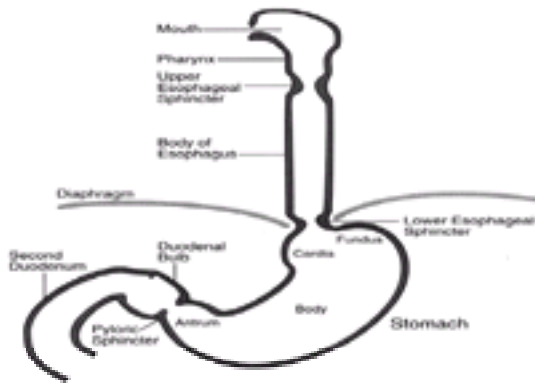

Figure 67.1. Anatomy of the upper gastrointestinal tract in man.

Human saliva contains two digestive enzymes, salivary amylase and lingual lipase. Lingual lipase has a limited role in digestion of dietary triglycerides; however, salivary amylase plays an important role in digestion of dietary starches. Although salivary amylase is secreted with the saliva into the mouth, little starch digestion occurs in the mouth because of the limited time of interaction of food with saliva there. Most of the enzymatic activity of salivary amylase occurs in the stomach, where there is a much longer time for it to interact with dietary starch.

After leaving the pharynx, the food bolus passes through the upper esophageal sphincter to enter the esophagus (2, 3). In the resting state, both the upper and lower esophageal sphincters are closed. After initiation of a swallow there is increased pressure in the pharynx and relaxation of the upper esophageal sphincter. This combination of events pushes the food bolus from the pharynx into the upper esophagus. Then the upper sphincter closes, and a peristaltic wave pushes the bolus through the esophagus. The lower esophageal sphincter relaxes after initiation of the swallow and contracts again after the bolus passes through it.

GASTRIC MOTILITY

Gastric Motility after a Meal

After a meal, the stomach relaxes, and its volume increases to accommodate the ingested food. In addition to this reservoir function, the stomach also grinds food into smaller particles through the action of the antral musculature. Finally, the stomach releases the gastric contents into the duodenum in a regulated fashion. The net effects of the motor activity of the stomach are to prepare food for digestion and absorption in the intestine by reducing it to small particles and to present these particles to the intestine at a rate that facilitates digestion and absorption by allowing maximal mixing with pancreatic and biliary secretions and maximal contact time with the small-intestinal

mucosa (4).

Motility is markedly different in the proximal and distal parts of the stomach (5). The proximal stomach, which includes the fundus and the upper part of the body, relaxes as it is filled with food. This relaxation increases gastric volume without increasing intragastric pressure. Relaxation of the proximal stomach in response to a meal includes both “receptive relaxation” and “gastric accommodation” (5, 6). Receptive relaxation is a reduction in proximal gastric tone in response to swallowing; it is mediated by neural pathways and occurs within 10 seconds of swallowing. In contrast, “gastric accommodation” is the reflex relaxation of the proximal stomach in response to gastric distention; this process is mediated by vagovagal reflexes. The vagal afferents are activated by the effects of gastric distention on pressure receptors in the gastric wall. The afferent messages are processed in the brain in the dorsal vagal complex of the medulla. This processing in turn initiates vagal efferent activity, which elicits effects in the stomach and other portions of the GI tract. In the stomach, the vagal efferent activity causes muscle relaxation in the proximal stomach (gastric accommodation), and muscle contraction in the antrum; it also induces secretion of gastric acid, pepsinogen, and gastrin. Vagal efferent activity induced by gastric distention also causes increased enzyme secretion in the pancreas, contraction of the gallbladder, and relaxation of the sphincter of Oddi.

The period of relaxation in the proximal stomach after a meal is followed by a period of contraction, which increases intragastric pressure. The proximal stomach produces slow, sustained tonic contractions to push the contents of the meal into the distal stomach. The intragastric pressure created by the tonic contraction of the proximal stomach increases the rate of gastric emptying, especially the emptying of liquids. Contraction of the proximal stomach is regulated by neural and hormonal input; among the hormones that influence this process are cholecystikinin (CCK), motilin, and gastrin.

The distal stomach includes the lower part of the body and the antrum. In contrast to the tonic contractions of the proximal stomach, the contractions of the distal stomach are phasic. (In “tonic” contractions, the muscle contracts over a long period of time; in “phasic” contractions, there is a rhythmic contraction and relaxation.) Tonic contractions of the proximal stomach influence the rate of gastric emptying, whereas phasic contractions of the distal stomach grind food into small particles. Phasic motor activity in the distal stomach migrates as a ring contraction, increasing in amplitude as it approaches the pylorus; these contractions can generate intragastric pressures as high as 100 mm Hg. Phasic contractions originate in an area of spontaneously depolarizing muscle in the proximal body termed the *gastric pacemaker*; depolarization travels in a wavelike manner from the pacemaker through the distal body and the antrum. The pattern of phasic antral contractions seen in the fed state begins 5 to 10 minutes after the ingestion of a meal and persists as long as food remains in the stomach. Fluoroscopic studies demonstrate that antral contractions first propel ingested material distally toward the pylorus. The pylorus is closed tightly enough that larger food particles cannot pass. The ingested material is then directed back from the distal antrum into the more proximal stomach, and the process is repeated (7). This to-and-fro action mixes and grinds solid food.

The pylorus is a sphincter that sits at the junction of the antrum and the duodenal bulb. It regulates the flow of intraluminal contents from the stomach into the duodenum (8). The rate of gastric emptying is determined by the pressure generated in the proximal stomach and by the size of the pyloric opening; the higher the pressure and the larger the opening, the faster the rate of emptying. During feeding, the pylorus acts as a sieve that impairs the emptying of particles greater than 1 mm in diameter (9). If the stomach is presented with a meal that is a mixture of small (<1 mm) and large (>2 mm) particles, the pylorus passes the smaller ones and retains the larger ones. Antral grinding of the larger particles reduces them to a size that can pass through the pylorus.

Gastric Motility during Fasting

In addition to the motor activity seen in the stomach in response to a meal, there is also activity in the fasting state. The migrating motor complex (MMC) clears the stomach and small intestine of undigested food particles and other particulate debris (10). The MMC has three phases of activity that repeat at periods of 90 to 100 minutes. Phase I, which occupies 40 to 60% of the cycle, is a period of little phasic motor activity. Phase II, which lasts 20 to 30% of the cycle length, is a period of irregular contractions of various amplitudes. Phase III lasts 5 to 10 minutes and is marked by high-pressure, propagative waves accompanied by pyloric relaxation. These waves clear undigested food particles from the stomach. Phase III is mediated by cyclic release of motilin from duodenal mucosal cells.

GASTRIC EMPTYING

Nonnutritional liquids, nutritional liquids, and solids each empty from the stomach at different rates, and these rates are regulated by different mechanisms (5, 11). Nonnutritional liquids, such as water or isotonic saline, empty rapidly from the stomach. The volume emptied into the duodenum is a constant fraction of the volume of liquid in the stomach. Thus, the initial rate of emptying of a 400-mL bolus of water is twice that of a 200-mL bolus; half the volume of a bolus of water empties from the stomach in about 10 to 15 minutes (12). The rate of emptying of liquids from the stomach is determined by the tonic contractions of the proximal stomach but is also influenced by the degree of pyloric resistance and the capacity of the duodenum to receive a volume of fluid.

When nutrients such as glucose are present in a liquid meal, the rate of gastric emptying is slowed in response to feedback from the small intestine (13). Neural reflexes from the small intestine modulate contraction of the muscles of the proximal stomach and thus affect intragastric pressure and the rate of gastric emptying. The rate of emptying of a liquid from the stomach is influenced by its caloric concentration, osmolality, fat content, and pH. Liquids of high caloric density empty more slowly than those with fewer calories per unit volume. The emptying of nutrients occurs at a rate that delivers approximately 200 kcal/h into the intestine. Carbohydrates and amino acids modulate intestinal nutrient delivery through their effects on small intestine osmolality. Nutritional liquids of high osmolality empty more slowly than those of low osmolality. A bolus of 300 mL of 0.1 M glucose empties from the stomach three times as fast as a bolus of 300 mL of 0.3 M glucose (14). The effects of fats on gastric emptying are

complex. Liquid fats empty from the stomach more slowly than aqueous liquids. Fats bind to solid food particles and float on the surface of aqueous gastric secretions, which slows their emptying from the stomach. The rate of liquid emptying from the stomach is also influenced by pH; acid solutions empty more slowly than neutral solutions. This reflex prevents acid solutions from entering the duodenum at a rate high enough to lower the pH of the duodenal contents and thus diminish the activity of pancreatic enzymes. Slowing the release of acid solutions from the stomach provides more time for neutralization by bicarbonate in biliary and pancreatic secretions.

Digestible solids empty from the stomach at a slower rate than liquids. Food particles need to be reduced in diameter to a maximum of 1 to 2 mm to allow passage through the pylorus (15). Small particles have a higher surface:volume ratio than large particles, which makes more of their contents accessible to the action of digestive enzymes in the intestine. Digestible solids empty after an initial lag phase that persists for up to an hour after the end of a meal. During the lag phase there is extensive mixing and grinding of solid food, but little or no solid material exits the stomach. The smaller the food particles, the shorter the lag phase. After this initial grinding period, the particles empty at a linear rate that is independent of the volume remaining in the stomach. Food particles larger than 2 mm in diameter that cannot be further reduced in size are emptied from the stomach by active contraction during phase III of the MMC. These strong contractions also clear foreign bodies from the stomach. In adults, coins as large as a quarter are cleared through the pylorus by the MMC.

DISORDERS OF GASTRIC EMPTYING

Most disturbances of gastric motor activity delay gastric emptying (16). Interference with production of normal gastric tone in the proximal stomach delays emptying of both liquids and solids, whereas disorders that interfere with grinding activity in the antrum result in delayed emptying of solids but normal emptying of liquids. The symptoms associated with delayed gastric emptying are nausea, vomiting, early satiety (feeling full after eating a small portion of a normal meal), weight loss, and abdominal distention. Delayed gastric emptying can result in vomiting of recognizable food particles many hours after ingestion of a meal. Delayed gastric emptying due to disorders of gastric motility may be difficult to distinguish from that due to gastric outlet obstruction by ulcer, scarring, or tumor; the two conditions cause the same set of symptoms.

Delayed gastric emptying is seen in a variety of conditions. Certain drugs can delay gastric emptying; among these are opiates, tricyclic antidepressants, phenothiazines, and calcium channel blockers. Alcohol, tobacco, and marijuana can also delay gastric emptying. Delayed gastric emptying is seen in anorexia nervosa. Malnutrition itself can delay gastric emptying; treatment of patients with anorexia nervosa with dietary supplements to induce weight gain improves gastric emptying.

The most common cause of clinically significant delayed gastric emptying is diabetic gastroparesis (17). This is especially common in insulin-dependent diabetes of long standing and is often associated with peripheral or autonomic neuropathy. At least 25% of insulin-requiring diabetics who have had their disease for 10 years, will have delayed emptying of liquids and/or solids (18). For some patients with long-standing

insulin-dependent diabetes, gastroparesis is a major cause of morbidity; severe upper abdominal discomfort, frequent vomiting, and substantial weight loss are common. The pathogenesis of the delay in gastric emptying in diabetes is not well understood, but there is evidence that it results primarily from neuropathy of the autonomic nervous system, with vagal neuropathy being the dominant abnormality (19). Reduced vagal input to the distal stomach results in reduced antral contractions. Pyloric dysfunction also occurs in diabetes and results in increased pyloric resistance and impairment of emptying. Evaluation of diabetic gastroparesis is difficult, and most patients are treated on the basis of suggestive symptoms in an appropriate clinical setting. Delayed gastric emptying may be suspected from retained gastric contents after a fast for an upper GI examination or endoscopy.

A radionuclide gastric-emptying study is the most sensitive clinical test. Solid-phase radionuclide tracers are normally used, as patients with delayed emptying for either liquids or solids may be detected by this method. Radionuclide emptying studies have a broad range of normal, and the results need to be carefully standardized. The correlation between symptoms and radionuclide studies is not good; some asymptomatic patients have markedly abnormal radionuclide studies, and some patients with severe symptoms have relatively normal studies.

The first approach to symptomatic relief in diabetic gastroparesis is better control of the blood sugar; hyperglycemia itself is thought to have adverse effects on gastric motor function. Other approaches include removing offending medications, increasing the liquid content of the diet, and reducing dietary fat. Over the past few years, a number of drugs that stimulate gastrointestinal motility have become available. Although some of these prokinetic agents are effective in diabetic gastroparesis, their efficacy is variable and tends to diminish over time. Metoclopramide has dopamine-antagonist and cholinergic-enhancing effects (20). The cholinergic effects increase the amplitude and frequency of antral contractions and relax the pylorus. Thus, metoclopramide produces an effect that mimics phase III of the MMC. The central dopamine antagonism of metoclopramide can cause side effects that mimic Parkinson's disease. The prokinetic effect of metoclopramide on the stomach is diminished after about 4 weeks of therapy. Cisapride accelerates emptying of both liquids and solids by enhancing the coordination of gastric and duodenal motor events (21). Like metoclopramide, cisapride produces a phase III-like effect through acetylcholine release. The prokinetic effects of cisapride are more sustained than those of metoclopramide but still diminish after 6 months. In contrast to metoclopramide, which activates motility primarily in the stomach and proximal small intestine, cisapride activates motility in the entire GI tract from esophagus to colon; as a consequence, diarrhea is its major side effect.

Accelerated gastric emptying occurs most commonly in patients who have had gastric surgery for peptic ulcer disease. This topic is discussed below in the section "[Nutrition and Gastric Surgery](#)."

GASTRIC SECRETION AND DIGESTION

The major organ for digestion and absorption of nutrients is the small intestine. The stomach primarily prepares ingested food for digestion and absorption in the small

intestine by grinding it into smaller particles and regulating its flow into the small intestine for optimal digestion and absorption. Although the intestine is the major digestive organ, appreciable digestion of carbohydrates, protein, and fats occurs in the stomach (22). Moreover, the stomach is the source of intrinsic factor, a protein required for absorption of vitamin B₁₂ in the ileum. Although the stomach facilitates digestion of macronutrients, its contribution to digestion is not absolutely required. Patients who have undergone total gastrectomy can maintain normal nutritional status on a regular diet despite the absence of the stomach. The only exception to this is the eventual requirement for administration of parenteral vitamin B₁₂ to compensate for the malabsorption of dietary vitamin B₁₂ due to the absence of intrinsic factor. In patients with gastrectomies, the major morbidity is not the absence of the stomach as a digestive organ but, rather, the absence of the stomach as a food reservoir and regulator of the flow of ingested food into the small intestine.

Digestive events in the stomach are tied to the functional capacity of the different populations of cells forming the gastric epithelial lining. The gastric lining consists of thick folds, each of which contains microscopic gastric pits (23). Four or five gastric glands drain into each of these pits. The mucosa of the body and fundus of the stomach contains oxyntic glands (Fig. 67.2). (The term *oxyntic gland* comes from the oxyntic, or parietal, cell, which is a prominent component of these glands.) Oxyntic glands are lined by parietal cells that secrete gastric acid (HCl) and intrinsic factor and by chief cells that secrete pepsinogen and gastric lipase. In contrast, the pyloric glands that form the mucosa of the antrum contain almost no parietal cells or chief cells but, rather, contain mucus-secreting cells and G cells, which produce the hormone gastrin.

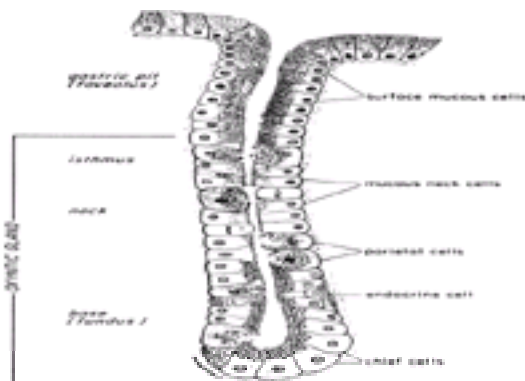

Figure 67.2. Gastric gland from the body of a mammalian stomach. (From Ito S, Winchester RJ. J Cell Biol 1963;16:541–78, with permission.)

Gastric Acid Secretion

The physiologic function most closely associated with the stomach is the production of

gastric acid (22). The physiologic stimulus for gastric acid production is food; although gastric acid is produced in response to a meal, it plays a relatively minor role in digestion. Patients treated with drugs that inhibit gastric acid secretion by blocking the parietal cell proton pump do not have clinically significant problems with maldigestion or malabsorption. Nonetheless, gastric acid does play some role in digestion. Conversion of pepsinogen to pepsin requires an acid pH that can only be achieved by gastric acid secretion. Moreover, pepsins, which break down proteins into peptides, have pH optima in the acid range. Gastric lipase cleaves triglycerides to yield free fatty acids. The pH optimum for gastric lipase is between 4 and 5.5; it is much less active at the neutral pH seen in the absence of gastric acid secretion. However, neither pepsins nor gastric lipase are required for digestion of food. The functional reserves of pancreatic peptidases and pancreatic lipase are large enough to make up for the loss of the contribution of pepsins and gastric lipase to digestion. Gastric acid secretion is important in the absorption of iron, particularly nonheme iron. Ferric salts are insoluble at neutral or slightly acid pH, whereas ferrous salts are much more soluble in this pH range (24). In acidic solutions ($\text{pH} < 4$), ferric salts dissolve and can be reduced to ferrous salts, which remain in solution at the neutral pH found in the duodenum where they are absorbed.

Gastric acid is secreted constantly, but the rate of secretion is increased with meals. During fasting, gastric acid is secreted at about 15% of its maximal rate. The food-stimulated increase in gastric acid secretion occurs in three phases: cephalic, gastric, and intestinal (22). The cephalic phase refers to the stimulation of gastric acid secretion by the smell, taste, or even thought of food. Gastric acid secretion induced by chewing or swallowing food is also part of the cephalic phase. The cephalic phase is mediated primarily by the vagus nerve; vagotomy abolishes this phase of gastric acid secretion. When food enters the stomach, gastric acid secretion is stimulated. One mechanism for the gastric phase of acid secretion is distention of the stomach by food, which activates stretch receptors in the gastric wall and thus initiates gastric acid secretion mediated by a vagovagal reflex. A second mechanism is activation of chemoreceptors by amino acids and peptides formed by partial digestion of dietary proteins by pepsins. The entry of partially digested food into the small intestine initiates the intestinal phase of acid secretion. This process is mediated by distention of the small intestine and by the presence of proteins and the products of protein digestion in the partially digested food. In contrast to the cephalic and gastric phases of gastric secretion, the intestinal phase is not mediated by vagal reflexes; the intestinal phase remains intact even after vagotomy.

Gastric acid secretion increases at the start of a meal; within 1 hour after the end of the meal, the rate of acid secretion reaches a peak that is near the maximal capacity of the stomach to secrete acid. Two to 3 hours after a meal, gastric acid production is reduced by the presence of acid and the products of digestion in the stomach and intestine. Although the rate of acid secretion peaks within the first hour after a meal, the total amount of acid in the stomach rises for an additional 1 to 2 hours.

The presence of acid in the gastric antrum shuts down gastrin release and thus reduces acid secretion. The presence of acid, fat, or hyperosmotic solutions in the duodenum inhibits gastric acid secretion. The inhibition of acid secretion by duodenal contents is at least partially humoral, because it persists after vagotomy. A number of hormones

including somatostatin, secretin, and CCK have been suggested as possible mediators of the inhibition of gastric acid secretion by duodenal contents.

Gastric acid secretion by parietal cells is regulated by acetylcholine, gastrin, and histamine (25). Parietal cells have specific receptors for each of these ligands. Acetylcholine is a neurotransmitter produced by the vagus and other parasympathetic nerves. Gastrin is a peptide hormone produced by G cells in the gastric antrum. Gastrin secretion is stimulated by specific nutrients in the gastric lumen, which include amino acids and small peptides but not glucose or fat. Gastrin release is also stimulated by a high pH in the gastric lumen. Histamine is secreted by mucosal mast cells and enterochromaffin-like cells. Drugs that block the binding of histamine to its receptor on parietal cells (H₂ receptor antagonists) are potent inhibitors of gastric acid secretion.

Gastric Protein and Fat Digestion

In the stomach, dietary proteins are cleaved into smaller peptides by the action of pepsins, proteases that are maximally active at low pH (pH 1.5–2.5) and are inactivated by neutral or alkaline conditions (26). Pepsinogens, the inactive precursors of pepsins, are secreted by chief cells and are autocatalytically cleaved to form pepsins under acidic conditions (pH < 6). Secretion of pepsinogens by chief cells, like secretion of gastric acid by parietal cells, occurs in response to the ingestion of food. Gastrin and acetylcholine are important mediators of pepsinogen secretion in response to a meal. Chief cells store pepsinogen in apical granules; stimulation by gastrin or acetylcholine results in the exocytosis of these granules. Parallel stimulation of parietal cells provides the acid environment required for cleavage of pepsinogens to form pepsins. Pepsins cleave dietary proteins into peptides but do not generate large amounts of free amino acids; they only cleave about 10 to 15% of the peptide bonds in food proteins. Peptides generated by pepsin digestion of dietary proteins act as signals for secretion of gastrin by G cells in the antral mucosa. These peptides are further hydrolyzed to amino acids by the action of pancreatic peptidases in the intestine.

The stomach contributes to fat digestion both by emulsifying dietary fats to prepare them for digestion by lipases in the intestine and by lipolysis of ingested fats by gastric lipase (27). Emulsification of dietary fats is initiated in the stomach by body heat, which liquifies most dietary fat, and by the grinding action of the antrum, which promotes the interaction of dietary lecithin with dietary triglyceride droplets. Gastric lipase, like pepsinogens, is secreted by chief cells in the oxyntic mucosa; its secretion is regulated by the same mechanisms that regulate secretion of pepsinogens. Gastric lipase differs from pancreatic lipase in several important respects. It has a pH optimum of 4 to 5.5, as opposed to the neutral pH optimum of pancreatic lipase. Moreover, gastric lipase acts preferentially on the 3-position long-chain fatty acid esterified on triglyceride. Thus, the major products of gastric lipase action on triglycerides are free fatty acids and diglycerides. Also, gastric lipase is activated by bile salts, whereas pancreatic lipase is not. Under normal circumstances, gastric lipase accounts for the digestion of 20 to 30% of total dietary fats, with pancreatic lipase accounting for most of the rest. When pancreatic lipase is present in decreased amounts, as in patients with pancreatitis or surgical resections of the pancreas, gastric lipase can account for a considerably larger percentage of lipid digestion. Gastric lipase is also important in lipid digestion in

neonates, because pancreatic lipase secretion is quite limited during the first weeks of life.

Intrinsic Factor

Intrinsic factor is secreted from parietal cells in response to stimulation by gastrin and acetylcholine (28). Dietary vitamin B₁₂ (cobalamin) can only be absorbed in the ileum when complexed with intrinsic factor. Other luminal proteins can also bind cobalamin; in the acidic environment of the stomach, cobalamin preferentially binds to R protein, a protein secreted in saliva, rather than intrinsic factor. In the duodenum and jejunum, salivary R protein is degraded by pancreatic proteases, and cobalamin is released. In the neutral pH of the small intestine, cobalamin preferentially binds to intrinsic factor. The intrinsic factor–cobalamin complex is then bound to a specific ileal receptor and absorbed. Even though the stomach secretes intrinsic factor in excess, a partial gastrectomy (especially one that involves resection of a significant portion of the body) may result in substantial loss of intrinsic factor secretory capacity, with clinically significant effects on cobalamin absorption. In the complete absence of intrinsic factor secretion (e.g., after total gastrectomy), dietary cobalamin is not absorbed. The very large stores of cobalamin in the liver prevent development of the clinical manifestations of cobalamin deficiency for 3 to 6 years after gastrectomy. In addition to total or partial gastrectomy, the other common cause of intrinsic factor deficiency is pernicious anemia, a disease that typically affects elderly Caucasians. It is characterized by atrophy of the oxyntic mucosa with resultant loss of gastric acid and intrinsic factor secretion. Over a period of years, the absence of intrinsic factor leads to clinical cobalamin deficiency. Patients with pernicious anemia and those with total gastrectomy should receive parenteral cobalamin once a month. In patients with partial gastrectomies, the risk of cobalamin deficiency is great enough that either the serum cobalamin level should be monitored carefully or the patient should be placed on prophylactic vitamin B₁₂ therapy.

DIET IN GASTROESOPHAGEAL DISEASES

Diet in Gastroesophageal Reflux Disease (GERD)

GERD is irritation and inflammation of the esophagus in response to reflux of gastric acid into the esophagus (29). In normal individuals, reflux of gastric contents into the esophagus is largely blocked by the lower esophageal sphincter (LES) at the junction of the esophagus and stomach. The LES is normally closed except during swallowing. Despite the presence of the LES, some reflux of gastric contents into the esophagus occurs in normal individuals. This reflux elicits esophageal contractions that push the refluxed gastric contents back into the stomach. GERD occurs when reflux of gastric contents into the esophagus occurs with excessive frequency or in excessive volume or if the refluxed gastric contents fail to elicit esophageal contractions to push them back into the stomach. When too much gastric acid is in contact with the esophageal mucosa for too long a time, the individual may experience heartburn. In milder cases of GERD, the patient experiences heartburn but the esophageal mucosa remains endoscopically and histologically normal. In more severe cases, the refluxed gastric contents cause the esophageal mucosa to become ulcerated. Healing of these esophageal ulcers can

result in stricturing of the esophagus and thus difficulty swallowing. Among the factors that contribute to GERD are an excessive volume of acidic contents in the stomach, looseness of the LES, and motility disorders in the esophagus that impair its ability to generate a coordinated contraction in response to reflux of gastric contents. The amount of acid refluxed, the severity of heartburn, and the damage to the epithelium do not always correlate. Sometimes, severe heartburn is seen in the absence of mucosal injury, or severe injury is seen in patients with minimal heartburn.

GERD is treated with drugs, physical measures, and diet. The drugs used to treat GERD are those that decrease gastric acid secretion (H₂ receptor antagonists and proton pump inhibitors), those that neutralize gastric acid (antacids), and those that enhance gastric emptying (metoclopramide and cisapride). One physical measure used to treat GERD is elevation of the head of the bed to keep gastric acid in the stomach and out of the esophagus during sleep.

Diet affects GERD in several ways. If the esophageal mucosa is damaged and sensory pain fibers are exposed or sensitized, acidic foods such as orange juice or tomato juice may elicit pain on swallowing. The more important impact of diet on GERD involves the effects of food on LES pressure and gastric acid secretion, which depend on both the kinds of food consumed and the timing of their ingestion. The amount of gastric acid in the stomach reaches a maximum 2 to 3 hours after a meal. When an individual is in the upright position, gravity keeps gastric acid in the lower portions of the stomach; however, reclining allows gastric acid to enter the upper part of the stomach where it can more easily reflux into the esophagus. Patients with GERD frequently complain that their symptoms worsen if they lie down after eating. Thus, patients with GERD should be told not to eat within 3 hours before going to bed. Alcohol, chocolate, and fatty foods have been implicated in relaxing the LES. In normal individuals, coffee tightens the LES; however, in patients with GERD it does not. Moreover, coffee and alcohol both increase gastric acid secretion. Thus, a bad combination of events for a patient with GERD is a large fatty meal eaten late in the evening and accompanied by alcohol, coffee, and chocolate.

Diet in Peptic Ulcer Disease

Peptic ulcer disease includes both gastric and duodenal ulcers (30). For many years, gastric acid secretion was thought to play a major role in the pathogenesis of peptic ulcer disease; however, recent studies have identified *Helicobacter pylori* as a causal agent for many, if not most, cases of peptic ulcer disease. Aspirin and other nonsteroidal antiinflammatory drugs play a part in the causation of many other cases of peptic ulcer disease. Although gastric acid does not have a primary causal role in the vast majority of cases of peptic ulcer disease, it does play a causal role when secreted at extremely high rates, as is seen in Zollinger-Ellison syndrome.

Although gastric acid does not play a primary causal role in the development of most cases of peptic ulcer disease, inhibition of gastric acid secretion is therapeutic. Both H₂ receptor antagonists, which inhibit gastric acid secretion by blocking the histamine receptor on parietal cells, and proton pump inhibitors, which inhibit the parietal cell pump that secretes hydrogen ions into the gastric lumen, are therapeutic in peptic ulcer

disease. Although these drugs that profoundly inhibit gastric acid secretion are therapeutic in peptic ulcer disease, there is no evidence that dietary manipulations that modulate gastric acid secretion are therapeutic.

Many ulcer patients remark that certain foods, particularly spicy foods, cause them epigastric discomfort, but there is no evidence that these foods cause peptic ulcer disease. Moreover, no causal role in peptic ulcer disease has been demonstrated even for foods known to be potent inducers of gastric acid secretion, such as milk, alcohol, and coffee. Just as there is no evidence for a causal role for diet in peptic ulcer disease, there is no evidence that diet influences the rate of ulcer healing. Many ulcer patients have been told to avoid alcohol, coffee, and other potent secretagogues, yet there is no evidence that these dietary factors, at least when taken in moderate quantities, retard ulcer healing. There are theoretical reasons to limit the consumption of alcohol, in particular, in patients with peptic ulcer disease. Beer and wine, even in modest amounts, induce near-maximal gastric acid secretion without providing any significant buffering capacity. There has been some interest in the potential role of dietary fiber in peptic ulcer disease; some studies suggest that the incidence of recurrence of peptic ulcer disease is higher in patients on low-fiber diets than in those on high-fiber diets (31).

Earlier in this century, diet management played a prominent, if unsubstantiated, role in the management of peptic ulcer disease. Patients were placed on bland diets and encouraged to consume small amounts of food frequently throughout the day. Pureed food was recommended to avoid mechanical irritation of the healing ulcer. Milk was a major component of these ulcer diets. These diets were based on the clinical observation that eating relieved ulcer pain and the laboratory observation that food, especially high-protein food, buffered gastric acid. Although these regimens were widely used for several decades, there was no scientific evidence to support their use. Controlled trials in the 1950s demonstrated no benefit of these ulcer diets to either the rate of ulcer healing or relief of symptoms compared with regular diets (32).

NUTRITION AND GASTRIC SURGERY

Surgery and Gastric Emptying

Two commonly performed surgical procedures for peptic ulcer disease are truncal vagotomy and pyloroplasty, and truncal vagotomy and antrectomy (for discussion of gastric surgery for cancer, see [Chapter 82](#)). Truncal vagotomy is cutting the main trunks of the vagus nerve on each side of the distal esophagus. Vagotomy is part of the surgical treatment of peptic ulcer disease because it eliminates the neural components of the stimulation of gastric acid secretion. However, truncal vagotomy also eliminates neural input to the antral musculature and thus reduces antral contractions and delays emptying of solids from the stomach. Truncal vagotomy also impairs relaxation of the pylorus, which further impairs gastric emptying. To compensate for these effects, truncal vagotomy is often accompanied by pyloroplasty, which is a surgical revision of the pylorus that makes it incapable of acting as a barrier to the emptying of gastric contents. A vagotomy and pyloroplasty results in accelerated emptying of liquids, whereas the

emptying of solids is frequently slowed (34).

Vagotomy and antrectomy is a more aggressive surgical procedure for peptic ulcer disease. Antrectomy is the resection of the antrum and pylorus; resection of the antrum removes the gastrin-secreting portion of the stomach and thus eliminates the gastrin-dependent component of the stimulation of gastric acid secretion. There are two operations for attaching the gastric remnant to the intestine after antrectomy. In the Billroth I, the gastric remnant is anastomosed to the duodenal bulb, and the flow of gastric contents is directly into the bulb. In the Billroth II, the gastric remnant is anastomosed to the jejunum; in this procedure, gastric contents bypass the duodenum and proximal jejunum. A vagotomy and antrectomy results in rapid and unregulated entry of gastric contents into the intestine; it also allows solid food particles to enter the intestine without having been reduced in size by antral grinding. With an antrectomy, the intestine sees the sudden entry of a large volume of liquids and unground solids after a meal rather than the slow regulated presentation of liquids and finely ground particles seen with an intact stomach. The larger the gastric resection, the more severe the problems with rapid entry into the intestine.

The highly selective vagotomy, or proximal gastric vagotomy, is a surgical procedure for peptic ulcer disease that is designed to reduce gastric acid secretion without interfering with antral motility. In a standard truncal vagotomy, the vagal input to gastric secretion and to antral contraction is lost. Truncal vagotomy also eliminates vagal innervation of the gallbladder, pancreas, and small intestine. In a highly selective vagotomy, the vagal branches going to the body of the stomach are cut, while the branches going to the antrum are not. This results in decreased acid secretion without impaired antral motility, thus eliminating the need for a pyloroplasty and the associated rapid gastric emptying (35). This procedure also spares the vagal innervation of the gallbladder, pancreas, and small intestine.

Dumping Syndrome

A vagotomy and pyloroplasty results in rapid entry of liquids into the intestine, whereas vagotomy plus antrectomy results in rapid entry of both solids and liquids. When nutrients empty from the stomach and enter the intestine in a rapid and unregulated fashion, the digestive and absorptive capacity of the intestine can be overwhelmed. The symptom complex induced by accelerated gastric emptying is termed the *dumping syndrome* (34). Diarrhea, abdominal pain, and the symptoms associated with hypoglycemia (diaphoresis, palpitations, weakness) are prominent components of the dumping syndrome. In response to rapid entry of a hypertonic meal into the intestine, water enters the intestinal lumen through the intestinal wall in an attempt to make the intestinal contents isosmotic. The sudden influx of the meal and water into the proximal intestine stretches the intestinal wall, causing abdominal distention and pain. Diarrhea results from the inability of the intestine to deal with the sudden load of volume and osmoles. This early phase of the dumping syndrome may also be marked by systemic symptoms, including weakness, tachycardia, and palpitations, thought to be due to the sudden fluid shifts from the intravascular space into the intestine with the release of vasoactive substances (bradykinin, serotonin, substance P). There is also a late phase of the dumping syndrome, which is related to hypoglycemia. Rapid gastric emptying

results in rapid glucose absorption from the intestine and an abrupt increase in insulin secretion. Not infrequently, insulin is secreted in excess of the amounts required to handle the glucose load. When carbohydrate absorption abruptly ceases and insulin secretion remains high, there can be a transient episode of hypoglycemia. In the dumping syndrome, diarrhea and abdominal pain occur 30 to 60 minutes after the meal, and the symptoms of hypoglycemia occur later. Some of the symptoms (weakness and palpitations) associated with hypoglycemia in the late phase of the dumping syndrome are similar to those seen with fluid shifts in the early phase. Dietary management usually controls the symptoms of the dumping syndrome. The core of dietary management is to avoid the sudden entry of large volumes into the proximal intestine. This is achieved by eating frequent small meals and by avoiding the intake of liquids with meals. Meals should be low in osmolality; thus, simple sugars should be avoided.

Iron and Calcium

Absorption of iron and calcium is frequently impaired after gastric ulcer surgery. Iron deficiency anemia is common in patients with vagotomy and antrectomy. There are several contributing factors. Frequently, total food intake is slightly decreased, especially in patients with antrectomy. There is also decreased digestion of iron-containing foods, particularly meats. Diminished acid secretion results in a higher gastric pH, which impairs the solubility of ferric ions and diminishes their conversion to the more easily absorbed ferrous ions (24). Moreover, the duodenum is an important site for iron absorption, and gastric surgery either bypasses the duodenum (Billroth II) or causes ingested materials to pass through the duodenum rapidly (Billroth I). When all these factors are combined with the marginal iron intake prevalent in society, the result is iron deficiency anemia.

Osteomalacia is also common after surgery for peptic ulcer disease (36). Osteomalacia is marked by low serum calcium, low urinary calcium, elevated alkaline phosphatase, and elevated parathyroid hormone levels and widened osteoid seams in the bones. The clinical outcome of this process is a fracture rate that is two to three times that of the general population (37). The mechanism for osteomalacia after gastric ulcer surgery is not fully defined. In normal individuals, the duodenum is an important site for calcium absorption, and the rapid transit through the duodenum seen after gastric ulcer surgery may contribute to calcium malabsorption. However, it is not clear that calcium malabsorption per se is a major feature in the pathogenesis of osteomalacia (see [Chapter 83](#)).

Short bowel syndrome (SBS) is a collection of signs and symptoms used to describe the nutritional and metabolic consequences of major resections of the small intestine. The syndrome is characterized by diarrhea, fluid and electrolyte abnormalities, malabsorption, and weight loss. Patients who have not had intestinal resections but who have marked reduction of small bowel absorptive surface area (e.g., diffuse inflammatory bowel disease, sprue, radiation enteritis) may have the same nutritional sequelae.

LENGTH OF SMALL INTESTINE

The length of the normal small intestine varies widely among individuals. Measurement of 260 autopsy specimens found a mean length of 620 cm, with a range of 300 to 850 cm (1, 2). The discrepancy in length is secondary to both the method of measurement and the tone of the intestine when measured. While most autopsy studies report pylorus to ileocecal valve as small bowel length, operative studies report small bowel length from the ligament of Treitz to ileocecal valve (3). Loss of intestinal tone at autopsy results in overestimation of actual small bowel length compared with intraoperative measurements. Measurements from barium x-rays appear to correlate well with surgical measurements (4). Classification of SBS by the length of intestine that has been resected is generally not accurate. The length of residual small intestine best determines prognosis. Resection of 75% or more of the small intestine usually leaves a patient with 70 to 100 cm (2–3 feet) of small bowel. Patients with less than 100 cm of small bowel who do not have a colon in continuity usually require parenteral nutrition

support (5).

The proximal two-fifths of small bowel is referred to as jejunum, and the distal three-fifths as ileum (6). Adults have approximately 240 cm of jejunum, 360 cm of ileum, and 150 cm of colon. Patients with SBS, depending on the extent of surgical resection, can be classified as either those with an end-jejunostomy or end-ileostomy, or those with a small bowel in continuity with colon (7). Knowledge of this classification is important for management and prognosis.

ETIOLOGY OF SHORT BOWEL SYNDROME

Crohn's disease, mesenteric vascular disease, and malignancy are the most common causes of SBS in adults. Crohn's disease may involve many segments of the small bowel that require multiple resections over several years before the SBS is functionally significant. Venous and/or arterial occlusion secondary to primary vascular disease or an underlying coagulopathy may result in intestinal infarction and subsequent resection. The jejunioileal bypass procedure that was popular 20 years ago for treatment of morbid obesity remains a major cause of SBS. Necrotizing enterocolitis, midgut volvulus, and intestinal atresia are the major reasons for SBS in infants.

FACTORS INFLUENCING PROGNOSIS

Positive prognostic factors after intestinal resection include youth, larger length of residual bowel, proximal resection (vs. distal), presence of ileocecal valve and colon, healthy residual bowel, and small bowel adaptation (8). Children have a better prognosis after massive small bowel resection because of a usual lack of comorbid conditions and greater potential for adaptation of the remaining bowel. Distal or ileal resections result in more disability than proximal or jejunal resections because of the specialized transport mechanisms for bile salts and vitamin B₁₂ in the ileum and a slower rate of peristalsis in the ileum than in the jejunum (9). Also, ileal resections result in the removal of the "ileal brake," with more rapid transit through the stomach and proximal small bowel.

The ileocecal valve is a physiologic sphincter that controls the rate of delivery of chyme from the small bowel to the colon and prevents bacterial overgrowth in the small bowel (10). Bacterial overgrowth can cause the deconjugation of bile salts with subsequent malabsorption of fat (11). The presence of a colon not only gives added bowel length but also slows intestinal transit. The colonic bacteria ferment unabsorbed complex carbohydrates to short-chain fatty acids that provide a source of calories and trophic stimuli to the intestine (12, 13).

The colon is also an important organ of fluid and electrolyte salvage, which is more critical in patients with short bowel (14). The status of the residual intestine is an obvious factor in determining long-term prognosis in patients with SBS and probably explains why patients with Crohn's disease and radiation enteritis generally do worse than comparably aged patients with a bowel infarction and healthy remaining small

bowel.

Small Bowel Adaptation

Following intestinal resection the remaining bowel undergoes both structural and functional changes that increase nutrient and fluid absorption (15). Structural changes (villus cell hyperplasia and increased crypt depth) begin days after resection and result in increased mucosal surface area. Functional adaptation (increased brush border enzyme activity and decreased gastrointestinal motility) also promotes fluid and nutrient absorption following resection (16, 17 and 18).

The controlling mechanism(s) of gut adaptation is not totally understood. Potential stimuli include luminal nutrients, intestinal hormones and pancreaticobiliary secretions (19). Intraluminal nutrients are essential in promoting intestinal adaptation and probably work by more than one mechanism. Support for the intraluminal theory includes finding mucosal atrophy within 5 days after proximal enterectomy in dogs receiving only parenteral nutrition (20). Surgical diversion studies have shown that small bowel not receiving direct nutrient flow develops mucosal atrophy (21). The contents of the diet are also important; trophic factors include dietary fiber (22), short-chain fatty acids (23), and glutamine (24). Intraluminal nutrients may promote adaptation by a direct “bathing” effect on the mucosa and/or a stimulation of pancreaticobiliary secretions and intestinal hormones. Pancreatic and biliary secretions (PBS) appear to be important in the adaptive process. Diversion studies by Altmann et al. in which PBS were diverted to the distal small intestine resulted in distal intestinal hyperplasia (25). PBS may also help explain the proximal-distal gradient of villus height found in health. Growth hormone, insulin-like growth factor-I (IGF-I), epidermal growth factor, and insulin are peptide hormones that appear to increase mucosal hyperplasia following intestinal resection in experimental animals (26, 27). The clinical role of other hormones such as enteroglucagon, prostaglandins, neurotensin, and testosterone are less well defined. Intestinal hormones may work by stimulating the production of polyamines (putrescine, spermidine, and spermine), trophic compounds whose production is regulated by the enzyme ornithine decarboxylase (28). Polyamines are known to stimulate cell proliferation, and blockage of ornithine decarboxylase inhibits the proliferative process (28).

COMPLICATIONS

Nutritional Deficiencies

After large resections of the small intestine there is impaired absorption of most nutrients, each with characteristic clinical or biochemical findings (29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41 and 42) (Table 68.1, see also specific chapters on each nutrient). Inadequate dietary intake and loss of micronutrients in the stool contribute to the development of vitamin and mineral deficiencies. Patients with end-jejunostomies or proximal ileostomies are the most difficult to manage because of recurrent dehydration and deficiencies in electrolytes and divalent cations (Ca^{2+} , Mg^{2+} , Zn^{2+}). Particularly problematic is Mg deficiency. While Ca and Zn can be administered orally when there is adequate absorptive surface, Mg should not be because it induces diarrhea. In some

situations, Mg has to be provided parenterally. The malabsorption of macronutrients (carbohydrates, fat, protein) can result in severe weight loss and malnutrition.

Nutrient	Disease	Reference
Copper	Neutropenia, anemia, scorbutic bone lesions, ↓ ceruloplasmin, kinky hair, impaired CNS development	29, 30
Zinc	Nasolabial and perioral acrodermatitis, alopecia, ↓ T cell function, ↓ alkaline phosphatase, dysgeusia	31
Chromium	Glucose intolerance, peripheral neuropathy	32, 33
Selenium	Myalgias, cardiomyopathy, ↓ glutathione peroxidase and serum selenium	34, 35
Molybdenum	AA intolerance, tachycardia, tachypnea, central scoliosis, instability, ↓ uric acid	36
Essential fatty acids	Eczymoid dermatitis, T 20/20-4	37
Vitamin A	Night blindness, impaired dark-field adaptation	38
Vitamin E	In vitro platelet hyperaggregation and H ₂ O ₂ -induced RBC hemolysis; agranulocytosis and symptoms suggesting subacute combined degeneration (posterolesional column) in the presence of a normal serum B ₁₂ level	39
Biotin	Szary dermatitis, alopecia, hypotonia in one child	40
Thiamin	Wernicke's encephalopathy, refractory lactic acidosis, cardiac failure	41
Cobalamin (B ₁₂)	Weakness, paresthesias, diarrhea, dermatitis, megaloblastic anemia, subacute combined degeneration	42

Table 68.1 Clinical Presentation of Nutrient Deficiencies

Bile salts are required for micellar solubilization of dietary fat and fat-soluble vitamins. After ileal resections, bile salts are malabsorbed, the bile salt pool becomes depleted, and consequently, fat malabsorption occurs. In addition to the malabsorption of fat and fat-soluble vitamins, the unabsorbed fatty acids complex with divalent cations such as calcium and magnesium, decreasing their availability. When the colon is present, malabsorbed bile and fatty acids can stimulate water and sodium secretion from the colonic mucosa and induce diarrhea, thus aggravating the clinical situation.

Most water-soluble vitamins are absorbed in the proximal jejunum. With the exception of vitamin B₁₂ and folate, deficiencies of water-soluble vitamins are rarely seen in SBS. Vitamin B₁₂ is absorbed by the terminal ileum after binding with intrinsic factor. When more than 60 cm of ileum has been resected, monthly B₁₂ injections are required indefinitely.

Deficiencies of trace elements such as zinc, copper, selenium, iron, chromium, and molybdenum can also occur in the short bowel patient (29, 30, 31, 32, 33, 34, 35 and 36) (Table 68.1). Oral vitamin and mineral supplements usually prevent or correct deficiencies. Zinc may be an exception, since zinc losses may be enormous in the stool, nasogastric aspirates, and fistulous drainage, and intravenous replacement is sometimes needed to restore positive zinc balance. Serum zinc levels may also be low because of low serum albumin, the major zinc-binding protein, and not necessarily reflect zinc deficiency. Patients with extensive small intestinal resections also have reduced disaccharidase enzymes, most commonly lactase. This may result in significant lactose intolerance.

Peptic Ulcerations

Gastric acid hypersecretion following small bowel resections may result in peptic ulcer disease, inactivation of pancreatic lipase, and deconjugation of bile salts (43). Increased gastric acid secretion is usually a transient phenomenon that subsides within 3 to 6 months. It may be treated with histamine-2 receptor antagonists or proton pump inhibitors (44). Surgery is seldom required, unless complications of peptic ulcers occur.

D-Lactic Acidosis

D-Lactic acid is produced by fermentation of malabsorbed carbohydrates in the colon (44). Humans lack the enzyme necessary to metabolize D-lactic acid. Increased serum levels of D-lactic acid are associated with marked metabolic acidosis with patients developing dysarthria, ataxia, and confusion (45). D-Lactate acidosis should be suspected when there is an unexplained metabolic acidosis and elevated anion gap in patients with short bowel and colonic continuity. Management is focused on carbohydrate-restricted diets and administration of nonabsorbable antibiotics that diminish D-lactate production by eliminating colonic bacteria.

Nephrolithiasis

Dietary oxalate normally binds to intraluminal calcium to form an insoluble complex that is excreted in stool. However, in SBS, calcium binds to unabsorbed fatty acids and leaves free oxalate to be absorbed from the colon (46). Malabsorbed bile salts that reach the colon increase oxalate absorption by increasing intestinal permeability (47). Hyperoxaluria and formation of oxalate stones can lead to significant renal impairment and formation of kidney stones. In addition to an increase in urinary oxalate, there are frequently very low urinary levels of stone inhibitors such as citrate and magnesium. Chronic dehydration in patients without SBS and colonic continuity usually results in the production of uric acid stones.

Cholelithiasis

Patients with short bowel have a two- to threefold increased risk of cholesterol gallstones (48). Precipitation of cholesterol occurs because of the decreased concentration of bile salts in bile secondary to ileal resections and bile salt malabsorption (49). Long-term parenteral nutrition also increases the risk of gallstones because of lack of oral intake and gallbladder stasis. The gallstones in short bowel patients receiving long-term total parenteral nutrition (TPN) are predominantly calcium bilirubinate, with cholesterol as a minor component. Bilirubin and ionized calcium levels are increased in bile in both man and the prairie dog receiving TPN (50).

TREATMENT

Optimal care for the patient with a short bowel begins in the operating room, where the surgeon, recognizing the inevitable result of extensive resection of the small intestine,

conserves as much bowel as possible, with a special effort to maintain the ileocecal valve and colon. Thereafter, medical care falls into three stages.

Stages of Medical Treatment

Stage I, the immediate postoperative period, dominated by problems with fluid and electrolyte balance, typically lasts 1 to 2 weeks. Fluid losses can exceed 2 L/day or more, which makes it very important to assess daily fluid balance and electrolytes. All patients require intravenous fluids and electrolytes to replace losses. Fluids should be infused to match losses and to maintain urine output of at least 1 L/d. Hypersecretion of gastric acid can contribute to significant intestinal fluid loss and can also inactivate pancreatic lipase, resulting in further fat malabsorption. Intravenous histamine-2 receptor antagonists can control gastric acid hypersecretion. Ranitidine (Zantac) 150 mg, or famotidine (Pepsid) 20 mg, can be given intravenously every 12 hours. Initially, diarrhea is managed by avoiding oral intake, to reduce any osmotic effects. If diarrhea exceeds 2 L/day, antidiarrheal agents can be used. Codeine in doses of 60 mg intramuscularly every 4 to 6 hours can be given. In some patients, octreotide, a somatostatin analogue, can reduce stool volume by 50% when given in a dose of 100 µg three times a day (51). Octreotide is usually reserved for patients with end-jejunostomies (<100 cm) who have more than 3 L of diarrhea per day (51). When the patient tolerates liquids by mouth, oral antidiarrheal agents can be used. Loperamide (Imodium), 16 to 20 mg/day in divided doses, or tincture of opium, 10 to 30 drops every 4 to 6 hours, can be used. Patients are usually started on clear oral liquids (small-volume isotonic feedings) when bowel sounds have returned postoperatively and stool losses are less than 2 L/day. Glucose-electrolyte solutions can be used for oral hydration. They should contain 3.4% glucose with at least 90 mmol/L of sodium (7). Oral hydration solutions are available commercially. They work by avoiding osmotic stimulation and promoting fluid and electrolyte absorption.

Stage II represents the transitional feeding period. The oral diet should be advanced slowly, using small, frequent feedings of solid food. The parenteral solution is reduced gradually as oral intake is increased. When oral caloric intake begins to exceed 1000 cal/day without worsening diarrhea, intravenous support can be reduced. There is no evidence that elemental or defined formula diets (DFDs) are more efficient than normal food in stimulating adaptation of the small bowel, and experimental evidence suggests that they may be less efficient (52, 53). It may take several weeks before the patient can completely discontinue TPN support.

Stage III begins when the patient is off parenteral nutrition, and attention to details of a permanent nutrition program becomes increasingly important.

Nutritional/Pharmacologic Treatment

Reduction of dietary fat from 90 to 100 g/day to 20 to 40 g/day was reported in early papers to decrease the number of stools, stool weight, and steatorrhea while increasing body cell mass (54). More-recent studies challenged the wisdom of low-fat diets in all patients with SBS (55). High-fat (60% of calories as fat) and low-fat (20% of calories as fat) diets were compared in crossover fashion in patients with the SBS. There were no

differences in stool volumes between patients on the two diets (55). Hence, dietary restriction of fat may be detrimental by restricting the nutrient of greatest caloric density (9 kcal/g). There is no reason to restrict fat in short bowel patients without a colon in continuity. Patients with colonic continuity may occasionally have worsening diarrhea from a high-fat diet secondary to colonic mucosal irritation from free fatty acids, which stimulate water and sodium secretion, and should then be fed a diet high in complex carbohydrates (50% of calories) and lower in fat (30% of calories).

Patients with hyperoxaluria and calcium oxalate renal stones should be treated with a low-oxalate, low-fat diet and high fluid intake. If these measures do not normalize urinary oxalate and reduce stone formation, other helpful measures include cholestyramine to bind intraluminal oxalate; calcium supplements, which increase calcium oxalate insoluble complexes; citrate (polycitra) to correct low urinary citrate levels; and parenteral magnesium to normalize urinary magnesium levels.

Fat-soluble vitamins also need to be evaluated and replaced as needed. Because of the high incidence (36%) of osteomalacia in short bowel patients (56), vitamin D therapy is often required. Serum 25-OH vitamin D levels can usually be normalized by giving oral vitamin D (i.e., Drisdol) 50,000 IU every other day as maintenance until plasma levels normalize, and then once or twice per week may suffice. Vitamin A can be replaced by an aqueous preparation (Aquasol A) and vitamin E by Liquid E. Vitamin K can be replaced by giving 5.0 mg/day orally and titrating to the frequency required to maintain a normal prothrombin time.

Of the water-soluble vitamins, vitamin B₁₂ is the one that may need to be replaced in patients with more than 60 cm of ileal resection. Since the enterohepatic circulation accounts for 10 µg/day, total malabsorption would require 300 µg/month for replacement. A monthly injection of 100 µg of vitamin B₁₂ is usually adequate. Other water-soluble vitamins can usually be maintained with a daily oral multivitamin.

Control of diarrhea is also very important in the treatment of SBS. Antidiarrheal agents should be used to decrease diarrhea and electrolyte losses. Loperamide (Imodium), 16 to 20 mg/day in divided doses, or tincture of opium, 10 to 30 drops every 4 to 6 hours, can be used. Oral histamine-2 receptor antagonists or proton pump inhibitors, such as omeprazole, can also be helpful in reducing gastrointestinal secretions and fluid losses. Sorbitol-containing elixirs should be avoided.

INTRACTABLE SHORT BOWEL SYNDROME

Home Parenteral Nutrition

In patients with intractable gut failure, home parenteral nutrition (HPN) can be life saving, and in many patients it provides the time bridge necessary for maximal adaptation to occur. HPN is designed to improve daily function of patients with gut failure by providing most or all of the daily nutrient needs through a central venous catheter. Parenteral nutrition is infused during an 8- to 12-hour overnight period, which frees the patient during the day for regular activities. Venous access is usually gained

by either implantable subcutaneous ports or silastic catheters that are placed in the subclavian vein and tunneled subcutaneously to exit low on the anterior chest wall.

The distribution of calories provided in parenteral nutrition varies, depending on what the patients eat and absorb. For patients who have to rely exclusively on HPN, 20 to 30% of total calories should be given as intravenous fat, which supplies 9 kcal/g fat and serves to prevent essential fatty acid deficiency. Patients are usually given 1.0 to 1.5 g protein/kg/day. The remaining calories are given as carbohydrate. Vitamins, minerals, and trace elements are given in TPN solutions in amounts adequate to maintain normal blood concentrations ([Chapter 101](#)).

Nutritional repletion by parenteral nutrition is dramatic. Ideal body weight is achieved in almost all patients. Measurements of visceral protein and skeletal muscle mass as well as body composition studies have confirmed nitrogen repletion. Many of these patients are also rehabilitated and return to gainful employment.

A rough estimate of the total U.S. home parenteral nutrition population in 1992 was 40,000 patients, with a major trend toward larger use in cancer patients ([57](#)). Active cancer is now the most common diagnosis, accounting for more than 40% of all new patients reported to the National HPN Registry ([57](#)).

Mortality from HPN complications has been approximately 5% ([57](#)). Outcome data have shown that HPN is safe, that the primary disease has the most impact on survival and rehabilitation, and that age is not a reason to deny HPN ([57](#)). Crohn's disease tends to have the best, and AIDS or active cancer the worst, prognosis in patients on HPN. HPN-related complications requiring hospitalization are infrequent. In the 1970s, most of the reported complications were micronutrient deficiencies and complications of carbohydrate overfeeding (e.g., hepatic steatosis). The last decade brought complications that might have been expected with increasing duration of HPN use such as venous thrombosis, chronic liver disease, cholelithiasis, and metabolic bone disease ([57](#)). Catheter-related septicemia has been the most common major complication, with coagulase-negative staphylococci, *Staphylococcus aureus*, and *Candida* being the most common organisms isolated.

Hepatobiliary dysfunction is frequent in patients receiving parenteral nutrition support and occurs more often in children. Most vulnerable are premature infants. Patients on short-term parenteral nutrition usually have mild-to-moderate elevations in transaminases and alkaline phosphatase levels. Patients on long-term HPN may develop persistent elevations in liver tests and steatohepatitis, with progressive fibrotic liver disease ([58](#)). The pathogenesis of parenteral nutrition–induced liver disease is not well understood. Theories include a high fat:carbohydrate ratio, amino acids or metabolites acting as hepatic toxins, portal endotoxemia, lithocholic acid toxicity, and carnitine deficiency. Although several attempts at preventing TPN-associated steatohepatitis have been tried, none have proven totally successful. In patients with certain HPN-related complications such as liver dysfunction and lack of venous access, small bowel transplantation may be an option.

Recently Byrne and colleagues reported that the combination of human recumbent

growth hormone, glutamine, and a high-carbohydrate, low-fat diet significantly increased nutrient absorption in an uncontrolled study of eight patients with SBS (58). Three weeks of this combination therapy resulted in a significant increase in protein, carbohydrate, sodium, and fluid absorption. In a subsequent uncontrolled study of 47 short bowel patients, the same investigators showed that 40% of treated patients remained off all parenteral support at 1-year follow-up (59). This form of therapy is thought to work by its ability to increase small bowel intestinal surface, i.e., increased villus height and crypt depth. However, it has not been shown in clinical trials that surface area is increased. Gastrointestinal motility may also be slowed with this therapy and allow increased contact time for nutrient absorption; however, this has never been documented with formal gastrointestinal transit studies. Most patients studied by Byrne et al. had colonic continuity, and since the colon can salvage calories by fermentation of carbohydrates to short-chain fatty acids, a high-carbohydrate diet may be the most important part of this regimen in those with colonic continuity. In fact, many patients can reduce their parenteral nutrition to three to four nights per week with appropriate use of diet and antidiarrheal agents alone. It remains to be determined whether such therapy as that proposed by Byrne and colleagues has long-term clinical benefit.

Surgical Treatment

The primary emphasis of surgery as it relates to SBS is to prevent intestinal resection by early diagnosis and conservative resections when possible. The two main goals of surgical treatment of SBS are to slow intestinal transit and increase intestinal surface area (60, 61).

Operations used to slow transit include construction of intestinal valves, antiperistaltic segments, colonic interposition, recirculating loops, and intestinal pacing. Clinical experience with intestinal valves is limited; complete intestinal obstruction and intussusception are concerns (61). Slowing intestinal transit by reversing segments of small intestine has been investigated. This procedure places a segment of bowel in the opposite direction of normal flow or peristalsis, which creates an antiperistaltic segment and hence slows transit, allowing added contact time for nutrient and fluid absorption. More than 30 patients have been reported in the literature, and 70% appear to have had good results. Other reports have not been so promising; these may be related to the length of the reversed small bowel segment used. Patients with short intestinal remnants are usually not able to sacrifice a 10-cm segment for reversal. Colonic interposition, both isoperistaltic and antiperistaltic, has been performed. Since colonic transit is slower than small bowel transit, this procedure slows transit and allows added contact time for nutrient absorption. Results with antiperistaltic colonic segments have been inconsistent (61). Recirculating loops are done by looping part of the small bowel, which theoretically allows luminal nutrients to be exposed to the absorptive mucosa several times before leaving the intestinal tract. However, recirculating loops are associated with high morbidity and mortality (61). Retrograde electrical pacing has been used in attempts to slow intestinal transit in dogs but has not been successful in man (62).

Operations used to increase the area of absorption include intestinal tapering and lengthening, intestinal transplantation, and growing neomucosa. Intestinal tapering and

lengthening have been reported to have good results in children (61). This procedure is done by dissecting longitudinally along the mesenteric border of the small intestine. Once transected longitudinally, the two parallel intestinal segments that result can be anastomosed end to end so that the initial dilated segment becomes a tapered segment of twice the length. More than 40 cases of intestinal lengthening procedures have been reported in children, and 10-year follow-up suggests long-term benefit. Intestinal transplantation is promising, but until improved immunosuppression is developed, graft rejection remains the obstacle. More than 100 intestinal transplants have been performed in humans over the last decade (61). Individuals with TPN-induced complications such as liver failure and poor venous access may be appropriate candidates. At this time, no operative procedure for SBS is safe and effective enough to recommend for routine use.

Inflammatory bowel disease (IBD) encompasses at least two forms of chronic intestinal inflammation: Crohn's disease (CD) and ulcerative colitis (UC) (1). The two conditions are currently defined empirically on the basis of clinical, radiologic, endoscopic, and histologic features. Debate continues as to whether these two major forms of IBD represent different manifestations of the same disease or distinct disorders with some pathogenetic and clinical similarities. The latter contention is favored by genetic and immunologic data. The natural history of IBD is variable. The observed spectrum of disease severity and nutritional impact is wide, in part related to the site, nature, and extent of intestinal involvement.

CD is a panenteric inflammatory process with focal microscopic inflammation identifiable throughout the gastrointestinal tract. The anatomic distribution of macroscopic disease varies but includes the terminal ileum more frequently than any other site. Initial patterns of localization include terminal ileal disease only (25–35% of patients), involvement of the terminal ileum and colon (35–45%), isolated colonic disease (15–25%), and, least commonly, proximal or diffuse small intestinal inflammation (5–10%). Following intestinal resection, CD almost invariably recrudesces in a new site, most commonly proximal to the anastomosis. Wherever it occurs, macroscopic disease is characteristically segmental with spared areas ("skip lesions").

The inflammation in UC is always confined to the colonic mucosa and hence is curable

by colectomy. Inflammation universally includes the rectum but extends proximally to varying degrees in a continuous fashion. Patients are typically classified as having proctitis, rectosigmoiditis, left-sided colitis, or extensive or pancolitis, depending on the length of diseased colon.

Many nutritional issues are important in the care of patients with IBD. Many patients feel that their problem is caused by, or is in need of, a special diet. This chapter reviews the question of the role of diet in the pathogenesis of IBD, discusses the problems of malnutrition and specific nutritional deficiencies and their management, and examines the use of nutritional therapies in the primary modulation of intestinal inflammation. Separate consideration of CD and UC is warranted, because of differences in the impact of disease on nutritional state and in the responsiveness of acute disease to nutritional therapies.

DIET AND THE PATHOGENESIS OF IBD

Pathogenesis of IBD: Current Concepts

Understanding the pathogenesis of UC and CD is a major challenge of gastroenterologic research (1). To date, a positive family history in a first-degree relative is the major known risk factor for IBD. Efforts to identify susceptibility genes through linkage studies among families with multiply affected members are under way. Environmental factors must also play a role, however, as evidenced by the increasing incidence of CD in recent decades and changing incidences of IBD in migrant populations (e.g., increased UC in Asians following emigration to England) (2).

The fundamental question regarding the pathogenesis of IBD has been framed as follows: does the chronic, recurring inflammatory activity reflect an appropriate response to a persistently abnormal stimulus (e.g., a persistent causative agent in the intestinal lumen) or an abnormally prolonged response to a normal stimulus (i.e., aberrant regulation of the immune response) (1). Although the search for a specific pathogen, in CD particularly, continues, the most widely accepted working hypothesis is that IBD represents a dysregulated immune response to intraluminal antigens, conceivably dietary, but more likely common enteric bacterial (1). An enormous antigenic load is regularly presented through the lumen of the gastrointestinal tract, but regulatory mechanisms normally prevent the immune and inflammatory responses from proceeding to cause tissue injury. The intestinal inflammation of IBD may be viewed as an exaggeration of the “physiologic” inflammatory response always present in the normal lamina propria of the intestine and colon. Candidate genes contributing susceptibility to IBD, therefore, include genes involved in determining the specificity of the immune system (class II genes of the HLA region, immunoglobulin genes, T-cell receptor genes) or the level of the immune response (cytokines, adhesion molecules) as well as mucin genes and genes responsible for the structures defining intestinal permeability (1). Such predisposing genes must interact with exogenous or endogenous triggers and modifying factors to result in a chronic inflammatory process in which tissue injury is mediated by the immune system (1).

Role of Diet

No specific dietary toxin or antigen has been incriminated. The rarity of IBD has limited traditional epidemiologic methods of determining causation to case-control studies, which have failed to provide a meaningful lead to the pathogenesis of CD and UC. Persson et al. reviewed studies comparing the reported preillness intake of refined sugar, cereals, fiber, and milk products by patients with CD or UC and controls (3). Increased intake of refined sugar before development of symptomatic CD has been fairly consistently reported, suggesting perhaps a modulating role, but the methodologic weaknesses of study design must be recognized (3). The association may represent a behavioral adaptation to, rather than a cause of, disease. Many IBD patients have circulating antibodies to milk protein, but this is also likely to be a secondary phenomenon; the inflamed intestine is abnormally permeable, permitting entry of intact dietary proteins to which an appropriate immune response is then mounted (4).

Recently, nutritional factors modulating the risk of IBD development have been examined. Breast feeding in infancy may reduce the risk of developing CD (2). Although not truly dietary, a clear dichotomy between UC and CD is indicated by the opposing effect of cigarette smoking on the two disorders (2). Smoking decreases and cessation of smoking increases the risk of developing UC, whereas smokers are at increased risk of developing CD. Some authors suggest that smoking may be a determinant of the type of IBD that develops in predisposed subjects. Finally, in a correlation study from Japan, the increasing incidence of CD in the racially homogeneous population was shown to parallel increasing daily intake of animal protein, total fat, and animal fat, especially n-6 polyunsaturated fatty acids (PUFAs) relative to n-3 PUFAs (5). These trends indicating "Westernization" of diet in Japan were determined from sequential population surveys of dietary habits. n-3 PUFAs found in marine oils have an antiinflammatory effect through modulation of proinflammatory cytokine synthesis (6). A recent placebo-controlled study using enteric-coated fish oil capsules designed for ileal release demonstrated a substantial reduction in clinical relapse rate among patients with CD in clinical but not biochemical remission at baseline (7). Confirmation from other studies is awaited. Prior studies with pharmacologic amounts of eicosapentanoic acid in UC and CD (but without such a coating to facilitate release in the distal intestine) have shown little or no clinical benefit.

INTESTINAL EFFECTS OF IBD

The impact of IBD on the gastrointestinal tract and its digestive and absorptive functions varies depending on the site(s), nature, and extent of intestinal inflammation.

Fat Absorption

Digestion and absorption of fat is unaffected by UC. In CD involving the ileum, fat digestion and absorption may be altered either by loss of gut surface area due to inflammation or by depletion of the circulating bile salt pool due to bile acid malabsorption in the diseased ileum or deconjugation by bacteria. However, studies

years ago confirmed that significant impairment of fat absorption occurs only when the extent of inflammatory involvement is massive, when the absorptive surface has been reduced by extensive small intestinal resection, or conceivably when there is bacterial overgrowth secondary to luminal stenosis and incomplete bowel obstruction (8, 9). Filipsson et al. studied fecal excretion in CD patients prior to intestinal resection and found predominantly mild steatorrhea in 24% of patients with ileal disease, 26% of those with ileocolonic involvement, and 17% of those with Crohn's colitis. Following resection of the ileum and ileocecal valve, fecal fat excretion was elevated in 48% of patients (8). The frequency and severity of the steatorrhea correlated with the extent of ileal resection, and it was infrequent and mild with resections of less than 30 cm.

Enteric Losses

More prevalent and significant than fat malabsorption is enteric leakage of protein, blood, minerals, electrolytes, and trace elements from the bowel during periods of active inflammation in both UC and CD. Patients with CD, even when clinically asymptomatic, frequently have laboratory evidence of protein-losing enteropathy and consequent hypoalbuminemia (10).

Digestion and Absorption of Specific Nutrients

Specific digestive or absorptive defects may occur in CD, but these also are not universal (8, 9). Vitamin B₁₂ malabsorption is the most common, because its site of absorption corresponds to the area most often inflamed. The prevalence of B₁₂ malabsorption correlates with extent of ileal disease and, among operated patients, with the length of ileum resected. Vitamin B₁₂ malabsorption has been reported in 21% of patients with less than 30 cm of terminal ileum involved, in 48% of those with 30 to 60 cm affected, and in 71% of patients with 60 to 90 cm resected (8). Other digestive or absorptive defects are uncommon, presumably reflecting the reserve of the gut and the large surface area that is usually relatively uninflamed. Lactase deficiency and lactose intolerance may coexist with IBD but are in general no more common than would be expected in an age- and ethnically matched control population (11).

Drug-Nutrient Interactions

Certain drugs used in the management of IBD contribute to selected nutrient malabsorption (12). For example, sulfasalazine reduces folate absorption, but supplementation to prevent anemia does not seem routinely necessary. Calcium metabolism is disturbed by corticosteroid treatment, which causes decreased absorption and increased urinary excretion.

NUTRITIONAL CONSEQUENCES OF IBD

Malnutrition

Weight loss and emaciation are the most prevalent nutritional disturbances in IBD (13,

14). Some 20 to 75% of adult patients experience weight loss with exacerbations, the incidence and magnitude of the loss varying with disease severity. At the time of first diagnosis, approximately 85% of pediatric CD and 65% of pediatric UC patients have lost weight.

Etiology of Malnutrition

As summarized in [Table 69.1](#) multiple factors contribute to malnutrition. However, reduced intake, rather than excessive losses or increased needs, is the major cause of the caloric insufficiency. Abdominal cramps and diarrhea are aggravated by eating; thus the patient consumes less. Disease-related anorexia may be profound in CD, particularly; cytokines produced by the inflamed bowel are likely responsible. Tumor necrosis factor α has been shown to produce anorexia in rats ([15](#)).

Decreased nutrient intake
Disease-related anorexia
iatrogenic (unjustified dietary restrictions)
Malabsorption
Diminished absorptive surface (disease, fistulae, resection)
Bacterial overgrowth
Bile salt deficiency
Increased gut losses
Protein-losing enteropathy
Electrolytes, minerals, trace metals (diarrhea and fistulae)
Bleeding
Increased requirements
Sepsis, fever
Increased cell turnover

Table 69.1 Factors Causing Malnutrition in Inflammatory Bowel Disease

Intestinal malabsorption may factor in the equation leading to energy imbalance, but it is seldom the major cause as discussed above. Increased energy expenditure associated with active inflammation has been suggested as a further mechanism accounting for the frequency of malnutrition. In general, resting energy expenditure (REE) does not differ from normal in patients with inactive disease but can exceed predicted rates in the presence of fever and sepsis ([16](#)). Furthermore, in comparison to comparably malnourished patients with anorexia nervosa a lack of compensatory reduction in REE has recently been described ([17](#)). Reduction in REE is a normal biologic response to conserve energy. Production of inflammatory mediators may explain the lack of REE adaptation in Crohn's patients and further augment the ongoing malnutrition.

Growth Impairment

Chronic malnutrition translates into impairment of linear growth and pubertal development in pediatric IBD ([18](#)). Inflammatory disease occurring during early

adolescence is likely to have a major impact on nutritional status and growth because of the very rapid accumulation of lean body mass that normally occurs at this time. Furthermore, boys are more vulnerable to disturbances in growth than girls because their growth spurt comes at a later stage of normal pubertal development and is ultimately longer and greater. Growth impairment is much less common in UC than in CD, at least in part because the more subtle intestinal symptoms in CD often go unrecognized and the inflammatory disease therefore untreated for longer (18).

Prevalence of Growth Impairment in CD

Several recent studies have characterized the growth of children with CD as treated in the 1980s and into the 1990s (19, 20, 21 and 22). They show that impaired linear growth is common prior to disease recognition as well as during the subsequent years and that height at maturity is often compromised. The percentage of patients with CD whose growth is affected varies with the definition of growth impairment and with the nature of the population under study (tertiary referral center vs. population based). Height velocity is the most sensitive parameter for diagnosing impaired growth and following the effects of therapy on growth. Kanof et al. reported a decrease in height velocity prior to onset of intestinal symptoms in 46% of newly diagnosed children and after development of symptoms in an additional 42%, implying that linear growth was unimpaired in only 12% at the time of diagnosis (23). It is important to obtain preillness heights, so that the impact of the inflammatory bowel disease can be fully appreciated. The greater the height deficit at diagnosis, the greater the demands for catch-up growth.

Children already significantly stunted at the time of diagnosis are a particular concern. In a Toronto study of 100 children with CD diagnosed prior to or at an early stage of puberty, 17 were below the Tanner and Whitehouse third centile for height at the time of disease recognition. Despite gains in growth following disease treatment at least comparable to those of other patients, 10 of these failed to reach the third centile for adult height when followed to maturity (19). This emphasizes the need for early recognition of CD in young patients and also for new approaches to optimizing the catch-up growth of those diagnosed late.

Mechanisms of Growth Impairment in Crohn's Disease

Several interrelated factors contribute to growth impairment in children with CD. Most emphasis has been placed on the importance of chronic undernutrition as the primary cause of growth retardation (24). The multifactorial etiology of the caloric insufficiency has been discussed. Serum levels of insulin growth factor-1 (IGF-1) are low in most patients with growth abnormalities and likely reflect a poor nutritional state (25). However, the growth-retarding effect of chronic inflammation per se is still poorly defined. A recent study has shown that interleukin-6 (IL-6) secreted from the inflamed gut may act to suppress growth (26). Daily corticosteroid use may inhibit growth, but it is often difficult to separate the relative contributions of disease activity from corticosteroid usage in the pathogenesis of slow linear growth in pediatric CD (13, 19, 22). From the above discussion, it follows that optimization of treatment of intestinal inflammation and provision of adequate nutrition are of paramount importance in preventing or remedying

growth impairment ([27](#), [28](#)).

Specific Nutrient Deficiencies

As with protein-calorie malnutrition, deficiencies of vitamins, minerals, and trace elements may result from either inadequate intake or increased losses. Most studies of micronutrition have focused on adults; reported frequencies pertain predominantly to CD ([29](#)). Observations based on small numbers of patients may not be generalizable. It is difficult to obtain an accurate and meaningful representation of the prevalence of specific deficiencies, but an appreciation of their relative frequencies is useful.

Water-Soluble Vitamins

Of the water-soluble vitamins, folic acid and vitamin B₁₂ deficiencies are relatively commonly encountered; others are extremely rare.

Fat-Soluble Vitamins

Vitamin D deficiency is the most commonly reported fat-soluble vitamin deficiency ([30](#)). However, although osteomalacia may be encountered in CD, especially following ileal resection, a more prevalent problem appears to be osteoporosis related to a direct effect of inflammatory disease on bone deposition or resorption ([31](#)). Identification and attempts at prevention or correction of this metabolic bone complication will undoubtedly receive increasing attention in the years ahead.

Minerals and Trace Elements

Iron deficiency is common, related to gut losses and inadequate intake ([32](#)). The ability to absorb iron is usually preserved. Low serum ferritin is the most reliable indicator of reduced iron stores. Anemia in IBD is frequently due to chronic disease rather than to iron deficiency. Of other minerals and trace elements, zinc has received considerable attention ([33](#)). Nevertheless, the true frequency of deficiency and its role in growth retardation are highly controversial because of inaccuracies in the measurement of total body zinc. Low serum levels of zinc reflect more the degree of hypoproteinemia than depletion of body stores. Avoidance of milk products and the effects of corticosteroids on calcium absorption and excretion predispose to calcium deficiency; documented hypocalcemia, however, is usually due to hypoalbuminemia.

NUTRITION IN THE MANAGEMENT OF IBD

Nutritional support is a vital component of the management of patients with IBD. The frequently encountered macronutrient deficiency can lead to altered cellular immunity with increased risk of infection, prolonged cellular renewal of inflamed tissues, delayed wound healing, diminished skeletal muscle function, and, in children, growth retardation ([13](#), [14](#)). Undernutrition and its associated complications may hence become as debilitating as the underlying IBD. Management goals must include correction and

prevention of nutritional deficits as well as control of symptoms. Nutritional assessment techniques are discussed in [Chapter 54](#), [Chapter 55](#), [Chapter 56](#) and [Chapter 57](#). [Table 69.2](#) correlates with the above discussion of nutritional problems encountered in IBD and summarizes the evaluation that should be considered an essential minimum for proper patient care.

Subject assessment
Detailed history
Complete physical examination, pubertal staging*
Dietetic evaluation (3-day diary)
Anthropometry
Height, weight
Growth velocity*
Height for age %*, weight for height %
Midarm circumference
Triceps skinfold thickness
Laboratory data
Complete blood count, red-cell morphology
Serum albumin
Folic acid, vitamin B ₁₂
Serum Fe, total iron-binding capacity, ferritin
Calcium, magnesium, alkaline phosphatase
Bone age*
Additional tests if growth failure or significant malnutrition is present
Vitamins A, D, E
Prothrombin time, partial prothrombin time
Zinc
Phosphorus

*In pediatric populations.

Table 69.2 Recommended Nutritional Assessment of Patients with IBD

General Dietary Measures

For most ambulatory patients, the most important advice is to consume a diet liberal in protein, with sufficient calories to maintain or restore weight or to support growth in children and adolescents. A caloric input of 35 to 40 kcal/kilogram ideal body weight (IBW) per day and 1 to 1.5 g/kg IBW protein per day will meet the protein and energy requirements of most adult patients with active inflammatory bowel disease. For children, recommendations should be made according to their height, age, and need for catch-up growth. Liquid dietary supplements may help motivated patients to achieve these goals, although in young patients these will often simply displace ingested calories from regular food without increasing total caloric intake ([34](#)).

The merits and necessity of dietary restrictions need to be critically examined. Controlled studies have not supported a role for a low-residue diet nor for a high-fiber, low-refined-sugar diet in the maintenance of remission in IBD ([35](#), [36](#)). Recent studies have suggested that exclusion of specific foods on the basis of individual clinical intolerance improves the clinical course of CD ([37](#)).

A major problem with dietary modifications is that they frequently result in a less appetizing diet, which discourages optimal caloric intake. Imposition of dietary restrictions can result in a major source of conflict between children with IBD and their parents. Except in specific circumstances (e.g., a low-residue diet to reduce obstructive symptoms in the setting of small intestinal stricture) a full diet for age is most

appropriate.

INTENSIVE NUTRITIONAL SUPPORT IN IBD

There are three broad indications for undertaking intensive nutritional support in patients with IBD. The first is adjunctive therapy to correct or avoid malnutrition and to facilitate growth. The second is primary therapy of active intestinal inflammation in CD but not in UC. The third includes the small proportion of CD patients who may require long-term nutritional support because of short bowel syndrome or extensive active disease. Nutritional therapy in these contexts may be provided by enteral nutrition using formulated food or via parenteral nutrition using a centrally placed intravenous catheter. Enteral nutrition has become the preferred and more frequent approach because of its lower complication rates and easier and less costly administration. Circumstances favoring long-term total parenteral nutrition (TPN) are limited to the patient with a very short gut or near-complete obstruction.

Adjunctive Nutritional Therapy

Adjunct to Drug Treatment

Intensive nutritional support will improve the nutritional status of the anorectic or malnourished patient with CD or UC. In the setting of acute severe colitis, which is often unresponsive to drug therapy, provision of TPN will prevent further loss of body protein and improve respiratory and peripheral muscle function ([38](#)). Postoperative respiratory complications were reduced among patients who ultimately required colectomy. These data argue for early use of parenteral nutrition in conjunction with corticosteroid therapy but do not justify delaying colectomy to improve nutritional state in the malnourished patient with fulminant disease who is clearly failing medical therapy.

Preoperative Nutritional Support

Adjunctive nutritional therapy has frequently been advocated prior to planned surgery in CD and UC to decrease postoperative morbidity on the basis of observations that protein-calorie malnutrition impairs wound healing and diminishes immunocompetence, thereby increasing the risk of infection. Collins et al. found that provision of calories with amino acids resulted in a lower complication rate postoperatively than either provision of amino acids alone or standard intravenous solutions ([39](#)). Clinically important benefits are observed only among patients with severe malnutrition ([40](#)).

Nutritional Treatment of Growth Impairment

Among children and adolescents prior to completion of puberty, consistent provision of adequate nutrition, either enterally or parenterally, effectively restores normal growth ([13](#), [24](#), [41](#), [42](#) and [43](#)). The most common approach involves nocturnal nasogastric infusion of formulated food ([41](#), [42](#) and [43](#)). Such intensive nutritional support rather than simple dietary counseling to increase caloric intake is required when growth is

retarded (13).

Primary Nutritional Therapy of Active Disease

Enteral Nutrition

The potential role of exclusive enteral nutrition as primary therapy of active CD was discovered fortuitously. Patients given elemental formulas preoperatively experienced improvement not only in their nutritional status as intended, but also in the inflammatory activity of their disease.

Efficacy: Controlled Trial Data. The controversy surrounding seemingly divergent outcomes in early small controlled trials of exclusive enteral nutrition and subsequent larger multicenter studies has fueled several metaanalyses (44). As summarized in Table 69.3, in all but two small trials, more patients achieved clinical remission with steroids than with enteral nutrition. The pooled odds ratio for likelihood of clinical response to enteral nutrition using elemental, semielemental, or polymeric formulas versus corticosteroids was 0.35 (95% CI, 0.23–0.53) (44). Thus, treatment with corticosteroids has greater benefit than treatment with enteral feeding. Furthermore, secondary metaanalysis excluding dropouts for apparent intolerance showed that poor compliance, although a factor, is not the major reason for the lower response rates to enteral nutrition (44).

Study (ref)	Number of Patients in Each Treatment Group		Formula Type	Percentage Achieving Remission		Difference in Remission Rate EN - Steroids
	EN	Steroids		EN	Steroids	
Luchs 1981 (40)	55	52	Semielemental	53	85	-32

Sachdev 1982 (52)	45	38	Elemental	75	88	-13

Table 69.3 Results of Trials Included in Metaanalyses: Enteral Nutrition (EN) versus Corticosteroids

No controlled trials have compared enteral nutrition with placebo or less effective drugs in active CD. Comparison of observed response rates to exclusive liquid diet therapy (53–82%) with usual placebo response rates in the controlled clinical trial setting suggests that enteral nutrition is of therapeutic benefit, even if efficacy does not equal that of corticosteroid treatment (44). Moreover, reduced gastrointestinal protein loss,

decreased intestinal permeability, and reduced fecal excretion of indium-labeled leukocytes have all been demonstrated, suggesting a direct effect on intestinal inflammation (45).

There are situations in which risk/benefit considerations may justify a preference for exclusive enteral nutrition, even if steroids induce clinical remission in more patients. Children with CD need special approaches to therapy (13, 27, 28). Enteral nutrition can provide optimal macro- and micronutrients and appears to ameliorate intestinal inflammation, all of which should facilitate growth. Enteral nutrition does seem to be more feasible, if not inherently more efficacious, in pediatric populations. The formula can be infused nocturnally in the home setting and not interfere with normal activities.

Site-Specific Efficacy. The site of intestinal inflammation has been postulated to influence the likelihood of response to nutritional therapy. Specifically, it has been suggested on the basis of retrospective data that Crohn's colitis responds less well to enteral feeding than ileocolitis or isolated small bowel disease. The large European Collaborative Crohn's Disease Study could not relate outcome to the site of intestinal inflammation, but the numbers of patients with isolated colonic disease were small, even in these trials (46, 47). The lack of site-specific data concerning rates of induction of clinical remission in other trials precludes prospective appraisal of the relationship between anatomic localization of CD and responsiveness to exclusive enteral nutrition. In one trial comparing two types of enteral nutrition, two-thirds of patients had disease confined to the colon, but excellent clinical response rates of 67 and 73% to elemental and polymeric formulas, respectively, were nevertheless observed (48).

Mode of Action. The mode of action of enteral nutrition as primary treatment of active CD remains conjectural. Hypotheses have included alteration in intestinal microbial flora, elimination of dietary antigen uptake, diminution of intestinal synthesis of inflammatory mediators via reduction of dietary fat, overall nutritional repletion, or provision of important micronutrients to the diseased intestine (49).

Importance of Formula Composition. The importance of formula composition to efficacy can be addressed by sensitivity analyses of trials versus corticosteroids, grouped according to type of liquid diet, or by metaanalysis of data from trials comparing an elemental with a nonelemental formula (see Chapter 101 for formula content). Trials versus corticosteroids, employing a low-fat elemental diet, included too few patients for any definitive conclusion. Results from directly comparative trials as summarized in Table 69.4 do not support a benefit for elemental formulas. The pooled odds ratio for likelihood of attainment of remission using an elemental versus nonelemental formula was 0.87 (95% CI 0.41–1.83) (44). However, the number of patients in the total sample would preclude detection of a difference in response rate even as large as 30%. Furthermore, the elemental and “nonelemental” formulas used in these studies were not consistently disparate. All elemental formulas contained amino acids as their protein source, but the “nonelemental” formulas contained either oligopeptides (also of low antigenicity) or intact proteins. Similarly, the percentage of total calories derived from fat varied greatly. Both a low total fat content and a low ratio of n-6:n-3 PUFAs have been hypothesized as necessary for reduction of intestinal inflammation (5, 6, 49). Data from randomized controlled trials are at present insufficient to establish definitively whether

either decreased antigenicity related to the protein content or an immunomodulatory or antiinflammatory effect related to low-fat content is important in reducing intestinal inflammation. These possibilities should both be further explored.

Study (N)	Elemental Diet			Nonelemental		
	Number of Patients Treated	Percentage Achieving Remission	Protein Source	Number of Patients Treated	Percentage Achieving Remission	Protein Source
Reed 1981 (63)	10	80	Amino acids	16	70	Intact milk
Reed 1981 (48)	15	67	Amino acids	15	70	Intact milk
						protein and egg or milk protein
Peck 1981 (64)	7	29	Amino acids	7	71	Whole whey
Reed 1984 (65)	10	94	Amino acids	21	71	Oligopeptides
						(10 LCT + 20 MCT)
Mallory 1987 (66)	11	70	Amino acids	16	70	Oligopeptides

Table 69.4 Formula Composition and Outcome in Trials of Elemental versus Nonelemental Liquid Diet Therapy

Importance of “Bowel Rest.” When used in the treatment of active CD, enteral nutrition is generally combined with “bowel rest.” However, in a randomized trial of adjunctive nutritional treatments, Greenberg et al. observed that partial parenteral nutrition plus an ad libitum oral diet was as effective in inducing clinical remission as either elemental liquid diets administered by nasogastric tube or TPN and complete bowel rest among patients hospitalized because of continuing activity of their disease despite high-dose steroid therapy (50).

Maintenance of Remission. One of the limitations of liquid diet therapy has been the observed tendency for symptoms to recur promptly following its cessation. In most studies, 60 to 70% of patients experience a relapse within 12 months of stopping enteral nutrition and resuming a normal diet (42, 44, 48). Nutritional strategies have been used in pediatric studies to keep children well and growing for a longer time after attaining remission through use of exclusive enteral nutrition. In a Canadian Pediatric Collaborative Trial, patients attaining remission through exclusive enteral nutrition or prednisone treatment were rerandomized to receive for 18 months either cyclical exclusive semielemental liquid diet therapy for 4 weeks out of every 16 or low-dose alternate-day prednisone. As recently reported, linear growth was better and rate of clinical relapse lower with the nutritional treatment (27). This confirms an earlier retrospective report of the beneficial effects of cyclical exclusive enteral nutrition on disease activity and growth (43). Continuation of nocturnal nasogastric feeding four to five times weekly as supplement to an unrestricted ad libitum daytime diet was also associated with prolonged disease quiescence and improved growth in a historical cohort study (42). In the long term, allowing normal food at times when family and friends are eating is particularly important in achieving compliance. The observation that

supplementary enteral nutrition is associated with prolonged clinical remission despite resumption of regular food is most consistent with a micro- or macronutritional effect (42).

Mode of Administration. Children become adept at passing a nasogastric silastic feeding catheter each night. However, if long-term therapy either in a cyclical exclusive or continuous supplementary fashion is contemplated, insertion of a gastrostomy tube may make administration easier. This procedure appears to be uncomplicated in CD patients, but experience is limited. One patient in a pediatric series had a persistent gastrocutaneous fistula when the gastrostomy tube was removed, but surgical closure was successful (51).

Parenteral Nutrition

Efficacy. Studies of TPN as primary treatment of active CD have been summarized in detail by Greenberg (14). In contrast to studies of enteral nutrition in active disease, there are numerous retrospective reports but few prospective, randomized, controlled trials of TPN. From retrospective series among CD patients, one can expect an in-hospital remission rate of 64% after 14 to 21 days of treatment, with isolated colonic CD responding less often than disease involving the small intestine alone or small intestine plus colon (14). Two small prospective controlled trials suggest that TPN combined with bowel rest is of no primary therapeutic efficacy in the management of patients with acute UC or of those with acute Crohn's colitis, although it will improve their nutritional status (52, 53). Only two randomized studies have compared TPN with exclusive enteral nutrition in the treatment of active disease; remission rates with either modality were comparable (50, 54). There is no evidence to suggest that TPN is superior to enteral nutrition in the treatment of acute inflammation. Indeed, enteral provision of nutrients may optimize the repair of inflamed mucosa. In animals, TPN administration is associated with subtotal villous atrophy of the intestine, and this physical alteration of the mucosal barrier promotes translocation of bacteria normally confined to the gastrointestinal tract (55). Permeability, in contrast, normalizes with enteral nutrition, so that access to factors that putatively may perpetuate intestinal inflammation is reduced (47).

Long-Term Nutritional Support

Fortunately, only a small minority of patients with CD have inadequate gastrointestinal reserve for maintaining a normal nutritional state on standard oral or enteral diets. Nevertheless, patients with CD often comprise the largest single group of adults on home TPN programs (56). The usual clinical setting involves persistent active inflammation after multiple small bowel resections. Either the remaining small bowel is incapable of sufficient nutrient absorption to sustain nutritional homeostasis (short bowel syndrome) or resection of the colon and ileum results in substantial losses of isotonic fluid, electrolytes, minerals, and trace elements, but with relatively normal macronutrient absorption (end-jejunostomy syndrome). Both of these circumstances may require permanent home parenteral nutrition for provision of complete nutritional support or alternatively to facilitate fluid and electrolyte balance. It is hoped that these situations will become less common with the more conservative approaches to surgery: operation

for complications of disease only, limited resections of only the most severely diseased bowel, and use of stricturoplasty to preserve absorptive surface area (See also [Chapter 101](#)).

Inflammatory bowel diseases ([Chapter 69](#)), the short bowel syndrome ([Chapter 68](#)), celiac disease ([Chapter 71](#)), and various intestinal parasite infections are the most common diseases of the intestinal tract that result in malabsorption and nutritional problems. This chapter addresses other, less common diseases that may also cause severe intestinal dysfunction, malabsorption, and malnutrition.

RADIATION ENTERITIS

Abdominal and pelvic radiation, commonly used in the treatment and palliation of various tumors can cause major gastrointestinal morbidity. With the development of supervoltage techniques, high doses can be administered to the tumor without skin toxicity, making gastrointestinal tolerance the main dose-limiting factor. The ileum and jejunum are felt to be the most susceptible, followed by the transverse colon, sigmoid, and rectum. During the time of radiation, most patients experience acute radiation toxicity, manifested by nausea, vomiting, abdominal cramps, and diarrhea. This form of toxicity is self limited and usually subsides within weeks of ending radiation therapy (RT). Chronic, late gastrointestinal complications occur less frequently and can cause

major morbidity and mortality.

Risk factors predisposing to radiation injury of the small and large intestine include previous abdominal surgery, thin physique, hypertension, diabetes mellitus, and pelvic inflammatory disease (1). Concomitant chemotherapy, especially with actinomycin D, seems to compound the damage (2). Total dose administered and volume of bowel irradiated are major determinants of late radiation damage. Significant injury generally occurs when more than 5000 rads are administered.

Prevention

Besides limiting the amount of radiation and appropriately fractionating the total dose schedule, prevention efforts are aimed at minimizing bowel exposure during RT. Several surgical techniques have been described that displace small bowel from the pelvic radiation field. These include intraoperative placement of a polyglycolic, absorbable intestinal sling that suspends the small bowel above the pelvic radiation field and resorbs several months postoperatively (3, 4); the “pedicled omentoplasty,” which uses the omentum as a sling to exclude the small bowel from the pelvis (5); and peritoneal reconstruction, used in patients with rectal carcinoma, in which the posterior rectus sheath and peritoneum are used to partition the abdominal cavity at the level of the umbilicus to the sacral promontory (6).

Medications have not generally been useful in prevention of radiation enteritis (RE). A randomized, placebo-controlled trial of 5-ASA, the active component of Azulfidine, did not demonstrate any protective effect and appeared to worsen diarrhea (7). An aminothioliol drug, given intravenously prior to RT in one trial protected against radiation injury, presumably acting as a free radical scavenger (8). Sucralfate reduced acute diarrhea and prevented late bowel disturbances in one trial (9).

Pathology

Acute Phase

Acute radiation changes are manifested primarily in the mucosal layer. Mitotic activity in the segment of irradiated intestinal epithelium decreases within 12 hours of the first treatment, continues to drop during the first week and persists at low levels throughout treatment (10). Mucosal injury occurs with shortening of villi, decrease in mucosal thickness, edema, erosions, inflammation, and ulcerations. Within 2 weeks after completion of therapy, the histologic picture returns to normal in most patients (10).

Subacute Phase

Vascular and connective tissue damage becomes evident in the subacute period, from 2 to 12 months after radiation treatment. Large “foam cells” beneath the intima, abnormal fibroblasts, and submucosal fibrosis are characteristic. As a result, there is obliteration of venules and arterioles and progressive ischemia, which can then insidiously lead to

clinically apparent chronic RE.

Chronic Phase

All layers of the gut wall and mesentery are involved in chronic radiation injury; submucosal fibrosis, edema, lymphatic ectasia, and obliterative endarteritis are characteristic ([Fig. 70.1](#)). These pathologic changes can result in ulcerations, perforations, strictures, and fistulas.

Figure 70.1. Chronic radiation enteritis. Small bowel biopsy demonstrating (*in the center*) three blood vessels partially occluded by fibrosis and inflammation in the walls.

Clinical Manifestations

Acute Phase

Acute gastroenterologic symptoms from abdominal RT are common. Most patients experience anorexia, nausea, and vomiting early in treatment, which seem to be mediated through the central nervous system. After 2 to 3 weeks of RT, abdominal cramping and watery diarrhea may occur. Slight-to-moderate weight loss is common, occurring more frequently with abdominal than with pelvic RT, and is attributed mainly to decreased food intake. Malabsorption of water, fats, bile salts, carbohydrates, calcium, magnesium, iron, and vitamin B₁₂ occurs commonly during RT. It is generally most pronounced at midtreatment and persists to the end of treatment.

Malabsorbed bile salts and carbohydrates play a major role in acute radiation-induced diarrhea. Bile salts that normally are absorbed in the terminal ileum reach the colon, where they induce secretion of fluids and minerals, inhibit absorption, and stimulate peristalsis (“choleric diarrhea”). Malabsorbed carbohydrates, presumably resulting from secondary brush border enzyme deficiencies, exert strong osmotic effects in the

intestinal lumen, compounding the fluid losses.

In most patients, acute radiation symptoms resolve within several weeks after cessation of therapy (11). In a small percentage, symptoms persist and merge with those of chronic RE.

Chronic Phase

The relationship between acute and chronic RE is unclear. Absence of early symptoms does not guarantee protection from delayed morbidity. An estimated 5 to 15% of patients suffer late sequelae of radiation, with latency periods ranging from 1 year to over 20 years, commencing in most studies at 1 to 2 years (12, 13). These percentages represent reported series of patients with severe disease and probably underestimate the incidence of chronic overall morbidity (14). In one study of 17 women with previous pelvic radiation, none of whom sought attention for gastroenterologic complaints, 12 reported a permanent change in bowel habits, 16 had abnormal cholyglycine breath tests, and 8 had abnormal small bowel radiologic studies (15).

Colicky abdominal pain, diarrhea, steatorrhea, and weight loss are the most common clinical manifestations. Small bowel obstruction, fistula and abscess formation, bleeding, and perforation are less frequent, but graver complications, often requiring operation, with its attendant high postoperative morbidity and mortality (16). Gallstones and hyperoxaluria may develop as a consequence of ileal dysfunction.

Several factors contribute to the malabsorption that occurs in late radiation damage: (a) bacterial overgrowth secondary to strictures, fistulas, and stasis; (b) decreased available absorptive surface area because of radiation damage and resection; (c) chronic lymphatic obstruction causing steatorrhea and protein loss; (d) secondary disaccharidase deficiency and subsequent osmotic catharsis; (e) bile salt malabsorption leading to choleric diarrhea; and (f) rapid intestinal transit.

Management

Specific therapeutic modalities are used to treat gastrointestinal pathology when the mechanism can be identified, including antibiotics for bacterial overgrowth; cholestyramine for bile acid malabsorption; antidiarrheal medications for rapid transit; and anticholinergic and antispasmodic preparations for pain and cramps. Most treatments are largely empiric, with few controlled trials. Sucralfate decreased acute symptoms in one trial (9). Azulfidine, in some cases with corticosteroids, was helpful in managing diarrhea of RE in a small number of reports (17). Loperamide-*N*-oxide, a peripheral opiate agonist precursor, decreased stool frequency and volume, slowed small bowel and whole gut transit, and improved bile acid absorption in a double-blind, randomized controlled trial (18). In a recent case report, hyperbaric oxygen was dramatically effective in a woman with severe chronic RE. Therapy consisted of 20 sessions of 100% oxygen inhalation, at 3 bar in a hyperbaric chamber. During treatment, nausea, vomiting and diarrhea abated, and weight gain occurred. Four and one-half months later, clinical improvement persisted, and the D-xylose test, previously

severely abnormal, normalized ([19](#)).

Nutritional Management

Nutrition is optimized by identifying the factors contributing to malabsorption and correcting those that are treatable. Dietary therapy can play a major role in both controlling symptoms and ensuring adequate nutrition. Enteral and parenteral nutrition should be used only in severe cases.

Acute Radiation Enteritis

During RT, control of diarrhea and prevention of weight loss constitute important goals. A diet low in lactose and fat is recommended, as transient ileal dysfunction and brush border enzyme deficiencies are highly prevalent, causing diarrhea and malabsorption. Experimental evidence suggests that intraluminal contents, especially pancreatic secretions and bile acids, potentiate acute small intestinal radiation damage ([20](#)). This finding has led to trials of enteral feeding with solutions containing amino acids or partially digested protein and very low fat content. These solutions are absorbed proximally in the small intestine and are thought to stimulate less pancreatic, biliary, and salivary secretion than normal diets. Studies in which patients received only such enteral feeding during RT indeed demonstrated less diarrhea and weight loss and less frequent interruption of the radiation schedule because of toxicity ([21](#), [22](#)). Enteral nutrition solutions used as dietary supplements provide no clinical benefit ([23](#)).

Despite data supporting the use of enteral feeding with partially or fully digested protein during RT, the transient nature of the acute injury, the inconvenience of limiting intake to these formulas, and their unpalatability requiring their administration through a tube make them impractical for general use. Such enteral feeding should be used only in patients who develop severe acute toxicity or who have preexisting malnutrition.

Several studies have evaluated the role of total parenteral nutrition (TPN) during pelvic and abdominal RT. TPN clearly prevents weight loss, and in some cases, lessens gastrointestinal toxicity, while enhancing the ability of the patient to tolerate RT on schedule. Survival is not affected. Two randomized prospective trials concluded that TPN should be reserved for patients malnourished before starting a course of curative RT ([24](#), [25](#)). This conclusion is reasonable considering the complexity of TPN and the fact that acute RE is a transient disorder.

Chronic Radiation Enteritis

Assessment of the functional outcome of chronic RE should be the first step in management of this disorder. The nutritional status of the patient should be evaluated, and a complete investigation for malabsorption and specific nutrient deficiencies should be performed ([Chapter 57](#) and [Chapter 65](#)). These may include radiographic studies of the intestinal tract, absorption studies (D-xylose, stool fat, and Schilling test), and assessment of blood levels of selected nutrients.

Dietary management is effective in treating both the diarrhea and the nutritional deficiencies of chronic RE. Sequential restrictions of fat, fiber, lactose, and gluten may establish an optimal diet that provides symptomatic relief and improves nutrition. In addition, such an approach may clarify which pathophysiologic mechanisms are salient in an individual patient. The histologic similarity between RE and other malabsorptive diseases, such as sprue, has led to trials using specific dietary therapy as the major form of treatment for RE. A diet free of gluten, cow's milk protein, and lactose, with low fat and fiber content was given to five children with severe, delayed injury manifested by small bowel obstruction after whole abdominal irradiation (2). In all patients, clinical symptoms improved, and radiographic studies and histologic pictures normalized. After 1 to 2 years, the gradual addition of fiber, gluten, milk, and fat was well tolerated by all. In another trial, dietary fat was restricted to 40 g/day in nine women with diarrhea after pelvic irradiation (26). Three to 6 months later, fecal excretion of bile salts decreased, and diarrhea abated in eight of the nine patients.

A trial of low-fat, partially digested protein liquid formula given through a tube may benefit patients who fail to improve with oral dietary therapy. Significant reductions in fecal fluid, fat, and nitrogen with the use of enteral feedings (27) were reported, while other authors found no such benefit (13). Patients with limited absorptive capacity can benefit from enteral feedings given in a pump-controlled, slow infusion through a gastrostomy tube. This technique avoids overwhelming the intestine's limited absorptive capacity, which can occur with bolus feedings or oral feeding. Using this mode of nutrition, some patients can be maintained in good nutritional state without the use of TPN.

In patients with severe RE who are unable to maintain their weight with oral or enteral diets, TPN is lifesaving. It achieves weight gain, improves overall nutrition, and may help in decreasing fistula drainage (28). Some evidence also suggests a direct therapeutic role for TPN. In a report on 31 patients (29) with severe RE treated with TPN, significant improvement in intestinal function, nutritional status, and weight gain was observed. Oral feeding was resumed in 11 of 31 (36%) patients after a mean of 3.6 months, and 8 of these patients had a sustained benefit. Factors predicting a poor response were age above 60 years, hypertension, diabetes mellitus, vascular occlusive disease, and intestinal fistula or perforation. TPN was well tolerated and was associated with few complications. However, TPN does not affect morbidity, overall survival rate, or clinical recurrence of severe RE (34% at 1 year, 47% at 2 years). Although these results are encouraging, most data indicate that the role of TPN is supportive, not therapeutic, and that TPN should be reserved for patients with nutritional failure refractory to dietary therapy and enteral feeding.

Surgical Treatment

High postoperative morbidity and mortality have been reported for surgical management of chronic RE due to extensive adhesions, fibrosis, and poor tissue healing. Surgery is generally reserved for patients whose symptoms are not relieved by conservative measures, usually those with small bowel obstruction. In one recent series of 20 patients over a 22-year period who underwent surgery for chronic radiation injury,

postoperative morbidity was 55%, consisting of diarrhea, fistula formation, ostomy complications, obstruction, and wound infection. The authors concluded that although intestinal resection and primary anastomosis are possible, judicious creation of stomas can avoid major morbidity and mortality (30).

EOSINOPHILIC GASTROENTERITIS

Eosinophilic gastroenteritis (EGE) is a spectrum of disorders characterized by food-related gastrointestinal symptoms, peripheral eosinophilia, and eosinophilic infiltration of the gastrointestinal tract (Chapter 92). Peak age of onset is in the third decade, and children constitute approximately 20% of reported cases (31). The disease shows a slight male predominance (32).

The cause of EGE remains unknown. An allergic basis is believed most likely, supported by frequent association with atopic disorders such as asthma, dermatitis, eczema, allergic rhinitis, and bronchitis and by the frequent finding of elevated serum IgE. The role of tissue eosinophilia remains unclear. Whether the eosinophils are mediating the injury or are responding to and modulating the inflammation is not known.

Parasitic infection can cause diffuse eosinophilic infiltration in the gut, with similar symptoms of abdominal complaints and weight loss. By definition, no infestation is found in idiopathic EGE, and in all cases, parasitic infection must be excluded with stool studies and careful inspection of biopsy specimens. Serologic testing and duodenal aspirate should be considered as well, particularly in patients from endemic areas.

Drug or toxin exposure can also produce a clinical picture of eosinophilic gastroenteritis, in particular, gold salts (33) and L-tryptophan ingestion (34).

Pathology and Clinical Manifestations

Three clinicopathologic patterns of EGE have been described (35).

Mucosal Layer–Predominant

Mucosal layer–predominant EGE is the most common pattern, generally involving the stomach alone or both the stomach and small intestine. Recent reports extend the spectrum of gastrointestinal tract involvement to include isolated eosinophilic esophagitis, paninvolvement of the gastrointestinal tract (36, 37), and cholangitis associated with colitis (38).

Presenting complaints include eating-related nausea, vomiting, and abdominal pain, occasionally with diarrhea. Approximately 50% of patients have a history of allergic disorders. Edema, pallor, occult fecal blood, and frequently, signs of allergic disease are present on physical examination. In children, growth retardation is prominent. Further evaluation typically reveals iron-deficiency anemia, peripheral eosinophilia (up to 55%), hypoproteinemia, and evidence of malabsorption and protein-losing enteropathy. The D-xylose test typically is abnormal, reflecting small intestinal mucosal dysfunction,

whereas the Schilling test for vitamin B₁₂ absorption and the fecal fat test are variably abnormal. Radiographic and endoscopic studies reveal edematous, distorted, and sometimes nodular folds, irritability, and increased secretion (39). Occasionally, ulcers are present, involving primarily the gastric antrum and proximal small intestine. The pathologic hallmark of the disease is eosinophilic infiltration and tissue edema without vasculitis (35). Villous architecture varies from normal to complete flattening as seen in sprue. Involvement is patchy, and several biopsies may be required to confirm the diagnosis.

Muscle Layer–Predominant

Obstructive symptoms are more prominent. Radiographic studies reveal thickening and rigidity of the gut. Full-thickness biopsy is often needed to demonstrate eosinophilic infiltration through the muscularis propria.

Subserosa-Predominant

The subserosa-predominant pattern is the least common. Patients typically present with ascites, which contains high numbers of eosinophils. The subserosa is thickened and infiltrated with eosinophils. Mucosal and muscle layers are variably involved.

Relationship to Food Allergy

EGE is distinguished from “food allergy” by the inability in EGE to identify a specific offending dietary agent. Many patients with EGE report intolerance to specific foods, most commonly beef, eggs, milk, and pork (35). Blind food challenges, using nasogastric tube delivery, demonstrate development of symptoms and an increase in white blood cells, IgE, and peripheral and tissue eosinophils in response to specific foods (35, 40, 41 and 42). Yet, dietary manipulation is generally ineffective, and patients with EGE are thus distinguished by their requirement for steroids to induce remission and by their chronicity.

Management

Given the high prevalence of food intolerance in EGE, the first step in treatment should be a trial of eliminating the suspected offending agent. In the absence of a suspect agent, sequential elimination of milk, eggs, pork, beef, and gluten has been recommended (43). Although some patients respond transiently to such measures, sustained response is rare.

Corticosteroids are the mainstay of therapy. Although efficacy has not been documented in controlled clinical trials, anecdotally, they are highly effective, produce quick resolution of symptoms, and allow weight gain in most patients (35, 44). Many patients require small maintenance doses; others need dietary restriction and short courses of steroids for exacerbations only.

Cromolyn, a mast cell stabilizer useful in treating food allergies, has been used in small

trials in EGE, with benefit in some (45, 46a, 46b and 46). A related drug, ketotifen, with antihistamine and mast cell stabilizing properties produced clinical improvement and weight gain and cleared tissue infiltration in a small open trial of six patients (47). Although these drugs do not appear to be as effective as steroids, they are worth a therapeutic trial because of their low toxicity. When patients fail to improve while receiving steroids and have exacerbation of symptoms with any oral intake (a rare occurrence), TPN and bowel rest may be necessary to provide nutrition and induce remission. In one such patient, TPN and intravenous administration of steroids led to a decrease in eosinophilia and in symptoms. When oral feeding was resumed, the disease worsened, and the patient died (48).

AMYLOIDOSIS

Amyloidosis is a multisystem pathologic complex characterized by extracellular deposition of amyloid. Amyloid consists of aggregated, linear glycoprotein fibrils arranged in a β -pleated sheet. Amyloid is classified to two major groups: primary amyloidosis is associated with no preceding or coexisting disease except in cases of multiple myeloma; secondary amyloidosis is associated with underlying conditions, mainly chronic infections (osteomyelitis, tuberculosis) and chronic inflammatory disorders (rheumatoid arthritis, inflammatory bowel disease). Other forms include localized, hereditary, senile, and β_2 -microglobulin-derived amyloidosis.

The biochemical classification is based on the structure of the fibrils: immunoglobulin light chains in primary and in multiple myeloma-related amyloidosis (AL amyloid); protein A in secondary forms and in familial Mediterranean fever (AA amyloid); prealbumin in other familial forms (AF amyloid), and β_2 -microglobulin (AH) in long-term hemodialysis-associated amyloid. Typically, AL affects the gastrointestinal tract (GIT), nerves, skin, heart, and tongue; AA more heavily involves liver, spleen, and kidneys; and AH the osteoarticular system, heart, GIT, and lungs. Actually, overlap exists, and the GIT is frequently involved in both primary and secondary forms.

Pathology

In the GIT, blood vessels are the earliest and most common site involved by amyloid deposition, usually at the submucosal level. Progression of vessel and wall thickening and luminal narrowing may cause bowel ischemia and infarction (49). Gastrointestinal smooth muscle is heavily infiltrated, leading to pressure atrophy and impaired motility. Only with massive deposition is mucosa invaded. Villous architecture in the small intestine most often is normal. Mucosal atrophy and ulceration may result from vascular insufficiency. Neurons in the myenteric plexus and visceral nerve trunks may be damaged by direct pressure from deposition (49).

Endoscopic features of small bowel amyloid vary according to the chemical type of amyloid protein. A fine granular appearance, mucosal erosions, friability, and shallow ulcers are more common in AA cases, reflecting the histologic pattern of wide granular deposition in the lamina propria, whereas multiple polypoid protrusions and thickening of the mucosal folds is found only in AL cases, relating to the massive AL amyloid deposits

in the muscularis mucosa, submucosa, and muscularis propria (50).

On routine hematoxylin and eosin staining, amyloid appears pink and amorphous. Congo red staining viewed under polarized light reveals its unique apple-green birefringence. Electron microscopy demonstrates its fibrillar structure.

Clinical Manifestations

Gastrointestinal symptoms may predominate in all forms of systemic amyloidosis and are particularly prominent in the familial forms (51, 52). Constipation or diarrhea typically occurs early in the course. Progression to severe, disabling diarrhea, often with incontinence, may occur subsequently (52). Autonomic neuropathy of the gut nerves and direct muscle layer infiltration underlie these abnormalities, causing dysmotility, stasis, and often bacterial overgrowth.

Abdominal pain, infarction, perforation and bleeding are less common manifestations and reflect vascular insufficiency or direct invasion (49). Occult gastrointestinal bleeding is common. Mechanical obstructions may occur, usually from massive localized amyloid deposition or from ischemia-induced strictures, and must be differentiated from pseudoobstructions, which result from severe motility abnormalities, stasis, and dilatation.

Malabsorption may occur in all forms of amyloidosis, but it is particularly prominent in the familial forms, in which it is an important cause of cachexia and death (51, 52). Multiple factors are involved, including bacterial overgrowth, direct mucosal and submucosal destruction, vascular insufficiency, pancreatic insufficiency, and autonomic neuropathy. In familial amyloidosis with polyneuropathy, the degree of steatorrhea and evolution of gastrointestinal symptoms has been correlated with severity of electromyographic changes in peripheral nerves (52), implicating the neuropathy as a major factor in producing these symptoms. While direct amyloid infiltration of GIT nerves obviously impairs intestinal motility, a reduction in intestinal endocrine cell is reported in familial amyloid-associated polyneuropathy (FAP), suggesting that local hormonal abnormalities may contribute to the dysmotility of GI amyloid (53). In addition, bile acid malabsorption has been demonstrated in most patients with FAP (54). The degree of bile acid malabsorption correlated more closely with gastric retention than with amyloid deposition in small bowel biopsy specimens, supporting dysmotility as the major factor causing malabsorption.

Fecal weight and fat content are elevated in most patients with significant gastrointestinal involvement (49, 51), whereas D-xylose absorption and results of Schilling and bile acid breath tests are variably abnormal. Orocecal transit time, as measured by lactulose hydrogen breath tests, is significantly delayed in both symptomatic and asymptomatic amyloidosis patients (55). Prothrombin time may be elevated, and carotene levels often are depressed (49). Hypocalcemia and hypokalemia occur occasionally. Anemia, when present, may reflect iron or vitamin B₁₂ deficiency or the underlying chronic disease. Hypoalbuminemia and edema are common (49), usually reflecting nephrotic syndrome (secondary to amyloid in the kidneys), hepatic

dysfunction, malabsorption, and, rarely, protein-losing enteropathy (56).

The most common radiographic appearance is diffuse thickening of the small bowel valvulae conniventes and polypoid appearance (57). Other radiographic features include pseudonodularity, atypical large nodules, pseudoobstruction, ischemic manifestations, dilation without thickening, and blunting of plicae folds (58).

The definitive diagnosis of amyloidosis is made by demonstrating amyloid on Congo red staining of a biopsy specimen. High-yield sites for biopsy include rectum, small bowel, and abdominal fat pad. Several biopsies should be performed because amyloid deposition may be patchy.

Management

The use of broad-spectrum antibiotics for enteric bacterial overgrowth often alleviates diarrhea, steatorrhea, and bile acid deconjugation (51); however, the effect is temporary, and repeated courses may be needed. A norepinephrine precursor, L-threo-3,4-dihydroxyphenylserine (L-threo-DOPS) has had efficacy in managing the diarrhea and orthostatic hypotension in amyloidosis (59), presumably acting on sympathetic nerve function. A recent study demonstrated significant short-term reduction in diarrhea and increased serum norepinephrine in patients with familial amyloid neuropathy using intranasal administration of this drug, whereas no significant effect was seen after oral administration, most likely because of drug malabsorption (59). Cisapride, a prokinetic agent, produced marked symptomatic resolution, with normalized bowel movements, decreased abdominal distention and peripheral edema, and increased serum albumin levels in a patient with intestinal pseudoobstruction due to amyloidosis (60).

In managing the nutritional state, special attention should be paid to supplement fat-soluble vitamins, which can be severely malabsorbed in the presence of steatorrhea. Sodium restriction is helpful in patients with edema, and dietary fat restriction is advisable for patients with significant steatorrhea. Pancreatic enzymes are useful when massive pancreatic acinar destruction contributes to the maldigestion. Both TPN and enteral feedings are useful in nutritional support of the cachectic patient with severe wasting and malabsorption related to gastrointestinal amyloidosis.

Combination chemotherapy with prednisone, melphalan, and colchicine may halt progression of nephropathy in some patients with AL amyloid (61). Treatment of the underlying inflammatory condition and adjunctive use of colchicine has been advocated in secondary amyloidosis (62, 63 and 64). Enterostomy may benefit patients with intractable diarrhea with incontinence.

INTESTINAL LYMPHANGIECTASIA

Intestinal lymphangiectasia (IL) is a protein-losing enteropathy characterized by dilated small bowel lymphatic channels (Fig. 70.2), obstruction to lymph flow, and leakage of protein and lymphocyte-rich chyle into the intestinal lumen. The primary form probably

represents a congenital malformation of lymphatics and generally presents in early childhood. Family history is often positive in these cases, and lymphatic abnormalities outside the gastrointestinal tract are common. Lymphatic blockage may occur in several locations—lamina propria, submucosa, serosa, and mesentery. A transient acquired type of primary IL has also been described. Secondary IL develops in a variety of disease states in which lymph flow is obstructed. These diseases include constrictive pericarditis, chronic congestive heart failure, left subclavian venous obstruction, retroperitoneal fibrosis or neoplasms, Crohn's disease, mesenteric diseases, tuberculosis, sarcoid, mesenteric panniculitis, RE, and chronic pancreatitis and after abdominal surgical procedures. IL has been reported rarely in systemic sclerosis (65), systemic lupus erythematosus (66), and autoimmune polyglandular disease type I (67). Celiac disease and IL are rarely associated (68), and in some cases IL may masquerade as celiac disease (69).

Figure 70.2. Endoscopic picture of the small bowel mucosa of a patient with lymphangiectasis. Dilated lymphatic channels can be seen in the form of many nodules carpeting the mucosal surface

Endoscopic changes of IL are occasionally seen incidentally, and despite biopsy demonstration of dilated lymphatics, laboratory studies are normal, and no clinical evidence of malabsorption is present, suggesting the presence of a “functional” degree of IL (70).

Pathology

The histologic hallmark is dilatation of mucosal and submucosal lymph vessels (Fig. 70.3). Foamy macrophages containing neutral lipids are found in the lymphatic channels, nodules, and lymph nodes. Mesenteric lymphatics are thickened by medial muscular hypertrophy, fibrosis, and elastosis.

Figure 70.3. Intestinal lymphangiectasia. Small bowel biopsy demonstrating dilated lymphatic channels with widened distorted villi.

Grossly affected small bowel is edematous and slightly dilated with thickened folds. The serosal surface appears congested. Serosal lymphatics are dilated and may contain yellow nodules. Mesenteric lymph nodes are variably enlarged and yellow. “Enlarged, bleblike tips” give the villous surface a pebbly, papillary appearance.

Clinical Manifestations

Edema, the typical presenting feature, may be generalized or localized. Diarrhea with variable steatorrhea, nausea, and vomiting occurs at some time in most patients. Chylous effusions and abdominal distension with ascites are common, but significant abdominal pain is unusual. Growth retardation may be prominent in children. Bacterial infections, related to lymphopenia and hypogammaglobulinemia, and hypocalcemic tetany secondary to vitamin D malabsorption, may occur in severely affected patients.

Hypoproteinemia and lymphopenia are the salient laboratory features. Serum albumin and globulin levels are markedly reduced, whereas those of other proteins are moderately reduced. Coagulation studies usually are normal, as is the hemoglobin concentration, although iron deficiency may occur. The cholesterol level is low to normal; deficiencies of fat-soluble vitamins occur to a variable extent. Hypocalcemia, hypomagnesemia, and alkalosis may develop. Results of fecal fat studies range from upper normal to significant steatorrhea. D-xylose absorption typically is normal. ^{99m}Tc-Scintigraphy using labeled albumin is useful in demonstrating gastrointestinal protein loss, as well as in localizing the region involved (71). Endoscopic features include well-circumscribed xanthomatous plaques, white-tipped villi, multiple submucosal nodules, and, rarely, cystic masses that exude chylous material on biopsy (72). The typical radiographic feature is diffuse, symmetric thickening of folds with increased secretion. Less common findings include dilatation, spiculation, disorganization, punctuate lucencies, and jejunization of ileum. Double-contrast technique is more sensitive in demonstrating the characteristic smooth nodular protrusions (73). Lymphangiography, generally not needed for diagnosis, may be helpful

in identifying discrete abnormalities amenable to surgical therapy.

Definitive diagnosis requires small bowel biopsy. The abnormally dilated submucosal lymphatics may be patchy; therefore, several biopsy samples should be obtained.

Management

Diet clearly plays a crucial role in the management of IL. Intestinal lymph production is stimulated by long-chain fatty acids in the intestinal lumen. Decreased production may diminish local lymphatic pressure, resulting in less enteral chyle leakage. Indeed, restricting fat to less than 5 g/day increases serum albumin and albumin half-life and decreases diarrhea and steatorrhea (74). A high-protein, fat-free diet with medium-chain triglyceride (MCT) supplements produced partial to complete remission in most of 15 patients (75).

The MCTs, containing C8-C10 fatty acids, are absorbed directly into the portal system and do not significantly increase lymph flow. When added to the fat-free diet of patients with IL, they enhance its palatability, while providing a good source of calories. In one report, all six children placed on a fat-free, MCT diet showed rapid and sustained long-term clinical improvement (76). Relapse occurred with introduction of long-chain triglycerides and responded to resumption of the previous diet. Despite clinical improvement, persistence of the underlying chyle leak was suggested by refractory lymphopenia and hypoglobulinemia. In several other reports, however, lymphocyte and globulin levels tended to parallel the disease course (75, 77). Short periods of fasting and TPN have been advocated to allow distended lymphatics to collapse and edema to resolve, maximizing conditions for treatment with a fat-free, MCT diet. This plan may be particularly useful for malnourished patients and those with severe diarrhea.

Low-sodium diets, diuretics, and intravenous albumin infusions provide symptomatic relief. Oral vitamin supplements are routinely prescribed. For the rare, highly localized lesion, segmental intestinal resection may be beneficial. Less often, lymphatic-mesenteric venous anastomosis and peritoneal LeVeen shunts are used (78).

Octreotide therapy resulted in a rise in serum albumin, normalization of sedimentation rate, and improvement in fecal albumin loss in a patient with IL associated with an inflammatory disorder that had been refractory to several other therapies (79). Antiplasmin therapy (*trans*-4-aminomethyl cyclohexane carboxylic acid) was dramatically helpful in one patient, with resolution of symptoms and of endoscopic lesions and normalization of protein levels (80), although in several other cases, no benefit was seen (81, 82). Corticosteroids, gluten-free diets, and g-globulin injections have repeatedly been ineffective (76).

In most patients, the disease is permanent, and its course is marked by spontaneously fluctuating symptoms. Dietary management is successful, for the most part, in maintaining remission. Occasionally, the defect is transient and is completely reversible (75, 76 and 77).

ABETALIPOPROTEINEMIA

Abetalipoproteinemia (AbL) is a rare, autosomal recessive disorder characterized by (a) abnormal lipid metabolism, (b) acanthocytosis (spiny or thorny red blood cells), (c) retinitis pigmentosa, and (d) progressive neurologic dysfunction. Failure of the intestinal mucosa to synthesize apoprotein B (apoB) is the basic defect. This results from mutations in the gene encoding for microsomal triglyceride protein (mtp), a lipid transfer protein within the endoplasmic reticulum of hepatocytes and enterocytes, required for assembly and secretion of apoB lipoproteins (83, 84). ApoB is essential for synthesis and structural integrity of chylomicrons (CMs) and very low density and low-density lipoproteins (VLDLs, LDLs). All of these lipoproteins are therefore absent in AbL. Defective CM formation leads to impaired transportation of fat out of enterocytes and malabsorption of fat-soluble vitamins. Acanthocytosis and lipid abnormalities are present from birth; neurologic and retinal findings generally develop in the second decade, perhaps reflecting deficiency states (vitamins E and A) rather than the underlying disease.

Pathology

Grossly, the mucosa has a diffuse yellow hue. Histologic appearance is unique. Enterocytes appear distended and vacuolated because of engorgement with lipid droplets, even in the fasting state. Nuclei are pressed to the base of cells (85). Villous structure is normal. In contrast to the enterocytes, the lacteals, submucosa, lamina propria, and lymphatics contain no fat. Immunofluorescence studies reveal absence of apoB in jejunal mucosa in the fasting state and lack of apoB synthesis after fat feeding (86).

Clinical Manifestations

Gastrointestinal symptoms of diarrhea, steatorrhea, anorexia, vomiting, and growth retardation manifest in the first year of life. In many cases, celiac sprue is diagnosed, and a gluten-free diet is administered without relief. When the appropriate diagnosis is made and a low-fat diet is prescribed, clinical improvement ensues. Symptoms of fat intolerance tend to diminish with age (86, 87), perhaps as a result of increased use of the portal route of fat absorption.

Neurologic problems begin toward the end of the first decade, years after the onset of gastrointestinal symptoms. These include ataxia, intention tremors, clumsiness, and muscle weakness. Examination reveals abnormalities of the posterior columns, peripheral nerves, cerebellum, and muscles similar to those in Friedreich's ataxia, which often is erroneously diagnosed. Visual complaints, scotomata, and decreased acuity are the last to develop. Ophthalmoscopic examination demonstrates fine mottling of the retina consistent with atypical retinitis pigmentosa. Decreased photoreceptor response in both light and dark conditions may be demonstrated on physiologic testing (electroretinography). Untreated, the neurologic and retinal features progress

relentlessly and cause severe impairment (88).

The biochemical hallmark of AbL is complete absence of apoB and undetectable or small amounts of b-lipoproteins—LDLs, VLDLs, and CMs—on plasma lipid electrophoresis (88, 89). Serum cholesterol and triglyceride levels are low, 0.78 to 2.07 mmol/L (30–80 mg/dL) and less than 0.11 mmol/L (10 mg/dL), respectively, and the triglyceride level fails to rise after fat ingestion (89). Although linoleic acid levels are reduced in blood and in tissue, essential fatty acid (EFA) deficiency does not contribute significantly to the clinical picture (89, 90).

Fecal fat content is mildly to moderately increased. D-xylose and Schilling absorption tests typically are normal, as are measurements of serum electrolytes and complete blood count. Examination of the blood smear preparations reveals spiny or thorn erythrocytes—acanthocytes. The lipid composition of the membranes of these red blood cells is abnormal with a unique phospholipid distribution: decreased lecithin and increased sphingomyelin (85). These changes may contribute to the abnormal configuration. Although acanthocytes function normally, increased autohemolysis and increased sensitivity to peroxide hemolysis, the latter of which is correctable with dietary vitamin E supplementation, are demonstrable (85).

A combination of impaired vitamin E absorption and defective transport (because of the absence of apoB, its normal carrier) results in severe vitamin E deficiency (88). Serum levels are undetectable; tissue levels are low (91). Vitamin E deficiency likely contributes significantly, if not entirely, to the neurologic and perhaps retinal manifestations of AbL (87, 88). Vitamin A is moderately to severely malabsorbed, and night blindness may compound the visual symptoms. Carotene levels are low. Coagulopathy from vitamin K deficiency is mild or nonexistent (85), whereas vitamin D deficiency has not been a clinical problem. The clinical features of fat malabsorption, growth retardation, and neurologic and visual abnormalities with acanthocytes on the blood smear and the absence of apoB strongly suggest the diagnosis. The histologic abnormality is diffuse, and small bowel biopsy is diagnostic. A normal biopsy rules out AbL (92).

Treatment

Oral supplementation with fat-soluble vitamins is the cornerstone of treatment. With high-dose oral supplementation (2.40–4.80 μmol of retinol [2286–4572 IU]/kg/day), vitamin A levels can be normalized (88, 93). Abnormalities in dark adaptation response and in electroretinography generally improve with supplementation, although retinal degeneration is not prevented (93). Massive oral doses of vitamin E (200–300 IU/kg/day) can produce detectable serum levels and correct in vitro red blood cell hemolysis (88, 91). Normal serum levels are rarely, if ever, attained (85, 88). Administration of vitamin E in the first few years of life may prevent retinopathy (93). Given later in the course of the disease, vitamin E may halt or retard neurologic and retinal deterioration and may even lead to improvement in some patients (88, 93). A water-soluble form of vitamin E has been used successfully in the treatment of serum vitamin E deficiency associated with fat malabsorption in chronic childhood cholestasis (94) and the short bowel syndrome (95). It is conceivable that this treatment may also

be useful in patients with IL. Oral vitamin K, 5 mg twice a month, has corrected the coagulopathy that seldom occurs.

Moderate fat restriction, initially to approximately 10% of ingested calories, ameliorates the gastrointestinal symptoms of diarrhea and steatorrhea and allows resumption of normal growth and even “catch-up” growth (88, 93). With age, the capacity to absorb fat increases, and patients should be encouraged to increase fat intake as tolerated (85, 90). Additional polyunsaturated fat as corn oil is sometimes recommended to correct the associated biochemical EFA deficiency (90). MCTs are useful as a source of extra calories and clearly aid in weight gain; however, their potential to worsen long-chain fat malabsorption and to cause hepatic steatosis makes their use controversial (88). Gluten-free diets, steroids and B-lipoprotein-rich plasma infusions have been administered without benefit (85, 89).

HISTORICAL BACKGROUND

An illness resembling celiac disease was described as early as the 1st century AD by Aretaeus of Cappadocia (1). In the 19th century, Dr. Samuel Gee provided an excellent clinical description and recommended dietary treatment of a diarrheal illness that he termed “the celiac affection” (2). However, determination of the cause and dietary therapy of celiac disease awaited the observations of W. R. Dicke, a Dutch pediatrician, who noted improvement followed by deterioration of his celiac patients as bread was first withdrawn and then reintroduced into their diets during and after the Second World War (3). Further progress in understanding the disease was facilitated by development of peroral intestinal biopsy devices by Shiner (4) and Crosby and Kugler (5) that confirmed Paulley's observation of intestinal mucosal flattening in surgically obtained specimens (6).

PATHOLOGY

The normal small bowel mucosa is thrown up in a series of concertina-like folds called the valvulae conniventes. Microscopically, the absorptive surface of the mucosa is configured as millions of villi covered by columnar epithelial cells, while the secretory mucosa primarily consists of the crypts of Lieberkuhn. In advanced celiac disease, the valvulae are thinner and more widely spaced than normal, and scalloping of their free margins has been described at endoscopy (7, 8). The microscopic changes are usually diffuse rather than focal and diminish in severity caudally. Changes range in severity from intraepithelial lymphocytic infiltration to complete loss of villi, crypt hyperplasia, and

infiltration of the lamina propria by plasma cells, lymphocytes, neutrophils, eosinophils, and mast cells (9). The remaining absorptive cells are cuboidal and vacuolated. Occasionally, changes are patchy (10).

The effects of gluten extend beyond the small intestine. A lymphoplasmacytoid reaction responsive to gluten has been demonstrated in the rectal mucosa of patients with celiac disease (11). Changes similar to those of celiac disease have been described in other local and systemic disorders that affect the intestinal mucosa. These include lymphoma, giardiasis, tropical sprue, bacterial overgrowth, viral gastroenteritis, cow's milk protein intolerance, and graft-versus-host disease (12).

Dietary exclusion of gluten usually results in restoration of a more normal mucosal appearance within 2 to 3 months. In children, complete recovery may occur, but some residual villous blunting and lymphocytic infiltration is the rule (13). If rechallenge with gluten is felt necessary to confirm the diagnosis, 10 g gluten per day should be added to the diet for up to 2 months, followed by rebiopsy. Some patients are unable to tolerate gluten for more than a few days because of nausea, bloating, and diarrhea. Occasionally, gluten challenge fails to cause typical histologic changes in patients who relapse years later (14). The presence of a normal mucosa, even on a normal diet, does not preclude eventual development of celiac disease (latent celiac disease) (15).

Since some gluten-sensitized people may have a normal mucosa, even in the presence of antigluten antibodies, and others with advanced jejunal mucosal atrophy may be asymptomatic, Marsh has emphasized the need to reconsider traditional definitions of celiac disease (16). He proposed that gluten sensitivity be regarded as a state of heightened T- and B-cell-based immunologic responsiveness to gluten proteins in DQW2 individuals (see below.)

PREVALENCE

Celiac disease has worldwide distribution, but there are significant variations in prevalence, ranging from 1:300 in Ireland (17) to 1:3500 in Finland (18). It is extremely rare in blacks, Chinese, and Japanese but has been described in India (19). Celiac disease is more common in women especially during the reproductive years, but this may be an artifact related to increased case finding. The prevalence of celiac disease is higher in adults than in children, and most such adults have no history of childhood symptoms. Peak prevalence in women occurs between 35 and 44 years of age (20). In Scotland, the incidence of childhood celiac disease appears to have fallen since 1976, perhaps because of changes in weaning practice, with later introduction of cereal products to the infant diet. However, the incidence of celiac disease in Sweden has not declined, despite similar infant feeding practices (21). An increased prevalence in diabetic patients has been reported from Sweden and Italy (22, 23). Celiac disease is also more common in cryptogenic cirrhosis (24).

GENETICS

There is strong evidence for an inherited predisposition to celiac disease (25). It occurs

up to 100 times more frequently in first-degree relatives of patients with the disease than in the general population. About half of these relatives are asymptomatic. Identical twin studies have shown a disease concordance of 70% (26). This inherited susceptibility is closely associated with HLAB8, HLA-DR3, and HLA-DQ alleles. The alleles encoding B8 are in linkage disequilibrium with DQW2 and DR3. More than 90% of celiac patients possess the HLA-DQW2 allele (27), but the nature of the pathogenetic connections between the HLA type and gluten sensitivity remains unclear. Some 70% of unaffected siblings have the same HLA-DR phenotype as their affected sibling (28), so some additional genetic or environmental factors appear necessary for gluten sensitivity to be manifest.

PATHOGENESIS

Gluten is a protein component of wheats, oats, barley, and rye, all of which belong to the genus *Triticum*. Gliadin is the toxic agent in gluten. It is rich in proline and glutamine, hence the term *prolamins* for alcoholic extracts of gluten. There are several subfractions of gliadin, the best studied being a, b, g, and w. These have in turn been subfractionated, and all the gliadin moieties appear harmful to the intestinal mucosa (29).

The causal relationship between dietary gluten and mucosal changes in susceptible patients is unquestioned. However, many questions remain regarding the mechanism by which gluten exerts its harmful effects. Initially, it was suggested that incomplete brush border hydrolysis of gluten as a consequence of enzyme deficiency led to formation of toxic products (30), but inability to demonstrate abnormally low mucosal peptidase or carbohydrase activity following treatment with a gluten-free diet rendered this hypothesis untenable (31).

There is widespread agreement that interaction between CD4 cells and prolamins peptides bound to a celiac-associated HLA-DQ molecule is important in bringing about the pathologic changes associated with celiac disease. Class II HLA molecules bind peptide fragments and present them after further intracellular processing on the cell surface, where they may interact with immunologically competent cells, causing crypt cell hyperplasia and villous atrophy (32). Translocation of gliadin has been shown in intraenterocyte vacuoles positive for HLA-DR antigens in patients with untreated celiac disease (33).

Kagnoff et al. noted significant structural amino acid homology between a gliadin fragment and a nonstructural component, E1B, of type 12 adenovirus and suggested that adenovirus infection of susceptible subjects brings about gluten sensitization through the process of molecular mimicry (34). Although his and other groups (35) found a significant increase in the prevalence of antiadenovirus 12 antibodies in patients with untreated celiac disease, others have failed to confirm this (36, 37).

A variety of antibodies directed against both dietary and self antigens have been found in serum and intestinal secretions of celiac patients (38, 39 and 40). Antigliadin IgA antibodies are found in up to 90% of untreated celiac patients and their titer gradually diminishes on gluten withdrawal (41). Other food-related antibodies such as

antiovalbumin and anticasein have been described. It appears likely that antibody production is related to increased paracellular intestinal permeability found in celiac disease. Although pathogenic mechanisms involving disordered humoral immunity have been proposed, such as antibody-dependent cell-mediated cytotoxic effects and immune complex formation, the role of antibodies in causing villous damage remains conjectural.

IgA antibodies directed against specific tissue components have also been identified. These include antireticulin (42), antijejunal (43), and antiendomysial (44) antibodies, which can be detected by immunofluorescence technique in both human and animal tissues. Antijejunal and antiendomysial antibodies likely recognize a common antigen (45). The endomysium is a delicate connective tissue layer surrounding intestinal smooth muscle, and antiendomysial antibodies have been found in more than 95% of patients with celiac disease (46, 47). The specificity of both antiendomysial and antigliadin antibodies is 90%. Antiendomysial antibody titers decrease after institution of a gluten-free diet. Measurement of antibody titers has been suggested as a screening test for celiac disease and a means of evaluating dietary compliance in nonresponsive patients (48, 49).

CLINICAL MANIFESTATIONS

The presentation of celiac disease is highly variable, ranging from mild, nonspecific features through monodeficiency states to a full-blown classic panmalabsorption syndrome (50). In adults, the classic form of the disease is now the least common presentation, and several authors have emphasized the need to consider celiac disease in patients with irritable bowel–like features occurring in association with another trigger finding such as anemia, weight loss, or a monodeficiency state (51, 52).

Diarrhea

Diarrhea is found in 70% of patients (53). It is usually intermittent, occurs three to four times daily, and is of mushy consistency. Celiac patients often have crampy abdominal pain that, in association with diarrhea and bloating secondary to fermentation of lactose and other maldigested compounds, may simulate the irritable bowel syndrome. In a few patients, the diarrhea is more severe, and stools have the classic malabsorptive features of large volume, frothiness, offensive odor, greasy appearance, and a tendency to float. This latter quality results from their increased gaseous content rather than their fat concentration.

Weight Loss

Some weight loss is usual, but the amount is highly variable, depending as much on associated anorexia as on malabsorption. Patients with villous atrophy confined to the proximal small intestine may lose no weight.

Malaise

A loss of general well-being is found in 80% of patients but is often so insidious in onset that it is only recognized retrospectively, after institution of a gluten-free diet.

Monodeficiency Syndromes

Isolated monomalabsorption of substances absorbed from the duodenum and proximal and midjejunum is well recognized (54). These include iron, vitamins D and K, calcium, magnesium, albumin, and folic acid (12, 55). A combination of iron and folate deficiency is not unusual. Bone mineral density is reduced in association with increased bone turnover and increased secretion of parathormone. The abnormal bone density may respond only partially to treatment with a gluten-free diet (56, 57). The increased metabolic demands of pregnancy may unmask marginal absorption, especially of iron and folate.

Associated Diseases

The clinical features of celiac disease may sometimes be overshadowed by the more dramatic manifestations of associated diseases, thus delaying diagnosis. Many of these diseases have an autoimmune basis. They include dermatitis herpetiformis (58), intestinal lymphoma (59), diabetes (60), thyroid disease (61), IgA deficiency (62), cerebellar atrophy (63), inflammatory bowel disease (64), and sclerosing cholangitis (65). Other diseases linked with celiac disease in addition to those listed above include psychiatric disorders, farmer's lung, autoimmune thrombocytopenia, anemia, and Berger's disease, but the evidence for these associations is not conclusive (75).

Dermatitis Herpetiformis

Dermatitis herpetiformis causes pruritic, vesicular, and papular lesions with an erythematous background, primarily on the extensor surfaces of the limbs. The lesions demonstrate granular or linear deposition of IgA at the junction of dermis and epidermis (66). Although intestinal symptoms are uncommon, virtually all patients with the granular pattern of IgA deposition show patchy mucosal changes identical to those of celiac disease. Linear deposition of IgA is not associated with celiac disease. Both the cutaneous and mucosal abnormalities respond to a gluten-free diet, and in some patients, dapsone therapy can be withdrawn (67, 68).

Malignancy

A number of malignant disorders have been associated with celiac disease, notably small intestinal lymphoma. Celiac-associated lymphoma is generally agreed to be of T-cell origin, though it has been variously described as a B-cell tumor and as a malignant histiocytosis (69). Although it has been suggested that the mucosal atrophy associated with this lymphoma is secondary to the lymphoma rather than vice versa (70), there is a reluctance to accept that the malignant features of lymphoma may be delayed for many years and that gluten exclusion would restore a normal mucosal appearance in intestinal lymphoma. Moreover, antigliadin antibodies have been noted in

patients who develop lymphoma in the course of celiac disease, whereas these antibodies are absent in patients who present with a lymphoma without a prior history of celiac disease (71).

A variety of presentations have been noted including diarrhea, intestinal obstruction, intestinal perforation, weight loss, abdominal pain, intestinal bleeding, fever, and finger clubbing. IgA levels may increase. Enteropathy-associated T-cell lymphoma (EATL) may be very difficult to diagnose (72). If routine investigations, including small bowel enema and abdominal computed tomography (CT) scanning, are negative and the clinical picture is suspicious, a laparotomy with full-thickness biopsies should be done. Local resection is rarely possible, and response to systemic chemotherapy is poor.

Other cancers also occur with increased frequency in celiac disease, including esophageal and pharyngeal cancer as well as small intestinal adenocarcinoma (73). A reduced incidence of small bowel lymphoma has been reported in patients adhering to a gluten-free diet (74).

INVESTIGATIONS

Hematology

Anemia is present in 40 to 80% of patients (76, 77). Unexplained iron or folate deficiency anemia rather than florid malabsorption is increasingly responsible for raising the suspicion of celiac disease (78). The simultaneous deficiency of both iron and folate produces a dimorphic blood picture, giving rise to an increased red cell distribution width (RDW). Hyposplenism is common in celiac disease and produces Howell-Jolly bodies (79). Folate deficiency may cause a slightly low serum B₁₂ level that responds to folate replacement. Rarely, mucosal atrophy extending to the terminal ileum or bacterial overgrowth secondary to celiac-associated intestinal stasis, may produce B₁₂ deficiency.

Biochemistry

Biochemical abnormalities in celiac disease essentially reflect both the extent and duration of malabsorption and range from none to multiple changes involving fluids, minerals, proteins, fat, and gut hormones. The stool fat content is usually increased in celiac patients with diarrhea but may be normal in those presenting in a monosymptomatic fashion with iron, folate, or vitamin D deficiency (80). Steatorrhea tends to be less marked in celiac disease than in chronic pancreatitis, and stool fat concentration is also relatively lower because of greater fluid losses in the celiac stool. The importance of stool fat measurement has diminished with increasing use of endoscopic small bowel biopsy.

D-Xylose is an inert sugar absorbed in the upper small intestine. Serum or urinary levels following oral administration provide a measure of jejunal absorptive capacity, but test reliability is influenced by variations in gastric emptying, age, and renal function (82) (see Chapter 65). Selective mucosal absorption has been tested with probes of different molecular size for both diagnosis and follow-up of celiac disease. These molecules

include mannitol, lactulose, and lactobiose. In celiac patients, larger molecules are selectively absorbed, probably via paracellular routes, and transcellular absorption of smaller molecules diminishes as a result of villous atrophy (83). Although a high sensitivity and negative predictive value have been claimed for tests of differential urinary excretion, they have not yet gained wide acceptance. Transaminase levels are frequently elevated in adult patients and normalize following treatment with a gluten-free diet (84, 85).

Radiology

The primary role of radiology of the small bowel is exclusion of other diseases such as Crohn's disease, jejunal diverticulosis, strictures, or lymphoma and barium studies are not routinely required. In celiac disease, the radiologic appearance is often normal but there may be dilatation of the lumen and thickening of mucosal folds.

Antigliadin and Antiendomysial Antibodies

Increasing recognition of the subtle and atypical modes of presentation of celiac disease has underlined the importance of noninvasive screening tests. Both IgG and IgA antigliadin antibodies are present in untreated celiac disease, but they lack sufficient diagnostic sensitivity and specificity, especially in the case of IgG antibodies. Antiendomysial antibodies, which are detected by binding to a variety of smooth muscle basement membranes including monkey esophagus and human umbilical cord (86), have a sensitivity and specificity of 100%. This results in a predictive accuracy of 100%, even with prevalence rates as low as 0.2% (87, 88 and 89). Titers of both antigliadin and antiendomysial antibodies fall rapidly in patients on a gluten-free diet.

The role of serologic testing remains controversial. It will likely become a valuable screening test but will not supplant intestinal biopsy as a diagnostic test. The positive predictive value of antiendomysial antibody testing is sufficiently high for use as a population screening tool, which has been suggested.

Intestinal Biopsy

Endoscopic biopsy of the second or third portion of the duodenum has largely replaced use of the Crosby or Watson capsule. Although these latter devices provide larger biopsy specimens, frustration with the technical difficulties associated with them compared with the ease of obtaining multiple, albeit smaller, endoscopic samples has led to a marked decline in their use. An immediate diagnosis of villous atrophy can be made by dissecting-microscopic examination of the biopsy material. Gastric antral histologic changes have been reported in celiac patients.

Endoscopy may reveal macroscopic changes in some patients. These include thinning, wider separation and scalloping of the margins of the valvulae conniventes (7, 8). In face, the mucosa may have a mosaic appearance that is enhanced when it is partially covered with blood following biopsy. Diagnostic sensitivity and specificity of about 90%

have been reported.

The appearance of celiac disease on biopsy specimens is nonspecific, and definitive diagnosis requires repeat biopsy to demonstrate histologic improvement on a gluten-free diet and reversion to abnormality after gluten challenge. In adults, the last step is frequently omitted.

TREATMENT

Dietary avoidance of gluten is central to management of celiac disease. Most patients notice a significant symptomatic improvement within days. Changes in mucosal histology take longer. A reduction in intraepithelial lymphocyte infiltration occurs within a few weeks (90), but recovery of the normal villous appearance usually takes 2 to 3 months. Some patients never fully recover, even though they feel well. The diet of patients with demonstrated deficiencies should be supplemented initially with appropriate vitamins and minerals, but long-term supplementation is unnecessary.

Wheat, barley, rye, and oats are the main sources of gluten, and foodstuffs derived from these products have been traditionally excluded. Oats contain less gluten than other cereals, and a recent Finnish study showed no adverse nutritional or mucosal effects from a daily intake of 50 g of oats (91). Adherence to a strict gluten-free diet may be difficult because cereal products are present in a variety of prepared foods, but deliberate noncompliance is a much larger problem. Dietary surveys show that 30% of patients admit to taking gluten and remaining asymptomatic (92, 93). However, in some patients, ingestion of even small amounts of gluten results in bloating and diarrhea. Attainment of expected adult stature may be compromised by gluten intake during childhood and adolescence (94). The desirability of adhering to a gluten-free diet is heightened by a study demonstrating a reduction in the malignancy rates of compliant patients (74). See Appendix [Table V-A-36](#) for details of a gluten-free diet and associated precautions.

Significant differences exist internationally in the constituents of a gluten-free diet. In Canada, the diet must not contain any wheat, barley, rye, oats, or triticale, whereas in many European countries, levels ranging from 5 to 50 µg gliadin per day are acceptable. The Celiac Sprue Association U.S.A., in addition to recommending complete exclusion of gluten-containing cereals, also advises avoiding buckwheat and any foods using cereal mash in their manufacture. These include distilled alcoholic beverages and white vinegar, which contain no detectable gliadins. Beer contains 3 µg/L prolamin and probably should be avoided. In vitro studies have shown that gliadin-deficient wheat is less toxic to enterocytes, thus revealing potential approaches to dietary treatment (95).

TREATMENT FAILURE

If a patient fails to respond to treatment, deliberate or inadvertent intake of gluten must be considered as well as diagnostic error. If there is any doubt about the adequacy of the original intestinal biopsies, further tissue should be obtained. Consideration must be given to other disorders associated with mucosal flattening, especially ulcerative

jejunoileitis and lymphoma.

True failure to respond to dietary treatment is rare, and its pathogenesis uncertain. Some patients respond successfully to corticosteroid treatment (96). Rapidly metabolized “first-pass” steroids have been used to treat celiac disease instead of dietary therapy, and such compounds may become the drugs of choice in nonresponsive patients (97). Cyclosporine has been used successfully in a few patients with resistant disease (98).

[Chapter References](#)

Each disorder of the exocrine pancreas requires special attention to nutritional aspects of treatment. In acute pancreatitis, nutrition is important in moderate-to-severe disease because the disease process often is complicated and prolonged, precluding eating. In chronic pancreatitis and pancreatic cancer, there is reduced secretion of pancreatic enzymes leading to malabsorption. In the former, the disease primarily affects acinar cells that manufacture enzymes, and in the latter, the tumor obstructs the pancreatic ducts, blocking pancreatic enzymes from entering the duodenum. In this chapter, we briefly discuss important clinical aspects of these diseases, particularly the assessments that should lead to treatment of the nutritional deficits of the diseases, parenteral or enteral nutrition in acute pancreatitis, and pancreatic enzymes in chronic pancreatitis and pancreatic cancer.

ACUTE PANCREATITIS

Depending on the population, alcohol abuse and biliary tract disease cause acute pancreatitis in 75 to 85% of patients. In addition to these common causes of acute pancreatitis, other factors have been implicated in the pathogenesis of acute pancreatitis, such as metabolic, traumatic, operative, infectious, and pharmacologic etiologies ([Table 72.1](#)). Patients with acute pancreatitis typically present with acute abdominal pain and elevation of pancreatic enzymes in the serum; amylase is the enzyme most commonly measured.

Biliary tract disease	Postoperative
Alcohol	Endoscopic retrograde pancreatogram
Idiopathic	Hypercalcemia
Anatomic causes	Infectious agents
Cholelithiasis	Pregnancy (usually biliary tract)
Pancreas divisum?	Hereditary
Duodenal diverticulum?	Pancreatic duct obstruction (worms, ampullary tumor)
Drugs	Hyperlipidemia (types I, IV, and V)
Cancer of the pancreas	Metastatic cancer to the pancreas
Vasculitis	Renal transplantation
Abdominal trauma	

Table 72.1 Etiology of Acute Pancreatitis

Acute pancreatitis ranges in severity from a slight edematous inflammation (interstitial pancreatitis) that usually resolves spontaneously and completely in a few days to a fulminate process that can progress to necrotizing pancreatitis because of inflammation and tissue necrosis following intra- and extrapancreatic spreading of active pancreatic enzymes. In acute pancreatitis, toxicity and complications are caused by extravasation of enzymes into the perarenal spaces, lesser sac, and peritoneal cavity and into the circulation by absorption through retroperitoneal venous and lymphatic vessels. Extravasation of enzymes into the abdominal cavities produces a “burn,” resulting in loss of protein and fluid. This third-space loss and escape of enzymes into the circulation causes hypovolemia and hypotension. In addition to circulatory collapse, this process also leads to other systemic complications such as renal insufficiency, respiratory distress syndrome, and findings akin to those of sepsis (leukocytosis, fever). Furthermore, escape of pancreatic enzymes and other pancreatic secretions into the pancreas and peripancreatic areas causes pancreatic and peripancreatic necrosis. Lipase most likely is the enzyme responsible for initiation of necrosis by digesting pancreatic and peripancreatic fat.

Clinical Assessment and Prediction of Need for Specialized Nutritional Treatment

Mild acute interstitial pancreatitis is characterized by abdominal pain, nausea, vomiting, anorexia, and low or no mortality (<2%). Although local complications such as third-space losses leading to hypovolemia and systemic complications such as respiratory or renal failure may occur in interstitial pancreatitis, they are uncommon, and resolution of symptoms and recovery occurs in several days. In these patients, simple supportive medical treatment suffices, and parenteral nutrition is rarely needed. However, in severe necrotizing pancreatitis, characterized by end-organ failure, the mortality rate may approximate 30% if the necrotic tissue is infected (1). These patients need parenteral nutrition instituted as soon as their severe pancreatitis is recognized, because a prolonged, complicated clinical course is extremely likely.

Clinical Predictors of Severity

Severity of acute pancreatitis is the major predictor of the outcome of an attack of pancreatitis and predicates the type of treatment patients will receive. Therefore, one *must* be able to predict the severity of the disease at presentation. A number of predictors of severity have been proposed, many carrying the name of the principal investigator who devised them. Among them are the criteria of Ranson (2), the first criteria proposed. In addition, Bank (3), Agarwal and Pitchumoni (4), and Imrie (5) have suggested criteria. All these criteria have the disadvantage of requiring 48 hours to measure at least some of their components. Ranson's criteria (Table 72.2) use age and laboratory measurements at admission and further clinical and laboratory measurements at 48 hours: 2 signs or less predict 0 mortality; 3 to 5 signs predict a mortality of 10 to 20%; and with 6 or more signs, mortality exceeds 50%. Patients with three signs or more have a high risk of developing pancreatic necrosis and systemic complications. The other named criteria are simpler and in general rely on development of cardiac, pulmonary, renal, metabolic, hematologic and neurologic complications within the first 48 hours; presence of one complication or more identifies patients with a high risk of complications and death.

At admission
Age > 55 years
WBC > 16,000/mm ³
Glucose > 200 mg/dL
LDH > 350 IU/L
AST > 250 IU/L
During initial 48 hours
Hct decrease of >10
BUN increase of >5 mg/dL
Ca ²⁺ < 8 mg/dL
PaO ₂ < 60 mm Hg
Base deficit > 4 mEq/L
Fluid sequestration > 6 L

From Banks PA. Medical management of acute pancreatitis and complications. In: Go VLW, et al., eds. The pancreas: biology, pathobiology, and disease. New York: Raven Press, 1993:583-611, with permission.

Table 72.2 Ranson's Criteria of Severity

At present, the most commonly used severity index is the APACHE-II score (Acute Physiology and Chronic Health Evaluation), with scoring on the basis of laboratory testing and vital signs. In contrast to other scoring systems, the APACHE score can be used repeatedly and at any time during the course of an attack. Scores of 9 or below predict survival, but scores of 13 or more have a high probability of death (6, 7, 8, 9 and 10, 11). On the basis of these data, we recommend that scores of 10 or more, particularly during the first 48 hours, should trigger a move to the intensive care unit and consideration of initiating parenteral nutrition, among other supportive measures.

Imaging and Serum Tests

Of the imaging and laboratory tests, computed tomography (CT) is currently considered the best to assess the severity of acute pancreatitis. Originally, the scoring system of Balthazar and Ranson ([12](#), [13](#)) was used (grades A to E: A, normal pancreas; B, focal or diffuse enlargement; C–E, pancreatic enlargement; C with mild peripancreatic inflammation, D with fluid in the anterior pararenal space, and E with fluid collections in more than one area). The prognosis for grades A and B is excellent. For grade C, pancreatic necrosis and infection approximates 10%. For grades D and E, infection is 50%, and mortality may reach 15%. Currently, however, the state of the art is to do a bolus contrast-enhanced CT when severe pancreatitis is suspected. This technique clearly differentiates interstitial from necrotizing pancreatitis.

Other methods of detecting severe pancreatitis such as peritoneal tap (recovery of dark fluid or recovery of >20 mL of free peritoneal fluid of any color) or serum tests such as C-reactive protein, α_2 -macroglobulin, phospholipase A₂ activity, and urinary trypsinogen activating peptide (TAP) are not popular because they are invasive or they lack proven diagnostic accuracy.

Treatment

Food and drink are withheld from all patients with acute pancreatitis. In addition, in moderate-to-severe attacks of pancreatitis, gastric contents are aspirated from the stomach through a nasogastric tube. Most patients have mild pancreatitis and are treated for several days with supportive care including pain control, intravenous fluids, and nothing by mouth. Most patients eat within 5 to 7 days and do not require parenteral nutrition. In contrast, patients with moderate-to-severe pancreatitis require nutritional support as a routine part of medical management ([14](#)), to prevent inanition because they rapidly become nutritionally depleted. However, total parenteral nutrition (TPN) does not affect the outcome of attacks ([15](#)).

Although resting energy expenditure in patients with uncomplicated acute pancreatitis (measured by indirect calorimetry) is no greater than predicted, 82% of patients with sepsis are hypermetabolic ($120 \pm 12\%$ of predicted value) ([16](#)). Indeed, patients with pancreatitis exhibit some of the same metabolic, cardiovascular, and hemodynamic features observed in sepsis. In addition, if pseudocysts, abscesses, or fistulas develop, a protracted course with increased metabolic needs should be anticipated; nutritional complications are most likely to arise in this setting.

In moderate-to-severe acute pancreatitis, parenteral nutrition is initiated as soon as the cardiorespiratory systems are stable. Nutritional support should include (a) hypertonic dextrose; (b) solution of crystalline amino acids; (c) fat emulsion to prevent fatty acid deficiency (except in patients with hyperlipidemia-induced pancreatitis); (d) daily requirements of electrolytes, vitamins, and trace elements; (e) insulin to control hyperglycemia; and (f) proton pump inhibitors (omeprazole) or H₂ blockers to reduce gastric acid secretion. After paralytic ileus has subsided and in patients requiring

surgery, oral low-fat feedings should be used instead of the parenteral route. The oral route, rather than TPN, should be used whenever possible, to eliminate the potential complications of TPN (see [Chapter 101](#)).

TPN has the advantage of maintaining “pancreatic rest” better than enteral nutrition. However, enteral feedings have a number of advantages over TPN: maintenance of intestinal integrity and the gut mucosal barrier, which may decrease the risk of bacterial translocation and subsequent septic complications of acute pancreatitis, lower cost, and elimination of complications related to parenteral nutrition. The farther down the upper gastrointestinal tract an elemental diet is infused, the less stimulation of pancreatic exocrine secretion, because the normal cephalic, gastric, and intestinal (more potent) phases of pancreatic stimulation are bypassed. Unfortunately, to date no prospective randomized trials have assessed the effect of early enteral nutrition on the course and outcome of acute pancreatitis.

Refeeding

When to begin oral feeding, what to feed, and how often to feed are questions that occur with every patient with acute pancreatitis. The answers to these questions are not based on scientific data from studies in patients with acute pancreatitis. Instead, they are based on physiologic studies in normal humans to determine the effects of nutrients on pancreatic enzyme secretion and on personal anecdotal experience. The criteria we use to initiate oral feedings are (a) absence of abdominal pain and tenderness, (b) reduction of amylase levels to near-normal levels, and (c) absence of complications.

We begin feeding patients by giving 100 to 300 mL of liquids containing no calories every 4 hours for the first 24 hours. If this diet is tolerated, oral feeding is advanced to giving the same volume of liquids containing nutrients. Subsequently, if patients continue to do well, feedings are changed gradually over 3 to 4 days to soft, and finally solid, foods. All diets contain more than 50% carbohydrate calories, and the total caloric content is gradually increased from 160 to 640 kcal per meal.

These recommendations are based on our studies in healthy humans in which we found that the rate of pancreatic enzyme secretion was related to the nutrient composition of meals ([18](#)) and the rate of delivery of kilocalories to the duodenum ([19](#)). Secretion of pancreatic enzymes decreased as more carbohydrate was ingested, particularly when carbohydrates were 50% or more of the total caloric content of the diet ([Fig. 72.1](#)). In another study, we found that when nutrients were infused into the duodenum, pancreatic enzyme secretion was directly related to the rate of caloric infusion, i.e., there was less secretion at infusions of 40 kcal/h than at 90 or 160 kcal/h ([Fig. 72.2](#)) ([19](#)).

Figure 72.1. Interdigestive (*top panel*) and postprandial (*bottom panel*) geometric mean total enzyme output (combined outputs of amylase, lipase, and trypsin) after following one of the five diets for 2 weeks. The interdigestive and postprandial enzyme outputs were significantly different among the five diets (one-way ANOVA, $P < 0.05$). (From Boivin M, Lanspa SJ, Zinsmeister AR, et al. *Gastroenterology* 1990;99:1763–71, with permission.)

Figure 72.2. Mean (SEM) total enzyme outputs for the 300 minutes of the study. Outputs of amylase, chymotrypsin, and trypsin were significantly associated with 40, 90, and 160 kcal/h infused ($r = 0.44$, $P < 0.02$; $r = 0.44$, $P < 0.03$; and $r = 0.32$, $P < 0.05$; respectively). (From Holtmann G, Kelly DG, DiMagno EP. *Gut* 1996;38:920–4, with permission.)

CHRONIC PANCREATITIS

Most patients who develop chronic pancreatitis are alcoholics, who may have nutritional deficiencies secondary to alcoholism ([Chapter 96](#)). However, about 20% of patients with chronic pancreatitis in our population have idiopathic chronic pancreatitis. Other causes

of chronic pancreatitis are much less common ([Table 72.3](#)). Some conditions give rise to exocrine insufficiency and malabsorption and malnutrition without causing chronic pancreatitis, such as trypsinogen or enterokinase deficiency or colipase or lipase deficiency, but these conditions are rare.

Alcohol	Idiopathic
Nonalcoholic tropical chronic pancreatitis	
Hereditary	Hypercalcemia
Stricture of the duct of Wirsung	Cystic fibrosis
Carcinoma of the pancreas	Pancreatic fistula
Schwachman's syndrome	Trypsinogen-enterokinase deficiency
α_1 -Antitrypsin deficiency	Isolated enzyme deficiency (e.g., lipase, colipase)

Table 72.3 Etiology of Chronic Pancreatitis and Exocrine Insufficiency

During early chronic pancreatitis in patients with abdominal pain but no steatorrhea, a low-fat, low-protein, high-carbohydrate diet is indicated. In dogs with profound exocrine pancreatic insufficiency, a diet containing a high proportion of fat (43 and 47%) along with sufficient lipolytic activity (bacterial or porcine lipase) decreases steatorrhea by increasing the coefficient of fat absorption ([20](#)).

Natural History and Clinical Aspects

Chronic pancreatitis causes both exocrine and endocrine insufficiency. What is not widely recognized is that the rate of progression to exocrine and endocrine insufficiency depends upon the underlying type of chronic pancreatitis. In our experience ([21](#)), about 60% of patients have chronic pancreatitis due to alcohol (defined as an average daily consumption of 50 g of alcohol or more), about 16% have idiopathic chronic pancreatitis, and the remainder ingest an unknown amount of less than 50 g of alcohol daily. The natural history of the latter group is not defined but is under study. However, patients with chronic pancreatitis due to alcohol develop exocrine ([Fig. 72.3](#)) and endocrine ([Fig. 72.4](#)) insufficiency a median of 13 and 20 years, respectively, from onset of disease. According to our studies, there are two forms of idiopathic chronic pancreatitis with quite different courses for development of pancreatic insufficiency. Patients with early-onset chronic pancreatitis (age 35 or younger) develop exocrine and endocrine pancreatic insufficiency at much slower rates (26 and 28 years from onset of disease vs. 17 and 12 years for late-onset disease).

Figure 72.3. Probability of remaining free of exocrine insufficiency for patients with early-onset or late-onset idiopathic chronic pancreatitis and alcoholic pancreatitis. Differences were significant between early-onset idiopathic chronic pancreatitis and late-onset idiopathic chronic pancreatitis ($P = 0.024$) and between early-onset idiopathic chronic pancreatitis and alcoholic chronic pancreatitis ($P = 0.0008$). (From Layer P, Yamamoto H, Kalthoff L, et al. *Gastroenterology* 1994;107:1481–7, with permission.)

Figure 72.4. Probability of remaining free of diabetes mellitus for patients with early-onset or late-onset idiopathic chronic pancreatitis and alcoholic pancreatitis. Differences were significant between early-onset idiopathic chronic pancreatitis and late-onset idiopathic chronic pancreatitis ($P = 0.01$) and between early-onset idiopathic chronic pancreatitis and alcoholic chronic pancreatitis ($P = 0.0025$). (From Layer P, Yamamoto H, Kalthoff L, et al. *Gastroenterology* 1994;107:1481–7, with permission.)

The onset and severity of pain are important differences among the groups of patients with chronic pancreatitis. All patients with early-onset chronic pancreatitis have pain, mostly severe. In contrast, at onset of the disease, about 75% of patients with alcoholic pancreatitis have pain (50% severe), and only 50% of patients with late-onset idiopathic

chronic pancreatitis have pain (mostly mild). Patients with late-onset chronic pancreatitis who do not have pain usually present with symptoms of malabsorption and later are found to have chronic pancreatitis; uncommonly, they may present with diabetes.

Clinically, recurrent attacks of abdominal and back pain characterize chronic pancreatitis of patients with alcoholic or early-onset idiopathic pancreatitis. Persistent abdominal pain usually indicates a complication, an inflammatory mass, pseudocyst, or obstruction of the bile duct or duodenum. Anorexia, nausea, and vomiting may accompany these complications. Eating may aggravate these symptoms as well as induce diarrhea. The clinical spectrum of chronic pancreatitis ranges from a benign chronic course to unremitting progressive weight loss and inanition complicated by narcotic abuse, addiction, and significant psychologic problems. Abdominal pain, malabsorption, and diabetes mellitus are complications of chronic pancreatitis that affect nutritional status and have important implications for nutritional treatment of chronic pancreatitis.

Some 33% of patients with chronic pancreatitis were reported to have a resting energy expenditure above the value predicted by the standard Harris and Benedict formula (16). In another series of stable outpatients with alcoholic chronic pancreatitis, hypermetabolism was observed in 48.5%, and this percentage rose to 65% in the subgroup of undernourished chronic pancreatitis patients (22). However, most patients with pancreatic insufficiency can maintain their weight and strength with a good appetite, high caloric intake, and ingestion of pancreatic enzymes. In our experience, more extensive measures are rarely needed to achieve or maintain an acceptable nutritional state. Usually, patients who become severely debilitated and malnourished do so in response to an acute complication such as an exacerbation of chronic pancreatitis, pancreatic ascites, or symptomatic pseudocysts. In these patients, enteral feeding or TPN may be necessary for extended periods of time. Similarly, enteral or parenteral nutritional support may be advisable to prepare a patient for surgery or to maintain the patient following an operation (23).

Assessment of Exocrine Insufficiency

Most patients with chronic pancreatitis who require long-term attention to nutritional status have malabsorption. Therefore, it is important to detect malabsorption promptly when suspected. The “gold standard” test for malabsorption is quantitative fecal fat excretion measurement (see Chapter 65). However, a qualitative fecal fat test may have more than 90% sensitivity (23). Other fecal tests devised to assess exocrine function (fecal chymotrypsin and elastase) as well as noninvasive tests of exocrine pancreatic function (bentiromide or pancreolauryl tests) are generally highly sensitive (>85%) only when malabsorption is present. Therefore, they can generally be used to detect malabsorption in chronic pancreatitis. The most accurate tests of pancreatic function are invasive tests that require duodenal intubation and stimulation of the pancreas by hormones (24) (we use CCK-OP; others use secretin or a combination of CCK and secretin). These tests measure the entire range of pancreatic function and are very useful to establish the diagnosis of chronic pancreatitis when mild or moderate exocrine dysfunction is present, but they are not necessary when malabsorption is present.

Relationship between Pancreatic Enzyme Secretion and Nutrition

As noted above, in chronic pancreatitis, it may take one to three decades for severe pancreatic chronic insufficiency with malabsorption to develop. Major reasons for the slow development of malabsorption are the slowly progressive destruction of the acinar cell mass and the large reserve capacity for enzyme secretion. There is a 10-fold reserve for exocrine pancreatic enzyme secretion; steatorrhea or azotorrhea occurs only after maximal lipase or trypsin secretion is reduced by more than 90% in patients with chronic pancreatitis or pancreatic cancer (25, 26, 27 and 28). In addition, in studies in normal humans we found that reducing intraluminal amylase activity to 10% of normal by use of an amylase inhibitor causes carbohydrate (starch) malabsorption (29, 30). Lipase secretion into the duodenum decreases more rapidly than secretion of proteolytic enzymes (26). Hence, steatorrhea often occurs earlier and is more severe than azotorrhea. This may be due to decreased pancreatic secretion of lipase relative to proteolytic enzymes, but lipase is much more fragile than proteolytic enzymes and amylase (31); it is more easily inactivated by acidic pH and is digested by proteolytic enzymes (chymotrypsin > trypsin) (32).

Effect of Pancreatic Enzyme Replacement on Absorption

Standard pancreatin treatment (a large amount of enzymes taken at doses of eight tablets with meals consisting of 25 g of fat) abolishes azotorrhea and reduces, but does not totally correct, steatorrhea (33) (Fig. 72.5). Most patients on this regimen achieve satisfactory nutritional status and become relatively asymptomatic. In many remaining symptomatic patients, simply reducing the amount of dietary fat alleviates diarrhea. For the occasional symptomatic patient, addition of cimetidine (34) or omeprazole (35) to standard pancreatin treatment usually abolishes steatorrhea and alleviates troublesome diarrhea. Similar results have been achieved with bicarbonate (36).

Figure 72.5. Results of various treatments on fecal fat excretions (g/24 h) in patients with chronic pancreatitis. Pancreatin used in these studies was Viokase. (From DiMagno EP, Layer P, Clain JE. Chronic pancreatitis. In: Go VLW, et al., eds. The pancreas: biology, pathobiology, and disease. New York: Raven Press, 1993;665–706,

with permission.)

When gastric pH exceeds 4 for approximately 2 hours postprandially, altering the dose schedule from 8 tablets with meals to 2 tablets hourly may alleviate steatorrhea. By contrast, when gastric pH does not exceed 5 and duodenal pH is maintained relatively acidic (below 4) for long periods of time postprandially, microencapsulated preparations may be effective (37).

If symptoms and steatorrhea continue, special intraluminal studies may be necessary to determine whether intraluminal conditions permit certain dose schedules to be effective or if the intraluminal conditions have been altered by adjunctive therapy. For example, if administration of 300 mg of cimetidine does not keep the gastric pH above 4, gastric secretion was not reduced enough. Either more cimetidine should be given or, if intraluminal conditions are constantly acidic, Pancrease may be the best preparation to use. Although microencapsulated preparations containing a high dose of lipase may correct steatorrhea in some patients (38), these preparations have been withdrawn from the U.S. market because of the association of colonic strictures in children with cystic fibrosis who were ingesting large numbers of these capsules (39, 40).

Effect of Nutrients (Diet) on Normal Pancreas Secretion

Single nutrients have different effects on exocrine pancreatic secretion when infused into the gut (41). Essential amino acids (41) and poorly absorbed carbohydrates (mannitol) (42) cause 50% maximal enzyme secretion, but calcium (43), triglycerides, and long-chain (C18) fatty acids (44) induce maximal enzyme secretion.

Similarly, in normal persons, diets containing carbohydrate as 50 to 80% of the caloric content cause the least postprandial and interdigestive pancreatic enzyme secretion (18), and high-fat diets (40% of the calories) stimulate maximal postprandial and interdigestive secretion. Postprandial effects occur immediately, whereas the carbohydrate effect on interdigestive secretion occurs within 24 hours, and that for fat after 24 hours. Thus, in patients with pancreatitis, high-carbohydrate, low-fat, low-protein diets may be useful to minimally stimulate exocrine pancreatic secretion.

Effect of Unabsorbed Nutrients on Pancreatic Secretion

In normal humans, ileal infusions of carbohydrate (starch plus glucose) proportionally decrease trypsin and bile acid secretion into the duodenum, slow gastric emptying (45), but increase amylase secretion relative to trypsin (46). These changes should increase digestion and absorption of carbohydrate by slowing gastric emptying of carbohydrate into the duodenum and increasing pancreatic amylase secretion. It is not known whether these changes in exocrine pancreatic secretion occur with other nutrients in the ileum or in diseases causing malabsorption.

PANCREATIC INSUFFICIENCY IN PANCREATIC CANCER

A common error in patients with pancreatic cancer is not recognizing that malabsorption is an important cause of weight loss (47). About 75 to 80% of pancreatic adenocarcinomas (the type of 90% of pancreatic cancers) arise in the head of the pancreas and are associated with obstruction of the pancreatic duct and severe exocrine pancreatic insufficiency (Fig. 72.6). In addition, patients who undergo the standard radical pancreaticoduodenectomy are frequently not given appropriate enzyme replacement therapy. These patients should receive pancreatin as described for treatment of chronic pancreatitis. In our experience, steatorrhea and creatorrhea can be appreciably improved (Fig. 72.6). (Also see Chapter 82.)

Figure 72.6. Coefficients of fat and protein absorption in pancreatic cancer patients with no treatment and when receiving pancreatic extract. The single patient who had severe steatorrhea and did not improve with pancreatin developed a biliary cutaneous fistula between no treatment and administration of pancreatin (*dotted line*). (From Perez MM, Newcomer AD, Moertel CG, et al. *Cancer* 1983;52:346–52, with permission.)

[Effect of Nutrition on the Liver](#)

[Chapter References](#)

The functional integrity of the liver is essential for use of nutrients. Disorders of this organ have far-reaching effects on nutritional status. This chapter first delineates the liver's role in normal processes. Then nutritional complications of liver dysfunction and approaches for correcting these nutritional deficiencies are assessed. Finally, nutritional factors that may themselves result in liver injury are discussed.

LIVER IN NORMAL NUTRITION

The liver influences nutritional status through its elaboration of bile salts and its role in intermediary metabolism of protein (amino acids), carbohydrate, fat, and vitamins.

Bile Salts

Bile salts are synthesized in the liver from cholesterol, secreted in bile, and mixed with intestinal contents in response to a meal. In the intestine, bile salts are active in the intraluminal phase of fat assimilation, their principal action being that of a detergent. Triglycerides enter the duodenum as an emulsion whose surface is covered by a relatively polar layer of phospholipids and proteins that must be removed by bile salts before lipolysis via pancreatic lipase can proceed. However, clearance of these polar substances from the emulsion also separates glyceride in the emulsion from lipase in the water phase; as a result, lipolysis becomes dependent on another enzyme, colipase, which is secreted with lipase in the pancreatic juice. By binding to lipase and altering its molecular conformation, colipase overcomes the inhibitory actions of bile salts on lipolysis (1, 2).

The products of lipolysis, such as fatty acids, monoglycerides, and small amounts of lysophospholipids form mixed micelles with bile salts. Intestinal uptake of long-chain fatty acids depends on these mixed micelles. In contrast, absorption of short- and medium-chain fatty acids proceeds in the absence of bile (3). Following uptake of fatty acids, bile salts are conserved by being recycled through an enterohepatic circulation. Bile salts, especially conjugates of the trihydroxy bile acid, cholic acid, are reabsorbed from the distal small bowel by an active, sodium-dependent process. Dihydroxy bile salts are absorbed by passive diffusion from the proximal small bowel (4). The liver extracts these reabsorbed bile salts from the portal vein blood and returns them to the biliary tree. Hepatic synthesis of bile salts replenishes the fraction of the bile salt pool that escapes reabsorption and is excreted in the feces (5).

Intermediary Metabolism

The liver plays a fundamental role in intermediary metabolism. This is a highly complex topic and is not covered here in an exhaustive manner. Instead, the highlights are reviewed to provide an overall view for understanding of the nutritional complications of liver injury.

Carbohydrates

The liver regulates carbohydrate metabolism by the synthesis, storage, and breakdown of glycogen. A polymeric form of glucose, large amounts of glycogen can be stored within the hepatocyte without major effects on the intracellular osmotic pressure. Glycogen is formed when the intake of glucose (or other gluconeogenic fuels) exceeds energy requirements; glycogen is broken down when intake lags behind energy needs. The principal enzymes controlling glycogenesis and glycogenolysis are glycogen synthase and phosphorylase, respectively. There is a reciprocal relationship between these two enzymes. Stimulation of glycogen synthetase is usually accompanied by inhibition of phosphorylase; conversely, agents that stimulate phosphorylase inhibit glycogen synthetase. Factors that control these enzymes include intracellular levels of glucose-6-phosphate and hormones such as epinephrine, glucagon, and insulin. Epinephrine and glucagon raise blood glucose levels by activating phosphorylase, whereas insulin lowers blood glucose, in part by stimulating glycogen synthetase.

Hepatocytes also possess enzymes that enable them to synthesize glucose from various precursors such as amino acids, pyruvate, and lactate (gluconeogenesis). Hypoglycemia promotes this process. The link between hypoglycemia and gluconeogenesis is probably mediated by secretion of cortisol from the adrenal medulla. Cortisol secretion is under pituitary control (adrenocorticotrophic hormone, or ACTH) and is known to mobilize glycogenic amino acids from various tissues.

Fat

The liver is a major site of fatty acid breakdown and triglyceride synthesis. The breakdown of fatty acids provides an alternative source of energy when glucose is

unavailable, as during fasting or starvation. Triglyceride in adipose tissue is hydrolyzed to release fatty acids. Bound to albumin in the blood, the released fatty acids are rapidly removed by the hepatocyte and transported into mitochondria by a carnitine-mediated process. Within the mitochondria, a number of enzymes degrade the fatty acid molecule to acetyl-CoA fragments, a sequence known as β -oxidation. In turn, acetyl-CoA can enter the citric acid cycle and generate adenosine triphosphate (ATP) by oxidative phosphorylation. Triglyceride synthesis occurs when carbohydrate intake exceeds energy requirements; under such conditions, glucose may overwhelm the glycogen reservoir, and the acetyl-CoA generated by glycolysis is not needed for oxidative phosphorylation. During such times of nutrient abundance, the energy charge inherent in acetyl-CoA is conserved by its conversion to fatty acids and, ultimately, triglycerides. Synthesis of fatty acids involves repetitive additions of two-carbon fragments (derived from acetyl-CoA) to malonyl-CoA. After reaction with α -glycerophosphate, the resulting triglycerides are transported to the adipose tissues as part of lipoproteins, specifically, the very low density lipoproteins (VLDL).

Proteins

The liver plays a central role in synthesis and degradation of protein. Thus it contains the enzymes necessary for transamination and oxidative deamination of amino acids as well as those required for urea synthesis. As noted above, amino acids can also participate in gluconeogenesis. Gluconeogenesis proceeds after conversion of deaminated amino acids to pyruvate or intermediates of the citric acid cycle. Plasma proteins, including albumin, coagulation factors, transferrin, and ceruloplasmin, constitute about one-half of the protein synthesized in the liver. These export proteins are synthesized on the rough endoplasmic reticulum and pass through intracellular pathways. Protein synthesis by the liver is influenced by the nutritional state, as well as by hormones, particularly insulin, glucagon, and glucocorticoids. Insulin and steroids stimulate synthesis of hepatic proteins, whereas glucagon inhibits their synthesis and promotes their degradation.

NUTRITIONAL CONSEQUENCES OF LIVER INJURY

Acute Liver Injury

Regardless of cause, acute liver injury is often associated with anorexia, nausea, and vomiting. When the liver injury is due to alcohol, these symptoms may be exacerbated by concomitant alcoholic gastritis. Thus, acute liver injury is likely to decrease the oral intake of food, but if the illness is short-lived and self-limited, nutritional consequences are minimal. Both alcoholic and nonalcoholic acute liver injury may cause fasting hypoglycemia. This has been attributed to depleted liver glycogen reserves and a block in gluconeogenesis from amino acids.

Chronic Liver Injury

Nutritional complications are frequent when hepatic function becomes impaired in chronic liver injury, particularly cirrhosis. Regardless of etiology, cirrhosis is likely to

cause patients to have abnormal anthropometric measurements (i.e., muscle wasting) and to be anergic to common antigens on skin testing (6). Circulating levels of both fat- and water-soluble vitamins are low in a high percentage of patients with alcoholic cirrhosis. Low serum levels of fat-soluble vitamins (rather than the water-soluble variety) are more characteristic of nonalcoholic cirrhosis (7). These nutritional deficiencies arise as a result of one or more of the following factors: inadequate dietary intake, maldigestion, malabsorption, and defective metabolism.

Dietary Intake

Inadequate intake of protein is common, especially among alcoholics with cirrhosis. Indeed, if the alcoholic patient continues to drink despite cirrhosis, protein intake may be low, and the bulk of dietary calories may be derived from carbohydrates and alcohol per se. Calories derived from alcohol are, in a sense, “empty” because alcoholic beverages are devoid of proteins, minerals, vitamins, and significant amounts of carbohydrate. Furthermore, their actual caloric contribution is less than that of an equivalent amount of carbohydrates (see [Chapter 94](#)). Changes in mental status that result from hepatic encephalopathy may also contribute to the poor intake of patients with advanced liver disease. Hepatic coma in turn is likely to result in hospitalization, which may itself exacerbate nutritional deficiencies in these patients. Malnutrition in hospitalized patients results from both diagnostic (radiologic or endoscopic procedures) and therapeutic (e.g., variceal sclerotherapy) interventions.

Maldigestion and Malabsorption

Decreased bile salt secretion and pool size have been demonstrated in patients with cirrhosis (8). In light of the role of bile salts in fat digestion (see “[Bile Salts](#)” above), contraction of the bile salt pool would be expected to impair micelle formation and lead to abnormalities of fat assimilation, especially in patients with underlying pancreatic insufficiency. Steatorrhea in turn causes deficiencies in fat-soluble vitamins, with clinical manifestations such as night blindness, osteoporosis, and easy bruisability or hemorrhage.

Metabolic Changes

A number of defects in protein metabolism have been noted in patients with chronic liver failure. These include decreased hepatic synthesis of export proteins (albumin, coagulation factors), decreased urea synthesis (9), and decreased metabolism of aromatic amino acids. The effect of advanced liver disease on protein catabolism is controversial. Using stable isotopes such as ^{13}C leucine, turnover studies indicate that protein degradation is normal in fasted cirrhotic patients (10). However, after feeding, protein flux appears to increase (11). These alterations have important clinical consequences. Decreased synthesis of plasma proteins may lead to hypoalbuminemia and exacerbate the formation of ascites in patients with portal hypertension. Depressed levels of coagulation factors may predispose these patients to the risk of gastrointestinal (GI) hemorrhage. Failure to detoxify ammonia and the abnormal amino acid profile of patients with cirrhosis may in part increase the likelihood of hepatic encephalopathy. Despite these abnormalities in intermediary metabolism, overall nitrogen balance can be

maintained at positive levels by amounts of dietary protein similar to that in the noncirrhotic individual (35 to 50 g/day) (12).

Glucose tolerance is frequently abnormal in the cirrhotic patient and has been linked to insulin resistance. The high fasting and postprandial insulin levels in these patients may be related to such factors as portosystemic shunting, increased levels of growth hormone, and depleted body stores of potassium (13, 14). Also, because glycogen stores are often depleted in the cirrhotic liver, fatty acid oxidation appears to supplant glucose as a source of fuel during fasting (10, 14, 15, 16 and 17). This is apparent when indirect calorimetry is performed, because stable cirrhotic patients have a significantly lower respiratory quotient (RQ) than normal controls. Energy expenditure in chronic liver injury is comparable to that in controls (15, 16, 18), making hypermetabolism per se an unlikely explanation for weight loss in these patients. A number of investigators have reported higher-than-predicted energy production rates in cirrhotic patients, but only when energy expenditure was related to urinary creatinine excretion (17, 19). However, as pointed out by Merli et al. (16) and Heymsfield et al. (20), the use of urinary creatinine excretion as a measure of active cell mass is invalid in patients with cirrhosis because their hepatic production of creatine is depressed. Isotopic methods involving labeled water and potassium have been recommended for estimating the metabolically active body cell mass in patients with decompensated cirrhosis (20).

Abnormalities of water- and fat-soluble vitamins are common in patients with cirrhosis. In the nonalcoholic with cirrhosis, deficiencies of fat-soluble vitamins are likely to arise from malabsorption. In part, abnormal bile salt metabolism and defective micelle formation limit the uptake of such vitamins in these patients. In the alcoholic, inadequate intake of vitamins, especially those that are water soluble (thiamin and folic acid), is important (see [Chapter 94](#)).

In addition to inadequate intake and decreased uptake, vitamin metabolism per se may be deranged in chronic liver injury. Defects have been described in phosphorylation of thiamin by alcoholic cirrhotic patients (21), in synthesis of retinol-binding protein (22), in degradation of pyridoxal-5'-phosphate (23), and in conversion of vitamin D to its active form (24). Hepatic vitamin A levels are depressed by both heavy alcohol consumption and drug use (25, 26). Part of the hepatic depletion may be due to mobilization, since hepatic lipoprotein secretion is increased by chronic alcohol consumption (27). "Induced" hepatic microsomes may enhance degradation of both retinol and retinoic acid (28, 29 and 30). As a result of these derangements, vitamin repletion strategies require modification in patients with liver failure, as discussed below.

NUTRITIONAL THERAPY IN LIVER DISORDERS

Protein and Amino Acids

To the extent that patients with liver injury, either acute or chronic, are in negative nitrogen balance, it has been assumed that liver regeneration will be delayed and that muscle wasting will be accelerated. However, when feeding protein or administering amino acids, one must be aware of the precarious balance between the need to restore protein intake and the potential risk of precipitating hepatic encephalopathy. There is

often only a small margin of safety in this respect. The amount of dietary protein that can be tolerated varies considerably. At times, only minimal amounts of protein can be ingested without altering the mental state. Under such circumstances, breakdown of remaining protein stores can be minimized by provision of calories in the form of fats and carbohydrates.

In acute liver injury, much work has focused on the role of protein or amino acid supplementation on the outcome of alcoholic hepatitis. Both enteral and parenteral routes have been used in these investigations. In general, studies in patients with acute hepatitis have demonstrated that hepatic encephalopathy can usually be avoided by judicious titration of dietary protein, that relatively little dietary protein can be associated with positive nitrogen balance, and that both symptomatic and biochemical improvement (if not prognosis) can be expected ([31](#), [32](#), [33](#), [34](#), [35](#), [36](#) and [37](#)). Positive nitrogen balance can be attained in patients with chronic liver injury (cirrhosis) with daily amounts of dietary protein (0.74 g/kg) similar to that required by normal individuals ([12](#)). Conflicting results have been obtained regarding the extent to which the source of the dietary protein (animal or vegetable) affects overall nitrogen balance ([38](#), [39](#)).

Attempts have been made to normalize the plasma amino acid pattern found in patients with cirrhosis. The ratio of branched-chain amino acids (BCAAs; isoleucine, leucine, valine, and lysine) to aromatic amino acids (phenylalanine, tryptophan, and tyrosine) is abnormally low in these patients, especially those who are malnourished. However, compared with standard mixtures of amino acids, administration of BCAAs has shown no significant advantage in terms of nitrogen balance ([40](#), [41](#), [42](#) and [43](#)).

There was hope that correction of the abnormal amino acid profile in patients with cirrhosis would be beneficial in the treatment of hepatic encephalopathy. To this end, mixtures with high BCAA:aromatic amino acids ratios have been administered, and the source of protein (vegetable-derived protein is relatively low in aromatic amino acids) has been varied. A potential benefit seemed plausible in light of the false neurotransmitter hypothesis of Fischer and Baldessarini ([44](#)). In this scheme, entry of aromatic amino acids into the brain is favored by low plasma levels of BCAA. In the brain, sympathomimetic amines are generated from these aromatic amino acids (especially phenylalanine) and hinder neuronal transmission by competitive interactions with bona fide neurotransmitters at the receptor level. Initial studies in humans involving infusion of BCAA-enriched mixtures were encouraging, but these early clinical trials were not fully controlled or randomized ([45](#)). Using tighter designs, most subsequent studies failed to confirm the efficacy of intravenous or orally administered enriched mixtures in treating acute hepatic encephalopathy ([6](#)). Despite a recent metaanalysis that detected a trend favoring this therapy ([46](#)), the evidence does not support routine clinical use of these amino acid mixtures in acute encephalopathy ([47](#)). However, a subset of protein-intolerant patients with chronic encephalopathy (and better liver function) might benefit from BCAA ([48](#)).

Some success has been achieved in treating hepatic encephalopathy with protein derived from vegetable sources ([38](#), [49](#)). However, improvement in encephalopathy does not correlate with changes in the plasma amino acid profile. As a result, it has been suggested that the beneficial effects of vegetable protein are due to its fiber

content rather than its amino acid composition per se (50). Fiber may increase elimination of nitrogenous waste, but the high fiber content of these diets is poorly tolerated.

Dietary restrictions of amino acids or protein are important in a number of inherited liver abnormalities, including disorders of the urea cycle and hypertyrosinemia (see Chapter 61). Specifically, reduced nitrogen intake is the cornerstone of therapy in hyperammonemia syndromes. In these disorders, activity of the urea cycle enzymes is diminished, ammonia accumulates in the blood, and central nervous system toxicity (lethargy, coma) develops. Depending on the specific location of the defect in the cycle, certain amino acids must also be supplemented. For example, in citrullinemia there is diminished conversion of citrulline to arginine as a result of a deficiency of argininosuccinic acid synthetase. Supplemental arginine bypasses this block and permits the urea cycle to proceed (51). In hypertyrosinemia, there is a defect in the final step in the breakdown of tyrosine and phenylalanine (52). This leads to high levels of tyrosine in the blood and urine, renal tubular dysfunction, and eventually death from liver failure. Dietary restriction of tyrosine and phenylalanine may be helpful.

Choline, Methionine, and S-Adenosyl-L-Methionine

For several decades, protein, methionine, and choline deficiencies have been implicated in the pathogenesis of liver injury. In growing rats, deficiencies in dietary protein and lipotropic factors (choline and methionine) can produce a fatty liver (53), and it has been reported that ethanol increases choline requirements in the rat (54), possibly by enhancing choline oxidation (55). Primates, however, are far less susceptible to protein and lipotropic deficiency than are rodents (56). Clinically, choline treatment of patients suffering from alcoholic liver injury has been ineffective in the face of continued alcohol abuse (57, 58, 59 and 60). Human liver contains very little choline oxidase activity, which may explain the species differences with regard to choline deficiency. In humans, choline deficiency (and thus a need for choline supplementation) has been documented in only very limited circumstances of extremely restricted diets (61). Moreover, in baboons fed ethanol, fatty liver as well as fibrosis (including cirrhosis) developed (62, 63) (Fig. 73.1), with striking ultrastructural changes (64), despite choline given at twice the dose recommended for the baboon (65).

Figure 73.1. Sequential development of alcoholic liver injury in baboons fed ethanol with an adequate diet (*left panel*) and prevention of septal fibrosis and cirrhosis by supplementation with polyunsaturated phosphatidylcholine (*PPC*) (*right panel*). Liver morphology in animals pair-fed control diets (with or without PPC) remained normal (not shown) (data from [117](#)). Whereas no cirrhosis or septal fibrosis developed in the animals fed alcohol with PPC, in the aggregate 67 baboons fed ethanol with adequate diets (usually for 5 years) in this ([117](#)), as well as other ([121](#), [169](#), [170](#)) studies, cirrhosis was observed in 14, and septal fibrosis developed in an additional 14 animals, an incidence comparable to that observed in alcoholics.

Nevertheless, since the possibility existed that massive choline supplementation might have a favorable effect on the process, this was the subject of an experimental study in baboons ([66](#)). They were given either normal or choline-supplemented diets, each with or without ethanol. For 3 to 4 years, they were pair-fed liquid diets with 50% of total energy as ethanol or isocaloric carbohydrate. Ten animals were given the regular diets, and in eight, the choline content was increased fivefold. Choline supplementation failed to prevent alcohol-induced steatosis and fibrosis. All parameters remained normal in the eight baboons fed the regular control diet. However, in the choline-supplemented controls, serum bilirubin, and aspartate amino transferase (AST) and glutamate dehydrogenase (GDH) activities increased moderately, and serum albumin levels decreased. Occasional fat droplets appeared in hepatocytes with mitochondrial changes (enlargement and alterations of the cristae) and an abundance of “myelin” figures in the cytoplasm, indicating that choline supplementation had exerted moderate hepatotoxicity ([66](#)). It was concluded that massive choline supplementation does not prevent alcoholic liver injury but may, in fact, be hepatotoxic.

Liberal supplementation with methionine ([62](#)) also failed to prevent alcohol-induced liver injury, including cirrhosis, from developing in baboons. In man as well, methionine supplementation was considered for the treatment of liver diseases, especially the alcoholic variety, but some difficulties were encountered. Indeed, excess methionine has some adverse effects ([67](#), [68](#)). Furthermore, whereas in some patients with alcoholic liver disease, circulating methionine levels are normal ([69](#)), elevated levels have been reported in others ([45](#), [70](#), [71](#)). Kinsell et al. ([72](#)) observed a delay in clearance of plasma methionine after its systemic administration to patients with liver damage. Similarly, Horowitz et al. ([73](#)) reported that the blood clearance of methionine after an oral load was slowed in such subjects. Since about half of the methionine is metabolized by the liver, the above observations suggest impaired hepatic metabolism of this amino acid in patients with alcoholic liver disease. Indeed, Duce et al. ([74](#)) reported decreased S-adenosyl-L-methionine (S-AdoMet) synthetase activity in cirrhotic livers. Chronic alcohol consumption was associated with enhanced methionine use and depletion ([75](#)). As a consequence, one can anticipate S-AdoMet depletion as well as decreased availability. The baboon model of alcohol-induced liver injury was used to verify the latter hypothesis and to explore the possibility that S-AdoMet repletion might oppose some of the adverse effects of alcohol on the liver ([76](#)). This study revealed that

in the baboon, chronic ethanol consumption is associated with significant depletion of hepatic SAMe and that SAMe supplementation attenuates ethanol-induced liver injury.

Studies in rodents also showed prevention of fat accumulation in the liver by SAMe (77). The significant hepatic SAMe depletion in primates after long-term ethanol consumption (76) is due in part to increased use of reduced glutathione (GSH) secondary to enhanced free radical and acetaldehyde generation by the induced microsomal ethanol-oxidizing system (MEOS) (Fig. 73.2) as well as GSH leakage (78). Under these conditions, increased GSH turnover may ensue, as evidenced by a rise in α -amino-*n*-butyric acid (79, 80) (Fig. 73.2 and Fig. 73.3). However, synthesis of SAMe may become rate limiting, especially since it is decreased in cirrhosis (74). As a consequence of this enzymic defect, SAMe is depleted and methionine supplementation may be ineffective in alcoholic liver disease, whereas SAMe can correct the defect.

Figure 73.2. Link between accelerated acetaldehyde production and increased free radical generation by induced microsomes, resulting in enhanced lipid peroxidation with metabolic blocks due to alcohol, folate deficiency, and/or alcoholic liver disease, illustrating possible beneficial effects of GSH, its precursors (including S-adenosylmethionine [SAMe]) and phosphatidylcholine (166).

Figure 73.3. Effect of ethanol consumption on plasma α -amino-*n*-butyric acid (mean \pm SEM); consumption of ethanol (4 g/kg/day) in addition to an adequate diet in three human volunteers resulted in doubling of plasma α -amino-*n*-butyric acid after 2 to 4 weeks, which was reversed after cessation of drinking (80).

Potentially, S-adenosylmethionine (SAME) depletion may have a number of adverse effects. SAME is the principal methylating agent in various vital transmethylation reactions that are important to nucleic acid and protein synthesis. Methylation is important to cell membrane function (81, 82), with phospholipid methylation active in membrane fluidity and transport of metabolites and transmission of signals across membranes. Thus, by being detrimental for methyltransferase activity, decreased SAME may thereby promote the membrane injury found in alcohol-induced liver damage (83). Not only is SAME the methyl donor in almost all transmethylation reactions, but it also plays a key role in synthesis of polyamines and provides one source of the cysteine needed for glutathione production. Alcohol-induced depletion of glutathione is particularly striking in primates (76, 84).

In rats, chronic alcohol feeding results in decreased methionine formation via the *n*-5 tetrahydrofolate pathway, an effect compensated for through an adaptive increase in betaine-homocysteine methyltransferase activity, which maintains hepatic SAME levels (85). This adaptive process may be particularly operative in the rodents and much less so in primates. Indeed, as mentioned above, rodents contain higher levels of choline oxidase than primates and therefore can produce significantly greater amounts of betaine, which may be one reason why rodents are less susceptible to alcohol-induced liver injury than primates (56) (see above). Thus, replenishment of methionine (in its activated form, SAME) may be particularly indicated in the primate subjected to an alcoholic insult.

Compared with methionine, administration of SAME has the advantage of bypassing the deficit in SAME synthesis from methionine, referred to above. Indeed, this deficit is due to decreased enzyme activity, not substrate, and hence it cannot simply be corrected by excess methionine. The hepatocyte can be replenished with SAME via ingestion of the compound; blood levels of SAME increase after oral administration in rodents (86) and in man (87). Although it has been claimed that the liver does not take up SAME from the bloodstream (88), other results indicate uptake of SAME by isolated hepatocytes at either pharmacologic (89) or physiologic (90, 91) extracellular levels. The liver SAME transport system appears to be saturable (90, 92). Results in baboons (76) also clearly indicate hepatic uptake of exogenous SAME. Furthermore, in these baboons, the ethanol-induced hepatic SAME depletion was partially corrected by oral SAME administration. In addition to uptake of extracellular SAME, extracellular methionine appears to play a major role in the synthesis of newly acquired intracellular SAME (91). Thus, orally administered SAME may play a precursor role for intracellular SAME, both as unchanged SAME and also by the methionine it provides. Since the SAME transport system does not appear to be saturated under physiologic conditions, it is likely that SAME levels in biologic compartments regulate, at least in part, the rate of transport

across membranes. Indeed, hepatic levels of SAME increase with increasing extracellular levels (91), and the intracellular concentrations reached are above or close to the K_m for SAME of both phospholipid methyltransferase (92, 93) and catechol-*o*-methyltransferase (94). Furthermore, effective use of SAME for both transmethylation and transsulfuration has been demonstrated in vivo (95).

Thus, the therapeutic use of SAME is a good example of a beneficial result from replenishment of a naturally occurring molecule that has been depleted by liver disease. The exact role of SAME in the treatment of liver disorders has been partly clarified by studies showing that this molecule is beneficial in intrahepatic cholestasis (reviewed in detail by Osman et al. [96].) Treatment with a stable salt of SAME resulted in both improvement of standard liver function tests and reduction in symptoms such as itch. It has also been successfully used in severe cholestasis of pregnancy, where it has the advantage of few, if any, untoward effects. Treatment with SAME also appears to be helpful in recurrent intrahepatic cholestasis and severe jaundice caused by androgens or estrogens, perhaps because of changes in membrane phospholipid composition. Experimentally, SAME prevented total parenteral nutrition–induced cholestasis in the rat (97).

Potentially beneficial clinical effects of SAME include enhanced bile salt conjugation with taurine in patients with liver cirrhosis (98). Other observations indicate that administration of exogenous SAME prevents the hepatic glutathione depletion observed in patients with liver disease (99). Loguercio et al. (100) measured glutathione and cysteine concentrations in erythrocytes of alcoholics with and without liver cirrhosis. Glutathione levels decreased and cysteine levels increased in all patients. Parenteral treatment with SAME corrected the erythrocyte thiol alterations. Furthermore, in patients given SAME, long-term treatment doubled the plasma concentrations of the secondary sulfur-containing amino acids cystine and taurine (on average, low normal at baseline), without any change in the concentrations of methionine, neutral amino acids, and polyamines. No changes in plasma amino acids were observed in the control group (101). In experimental animals, SAME prevented and reversed erythrocyte membrane alterations in cirrhosis (102). It also protected against liver damage induced by biliary obstruction in rats (103), prevented carbon tetrachloride–induced SAME synthetase inactivation and associated liver injury (104), and improved the hepatic histologic picture in rats treated with CCl_4 and ethanol for 1 month (105). Betaine administration was reported to elevate hepatic SAME levels and to prevent ethanol-induced fatty liver in rats (106).

Lack of methionine may also result from a deficit in methylation of homocysteine to methionine, mainly by the folate- and vitamin B_{12} –dependent enzyme methionine synthetase. Since most alcoholics have disturbed folate metabolism (attributable to multiple mechanisms, including an inadequate diet), elevated plasma homocysteine levels in alcoholics could have been anticipated and have now indeed been noted (107). Since hyperhomocysteinemia has been associated with premature vascular disease (108), the increased plasma homocysteine levels in alcoholics could contribute to the increased incidence of stroke in these patients. Furthermore, SAME-dependent methylation of specific DNA cytosine bases to form 5-methylcytosine may block gene expression, and abnormalities in DNA methylation contribute to the loss of normal

controls on protooncogene expression ([109](#), [110](#) and [111](#)). Indeed, a methyl-deficient diet has been linked to early stages of colorectal neoplasia ([112](#)). These observations illustrate the need to correct underlying malnutrition in the alcoholic, which may exist irrespective of the social and medical situation of the patient ([113](#)). Nutritional support successfully decreased nutrition-associated complications in patients with alcoholic liver disease ([114](#)). The rationale for the various modalities of nutritional intervention has also been reviewed ([115](#)). It is now clear, however, that mere nutritional repletion may not suffice and that “supernutrients” may be needed, such as SAME and possibly polyunsaturated phospholipids (see below).

Carbohydrates

Cirrhotic patients are prone to develop diabetes. As noted above, insulin resistance appears to account for this abnormality of glucose homeostasis. In patients with portal hypertension complicated by portosystemic shunting, an alteration in insulin metabolism may contribute to this resistance. Depleted body stores of potassium and elevated levels of growth hormone are probably also significant. As in other patients with diabetes, nutritional management plays an important role in therapy. Specifically, providing calories as complex carbohydrates effectively reduces insulin requirements. Increasing intake of complex carbohydrate may also be of benefit in hepatic encephalopathy because the nonabsorbable fiber found in such foods decreases colonic transit time and lowers colonic pH. Indeed, the efficacy of lactulose, one of the mainstays in treatment of hepatic encephalopathy, has been related to these same effects.

Inherited disorders of hepatic carbohydrate metabolism may also benefit from dietary manipulation. This heterogeneous group of disorders, which includes galactosemia (see [Chapter 61](#)), glycogen storage disease, and fructose intolerance, can be traced to specific enzymatic deficiencies. These defects impair the orderly flow of substrates along pathways involved in anaerobic glycolysis. Accumulation of these substrates in various organs, especially the liver and muscle, results in organ injury and, frequently, hypoglycemia. Galactosemia can be successfully controlled by strict dietary exclusion of milk products containing galactose. Likewise, fruit, vegetables, and sucrose must be eliminated from the diets of children who are fructose intolerant. At least in type I glycogen storage disease (von Gierke's disease), biochemical improvement can be expected when hypoglycemia is prevented by frequent intake of glucose-rich formulas ([116](#)).

Lipids

Fat accumulation in the liver is strikingly affected by the amount and type of dietary triglycerides (see [Chapter 94](#)). With alcohol, the more triglycerides in the diet, the more fat accumulates in the liver ([Fig. 73.4](#)), at least down to a level of 10% of total energy. Below that, fat accumulates even when dietary fat is extremely low (2%), probably because of stimulation of lipogenesis.

Figure 73.4. Effect of varying amounts of dietary fat. Hepatic triglycerides in seven groups of rats given ethanol (36% of calories) with a diet of normal protein (18% of calories). Average hepatic triglyceride concentration in the control animals is indicated by a *dotted line* (167).

Dietary phospholipids also have striking effects on liver structure and function. Indeed, in primates, chronic ethanol consumption results in a decrease in liver phospholipids and phosphatidylcholine (PC) levels; both can be corrected by PC supplementation (117). The total phospholipid content of the mitochondrial membranes is decreased, with significant reduction in the levels of PC (64); associated striking morphologic changes have a functional counterpart—diminished mitochondrial oxidation mainly due to decreased cytochrome oxidase activity (64, 118). The latter appears to result from alterations in the phospholipid composition of the mitochondrial membranes. Indeed, in vitro cytochrome oxidase activity could be restored with phospholipids extracted from normal mitochondria or synthetic ones, with PC being the most active (64).

The mechanism whereby chronic ethanol consumption alters phospholipids is unknown but may be related, at least in part, to decreased phosphotidylethanolamine/methyltransferase activity described in cirrhotic livers (74) (Fig. 73.2). That this is not simply secondary to the cirrhosis but may in fact be a primary defect related to alcohol is suggested by the observation that the enzyme activity is decreased before development of cirrhosis (117). Ethanol may also affect phospholipids via formation of phosphatidylethanol, with possible impact on signal transduction, as shown in isolated rat hepatocytes (119). A third mechanism involves increased lipid peroxidation, as reflected by increased F_2 isoprostanes and 4-hydroxynonenal (120), which could explain the associated decrease of arachidonic acid in phospholipids (118).

In alcoholic patients, reduced phospholipid methyltransferase activity together with the decreased activity of SAMe synthetase (see above) may promote the membrane injury seen experimentally in alcohol-induced liver damage (83). The question then is whether such deficiency could be attenuated, at least in part, by bypassing the enzyme defects via phospholipid supplementation. This was tested by feeding baboons alcohol in a diet

supplemented with polyunsaturated lecithin. Administration of phospholipid preparations rich in polyunsaturated phosphatidylcholine (PPC) ([121](#)) or virtually pure PPC ([63](#)) ([Fig. 73.1](#)) was found to fully prevent alcohol-induced fibrosis and cirrhosis in the nonhuman primate. PPC contains choline, but, as discussed above, choline in the amounts present in PPC has no protective action against the fibrogenic effects of ethanol in the baboon ([66](#)). PPC is rich in linoleic acid, but this fatty acid per se is probably not responsible for the protective effect because the basic diet was supplemented with linoleate and contained large amounts of corn oil, which is rich in linoleic acid. Furthermore, this fatty acid has been incriminated as a permissive, rather than a protective, factor in alcoholic liver injury ([122](#)). Thus, the polyunsaturated phospholipids themselves appear to be responsible for protection, perhaps because of their high bioavailability and selective incorporation into liver membranes ([123](#)). Furthermore, PPC directly affects collagen metabolism and opposes the oxidative stress ([120](#)).

While there is still some discussion about the relative contributions of hepatocytes and stellate cells in the production of collagen in the liver, stellate cells are “activated” after chronic alcohol consumption and appear to play a major role ([124](#), [125](#)). When normal stellate cells are isolated and cultured on plastic surfaces, they undergo spontaneous transformation into myofibroblast-like cells, thus mimicking in vitro the “activation” that prevails in vivo after chronic alcohol consumption ([126](#)). These cells produce collagen in culture ([126](#)). When acetaldehyde is added to these cells, collagen accumulation increases further ([126](#)), with enhanced mRNA for collagen ([127](#)). Other aldehydes (such as malonaldehyde) are produced from lipid peroxidation, and they may also stimulate collagen production. Acetaldehyde stimulates collagen synthesis in cultured myofibroblasts as well ([128](#)), and a similar effect was observed with lactate. These cells were shown to proliferate in the perivenular zones of the liver after chronic alcohol consumption ([129](#)); they are similar to “activated” stellate cells, although they can be differentiated by ultrastructural and cytochemical characteristics ([130](#)). The normal liver contains a negligible number of “activated” stellate cells, whereas after chronic alcohol consumption, most stellate cells (more than 80%) are transformed. The protection afforded by PC against fibrosis ([Fig. 73.1](#)) was associated with a lesser transformation of stellate cells to transitional cells in vivo (48 vs. 81%). Thus, to the extent that transformation of stellate cells in alcohol-fed animals was responsible for the fibrosis, the lesser transformation after PC may be one reason for the decreased fibrosis.

Fibrosis and the associated collagen accumulation does not result simply from enhanced collagen production but from an imbalance between collagen production and breakdown. Breakdown was assessed in cultured rat stellate cells by measuring collagenase activity with different phospholipids, including various species of PC. It had been reported that a mixture of PCs affected the breakdown, but not the synthesis, of collagen under these conditions ([131](#)). The PC preparation used contained 18:2-18:2 PC (DLPC), 16:0-18:2 PC (PLPC) and other minor PC species. We found that pure DLPC stimulates collagenase activity in vitro. Increased collagenase activity can be expected to oppose collagen accumulation and development of fibrosis by promoting the breakdown of collagen. Increased collagenase activity was observed both in the absence and the presence of acetaldehyde, the metabolite of ethanol that has been incriminated in many of its effects ([132](#)). The specificity of the DLPC effect was illustrated by the fact that the other main component of the administered PC, namely PLPC, or other unsaturated or saturated PCs such as dioleoyl-PC, diarachidonoyl-PC,

distearoyl-PC, dilauroyl-PC, or another polyunsaturated phospholipid (dilinoleoylphosphatidylethanolamine) or polyunsaturated free fatty acids (linoleic, arachidonic) had no effect on collagenase activity. A similar lack of effect had been shown earlier with dilauroyl-PC (131). Choline was inactive in vitro and found to be ineffective in vivo (see above). Taken together, these findings suggest that DLPC is responsible, at least in part, for the protection afforded by PPC against development of fibrosis and its ultimate stage of cirrhosis, most likely because of stimulation of collagen breakdown. Collagenase activity generally increases during the early stage of liver injury (133). Our previous studies revealed that fibrosis coincides with the stage at which collagen breakdown slackens and stops keeping pace with increased production (134). Thus these findings suggest that studies on collagenase activity associated with hepatic injury may be relevant to elucidation of the pathogenesis of liver fibrosis and its treatment and prevention.

PPC could of course also act in other ways. Phospholipids rich in essential fatty acids have a high bioavailability. More than 50% of orally administered PC is made biologically available either by intact absorption (lesser extent) or by reacylation of absorbed lysophosphatidylcholine (greater extent) (135). Pharmacokinetic studies in man, using $^3\text{H}/^{14}\text{C}$ -labeled phosphatidylcholine, showed the absorption to exceed 90% (136). Similar observations were made in animals (137, 138 and 139). Indeed, although much of the PC in the diet is degraded by pancreatic phospholipase A2 (140), the products (*l*-acyl-lysophosphatidylcholine and fatty acids) are absorbed in the jejunum (141). Animal studies show that PCs recovered in intestinal lymph after feeding fat enriched with single fatty acids are highly enriched in both *sn*-1 and *sn*-2 positions with the same acyl groups that were fed (142). Thus, it can be anticipated that during absorption of a diet enriched with 18:2 fatty acids, new PCs will be formed from dietary 18:2-lysoPC that will have an 18:2-18:2 composition. Various authors (123, 143, 144) reported PC accumulation in the liver during the first 24 to 48 h after administration. Furthermore, all 18:2 PCs were present in the liver in significantly increased amounts in baboons fed 18:2-18:2PC (117).

PC has been used before empirically in nonalcoholic liver diseases; beneficial histologic effects were reported in recovery from kwashiorkor (145), in HBsAG-positive patients with cirrhosis (146), and in inflammatory parameters in patients with chronic active hepatitis (147). PC was also used for treatment of alcoholic hepatitis (147) and alcoholic fatty liver (148), but not as yet for prevention or treatment of hepatic fibrosis or cirrhosis. In view of the lack of toxicity of PC (demonstrated in its use for these other indications) and its effectiveness in prevention of alcoholic fibrosis and cirrhosis in the baboon (demonstrated with a virtually pure PC preparation [63] and a less pure extract before [121]), PC or, if possible DLPC, both natural compounds, should now be tried for the control of alcoholic fibrosis and cirrhosis in humans. Since DLPC promotes breakdown of collagen, there is a reasonable hope that this treatment may not only affect the progression of the disease but may also reverse preexisting fibrosis, as demonstrated for CCl_4 -induced cirrhosis in the rat (149). For the same reason, it may be useful for the management of fibrosis of nonalcoholic etiologies as well. Indeed, fibrosis is a common end stage for most chronic liver diseases.

Vitamins

Fat-Soluble Vitamins

Poor dietary intake, together with changes in bile salt metabolism and pancreatic function, increases the likelihood of fat-soluble vitamin deficiency in patients with both alcoholic and nonalcoholic cirrhosis.

Vitamin A. It is recommended that the diet of the nonalcoholic with cirrhosis be supplemented with 5000 to 15,000 IU vitamin A. In patients with alcoholic cirrhosis, caution must be exercised in this respect because microsomal induction may increase the toxicity of this vitamin (150, 151) (see Chapter 94), and ethanol can potentiate liver damage caused by excessive vitamin A (152). Although b-carotene, the precursor of vitamin A, is less toxic, studies in primates have shown that its toxic effects are also enhanced by alcohol (153). Furthermore, b-carotene increases the risk of pulmonary cancer in smokers (154), an effect related to a concomitant consumption of alcohol (155, 156). Thus, vitamin A or b-carotene supplementation must be used cautiously in alcoholics.

Vitamin D. Supplementation of the diet with vitamin D may fail to halt the progression of osteoporosis and osteopenia. However, there appears to be no hazard in recommending ingestion of additional 25-OH D₃ (100 to 300 nmol [40–120 µg]/day) when patients complain of bone pain or demonstrate pathologic fractures (157).

Vitamin E. In children with biliary atresia and cholestasis, vitamin E deficiency may be associated with a number of neurologic alterations. Although such infants and children may benefit from supplementation, repletion of vitamin E stores in adults with liver injury has no proven clinical benefit. Actually, in patients with liver disease of various etiologies, hepatic vitamin E concentrations were rather normal except in the presence of cirrhosis, alcoholic and nonalcoholic (Fig 73.5).

Figure 73.5. Effects of various liver diseases on total hepatic tocopherol levels. Only the

cirrhotic groups had significantly lower a-tocopherol levels ([168](#)).

Vitamin K. Deficiency of vitamin K leads to easy bruisability and, at times, to overt bleeding from esophageal varices or hemorrhoids. When the prothrombin time is lengthened, parenteral supplementation of vitamin K (10 mg/day for 3 days) will serve to discriminate between vitamin K deficiency and failure of the liver to synthesize normal coagulation factors; after vitamin K, an abnormal prothrombin time is corrected in the former setting but not in the latter.

Water-Soluble Vitamins and Trace Minerals

Deficiencies of water-soluble vitamins (folic acid, thiamin, and pyridoxine) are most likely to occur in the malnourished alcoholic with advanced liver injury. Patients with Wilson's disease and those with chronic cholestasis (e.g., primary biliary cirrhosis) have excessive copper accumulation in the liver ([158](#)). Although chelation of copper by penicillamine is highly effective, it is also advantageous to reduce the intake of foods rich in this mineral. Foods rich in copper include chocolate, shellfish, and liver. Zinc deficiency occurs in alcoholics with liver injury and is discussed in [Chapter 74](#).

EFFECT OF NUTRITION ON THE LIVER

At least in children, protein deficiency (kwashiorkor) is associated with development of fatty liver ([159](#), [160](#)). Studies performed during and after World War II indicated that severe malnutrition could also lead to liver injury in adults ([161](#)). These studies did not convincingly prove that malnutrition per se caused liver injury. Indeed, a number of other factors, including hepatotoxins (e.g., aflatoxin) and parasites (schistosomiasis) prevalent in war-ravaged or underdeveloped countries may have mediated the relationship between liver injury and poor nutrition ([162](#)).

Because malnutrition is also common in alcoholics, these early findings were used to bolster the argument that malnutrition, rather than alcohol per se, could explain the pathogenesis of alcohol-induced liver injury. Over the past three decades, however, a more balanced view has evolved. Studies in humans, subhuman primates, and rodents have established that alcohol can cause liver damage in the absence of dietary deficits. Epidemiologic data also support this revised concept. In both France and Germany, a close correlation exists between per capita alcohol consumption and the likelihood of cirrhosis ([163](#), [164](#)). Moreover, no relationship has been documented between nutritional status and the severity of alcohol-induced liver injury as defined histologically ([165](#)). The above notwithstanding, it is now becoming clear that nutrition and the toxic effects of alcohol are often intertwined at the biochemical level. For example, by inducing microsomal cytochromes, chronic ethanol consumption results in energy wastage and promotes breakdown of nutrients, including retinol ([28](#), [30](#), [152](#)).

[Selected Readings](#)

Lipoproteins are important in the pathogenesis of vascular disease. Production and removal of circulating lipoproteins are dynamic processes affected by many variables, two of which are nutrient intake and the genetic composition of an individual.

Nutrients transported into the cell can have direct effects by altering expression of a protein such as apolipoprotein B (apo B) critical for lipoprotein assembly. Effects can also be indirect, as when nutrients increase expression of other factors (e.g., insulin) not intrinsic to lipoproteins but critical for their metabolism. Genetic effects can also be complicated. Mutations (changes in the DNA sequence encoding a protein that alter expression of that protein) can result in a loss of function, a gain of function, or a dominant negative effect. The latter occurs when a protein has more than one subunit and a mutation in a single subunit dominantly interferes with the function of other nonmutated subunits. Inherited diseases may not be due to mutations in the gene for the protein affecting the phenotype; instead, the defect can reside in other genes controlling expression of the protein of interest (see [abetalipoproteinemia](#) below).

Regulated expression of genes involved in lipoprotein metabolism is necessary for survival. This regulation can occur at many levels ([Fig. 74.1](#)). However, for a particular gene and its protein product, there are one or two predominant levels of regulation. Typically, regulation can be classified as transcriptional, posttranscriptional, translational, or posttranslational. [Figure 74.1](#) illustrates that genes, consisting of DNA, are transcribed to produce nuclear RNA that is processed to new messenger RNA (mRNA). Transcription can be affected by nutrients. For example, cholesterol decreases expression of the low-density lipoprotein receptor by suppressing transcription of its gene (see below), and transcription of the fatty acid synthase gene is blocked by essential amino acid deficiency (1) and polyunsaturated fatty acids (2). Regulation of gene expression can be posttranscriptional. One such mechanism is the regulation of mRNA stability; a stable message will be translated more times, forming more protein, than an unstable one. Nutrients can alter message stability. The nutrient iron regulates transferrin receptor expression by altering the stability of the transferrin receptor message; glucose increases fatty acid synthesis in part by stabilizing the fatty acid synthase mRNA (3).

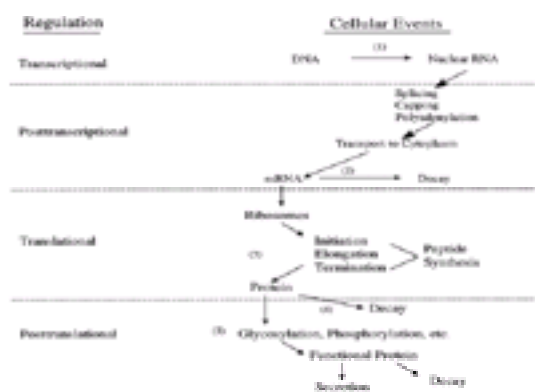

Figure 74.1. Regulation of gene expression. Major levels of regulation of gene expression are shown on the *left*, and corresponding cellular events are schematically depicted on the *right*. Transcriptional regulation is associated with recruitment of transcription factors to specific elements in the promoters of genes in response to nutrients, etc. These transcription factors affect production of new nuclear RNA by the enzyme RNA polymerase II at step 1. Expression of the LDL receptor is regulated at the transcriptional level. Posttranscriptional regulation can occur through changes in the processing (splicing, capping, and polyadenylation) of nuclear RNA and its transport to the cytoplasm as mRNA. Once in the cytoplasm, factors can affect mRNA stability; alteration of mRNA stability is another form of posttranscriptional regulation. Expression of the enzyme fatty acid synthase is regulated in part by controlling the rate of decay of its mRNA in the cytoplasm (step 2). Translational regulation involves the efficiency with which mRNA is translated into a peptide. Ferritin expression is regulated at this level (step 3) by the nutrient iron. Posttranslational regulation involves events following peptide synthesis. Such regulation can include control of the rate at which a newly synthesized peptide decays (step 4). Apo B expression is regulated at this level ([Fig. 74.2](#)). Posttranslational events can also include modifications to proteins, such as glycosylation (step 5). Lipoprotein lipase expression is regulated in part at

posttranslational levels by nutrients.

Figure 74.2. Posttranslational regulation of apo B gene expression in the liver. Apo B is a critical component of several lipoproteins. Its regulation is predominantly posttranslational. Transcription (step 1) and translation (step 2) for apo B are thought to be constitutive. These processes yield newly synthesized apo B protein with its amino terminus (indicated by “N”) and carboxyl terminus (“C”) connected by a *twisted line* representing the complex secondary structure of the protein. Dietary lipids are catabolized for absorption and eventually reach the hepatocyte. Triglycerides and cholesteryl ester are then resynthesized in the liver cell. When these lipids are available (step 3), they are transferred to apo B by microsomal transfer protein (MTP). The association of lipids with the apo B protein stabilizes the protein so it can be used for the assembly of VLDL, which is eventually secreted into the circulation. Absence of MTP produces the clinical disorder abetalipoproteinemia. Without new lipid (step 4), apo B protein is degraded, which prevents VLDL production.

Gene expression can be regulated at the level of translation. In this process, preexisting cytoplasmic mRNA becomes associated with ribosomes that synthesize the protein encoded by the mRNA. For example, iron regulates ferritin gene expression by a translational mechanism. Finally, genes can be regulated posttranslationally. The stability of preexisting proteins can be altered by nutrients. For example, cholesterol regulates HMG-CoA reductase expression by controlling the stability of the HMG-CoA reductase protein; dietary fats stabilize the apo B protein (see below). Posttranslational mechanisms are not limited to protein stability. Some proteins require posttranslational modifications for normal function. These modifications include glycosylation, the addition of sugars to peptides (see [lipoprotein lipase](#) below), and fatty acid acylation (see [Chapter 25](#)).

This chapter focuses on nutrient and genetic regulation of the expression of genes involved in lipoprotein synthesis and catabolism. The discussion illustrates several

mechanisms of regulation, some of which are applicable to the regulation of numerous genes, and others, such as apo B editing, that are relatively unique.

APOLIPOPROTEIN B (APOB)

Apo B Expression

Apo B is the major protein of chylomicrons, chylomicron remnants, very low density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), and low-density lipoproteins (LDL). In general, apo B-containing lipoproteins are associated with increased atherosclerotic risk. Therefore, lowering apo B levels is desirable. The protein exists in two forms, apo B100 (4536 amino acids) and apo B48 (2152 amino acids), so named because it is 48% of the size of apo B100. The two forms are derived from the same gene through editing of the apo B mRNA (see below). In humans, apo B100 is made only in the liver and apo B48 only in the small intestine. Human VLDL, IDL, and LDL contain B100, while human chylomicrons and their remnants contain B48. In other species, including rodents and dogs, both B100 and B48 are made in the liver (4).

Regulation of apo B expression occurs posttranslationally, i.e., after the protein is made (Fig. 74.2). Apo B gene transcription and mRNA translation appear to be constitutive; apo B protein is made continuously. If sufficient lipid associates with apo B at the appropriate intracellular location, the protein is stabilized, and VLDL particles (in the liver) or chylomicrons (in the intestine) are assembled around the scaffolding provided by apo B and secreted. Without sufficient lipid, the apo B protein is degraded. The exact lipid required to stabilize apo B and promote the maturation of nascent lipoproteins is uncertain; experimental evidence supports the role of both triglycerides (5) and cholesteryl esters (6). Excessive secretion of apo B-containing lipoproteins mediated by this mechanism likely contributes to human hyperlipidemia associated with excessive intake of dietary fat and cholesterol. These nutrients also affect LDL receptor expression (see below).

Apo B Editing

Apo B editing is a posttranscriptional event. As noted above, a single gene encodes apo B100 and apo B48. The apo B gene is transcribed into a single mRNA. In humans, this mRNA is modified only in the intestine, and the specificity of this modification is remarkable. Of the more than 14,000 nucleotide bases in the apo B mRNA sequence, only the cytidine at position 6666 is edited to uridine, resulting in the conversion of the glutamine codon CAA to the stop codon UAA (7). When this message associates with ribosomes, instead of placing a glutamine residue at this position and continuing with translation (as for apo B100), the translational complex stops synthesizing protein, yielding apo B48, 48% the size of apo B100.

A multisubunit enzyme edits apo B mRNA. The catalytic subunit is a zinc-dependent cytidine deaminase called apobec-1 (8). Inactivation of this subunit by genetic techniques in mice abolishes apo B mRNA editing (9). Editing is regulated by fasting and refeeding a high-carbohydrate diet in rats (10). Zinc is known to affect lipid

metabolism, and apobec-1 is zinc-dependent, but zinc deficiency in rodents does not affect apo B editing (11).

Apo B100 is essentially the only protein in LDL, a critical lipoprotein in the development of atherosclerosis. Theoretically, it should be possible to decrease apo B100 levels (through metabolism to apo B48) in humans by supplying the liver with the editing enzyme via gene therapy. However, one group has reported that transgenic mice and rabbits expressing apobec-1 in liver develop hepatocellular carcinoma, perhaps because of editing of other messages involved in cell growth (12).

Abetalipoproteinemia and Microsomal Transfer Protein

Abetalipoproteinemia is a rare, autosomal recessive disorder characterized by absence of apo B in the plasma (see Chapter 70). Triglyceride and cholesterol levels are extremely low, even after ingestion of dietary fat. Chylomicrons, VLDL, and LDL are absent (see Chapter 75). Patients usually present with symptoms of fat malabsorption and, if untreated, develop debilitating neurologic dysfunction leading to death. Other complications include retinopathy, which progresses to blindness, and hematologic problems including anemia and coagulation defects. Clinical features of the disease are related to the inability to secrete apo B-containing lipoproteins. Because of this defect, patients are probably unable to deliver essential fatty acids to critical tissues and definitely unable to transport certain fat-soluble vitamins. Of the fat-soluble vitamins A, D, E, and K, vitamin E is the most severely affected in abetalipoproteinemia; high-dose supplementation with vitamin E may prevent clinical sequelae (13).

Surprisingly, defects in the apo B gene are not responsible for abetalipoproteinemia. Instead, the defect is probably exclusively associated with mutations in a protein essential for secretion of apo B-containing proteins, microsomal transfer protein (MTP) (14). The active MTP complex consists of two subunits, MTP itself and protein disulfide isomerase (PDI), an endoplasmic reticulum protein with several catalytic activities. This complex transfers triglycerides and cholesteryl esters from their site of synthesis to apo B, thereby preventing apo B degradation and facilitating lipoprotein assembly. Several MTP mutations have been described, and their characterization suggests that the carboxyl terminus of MTP is essential for lipid transfer activity (15).

Within 24 hours of high-fat feeding, MTP gene expression is stimulated in the intestine but not in the liver. Expression in the liver increases with longer-term dietary interventions (20). There is considerable interest in development of pharmacologic inhibitors of MTP activity; such agents would be expected to lower circulating lipids by interfering with the assembly of VLDL (in liver) and chylomicrons (in the intestine).

Hypobetalipoproteinemia

Unlike abetalipoproteinemia, hypobetalipoproteinemia is not usually associated with clinical manifestations. Patients have low LDL cholesterol levels (<90 mg/dL [2.33 mmol/L], roughly the fifth percentile for Western populations) but not absent concentrations of apo B lipoproteins. Although not well studied, these individuals may be at lower risk for cardiovascular disease. The causes of most cases of

hypobetalipoproteinemia are unknown, but some are familial and inherited in an autosomal dominant fashion (17). A significant proportion of these families carry mutations encoding truncated forms of apo B.

Several apo B truncations have been described, ranging from apo B2 (2% of the size of apo B100) to apo B89. The molecular bases for these truncations are diverse and include nonsense mutations (producing premature stop codons), frameshift mutations, and deletions. The production rate of these truncations is related to their size (i.e., very short apo B proteins are produced at very low rates). Most subjects are heterozygotes; they carry a truncated allele as well as a normal apo B100 allele. For unknown reasons, the rate of apo B100 production is much lower than expected in these heterozygotes.

Individuals with heterozygous familial hypobetalipoproteinemia do not malabsorb fat and are clinically normal. Patients carrying two alleles for apo B truncations can resemble those with abetalipoproteinemia.

Familial Defective Apo B and Other Variants

Apo B100 on LDL particles is a ligand for the LDL receptor. Substitution of glutamine for arginine at amino acid residue 3500 of the apo B100 protein interferes with the normal interaction of apo B with the LDL receptor, resulting in reduced clearance and hypercholesterolemia. This mutation, called familial defective apo B, is fairly common, with a frequency of 1:500 to 1:700 in the general population. These patients appear to respond appropriately (18) to dietary and pharmacologic therapies for hyperlipidemia (see [Chapter 75](#)).

There are several additional variants of the apo B gene, some of which appear to predict serum lipid responses to a high-fat diet (19). However, the exact regions of the gene responsible for these effects are unknown.

LIPOPROTEIN LIPASE (LPL)

Lipid Metabolism

The enzyme LPL is bound to proteoglycans on the capillary endothelium of essentially all adult tissues except the liver. This binding is disrupted by heparin, an agent commonly used to release LPL into the circulation to assess whole body stores of LPL enzyme activity. The greatest mass of LPL is found in adipose tissue, cardiac muscle, and skeletal muscle (20), and in the mammary glands during lactation. Free fatty acids produced after hydrolysis of triglycerides by LPL are taken up by adipose tissue for storage or by muscle for oxidation.

LPL hydrolyzes triglycerides in VLDL and chylomicrons, yielding the smaller, denser IDL and chylomicron remnants, respectively. During this process, excess lipoprotein surface components are released to form HDL particles. Thus, LPL is thought to be crucial for normal lipoprotein physiology. The recent inactivation of the LPL gene in mice (21) supports this concept; in the absence of LPL, triglyceride-rich lipoproteins accumulate in

high concentrations since they cannot be metabolized, and HDL particles are not generated.

LPL Expression

High-fat intake increases heparin-releasable LPL activity in humans (22), but diet has complex, tissue-specific effects on LPL expression. In general, eating a mixed meal induces adipose tissue and suppresses skeletal muscle LPL activity. The differential response between muscle and fat may be due to meal-associated stimulation of insulin. Insulin infusion in humans increases adipose tissue and decreases skeletal muscle LPL (23). LPL is important for partitioning energy stores. It may play a role in certain types of obesity by preferentially directing triglyceride-rich particles to fat instead of muscle (24).

In adipose tissue, regulation of LPL expression by both macronutrients and insulin is predominantly posttranslational (25, 26 and 27). Stores of inactive LPL protein probably exist intracellularly and are activated by insulin or nutrients. Normal LPL is glycosylated (28); glycosylation may be responsible for the posttranslational regulation of LPL activity. LPL regulation may be pretranslational in muscle. Exercise increases human muscle LPL pretranslationally (20), and insulin suppresses LPL mRNA in human muscle (29).

LPL Mutations

Rare individuals homozygous for mutations in the LPL gene can present with the chylomicronemia syndrome (30). Triglyceride concentrations commonly exceed 2000 mg/dL (22.6 $\mu\text{mol/L}$) in fasting plasma and can be considerably higher. Affected subjects have abdominal pain, recurrent episodes of pancreatitis, eruptive xanthomas (caused by uptake of chylomicrons by macro-phages in the skin), hepatomegaly, and neurologic dysfunction, including memory loss and the carpal tunnel syndrome. Patients usually present in early childhood with failure to thrive. Treatment includes a diet that restricts fat to 15% or less of daily caloric in-take.

While homozygous LPL deficiency is rare, heterozygous LPL deficiency is fairly common in the general population (~ 1:35). Heterozygotes (carrying one normal and one mutant LPL allele) may have normal fasting lipid levels. However, considerable evidence links lipid levels in the postprandial state with development of atherosclerosis, and individuals with heterozygous LPL deficiency have higher concentrations of atherogenic lipoproteins after intake of a fatty meal (31). More than 40 different mutations have been described in the LPL gene; the frequency of just one, a serine for asparagine substitution at amino acid residue 291, was recently reported to be 5.2% in patients with premature atherosclerosis (32). These data suggest that heterozygous LPL deficiency may interact with a high-fat diet to increase the risk for cardiovascular disease.

LOW-DENSITY LIPOPROTEIN (LDL) RECEPTOR

Lipid Metabolism

The LDL receptor binds LDL, an atherogenic lipoprotein carrying cholesterol. When low levels of the receptor are present because of nutrient or genetic effects on its expression, LDL accumulates in plasma, and the risk for cardiac disease increases. The LDL receptor is not thought to be directly involved in the pathogenesis of atherosclerosis. Normal LDL particles do not induce the cellular changes of early atherosclerosis. Such changes require modified (e.g., by oxidation) LDL. Modified LDL binds to scavenger receptors but not to the LDL receptor. The LDL receptor is found on essentially all cells, but the most important tissue for its expression is the liver, where the vast majority of LDL-cholesterol metabolism takes place (33). Humans cannot degrade cholesterol. However, free cholesterol in the liver can be converted to bile acids, and the major route for cholesterol excretion is through bile.

Both dietary cholesterol and saturated fatty acids increase LDL cholesterol levels by decreasing LDL receptor activity. When dietary cholesterol is high, cholesterol stores in the liver increase. This sterol pool has numerous effects on cell physiology. ACAT (acyl-CoA:cholesterol acyltransferase), the enzyme that esterifies cholesterol for intracellular storage, is induced. HMG-CoA reductase, the rate-limiting enzyme for cholesterol synthesis, is suppressed. Most importantly, increased cholesterol signals the hepatocyte to suppress transcription of the LDL receptor gene. Fewer receptors are synthesized, less LDL is removed from the plasma, and circulating LDL levels increase. Dietary fatty acids may also suppress transcription of the LDL receptor gene (34).

LDL Receptor Expression

The LDL receptor is a glycosylated protein that, after translation, is directed to the cell membrane where it binds apo B-containing lipoproteins such as LDL. Upon binding, receptors migrate to specialized regions of the cell surface known as coated pits. Bound lipoproteins then undergo endocytosis and are transported to lysosomes where the cholesteryl esters of LDL are hydrolyzed to yield free cholesterol. The level of free cholesterol in this sterol pool regulates transcription of the LDL receptor gene.

Promoters are regions of genes usually closely associated with the DNA encoding the protein of interest. Within promoters are response elements, comprising DNA sequences that bind to specific proteins known as transcription factors. The levels of these factors can be influenced by nutrients, their metabolites, and by intracellular signals sent by hormones. Transcription factors bind to response elements, causing genes to be transcribed, ultimately producing new mRNA.

For the LDL receptor, the critical transcription factors are two structurally similar sterol regulatory element-binding proteins (SREBPs) called SREBP-1 and SREBP-2 (35, 36). These proteins reside in an inactive form in the cytoplasm, attached to the endoplasmic reticulum. When free cholesterol levels are low, a sterol-sensitive protease cleaves an SREBP, releasing a large fragment of the protein. This amino-terminal fragment (the active transcription factor) migrates to the cell nucleus, binds to sterol regulatory elements in the LDL receptor promoter, and stimulates transcription of the LDL receptor

gene. When intracellular free cholesterol levels increase, cleavage of the SREBP ceases, and the nuclear SREBP fragment is rapidly degraded. In hamsters, SREBP-2 appears to be more important than SREBP-1 in responding to changes in cellular cholesterol levels (37).

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is an autosomal dominant disorder caused by mutations in the gene for the LDL receptor. More than 150 different mutations responsible for the disease have been described (38), including promoter mutations preventing normal transcription of the gene.

Homozygous FH (characterized by two defective LDL receptor alleles) is rare but clinically striking. Patients have extreme elevations of fasting cholesterol, with total cholesterol levels of ~700 mg/dL (18.1 $\mu\text{mol/L}$) and mean LDL cholesterol levels of ~625 mg/dL (16.1 $\mu\text{mol/L}$). They also have xanthomas (caused by deposition of lipid in skin and tendons) and severe premature atherosclerosis. Myocardial infarction (MI) has been described at age 18 months in this disorder. The frequency of heterozygous FH ranges from 1:200 to 1:500 in most populations. About 5% of all individuals who have suffered a premature MI (defined as before age 55 in males and 65 in females) are FH heterozygotes. These individuals have one normal allele, which allows them to respond to pharmacologic and dietary interventions aimed at lowering LDL cholesterol by increasing LDL receptor expression. Such treatments are discussed in [Chapter 75](#).

APOLIPOPROTEIN E (APO E)

Lipid Metabolism

Apo E, like apo B100, is a ligand for the LDL receptor. It is a prominent component of triglyceride-rich lipoproteins such as VLDL and chylomicrons, as well as HDL. Apo E is necessary for normal clearance of triglyceride-rich lipoproteins from the circulation through its interaction with both the LDL receptor and another receptor, the LDL receptor-related protein (commonly known as the LRP). Genetic inactivation of apo E in mice results in massive hyperlipidemia and spontaneous atherosclerosis on a low-fat, low-cholesterol diet (39), compelling evidence that apo E is important in mediating cardiovascular risk.

Three common alleles at the apo E gene locus (e2, e3, and e4) encode the three major isoforms of the apo E protein in plasma, E2, E3, and E4. E3 is considered normal and carries a cysteine at residue 112 and an arginine at residue 158. An arginine for cysteine substitution at residue 112 produces E4, and a cysteine for arginine substitution at residue 158 produces E2. Since humans have two copies of each chromosome and both alleles are expressed, the six phenotypes (with frequencies in parentheses) are E3/E3 (~60%), E3/E2 (~15%), E3/E4 (~20%), E4/E2 (~2%), E4/E4 (~2%), and E2/E2 (~1%). Individuals with E4 isoforms are at increased risk for cardiovascular disease and, surprisingly, Alzheimer's disease (40). The explanation for the latter is incomplete, but apo E is found in the senile plaques in the brain that

characterize Alzheimer's disease. E2/E2 individuals are at risk for dysbetalipoproteinemia (see below).

Apo E and Diet

Apo E isoforms can predict responses to dietary interventions aimed at lowering serum lipoproteins. Subjects with the fairly common E3/E4 phenotype show greater decreases in LDL cholesterol than those with the E3/E3 or E3/E2 phenotypes when consuming a low-fat, low-cholesterol diet ([41](#), [42](#) and [43](#)). In population studies, individuals with E2 isoforms have lower levels of LDL-cholesterol, E3 subjects have intermediate levels, and those with E4 have higher levels. E4 subjects may also have an impaired ability to clear atherogenic, postprandial triglyceride-rich lipoproteins ([44](#)).

Dysbetalipoproteinemia

Dysbetalipoproteinemia is rare but important to recognize because it can be effectively treated. Also called type III hyperlipoproteinemia, dysbetalipoproteinemia occurs in subjects with the E2/E2 phenotype. Although the frequency of this phenotype is 1:100, the rate for dysbetalipoproteinemia is from 1:5,000 to 1:10,000. Thus, the E2/E2 phenotype is necessary but not sufficient for development of the disorder. The clinical manifestations of the disease are usually not apparent until the middle decades of life. Additional factors postulated to be required for clinical manifestation of dysbetalipoproteinemia include alcohol intake, high intake of dietary fat, hypothyroidism, and inheritance of genes associated with obesity and diabetes.

Affected individuals classically have elevations of serum triglycerides and cholesterol, severe peripheral vascular disease, coronary artery disease, and xanthomas ([30](#)). While the latter can develop at several sites, xanthomas occurring in the palms of the hands are relatively specific for dysbetalipoproteinemia (see [Chapter 75](#)). Dietary and pharmacologic treatment of affected individuals is thought to decrease the risk of adverse clinical outcomes such as myocardial infarction and limb loss due to peripheral vascular disease.

HIGH-DENSITY LIPOPROTEIN (HDL)

Lipid Metabolism

There is a strong inverse relationship between HDL-cholesterol levels and the risk of cardiovascular disease. The exact basis for this epidemiologic observation is still unresolved. One possibility is that HDL is critical for reverse cholesterol transport, the process by which excess cholesterol in tissues (including the arterial wall, the site of atherosclerosis) is transported back to the liver for excretion from the body. Forward cholesterol transport is mediated by apo B100-containing lipoproteins, which are known to be atherogenic. By the former mechanism, elevated levels of HDL cholesterol reflect an efficient ability to excrete excess cholesterol.

Another possibility is that HDL serves as marker for the efficiency of metabolism of

postprandial, triglyceride-rich lipoproteins. These lipoproteins are atherogenic, and their concentration is inversely related to HDL cholesterol levels: when triglycerides are elevated, HDL cholesterol levels are low. Thus, a low HDL cholesterol level may increase cardiac risk indirectly through its association with elevated concentrations of atherogenic, triglyceride-rich lipoproteins. There is also experimental evidence supporting other mechanisms. HDL carries paraoxonase, an enzyme that can protect LDL from oxidation in vitro. LDL modifications such as oxidation may be critical in the pathogenesis of atherosclerosis (see above). In a mouse model of diet-induced atherosclerosis, an atherogenic diet decreases both HDL and expression of the paraoxonase gene (45).

Not all HDL particles are necessarily associated with protection against atherosclerosis. Apo AI and apo AII are the major protein components of HDL particles. There are at least two populations of HDL particles: those containing apo AI only and those containing both apo AI and apo AII. Apo AI is clearly antiatherogenic. Overexpression of apo AI decreases atherosclerosis in mice with spontaneous atherosclerosis caused by genetic inactivation of the apo E gene (46). However, overexpression of apo AII in mice appears to be proatherogenic (47, 48).

Several factors are associated with lower HDL cholesterol levels, including central obesity, androgens such as testosterone, medications that block b-adrenergic receptors, smoking, and reduced intake of dietary fat. Aerobic exercise, estrogens, alcohol, and the vitamin niacin (in pharmacologic doses) increase HDL cholesterol levels.

Genetic Regulation of HDL Levels

Several familial disorders are associated with inherited changes in HDL levels. As noted above, LPL is involved in HDL synthesis, and defects in the LPL gene are associated with HDL deficiency. Normal clearance of HDL particles depends on cholesteryl ester transfer protein (CETP), and defects in the CETP gene are associated with elevated HDL levels (49). Hepatic lipase also participates in HDL clearance, and genetic defects in hepatic lipase are associated with elevated HDL levels. However, for each of these inherited defects, the level of HDL does not necessarily predict cardiovascular risk as it does in the general population. For example, despite very low levels of HDL in LPL deficiency, these patients do not appear to be at greatly increased risk for atherosclerosis.

Genetic absence of apo AI in humans results in HDL deficiency and increased susceptibility to cardiovascular disease (50). However, another human genetic variant of apo AI produces HDL deficiency but apparently protects from heart disease. This variant, apo AI_{Milano}, is caused by a cysteine for arginine substitution at amino acid residue 173 of the apo AI protein. This human variant diminishes vascular damage without affecting cholesterol levels in rabbits (51), suggesting that apo AI has a direct protective effect on the vascular wall.

In populations, genetics appears to play a major role in determining HDL levels, but the exact loci responsible for these effects are unknown. Kindreds with very low and very high HDL levels are fairly common and identified as having familial

hypoalphalipoproteinemia and familial hyperalphalipoproteinemia, respectively. Until the use of genetic markers for determining vascular risk becomes widespread, family history is the most powerful way to determine the clinical significance of inherited levels of HDL cholesterol. For example, a very low HDL cholesterol in an asymptomatic patient with several first-degree relatives with low HDL cholesterol and premature cardiovascular disease indicates an increased risk of heart disease in that patient.

The last decade has witnessed growing acceptance of the concept that a high serum cholesterol level and related disorders of serum lipoproteins critically influence development of coronary heart disease (CHD) and other atherosclerotic diseases. Support for this concept comes from studies in animal models, surveys of different populations, findings of premature CHD in persons with genetic forms of hyperlipidemia, investigations in laboratory animals, and clinical trials (1, 2). Recent clinical trials (3, 4, 5, 6 and 7) provide irrefutable evidence that high serum cholesterol levels predispose to CHD; these trials moreover demonstrate conclusively that reducing serum cholesterol levels decreases the incidence of CHD. Dramatic results from recent clinical trials (3, 4, 5, 6 and 7) have greatly heightened interest in cholesterol as a risk factor for CHD.

This chapter outlines the major abnormalities of serum cholesterol and other disorders of serum lipids and lipoproteins. It also links these abnormalities to disease endpoints, notably, coronary atherosclerosis and CHD. Serum lipids (cholesterol and triglycerides) do not circulate as independent molecules but are solubilized by specific apolipoproteins to form macromolecular complexes called lipoproteins. The serum contains several distinct species of lipoproteins. Among these, low-density lipoprotein (LDL) is the major cholesterol-carrying lipoprotein. Strong evidence indicates that high serum levels of LDL, called hypercholesterolemia, accelerate coronary atherogenesis and predispose to CHD. An elevated serum LDL cholesterol has been identified as the predominant atherogenic lipoprotein by the U.S. National Cholesterol Education Program (NCEP) (1, 2). Although cholesterol has received more attention, another important lipid carried in

serum lipoproteins is triglyceride. There are several species of triglyceride-rich lipoproteins (TGRLPs). Those made by the intestine are called chylomicrons; TGRLPs produced by the liver are named very low density lipoproteins (VLDLs). Although chylomicrons generally are not considered atherogenic lipoproteins, there is growing evidence that VLDL can have atherogenic potential. Another species of lipoprotein is high-density lipoprotein (HDL). This lipoprotein also contains cholesterol, but HDL does not promote atherosclerosis; in fact, high serum levels of HDL seemingly protect against CHD.

The lipoprotein disorders can be conveniently divided into three categories: hypercholesterolemia, chylomicronemia, and atherogenic dyslipidemia. Hypercholesterolemia occurs in varying degrees from mild to severe and is characterized by high serum levels of LDL cholesterol. Chylomicronemia consists of marked elevation of chylomicrons, with or without high VLDL levels. Finally, atherogenic dyslipidemia is a disorder characterized by multiple lipoprotein abnormalities occurring simultaneously in a single person; this disorder is described in more detail below. Each category of lipoprotein abnormality is considered separately.

HYPERCHOLESTEROLEMIA

Hypercholesterolemia denotes an isolated elevation of serum LDL cholesterol. Several lines of evidence indicate that elevated serum concentrations of LDL promote atherogenesis and increase the risk for CHD ([1](#), [2](#)). The increment in risk for CHD is proportional to the elevation of the serum LDL level ([2](#)). In fact, risk is compounded by progressively increasing serum LDL concentrations. Conversely, in populations in which serum LDL concentrations are very low, CHD is rare ([8](#)); this is true even when other CHD risk factors—cigarette smoking, hypertension, and diabetes mellitus—are relatively common. This latter observation ([8](#)) strongly suggests that LDL is an essential atherogenic agent. For populations, although not necessarily for all individuals, there is a high correlation between serum LDL-cholesterol levels and total cholesterol levels. This is because about two-thirds of the serum total cholesterol is normally transported as cholesteryl esters in LDL. However, this generalization does not necessarily hold for all persons; thus, for individuals, laboratory measurements of LDL cholesterol are required to accurately define the level.

The NCEP ([1](#), [2](#)) classifies total serum cholesterol according to the degree of severity as shown in [Table 75.1](#); corresponding values for LDL cholesterol are also listed in [Table 75.1](#). In the current review, this classification is modified slightly and expressed in terms of “hypercholesterolemia” ([Table 75.2](#)). According to this latter classification, hypercholesterolemia can be divided into mild, moderate, and severe categories. Lower ranges of serum cholesterol can be separated into “optimal” and “desirable.” Optimal levels of cholesterol are those associated with minimal risk for CHD. Desirable levels can be somewhat higher than optimal but are usually associated with relatively low rates of CHD.

Classification	Total Cholesterol mg/dL (mmol/L)	LDL-Cholesterol mg/dL (mmol/L)
"Optimal"	<150 (<3.88)	<100 (<2.59)
Desirable	150-199 (3.88-5.15)	100-129 (2.59-3.34)
Borderline-high	200-239 (5.17-6.19)	130-159 ^a (3.36-4.11)
High	≥240 (≥6.21)	≥160 ^b (≥4.14)

^aFor LDL-cholesterol 130-159, the term *borderline-high risk* is used.

^bFor LDL-cholesterol ≥160, the term *high-risk* is used.

Table 75.1 Classification of Total and LDL-Cholesterol

Degree of Hypercholesterolemia	Total Cholesterol mg/dL (mmol/L)	LDL- Cholesterol mg/dL (mmol/L)
Mild	200-239 (5.18-6.19)	130-159 (3.36-4.11)
Moderate	240-299 (6.21-7.76)	160-219 (4.14-5.57)
Severe	≥300 (≥7.76)	≥220 (≥5.69)

Table 75.2 Classification of Hypercholesterolemia

Optimal Cholesterol Levels

Total cholesterol levels below 150 mg/dL (LDL-cholesterol < 100 mg/dL) are considered "optimal" (2). Within this range, atherosclerosis develops at a very slow rate; consequently CHD is rare. Optimal serum cholesterol levels typically occur in children and young adults but also are present in middle-aged and older persons in various populations around the world (e.g., rural Asia). In these latter populations, intakes of saturated fatty acids and cholesterol typically are very low, daily physical activity is high, and body fat content is low; this combination of dietary and life habits apparently keeps serum cholesterol levels in the optimal range throughout life. The very low rates of atherosclerotic disease in these populations demonstrate the benefit of keeping serum cholesterol levels low (8). It has been suggested that very low serum cholesterol levels in these populations can be explained by genetic factors; however, changes in eating and exercise habits have caused cholesterol levels to rise, even in populations that

historically have exhibited very low cholesterol levels (9).

Not only does an elevated serum cholesterol level promote atherogenesis, but restoration of serum cholesterol to optimal levels markedly reduces the risk for CHD, even in persons who already have advanced atherosclerotic disease. For example, in patients who have established CHD, reducing serum cholesterol levels to near the optimal range decreases their risk of recurrent myocardial infarction (3, 4). Similar risk reduction follows therapeutic lowering of serum cholesterol levels in hypercholesterolemic patients who have not yet developed CHD (5). Several other clinical trials (7, 10), in which coronary arteries were visualized directly by angiography, revealed that reducing serum cholesterol levels retards progression of coronary atherosclerosis. Thus, an elevation in serum cholesterol contributes to initiation and progression of coronary atherosclerosis; but of equal importance, it plays a critical role later in the course of atherosclerotic disease by predisposing to acute coronary events, e.g., myocardial infarction. Thus, there is a growing recognition that optimal cholesterol levels convey substantial protection against development of CHD.

Desirable Cholesterol Levels

The NCEP (1, 2) defines total cholesterol levels in the range of 150 to 199 mg/dL (LDL-cholesterol 100 to 129 mg/dL) as “desirable.” Although “desirable” cholesterol levels may still promote atherogenesis, compared with optimal levels, premature CHD (i.e., onset of CHD before age 65) is relatively rare in the absence of other CHD risk factors (11). For most adult Americans living in an urbanized setting and other populations in similar circumstances, it is unrealistic to expect cholesterol levels to remain at optimal levels throughout life (e.g., LDL-cholesterol below 100 mg/dL). Serum levels in the somewhat higher but still desirable range are mainly the product of small increments in dietary saturated fatty acids and cholesterol, modest excesses in body fat, and failure to maintain vigorous physical activity (12). Premature CHD nonetheless is uncommon in people who have desirable cholesterol levels, provided they avoid cigarette smoking and maintain a normal blood pressure (11). It is a major goal of the NCEP to bring about a change in serum cholesterol levels in the American public so that a greater proportion of the population achieves and sustains cholesterol concentrations in the desirable zone (13). At present, almost half of all American adults have total cholesterol levels below 200 mg/dL (2, 14). Fortunately, serum cholesterol levels in the general public have been declining over the past three decades (14); as a result, a larger fraction of the population now has desirable cholesterol levels than it did in the past.

An important public health goal for adults of the general population thus is to maintain serum cholesterol levels in the desirable range. Reduction in intakes of saturated fatty acids and cholesterol over the past 3 decades in the United States has increased the proportion of the U.S. general population with desirable cholesterol levels. [Table 75.3](#) compares current macronutrient intakes in the U.S. public (15) with intakes recommended by the NCEP (13) and the American Heart Association (AHA) (16). If population-mean intakes of saturated fatty acids and cholesterol could be reduced to recommended levels, a greater proportion of the population would achieve serum

cholesterol levels in the desirable range.

	Recommended Intake ^a (% of total calories)	Current American Intake ^b (% of total calories)
Total fat	<30	35
Cholesterol-raising fatty acids	<10	
Saturated		12
Trans		3
Monounsaturated	10–15	14
Polyunsaturated	<10	6
fatty acids		
Carbohydrate	55	50
Protein	15	15
Cholesterol (mg/day)	<300	300–400

^aRecommended macronutrient intakes (13, 10).

^bValues approximated from existing data (15).

Table 75.3 Current Macronutrient Intakes in the American Public

Overweight is another factor responsible for the rise of serum cholesterol levels to above the desirable range. It has been estimated that the weight gain that typically occurs with aging accounts for a rise in serum cholesterol of approximately 25 mg/dL (12). The average American adult gains about 10 kg between ages 20 and 50 years. A significant increase in serum cholesterol levels is one consequence of this weight gain (18, 19). Thus, weight control, particularly a reduction in the amount of weight gained with aging, is an important public health goal. Weight gain with aging is due to two factors: (a) a decline in basal metabolic rate with aging (see Chapter 87) and (b) a reduction in physical activity. The metabolic rate decline results largely from a decrease in muscle mass (20), which likewise is due in part to reduced physical activity. Although increased physical activity that does not produce weight loss will not significantly lower cholesterol levels, maintaining a high enough level of exercise to prevent weight gain will contribute to lower serum cholesterol levels. In most persons, however, maintaining a moderate level of physical activity will not be enough to prevent an increase in body weight with aging; therefore, some reduction in caloric intake also will be required.

In spite of the success in reducing serum cholesterol levels among Americans through decreased intakes of saturated fatty acids and cholesterol, the public has not been successful in weight control. Indeed, obesity in the United States has progressively increased (see Chapter 87). Table 75.4 shows the proportion of the U.S. population within each category of body mass index (BMI) (21). A desirable BMI ranges from 21 to 25 kg/m². In this category, cholesterol levels are at their lowest (18, 19). BMIs in the ranges of 25 to 26.9 kg/m², 27 to 29.9 kg/m², and more than 30 kg/m² can be called mild, moderate, and severe overweight, respectively. As noted in Table 75.4, approximately half of Americans fall into the overweight range. This high prevalence of overweight stands in the way of achieving desirable serum cholesterol levels for many persons.

Body Mass Index (kg/m ²)	Adult Men (%)	Adult Women (%)
21–24.9	37	55
25–26.9	25	15
27–29.9	25	10
≥30	13	20

Distribution of body mass indexes estimated from the data of Shah et al. (21).

Table 75.4 Distribution of Body Mass Indexes in the American Public

Mild Hypercholesterolemia

About 25% of American adults have mild hypercholesterolemia (total cholesterol 200 to 239 mg/dL; LDL-cholesterol 130 to 159 mg/dL) (2). These levels are called “borderline high” by the NCEP. In middle-aged adults with mild hypercholesterolemia, the risk for CHD in the short term (5–10 years) is about 1.5 times that accompanying serum cholesterol levels in the desirable range (11). Recent analyses suggest that the risk differential over a lifetime is even greater, i.e., in the presence of mild hypercholesterolemia, long-term (30–40 years) risk is three to four times that associated with a desirable cholesterol level (22, 23).

In most persons, several causative factors underlie mild hypercholesterolemia (12): (a) diets high in cholesterol, (b) diets high in cholesterol-raising fatty acids (saturated fatty acids and *trans* fatty acids), (c) increasing body weight with aging, (d) aging per se, (e) genetic factors, and (f) estrogen loss in postmenopausal women. Each of these factors deserves some attention. If a greater portion of the public is going to achieve desirable cholesterol levels, it will be necessary to modify some of these factors. The effects of two factors—genetics and aging per se—cannot be mitigated short of treatment with cholesterol-lowering drugs; however, the other factors listed above can be changed by modifying life habits.

Causes of Mild Hypercholesterolemia

Genetic Causes. Some people appear to be unusually susceptible to higher serum cholesterol levels. In addition, the broad range of serum cholesterol concentrations in the general population suggests variability in genetic susceptibility. Genetic epidemiologists (24) have calculated that about 50% of the variation in cholesterol levels in the general population can be explained by polymorphism in the genes influencing

serum total cholesterol and LDL-cholesterol.

Genetic factors potentially regulate LDL-cholesterol levels at multiple control points. A discussion of these sites of control requires examining the origins and fates of serum LDL. LDL is derived from catabolism of TGRLPs produced by the liver. Hepatic TGRLPs, called VLDLs, contain mainly triglycerides in their lipoprotein core and three apolipoproteins in their surface coat: apo-B-100 (apo-B), apo-Cs, and apo-E. VLDL-triglycerides are hydrolyzed by lipoprotein lipase (LPL) (see "[Chylomicronemia](#)," below), degrading VLDLs to smaller TGRLPs called VLDL remnants; most apo-Cs are lost from VLDL particles during this process (see [Chapter 4](#)). VLDL remnants can either be taken up by the liver (via LDL receptors) or converted to LDL. Hepatic triglyceride lipase (HTGL) probably hydrolyzes the remaining triglycerides in remnants, causing their conversion to LDL. The only apolipoprotein remaining on LDL is apo-B-100; it is apo-B-100 on LDL that is recognized by LDL receptors ([25](#)). Most LDL particles are removed via LDL receptors on liver parenchymal cells ([25](#)). Synthesis of each of the proteins that influence LDL levels is under genetic control and is subject to modification by genetic aberrations.

One factor influencing LDL levels is the rate of formation of lipoproteins by the liver. Most lipoproteins made by the liver are rich in triglycerides and hence are secreted as VLDLs. The amount of hepatic triglyceride available for incorporation into VLDL may influence the rate of VLDL secretion. In cultured hepatocytes, supplying more fatty acids for triglyceride synthesis increases the number of VLDL particles secreted by these liver cells ([26](#)). Transfer of triglycerides into newly forming VLDL particles is mediated by microsomal lipid-transfer protein (MTP) ([27](#), [28](#)). This protein shuttles both triglyceride and phospholipid into VLDL particles. In patients with a genetic absence of MTP, VLDL particles do not mature; affected individuals consequently lack apo-B-containing lipoproteins in the circulation (abetalipoproteinemia) ([27](#)). The rate of formation of apo-B-100 itself could affect the rate of VLDL secretion. At the other extreme, high serum levels of both cholesterol and triglycerides (combined hyperlipidemia) could be due to excessive synthesis of apo-B-100 by the liver ([28](#)); this possibility, however, has not been proved through definitive studies ([29](#)). Whether the availability of cholesterol in the liver influences the rate of secretion of VLDL also remains to be determined. In laboratory animals, high doses of drugs that inhibit cholesterol synthesis reduce VLDL secretion; whether usual doses of these drugs have this same effect in humans is uncertain. In sum, multiple factors under genetic control undoubtedly affect the assembly and secretion of hepatic VLDLs; and because LDL particles are derived from VLDL, VLDL secretion rates can influence LDL-cholesterol levels ([28](#)). Consequently, genetic aberrations leading to overproduction of apo-B-containing lipoproteins by the liver may be one of the causes of hypercholesterolemia.

The rate of removal of LDLs from the circulation also influences serum LDL levels. The clearance of LDLs has been studied extensively. Most circulating LDL particles are removed via LDL receptors located on liver cells ([25](#)). As noted above, LDL receptors specifically bind apo-B-100. Variation in the number of LDL receptors expressed on liver cells is a major determinant of serum LDL-cholesterol levels. A critical factor controlling expression of hepatic LDL receptors is the amount of cholesterol in the liver cell ([25](#)).

When the cholesterol content of the liver rises, synthesis of LDL receptors is reduced.

The mechanisms whereby this occurs have recently been elucidated. Specialized proteins, called sterol regulatory element-binding proteins (SREBP), span the microsomal (endoplasmic reticulum) membranes (30). When the cholesterol content of membranes falls, an enzyme is activated that clips SREBP in two so that a fragment of SREBP is freed to move into the cell nucleus. This protein binds to the promoter region of the gene for the LDL receptor and stimulates its transcription (see Chapter 74). Increased availability of cholesterol in the liver has the opposite effect; namely, it suppresses LDL-receptor activity.

Steady-state amounts of cholesterol in the liver cells depend on the rate of synthesis of cholesterol, the rate of secretion of cholesterol into bile, and the rate of conversion of cholesterol into bile acids (12). All of these metabolic pathways are under genetic regulation; thus, genetic polymorphism of multiple proteins regulating these pathways could enhance the availability of intracellular cholesterol. This event, in turn, can raise LDL-cholesterol levels through the SREBP mechanism. Moreover, genetic variation in SREBPs, or the gene encoding LDL receptors, may affect the expression of LDL receptors. Future research may uncover a variety of genetic polymorphisms in the complex system of LDL-receptor regulation that lead to higher LDL-cholesterol levels. Genetic polymorphisms likely account for much of the variability in LDL cholesterol levels in the U.S. population, and some polymorphisms undoubtedly contribute to the development of mild hypercholesterolemia.

Rise of Cholesterol Levels with Age. Decline in LDL Receptor Activity with Aging. In the United States, the average serum total cholesterol level rises by about 40 to 50 mg/dL between ages 20 and 50 (2, 12). About half of this rise apparently results from increased body weight; but another portion seems to be linked to aging per se (31, 32). The aging process is accompanied by delayed clearance of LDL from the circulation; presumably, the complex mechanisms regulating LDL-receptor function become less efficient with aging. For example, hepatic disposal of cholesterol may be slightly retarded with aging, leading to increased hepatic cholesterol content. Alternatively, synthetic mechanisms for LDL receptors may become sluggish, causing decreased receptor expression and LDL catabolism. There is, however, a curious observation: serum cholesterol levels do not rise progressively from middle age into older age (2). Most of the increase occurs between the ages of 20 and 50 years; thereafter, LDL-cholesterol levels reach a plateau or even decline somewhat. This suggests that external, controllable factors, such as weight gain, play critical roles in the age-related increase in cholesterol levels.

Obesity and the Rise of Cholesterol with Aging. There is a strong correlation between changes in serum cholesterol concentrations and changes in body weight from young adulthood into middle age (18, 19). Most weight gain in adults occurs between ages 20 and 50 years; during this same period, serum cholesterol concentrations rise. Although epidemiologic studies have indicated that serum cholesterol levels rise with aging, even in persons who show little weight gain (18, 19), those who gain more weight manifest greater increments in serum cholesterol. The increase of serum cholesterol with aging occurs in both VLDL and LDL fractions (18, 19). This combined change further suggests

an effect of obesity on serum cholesterol. The major influence of obesity on lipoprotein metabolism is upon the input pathway (33, 34), and isotope kinetic studies suggest that obesity induces overproduction of hepatic VLDLs (33, 34). Consequently, the rise in LDL-cholesterol levels with increasing body weight is likely to be secondary to an increased rate of input of VLDLs, followed by an increased rate of conversion of VLDLs to LDLs. Thus, it is not surprising that both VLDL and LDL levels rise concomitantly with increasing obesity.

Cholesterol-Raising Fatty Acids. Two classes of dietary fatty acids can raise serum cholesterol levels: saturated fatty acids (35) and *trans* monounsaturated fatty acids (36, 37). These fatty acids induce increments in total cholesterol levels that occur largely in the LDL fraction. Specifically, these fatty acids elevate LDL-cholesterol concentrations relative to the effects of other nutrients: polyunsaturated fatty acids, *cis* monounsaturated fatty acids, and carbohydrates (35). Since the latter nutrients do not raise LDL-cholesterol levels, they are called “neutral.” Although saturated fatty acids as a class raise serum LDL levels, compared with “neutral” nutrients, even the different types of saturated fatty acids differ in their influence on LDL-cholesterol levels. The saturated fatty acid present in the largest quantities in the U.S. diet is palmitic acid (C16:0); a review of the literature shows palmitic acid to be a potent cholesterol-raising fatty acid (35). Another saturated acid, myristic acid (C14:0), occurs in lesser amounts in the diet, but it appears to be even more potent than palmitic acid in elevating the serum LDL-cholesterol concentration (38). Recent investigations reveal that shorter-chain saturates—lauric acid (C12:0) (36) and medium-chain fatty acids (C10:0 and C8:0) (40)—also raise serum LDL levels, although somewhat less than does palmitic acid. Still another saturated fatty acid, stearic acid (C18:0) (41, 42), *does not* increase LDL-cholesterol levels relative to unsaturated fatty acids. Hence, stearic acid is a “neutral” fatty acid. This apparently is because stearic acid is rapidly converted into oleic acid (C18:1) once it enters the body (43).

Although the saturated fatty acids make up the lion's share of cholesterol-raising fatty acids in the diet, recent studies have indicated that *trans* monounsaturated fatty acids also increase LDL levels (36, 37, 44). *Trans* fatty acids are produced by hydrogenation of vegetable oils. The *trans* configuration of these fatty acids gives them structural properties similar to those of saturated fatty acids, which may explain their action in raising serum LDL concentrations. In the typical American diet, *trans* fatty acids account for only about one-fourth as much energy intake as do saturated fatty acids; however, their role as a contributor to mild hypercholesterolemia is nonetheless significant and should not be discounted.

The mechanisms by which cholesterol-raising fatty acids elevate the serum LDL cholesterol concentration remain to be fully elucidated. Investigations carried out in animal models point to suppression of LDL-receptor activity as the primary site of the action of fatty acids (45). One hypothesis holds that these fatty acids interfere with esterification of cholesterol in the liver (46). Saturated fatty acids seemingly interfere with the cholesterol-esterifying enzyme acyl-CoA cholesterol acyl transferase (ACAT). If saturated fatty acids retard formation of cholesteryl esters in the liver, more unesterified cholesterol is available for action on SREBPs and hence, secondarily, for suppression of LDL-receptor activity, so that LDL accumulates in plasma. Other mechanisms have been proposed to explain the action of saturated fatty acids in raising cholesterol levels,

but most data support the concept that, by one means or another, they suppress the activity of LDL receptors.

Dietary Cholesterol. In many animal models, high intakes of cholesterol exert a powerful hypercholesterolemic action (47, 48). The mechanism of this response seems to be straightforward. When the diet is enriched with cholesterol, hepatic cholesterol content rises. This suppresses SREBPs cleavage and thus downregulates LDL-receptor synthesis. The same mechanism presumably obtains in man. Humans, however, are less susceptible to the hypercholesterolemic action of dietary cholesterol than many experimental animals (49). Increasing dietary cholesterol apparently fails to induce such marked rises in unesterified cholesterol concentrations in the liver of humans. There could be several reasons. First, in humans, less than half of dietary cholesterol is absorbed, which limits its availability to the liver. Also, humans may be more efficient in esterifying cholesterol in hepatocytes or secreting it into bile; both mechanisms will reduce unesterified cholesterol in liver cells. In spite of these protective mechanisms, an increased amount of cholesterol in the diet definitely raises LDL-cholesterol in many people. A relatively high level of cholesterol in the American diet is one of several factors contributing to a high frequency of mild hypercholesterolemia in the general population.

Rise of Cholesterol after Menopause. Loss of estrogen after menopause leads to increased serum cholesterol in many women (2, 12). Estrogens stimulate LDL-receptor synthesis in several animal models (50), and the same response presumably occurs in humans. After menopause and with a loss of estrogens, LDL-receptor activity falls. This decline in receptor function and consequent rise in LDL-cholesterol levels can be reversed by estrogen replacement therapy after menopause (51).

Management of Mild Hypercholesterolemia

Detection and Classification. The first step in the management of mild hypercholesterolemia is measuring concentrations of serum lipids and lipoproteins. Initial measurements should include total cholesterol (C), triglycerides (TG), and HDL-cholesterol (HDL-C) (1, 2). When triglycerides are below 300 mg/dL, serum LDL-cholesterol (LDL-C) can be estimated as follows:

$$LDL-C = C - HDL-C - TG/5$$

The term $TG/5$ represents the concentration of very low density lipoprotein (VLDL) cholesterol. When triglycerides exceed 300 mg/dL, measurement of LDL cholesterol requires removing VLDL by ultracentrifugation. After removal of VLDL, the LDL cholesterol is calculated as

$$LDL-C = (C - VLDL-C) - HDL-C$$

Sometimes the LDL-cholesterol level is in the desirable range even when total cholesterol falls into the elevated range; this occurs when HDL-cholesterol levels are relatively high. Alternatively, when the HDL-cholesterol level is low, the LDL-cholesterol

level can be high, even when the total cholesterol concentration is in the desirable range. For purposes of clinical management, *mild hypercholesterolemia* can be defined as a serum LDL-cholesterol level of 130 to 159 mg/dL.

Modification of Diet Composition. For most people without established CHD, treatment of mild hypercholesterolemia consists of dietary modification. The major factors responsible for mild hypercholesterolemia are (a) relatively high intakes of cholesterol, (b) high intakes of cholesterol-raising fatty acids, and (c) overweight. Modifying the dietary composition by reducing offending nutrients and weight reduction thus will reduce LDL-cholesterol levels into the desirable range for many persons.

Modifying dietary composition requires adopting the step I diet of the American Heart Association (1, 2) (Table 75.5) or a similar diet plan. The essential features of the step I diet are reducing intake of cholesterol-raising fatty acids to less than 10% of total calories, dietary cholesterol to less than 300 mg/dL, and total fat to 30% of total calories or less. Most persons with mild hypercholesterolemia in the United States exceed these recommendations in all categories. Reductions designed to achieve the goals of the step I diet can be expected to decrease serum LDL-cholesterol levels by about 10% (52).

Nutrient	Percentage of Total Calories
Total fat	≤30
Cholesterol-raising fatty acids ^a	<10
Monounsaturated fatty acids	10-15
Polyunsaturated fatty acids	<10
Carbohydrates	≥55
Protein	15
Cholesterol	<300 mg/day

^aIncludes saturated fatty acids (C8-C16) and trans fatty acids.

Table 75.5 Step I Diet

Cholesterol-raising fatty acids can be calculated as the sum of cholesterol-raising saturated fatty acids plus *trans* fatty acids. About two-thirds of saturated fatty acids in the American diet comes from animal fat. Sources of animal fat include milk fat and meat fat. Milk fat is more hypercholesterolemic than meat fat because of its higher content of cholesterol-raising fatty acids. The remainder of saturated fatty acids in the diet comes from vegetable fats. The tropical oils (i.e., palm oil, coconut oil, and palm kernel oil) have a very high content of saturated fatty acids. Other vegetable oils have a lower content but still contribute some saturated fatty acids to the diet. In recent years in the United States, use of tropical oils by the food industry has decreased. A further reduction in saturated fatty acids in the American diet must come through decreasing

the consumption of animal fats. Replacing fatty meats, including fatty cuts of steak, hamburger, and processed meats, with leaner products is one important way to decrease saturated fatty acids. Also, replacing traditional milk-based products (whole milk, butter, cream, ice cream, and cheese) with low-fat or fat-free milk products likewise will reduce the consumption of saturated fatty acids. The goal for the general population is to decrease dietary saturated fatty acids by at least one-third.

Since *trans* fatty acids are now known to belong to the category of cholesterol-raising fatty acids, intake of these must also be reduced to achieve the goals of the step I diet. Estimates of the intake of *trans* fatty acids in the United States vary, ranging from 2 to 5% of total calories; the average intake is about 3% of total calories. This percentage of *trans* fatty acids in the diet can be cut in half by avoiding hard (hydrogenated) margarine as a spread and baked products containing hydrogenated shortenings. At present, commercially produced bakery goods and snack foods tend to be rich in *trans* fatty acids. Thus, to promote lowering of cholesterol, the food industry should make an effort to decrease the *trans* fatty acid content of food products by modifying the types of fats used in food manufacture.

Reduced consumption of animal fats will also decrease cholesterol intake. This reduction will further lower serum LDL-cholesterol levels. Intakes of cholesterol typically are divided about equally among eggs, milk-based products, and meats. Keeping the intake of foods containing egg yolks low, using low-fat or fat-free milk products, and decreasing meat fats can cut the current cholesterol intake by one-third to one-half.

Weight Control. The rise of body weight with aging contributes importantly to mild hypercholesterolemia (12, 18, 19). Consequently, weight reduction also is required for many overweight people to restore serum cholesterol to the desirable range. For a large number of persons, reducing intake of cholesterol and cholesterol-raising fatty acids will not suffice to obtain the desirable range for serum cholesterol unless weight reduction is carried out concurrently. Effective weight reduction usually requires a combination of calorie control and increased exercise. Most people with mild hypercholesterolemia are moderately overweight and consume an excess of 300 to 500 calories/day (18, 19). Most overweight persons are only moderately overweight, i.e., they have a BMI ranging from 25 to 30 kg/m² (21). Restoring the caloric balance required to achieve and maintain desirable body weight thus should not be difficult, but it requires continuous attention to body weight, moderate reduction of food intake, increased exercise, and both mental and physical discipline.

Certain foods should be targeted for caloric restriction to achieve a desirable body weight. Highest on the list for elimination are animal fats (milk fat and meat fat); their removal will not only decrease caloric intake but also reduce the intake of saturated fatty acid and thereby lower serum cholesterol levels. To achieve weight loss, the animal fats removed from the diet must *not* be replaced by calories of other types. Second on the priority list for reduction are high-sugar foods, such as soft drinks, desserts, candies, and cookies. High-sugar products, advertised as low-fat, have become popular in the United States. The increased use of these foods has offset much of the benefit derived from reduction of high-fat foods. Thus, to achieve weight reduction, high-sugar foods must be controlled as well. Third on the list are high-starch foods such as breads,

potatoes, rice, and pasta. When less-desirable sources of calories of the first and second type are removed, care must be taken not to replace them with excessive intakes of high-starch foods. The same holds for replacement with vegetable oils. Although oils such as olive oil, canola oil, and soy bean oil produce a favorable lipoprotein pattern compared with saturated fatty acids, too much of these oils can provide excess calories and prevent weight reduction.

A second approach to weight reduction is to increase physical activity. The caloric balance required to achieve and maintain desirable weight can be restored in part by increased use of calories in physical exercise. Suitable exercises include regular walking, swimming, biking, and competitive sports (2, 53). For purposes of caloric expenditure, aerobic exercise is preferable to weight training. The latter, however, is also useful in older persons to maintain muscle mass and improve musculoskeletal function, which may prevent falls (53). Thus, instituting an appropriate regimen of regular exercise that expends excess calories is an integral element in the management of mild hypercholesterolemia.

A third recommendation incorporated in the step I diet is to reduce the intake of total fat to 30% or less of total calories. Most of the fat calories in this diet should come from vegetable oils. Currently, the most desirable percentage of calories from fat in the diet is disputed. Some investigators favor a higher fat content (e.g., 30–35% fat [54]), and others a lower intake (e.g., 15–25% fat [55]). The argument favoring a lower percentage of fat is that it may promote weight reduction. Certainly, reducing animal fat intake without replacement of fat will decrease total calories and promote weight reduction. Whether vegetable oils should be listed as a high priority for reduced intake is problematic. Maintaining a moderate intake of vegetable oils will help to sustain a relatively low level of triglycerides and a high level of HDL cholesterol. Assigning a higher priority to reduction of high-sugar foods seems preferable to decreasing the intake of vegetable oils. The current recommendation of about 30% of total calories from fat, mostly in the form of vegetable oils, seems reasonable (16, 17).

The one category of foods that can be safely increased includes fruits and colored vegetables (56). These products are relatively low in calories and rich in other nutrients. The latter include antioxidants along with fiber, phytoestrogens, phytosterols, polyphenols, carotenoids, indoles, quinones, and organosulfur compounds. Epidemiologic studies and investigations in laboratory animals suggest that some of these substances may protect against CHD, stroke, or cancer (57). There also is interest in the possibility that supplemental antioxidants, especially vitamins E and C, will give added protection against CHD or cancer (58). Although studies of several types support this possibility, a benefit of antioxidant supplements has not been proved through controlled clinical trials. In many persons with hypercholesterolemia, elevated blood pressure is a concomitant risk factor; thus, reduced salt intake combined with increased consumption of potassium from fruits and vegetables may reduce the risk for CHD and stroke by decreasing blood pressure (59).

Estrogen Replacement Therapy. In postmenopausal women with elevated serum LDL-cholesterol, consideration can be given to estrogen replacement therapy (ERT). Estrogens partially restore LDL-receptor activity that normally declines after menopause

(51). ERT thus reduces serum LDL-cholesterol levels by 10 to 15%. In addition, prospective studies suggest that postmenopausal ERT reduces the risks for both CHD and osteoporotic fractures (2). The major concern about ERT is the possibility of an increased risk for breast cancer. Expert opinion based on available data is divided about this risk. Moreover, the fear of breast cancer dissuades many women from starting ERT. Most investigators believe that the reduction in deaths from CHD and osteoporosis will exceed the increase in deaths from breast cancer, but the precise balance between positive and negative aspects of ERT must await a controlled clinical trial.

Maximal Nondrug Therapy. The combination of changes in eating habits and other life habits that reduce risk for CHD can be termed *maximal nondrug therapy*. The concept of maximal nondrug therapy is useful because it incorporates all of the changes, short of drugs, that can be used to achieve risk reduction. [Table 75.6](#) lists the components of maximal nondrug therapy. In addition to the factors discussed above, avoiding smoking or smoking cessation must top the list. Adoption of this list of habits throughout life should lead to a low incidence of CHD into old age. What can be achieved by the combination of all of these beneficial life habits is illustrated by populations in many countries where CHD rates are low (60). Unfortunately, urbanization and industrialization occurring in many previously low-risk populations are changing eating patterns and life habits and are markedly increasing the risk for cardiovascular disease in these populations.

Smoking avoidance or cessation
Reduced dietary cholesterol-raising fatty acids
Reduced dietary cholesterol
Achieve and maintain desirable body weight
Regular physical activity
Reduced dietary salt
Increased fruits and colored vegetables
Antioxidant vitamins

Table 75.6 Maximal Nondrug Therapy

Cholesterol-Lowering Drugs. For patients with established CHD, it has been recommended that LDL-cholesterol levels be reduced to the optimal range (i.e., ≤ 100 mg/dL) (1, 2). Many patients with mild hypercholesterolemia cannot achieve this goal by dietary change alone. Cholesterol-lowering drug therapy is required in addition to dietary change. The drugs in this category and their characteristics are considered below.

Moderate Hypercholesterolemia

Total cholesterol levels in the range of 240 to 300 mg/dL constitute moderate hypercholesterolemia, defined more specifically as serum LDL-cholesterol levels in the range from 160 to 219 mg/dL (1, 2). These higher cholesterol levels produce a still greater increment in CHD risk. Approximately 20% of American adults have moderate hypercholesterolemia (2). The causes of moderate elevations of LDL-cholesterol are similar to those for mild hypercholesterolemia, except that genetic factors play an increasingly dominant role. For most people with moderate hypercholesterolemia, diet modification alone will not reduce their serum cholesterol levels to the desirable range. Instead, responsible genetic factors will maintain some LDL elevation. Our studies have identified several different patterns of LDL metabolism that underlie a rise in LDL-cholesterol from the mild to the moderate range (12, 61). These patterns include (a) higher rate of formation of LDL, (b) lower fractional clearance rate for LDL, and (c) enrichment of LDL particles with esterified cholesterol. The mechanisms underlying each of these factors are examined briefly below.

Causes of Moderate Hypercholesterolemia

Overproduction of LDL. In patients with moderate hypercholesterolemia, two potential mechanisms underlie the overproduction of LDL: (a) increased input of VLDL particles and (b) reduced uptake of VLDL remnants by the liver (12, 61). Both changes should increase total amounts of VLDL converted to LDL. Isotope kinetic studies (61) suggest that either mechanism can occur in persons with moderate hypercholesterolemia. These mechanisms seemingly can be distinguished by differences in the fractional catabolic rate (FCR) for LDL. In persons who overproduce VLDL particles, input rates for LDL are high and FCRs for LDL are relatively low; low FCRs for LDL occur because LDL receptors are relatively overloaded with an excess of lipoprotein particles, reducing the fractional clearance of LDL. On the other hand, in persons who have a decreased uptake of VLDL remnants, high rates of LDL input are combined with increased FCRs for LDL. High inputs of LDL are due to increased fractional conversion of VLDL to LDL; high FCRs for LDL can be explained by increased availability of LDL receptors because of reduced uptake of VLDL remnants by LDL receptors. Our studies (61) suggest that the first pattern (overproduction of lipoprotein particles) probably occurs because of heightened genetic sensitivity to the effects of mild obesity. The mechanism for the second pattern (reduced remnant uptake and increased conversion of VLDL to LDL) has not yet been determined.

Reduced Clearance of LDL. Another pattern of LDL metabolism responsible for moderate hypercholesterolemia is reduced fractional clearance of LDL. This abnormality presumably reflects decreased availability of LDL receptors (12, 61). Some of the dietary or acquired factors listed above can suppress synthesis of LDL receptors. In patients with moderate hypercholesterolemia, however, genetic factors presumably become increasingly important. Since regulation of LDL-receptor expression is complex, the genetic aberrations underlying a moderately reduced synthesis of LDL receptors have not been fully elucidated. A few individuals may have mutations in the gene encoding LDL receptors (62), although such mutations usually produce severe hypercholesterolemia. Polymorphisms in other genes that indirectly influence LDL receptor synthesis are more likely candidates to explain moderate

hypercholesterolemia. To date, few of these genetic polymorphisms have been discovered.

Cholesterol-Enriched LDL. Some individuals have moderately elevated serum LDL-cholesterol concentrations because their LDL particles contain excessive amounts of cholesteryl ester (12, 60, 61 and 62). The reasons for this compositional change are not known. Cholesteryl ester-enriched LDL particles are more likely to occur in persons who have relatively low FCRs for LDL; in such persons, the slow clearance of LDL may allow more time for cholesteryl esters to enter LDL particles through the action of the plasma cholesteryl ester transfer protein (CETP) (64, 65). In patients without a reduced clearance rate for LDL, an increased plasma concentration of CETP may account for cholesterol-enriched LDL particles (65).

Management of Moderate Hypercholesterolemia

According to the NCEP (1, 2), the intensity of cholesterol-lowering therapy in patients with moderate hypercholesterolemia depends on their absolute risk status. Patients can be classified as being at either *moderate risk* or *high risk*, according to the number of other coronary risk factors present. The risk factors used in this classification are listed in Table 75.7. Patients with moderate hypercholesterolemia who have zero or one other risk factor are designated at moderate risk; those who have two or more additional risk factors are considered at high risk. All patients in these categories must be devoid of clinical CHD.

Cigarette smoking
Hypertension
Diabetes mellitus
Low HDL cholesterol (<35 mg/dL)
Advancing age
Men >45 years
Women >55 years or postmenopausal

Table 75.7 Coronary Heart Disease Risk Factors

Table 75.8 outlines the general therapeutic approach to patients with moderate hypercholesterolemia, as recommended by NCEP (1, 2). Treatment decisions are based on LDL-cholesterol levels. Moderate-risk patients can be separated into those with moderately elevated LDL-cholesterol levels of 160 to 189 mg/dL and those with higher levels, from 190 to 219 mg/dL. The goal of therapy in both subgroups is to reduce the serum LDL-cholesterol level below 160 mg/dL. Most patients with LDL-cholesterol levels

of 160 to 189 mg/dL should reach their treatment goal by maximal nondrug therapy ([Table 75.6](#)). However, some patients may require low doses of drugs to achieve their LDL-cholesterol target. Most patients with still higher LDL-cholesterol levels (190–219 mg/dL) will require cholesterol-lowering drugs at standard doses to lower LDL-cholesterol below 160 mg/dL. The major cholesterol lowering drugs currently available are listed in [Table 75.9](#). They include bile acid sequestrants and HMG-CoA reductase inhibitors (statins). The daily doses of sequestrants and statins required to produce approximately 15 and 30% lowering of LDL-cholesterol levels, respectively, are shown.

Dietary (nondrug) therapy		
	Initiation level	LDL goal
Without CHD and with fewer than 2 risk factors	≥160 mg/dL	<160 mg/dL
Without CHD and with 2 or more risk factors	≥130 mg/dL	<130 mg/dL
Drug treatment		
	Consideration level	LDL goal
Without CHD and with fewer than 2 risk factors	≥190 mg/dL ^a	<160 mg/dL
Without CHD and with 2 or more risk factors	≥160 mg/dL	<130 mg/dL

^aIn men under 35 years old and premenopausal women with LDL-cholesterol levels 190–219 mg/dL, drug therapy should be delayed except in high-risk patients, such as those with diabetes.

Table 75.8 Treatment Decisions Based on LDL-Cholesterol

Drugs	Dose
Bile acid sequestrants	
Cholestyramine	8–12 g/day ^a
Colestipol	10–15 g/day ^a
HMG-CoA reductase inhibitors	
Lovastatin	40 mg ^b
Pravastatin	40 mg ^b
Simvastatin	20 mg ^b
Fluvastatin	80 mg ^b
Atorvastatin	10 mg ^b

^aDose required to produce an approximate 15% reduction in LDL-cholesterol.

^bDose required to produce an approximate 30% reduction in LDL-cholesterol.

Table 75.9 Cholesterol-Lowering Drugs

The major drugs currently in use in the United States are statins. These drugs inhibit cholesterol synthesis in the liver and raise the activity of LDL receptors ([66](#), [68](#)). All statins are identical in mechanism, but they differ in dose responsiveness. Side effects

appear to be mechanism related; it is doubtful that any of the statins carry unique advantages. Bile acid sequestrants also can be effective cholesterol-lowering drugs. Sequestrants interfere with the reabsorption of bile acids by the intestine; this action enhances conversion of cholesterol into bile acids in the liver, reducing hepatic cholesterol content and enhancing the activity of LDL receptors (68).

Physicians may be tempted to use cholesterol-lowering drugs and ignore dietary modification in hypercholesterolemic patients who are at moderate risk for CHD. There are two reasons to resist this temptation. First, effective dietary modification alone may achieve the LDL-cholesterol target without the need for drugs; moreover, when drugs are required, the dose of drug may be lessened by use of maximal nondrug therapy (Table 75.6). Second, implementation of a maximal nondrug regimen addresses multiple factors involved in CHD risk and should reduce the risk for CHD beyond that achievable by lowering LDL-cholesterol per se.

The NCEP recommends that cholesterol-lowering drugs generally be avoided in men below age 35 and in premenopausal women who are at only moderate risk of CHD (2). The very long term consequences of cholesterol-lowering drugs are unknown; side effects possibly could develop after prolonged drug usage. In addition, the cost:benefit ratio for long-term therapy will be high. However, some authorities believe that bile acid sequestrants are indicated for young adult men who have LDL-cholesterol levels in the range of 190 to 219 mg/dL (2). Some authorities also contend that hypercholesterolemic, diabetic patients deserve intensive cholesterol-lowering therapy, even in the absence of other risk factors.

Maximal nondrug therapy for patients with moderate hypercholesterolemia includes the step II diet (Table 75.10). This diet calls for reducing dietary cholesterol to less than 200 mg/day and cholesterol-raising fatty acids to less than 7% of total calories (2). The step II diet should be supplemented by weight control, increased exercise, and other modifications noted in Table 75.6.

Nutrient	Percentage of Total Calories
Total fat	≤30
Cholesterol-raising fatty acids ^a	<7
Monounsaturated fatty acids	10-15
Polyunsaturated fatty acids	<10
Carbohydrate	≥55
Protein	15
Cholesterol	<200 mg/day

^aIncludes saturated fatty acids (C13-C18) and trans fatty acids

Table 75.10 Step II Diet

For patients classified as high risk because of multiple (two or more) risk factors, the goal of therapy is to reduce LDL-cholesterol to less than 130 mg/dL (2). Most high-risk patients will require cholesterol-lowering drugs to achieve this LDL-cholesterol target. Again, *maximal dietary therapy will facilitate obtaining this LDL target and will provide additional benefits to further reduce risk.*

Frequently, however, it is not possible to reach an LDL-cholesterol below 130 mg/dL without the use of cholesterol-lowering drugs. In patients with LDL-cholesterol levels in the higher ranges, appropriately higher doses of statins may be required. Alternatively, a lower dose of statin can be combined with a bile acid sequestrant to obtain an enhanced LDL-lowering response.

The benefits of cholesterol-lowering drugs in high-risk patients with moderate hypercholesterolemia were demonstrated in the West of Scotland Coronary Prevention Study (WOSCOPS) (5). In this study, 6595 middle-aged men were randomized between placebo and the statin pravastatin (40 mg/day). After 5 years, pravastatin therapy produced a 31% reduction in recurrent coronary morbidity, a 33% reduction in CHD mortality, and a 22% reduction in total mortality.

In very high risk patients with moderate hypercholesterolemia (i.e., those with established CHD or other forms of clinical atherosclerotic disease), the target for LDL-cholesterol reduction is still lower, namely, 100 mg/dL or less (2). Most hypercholesterolemic patients with CHD require aggressive therapy with cholesterol-lowering drugs. The benefit of statin therapy in patients in this category was documented by the Scandinavian Simvastatin Survival Study (3). This study randomized 4444 hypercholesterolemic patients with established CHD to placebo or simvastatin (20–40 mg/day) for 5 years. At the end of this period, the group that received simvastatin therapy experienced a 34% reduction in myocardial infarction, a 42% reduction in CHD mortality, and a 30% reduction in total mortality, compared with the group receiving placebo.

Severe Hypercholesterolemia

Causes of Severe Hypercholesterolemia

A small portion of the population has *severe hypercholesterolemia*, i.e., serum LDL-cholesterol levels of 220 mg/dL or higher. Most patients with severe hypercholesterolemia have reduced LDL receptor activity, although the elevated LDL-cholesterol concentrations may be accentuated in some persons by overproduction of lipoproteins by the liver or by enrichment of LDL particles with cholesteryl ester (12, 61). Almost certainly, genetic factors play the predominant role in development of severe hypercholesterolemia; in most patients of this type, however, the precise genetic defect(s) has not been elucidated.

A small portion of severely hypercholesterolemic patients have mutations in the gene encoding the LDL receptor. This genetic abnormality produces the hereditary condition

called familial hypercholesterolemia (FH) (25). Affected patients can have either heterozygous FH or homozygous FH, depending on whether one or both alleles for the LDL-receptor gene are defective. Heterozygous FH occurs once in 500 people, whereas homozygous FH is present once in 1,000,000 people. LDL-cholesterol concentrations are approximately doubled in heterozygous FH and are elevated fourfold in homozygous FH. A related disorder is called familial defective apolipoprotein B-100 (FDB) (69, 70). This form of hypercholesterolemia is characterized by a defect in the structure of the apo-B-100 protein such that it fails to bind normally to LDL receptors; consequently, clearance of LDL from the circulation is retarded. Patients with FDB can have either moderate or severe hypercholesterolemia.

Management of Severe Hypercholesterolemia

Patients with severe hypercholesterolemia must be considered at high risk, and most will require cholesterol-lowering drugs. However, the choice of drugs and timing of their institution requires clinical judgment. Drug therapy can be delayed in most children with heterozygous FH until adolescence (71). Exceptions are those with very severe hypercholesterolemia. Before adulthood, FH patients generally should avoid statins but can be treated with bile acid sequestrants. Later, statins can be introduced. In adults with heterozygous FH, use of statins and bile acid sequestrants in combination may be required to achieve an acceptably low level of LDL-cholesterol (72, 73). Even when drugs are used to treat heterozygous FH, maximal nondrug therapy should be used to maximize risk reduction. Patients with oligogenic (or polygenic) forms of severe hypercholesterolemia should be treated similarly to patients with monogenic, heterozygous FH.

The very rare patients with homozygous FH must undergo lipid-lowering therapy from early life. Some patients have defective but mildly functioning LDL receptors; these patients show some response to statin therapy. When serum cholesterol levels remain severely elevated, which is usually the case, a procedure to remove LDL directly from the circulation will be required. The procedure currently used, called LDL pheresis, filters plasma through a resin that binds LDL, reducing the plasma LDL concentration (74).

CHYLOMICRONEMIA

Chylomicrons are lipoproteins that carry newly absorbed dietary fat into the circulation. These lipoproteins derive their triglycerides from dietary fat (also see Chapter 4). When fat enters the intestinal tract, it is hydrolyzed by pancreatic lipase into fatty acids and monoglycerides. Uptake of these lipids into intestinal mucosal cells is facilitated by biliary products—the bile salts and phospholipids. Following uptake by enterocytes, fatty acids and monoglycerides are resynthesized into triglycerides. These triglycerides are transferred into newly formed chylomicron particles by MTP (27, 28).

The core of chylomicron particles is composed almost exclusively of triglycerides, but a small amount of cholesteryl ester, derived from newly absorbed cholesterol, also is present. The major apolipoprotein of chylomicrons is apo-B-48. In addition, apo-Cs (CII and CIII), and apo-As (AI and AIV) are present on the surface of chylomicrons.

Chylomicrons are secreted into the lymphatic circulation where they pass via the thoracic duct into the systemic circulation. When chylomicrons distribute into the peripheral microcirculation, they come into contact with LPL located on the surface of capillary endothelial cells. LPL hydrolyzes the triglycerides of chylomicrons and releases their free (unesterified) fatty acids (FFAs) into the circulation. Much LPL is located in the capillary beds of adipose tissue and, consequently, much of the newly released FFA is taken up directly by adipocytes where FFAs are reesterified to form triglycerides for storage. FFA released during lipolysis of chylomicron triglyceride also can be taken up by liver or muscle. In fact, muscle cells also express LPL, which facilitates FFA uptake by muscle. When lipolysis of triglycerides is almost complete, a residual lipoprotein, called a chylomicron remnant, reenters the circulation and is removed rapidly by the liver. Chylomicron remnants are cholesterol-enriched lipoproteins, and some investigators believe that they have atherogenic potential.

Type I Hyperlipoproteinemia

Lipoprotein Lipase Deficiency

A lipoprotein pattern of increased chylomicrons with relatively normal VLDL concentrations is called *type I hyperlipoproteinemia* (75). Mutations in the gene for LPL can lead to deficient enzyme activity that results in type I hyperlipoproteinemia (75). The severity of the resulting chylomicronemia depends on the nature of the mutations. A few patients are homozygous for severe defects; they develop severe chylomicronemia when the diet contains appreciable amounts of fat. A sizable number of defects in the LPL gene responsible for this form of hyperlipidemia have been discovered (76). The severity of the resulting hypertriglyceridemia depends on whether the LPL gene is functionally absent or has some, but diminished, function.

Patients who completely lack LPL activity develop severe chylomicronemia shortly after birth (77). Depending on the level of fat intake, triglyceride levels can vary from 1,000 to 10,000 mg/dL. When triglycerides exceed 2000 mg/dL, the risk for acute pancreatitis increases greatly. Pancreatitis can occur even in infancy when chylomicronemia is severe. In LPL-deficient patients, increases in plasma triglycerides are predominantly in chylomicrons; serum VLDL triglycerides generally are not strikingly elevated. This lack of severely raised VLDL triglycerides probably reflects a relatively low hepatic output of VLDL particles by the liver. An increase in serum chylomicrons alone probably does not promote development of atherosclerosis, because chylomicrons are large lipoproteins and seemingly do not penetrate into the arterial wall.

Apolipoprotein CII Deficiency

Apo-CII is an apolipoprotein that activates LPL. Rare patients have a genetic deficiency of apo-CII (77, 78); as a result, LPL remains nonfunctional, and chylomicron triglycerides cannot be hydrolyzed. Affected patients have severe chylomicronemia similar to those with LPL deficiency. They, too, have the pattern of type I hyperlipoproteinemia.

Type V Hyperlipoproteinemia

Type V hyperlipoproteinemia is characterized by high serum levels of both chylomicrons and VLDL (75, 79). In contrast to genetic deficiencies of LPL and apo-CII, type V hyperlipoproteinemia typically appears later in life (79). Two defects in triglyceride metabolism appear to underlie this disorder (80): overproduction of VLDL particles by the liver and a delay in lipolysis of TGRLPs. An excess of circulating VLDL particles caused by overproduction will accentuate any defect in lipolysis for TGRLP, because lipolytic mechanisms become saturated with excess TGRLP, causing their retention in plasma (81). Elevations of chylomicrons in type V hyperlipoproteinemia can be explained in part by saturation of lipolysis with excess VLDL. In addition, the inherent activity of LPL may be reduced in some patients with type V hyperlipoproteinemia (77). This added defect exacerbates the serum accumulation of both VLDL and chylomicrons.

Overproduction of VLDL triglycerides in type V hyperlipoproteinemia usually results from hepatic overload of lipids secondary to excessive release of FFA by adipose tissue. High serum FFA levels most often result from obesity and other disorders of adipose tissue (82, 83). In obese patients, the rate of lipolysis of adipocyte triglyceride is abnormally high, leading to increased release of FFAs; increased hepatic uptake of FFAs; oversynthesis of hepatic triglycerides; and overproduction of VLDL triglycerides (84, 85). When obese patients have predominantly truncal obesity, the release of FFAs from adipose is further accentuated and hypertriglyceridemia is more severe (86, 87). The same is true in patients with non-insulin-dependent diabetes mellitus (NIDDM) in whom insulin levels are not raised enough to dampen FFA release from adipose tissue. Rare patients with partial lipodystrophy, in whom regions of adipose tissue are absent, are prone to hepatic lipid accumulation and type V hyperlipoproteinemia (88). An even more-severe accumulation of hepatic lipid occurs in patients who completely lack adipose tissue (generalized lipodystrophy) (89). Because of high serum FFA levels, patients with generalized obesity and other disorders of adipose tissue usually have lipid overloading in liver and skeletal muscle. These excess accumulations of tissue lipids interfere with the normal cellular metabolism of glucose, producing a condition called insulin resistance (90, 91). Insulin resistance in skeletal muscle interferes with glucose uptake by this tissue. Most patients with type V hyperlipoproteinemia also have insulin resistance in liver that appears to be intimately related to overproduction of VLDL triglycerides (92, 93).

As mentioned above, another defect in type V hyperlipoproteinemia is defective lipolysis of TGRLPs (80). Many patients appear to have an inherent defect in lipolytic capacity in addition to having the lipolytic system saturated by excess TGRLP. Some probably have polymorphisms in LPL that reduce lipase function. However, insulin resistance in the liver again is involved because it raises hepatic production of apo-CIII (94), an apolipoprotein that interferes with LPL activity (95). Thus, not only do lipid overload and insulin resistance in the liver lead to overproduction of VLDL triglyceride, but they also cause a lipolytic defect for TGRLP by inducing excessive synthesis of apo-CIII.

Management of Chylomicronemias

Type I Hyperlipoproteinemia

Patients with type I hyperlipoproteinemia lack LPL activity because of mutations in the LPL gene or the apo-CII gene. No triglyceride-lowering drugs are available to overcome these defects. The only effective means of preventing severe chylomicronemia is to reduce dietary fat. Fat intake should be reduced below 10% of total calories. Triglycerides containing medium-chain fatty acids can be substituted in part for long-chain fatty acids because medium-chain fatty acids are not incorporated into chylomicrons, and thus, their ingestion does not induce chylomicronemia. The purpose of treatment of severe chylomicronemia is to lessen the danger of acute pancreatitis—not to decrease the risk of CHD.

Type V Hyperlipoproteinemia

In type V hyperlipoproteinemia, very low fat diets also are necessary to reduce the severity of chylomicronemia. Moreover, weight reduction in obese patients, combined with increased physical activity, will lessen overproduction of VLDL by reducing hepatic lipid overload. However, in many patients with type V hyperlipoproteinemia, changes in eating and exercise habits alone do not effectively control their severe hypertriglyceridemia. Such patients require triglyceride-lowering drugs.

The fibric acids are one class of effective drugs (96). Available fibric acids include clofibrate, gemfibrozil, fenofibrate, and bezafibrate. Gemfibrozil is the agent currently used in the United States, whereas the latter two are more commonly used in Europe. All the fibric acids have a similar mechanism of action. Recent studies show that they act mainly by binding to the class of nuclear receptors called peroxisomal proliferation-activating receptors— α (PPAR- α) (97) (see also [Chapter 36](#)). Activation of these receptors initiates a cascade of reactions that elicits changes in apo-CIII and LPL: synthesis of apo-CIII in liver is reduced, and synthesis of LPL in peripheral tissues is increased. In addition, fibrates may increase oxidation of fatty acids in the liver. All of these changes act to lower serum concentrations of TGRLP. Most patients with type V hyperlipoproteinemia require fibric acids for effective control of hypertriglyceridemia. Reduction of chylomicronemia lessens the risk for acute pancreatitis; decreasing VLDL levels may also reduce the risk for developing CHD, although this latter benefit has not been proven.

Another agent for treatment of type V hyperlipoproteinemia is nicotinic acid. At low intakes, nicotinic acid acts as a vitamin (see [Chapter 23](#)); in high doses, it becomes a triglyceride-lowering drug. Its precise mechanism of action is not known, although it appears to act in the liver to reduce formation of VLDL (98). This action often controls severe hypertriglyceridemia. Although nicotinic acid is highly effective as a triglyceride-lowering drug, side effects are not uncommon. Typical side effects include gastrointestinal irritation, hepatotoxicity, flushing and itching of the skin, and hyperuricemia. In diabetic patients, nicotinic acid can worsen insulin resistance and raise glucose levels (99). For these reasons, this drug is used less frequently in the treatment of type V hyperlipoproteinemia than are the fibric acids.

ATHEROGENIC DYSLIPIDEMIA

Causes of Atherogenic Dyslipidemia

A third major category of lipoprotein abnormalities can be called *atherogenic dyslipidemia* (100). This form of dyslipidemia is characterized by a constellation of lipoprotein abnormalities occurring together. Four components typically make up atherogenic dyslipidemia: (a) mild hypercholesterolemia, (b) mild-to-moderate hypertriglyceridemia, (c) small, dense LDL particles, and (d) low HDL-cholesterol. Atherogenic dyslipidemia generally does not result from a single metabolic defect but from the coexistence of several defects. Five causes for atherogenic dyslipidemia are recognized: (a) obesity, (b) diets high in cholesterol-raising fatty acids, (c) physical inactivity, (d) aging, and (e) genetics (100). These causes resemble the categories of factors underlying hypercholesterolemia; however, among them, obesity and physical inactivity tend to predominate in atherogenic dyslipidemia, whereas a diet high in cholesterol-raising fatty acids and aging more commonly cause hypercholesterolemia. Patterns of genetic aberration also tend to differ in patients with atherogenic dyslipidemia and those with predominant hypercholesterolemia.

Atherogenic Dyslipidemia and the Metabolic Syndrome

The major causes of atherogenic dyslipidemia may, simultaneously, be responsible for other nonlipid risk factors, notably hypertension, NIDDM, and a prothrombotic state. The coexistence of these several risk factors can be called the syndrome of multiple metabolic risk factors, or simply the “metabolic syndrome” (100). This syndrome is extremely common in patients with atherogenic dyslipidemia. Obesity usually is present in patients with the metabolic syndrome and is often the predominant cause. As indicated above, obesity produces high levels of FFA that overload the liver with lipid, and excess hepatic lipid predisposes to atherogenic dyslipidemia. This sequence also causes insulin resistance, which may cause NIDDM; it also can raise blood pressure; and it may induce a prothrombotic state (101). These multiple actions of obesity that initiate the metabolic syndrome are commonly augmented by lack of exercise, aging, diet, and genetic factors. Because of the concurrence of several metabolic risk factors in the metabolic syndrome, it is difficult to dissect the relative contributions of each risk factor to atherogenesis. Nonetheless, evidence exists that each of them are independently atherogenic, and when the impact of all of the risk factors is summed, together they substantially raise the risk for CHD.

Some investigators postulate that the underlying abnormality responsible for the metabolic syndrome is a state of insulin resistance (102). The metabolic basis of insulin resistance is exceedingly complex and may arise from a host of different biochemical defects. These defects produce a generalized metabolic disorder. A common feature of this disorder is one in which fatty acids displace glucose as the predominant energy source (91, 92). For example, one cause of insulin resistance is tissue uptake of excess fatty acids derived from adipose tissue. The metabolic consequence of this overloading of tissues with lipids is inhibition of insulin action at the cellular level, which leads secondarily to hyperinsulinemia. Thus, a state of disordered metabolism, which has

been called insulin resistance, is commonly present in patients exhibiting multiple metabolic risk factors, including atherogenic dyslipidemia (102). The following discussion briefly reviews the causes and features of each component of atherogenic dyslipidemia.

Components of Atherogenic Dyslipidemia

Mild Hypercholesterolemia

Most persons in the United States having the other components of atherogenic dyslipidemia also manifest mild hypercholesterolemia, i.e., a serum LDL-cholesterol concentration ranging from 130 to 159 mg/dL (borderline high, see [Table 75.1](#)). Since some LDL elevation is prerequisite for atherogenesis, LDL concentrations are usually in the mildly elevated range when patients with atherogenic dyslipidemia develop premature CHD. The causes of mild hypercholesterolemia are described above. In patients with atherogenic dyslipidemia, obesity often is a major contributing cause of elevated serum LDL, but the other factors considered above can play a role as well.

Mild-to-Moderate Hypertriglyceridemia

Most people with atherogenic dyslipidemia have some elevation in plasma triglycerides. Two categories of triglyceride elevation are mild hypertriglyceridemia (tri-glycerides 150–199 mg/dL) and moderate hyper-triglyceridemia (200–500 mg/dL). Elevations of serum triglycerides occur mostly in the VLDL fraction. The usual cause of mild-to-moderate hypertriglyceridemia is increased hepatic production of VLDL secondary to obesity (84, 85). Production rates of VLDL triglycerides can be further enhanced by decreased physical inactivity or by high-carbohydrate intakes (103). Overproduction of VLDL triglycerides often unmasks mild defects in lipolysis; this combination of abnormalities frequently raises serum triglycerides into the hypertriglyceridemic range (85, 104). Mild lipolytic defects may be of genetic origin, possibly due to mild abnormalities in the expression of LPL. As already noted (69), insulin resistance, common in patients with atherogenic dyslipidemia, is accompanied by overproduction of apo-CIII (94), an apolipoprotein that inhibits the activity of LPL (95) and induces a lipolytic defect.

An important question is whether an elevation of VLDL particles directly promotes development of atherosclerosis. To address this question, it must be recognized that VLDL particles are not homogenous in size or composition. At least two varieties of VLDL should be distinguished: (a) newly secreted VLDL and (b) VLDL remnants. Although they are similar in density, the lipid compositions of newly secreted VLDL and VLDL remnants differ. VLDL remnants consist of partially catabolized VLDL; some of their triglycerides have been hydrolyzed, and they have acquired more cholesteryl esters. In fact, in fasting serum, most VLDL particles are remnants. There is growing evidence that VLDL remnants have an atherogenic potential comparable to that of LDL. In contrast, newly secreted VLDLs probably are not atherogenic. The atherogenicity of VLDL remnants is most striking in type III hyperlipoproteinemia (75, 105). In this condition, catabolism of VLDL remnants is curtailed because of a genetic defect in the structure of apo-E that impairs binding of VLDL remnants to hepatic LDL receptors

(105). Because of their slow removal from the circulation, remnants in type III hyperlipoproteinemia accumulate excessive amounts of cholesteryl esters; apparently, this excess cholesterol makes them highly atherogenic.

Small Dense LDL Particles

Another feature of atherogenic dyslipidemia is an abnormality in LDL particle size, specifically, the abnormally small LDL particles (100, 106). Small LDL particles frequently occur in patients with premature CHD (106, 107 and 108). They may have greater atherogenic potential than normal-sized LDL. The unusually high atherogenicity of small LDLs could have several reasons. For example, they could enter the arterial wall more readily than larger LDLs. Moreover, they appear to be more sensitive to oxidation than larger LDLs (109); this too could enhance their atherogenicity. In spite of these possibilities, it is difficult to quantify the increased risk that accompanies having small LDL particles, mainly because of confounding associations between small LDLs and other components of atherogenic dyslipidemia and/or other risk factors of the metabolic syndrome (100).

One cause of small LDL particles is an elevation of serum triglycerides. High triglyceride levels partially deplete LDLs of cholesteryl esters because cholesteryl esters in LDLs are exchanged for excess triglycerides in VLDLs. As hydrolysis of LDL triglycerides by LPL continues, small relatively cholesterol-depleted LDLs are formed. Another cause of small LDLs may be an increased activity of HTGL. This enzyme degrades both triglycerides and phospholipids in LDLs, thereby reducing LDL size and increasing LDL density. The link between small LDL and elevated HTGL also may result from elevated HTGL activity. High HTGL activity may accelerate catabolism of VLDL remnants to LDLs, which will result in fewer VLDL remnants being removed directly by the liver. Consequently, more LDL receptors are available to remove LDLs, and the fractional clearance rate for LDL increases. The amount of cholesteryl ester that accumulates in LDL is a function of the half-life of LDL. If the half-life of LDL is shortened by increased HTGL activity, LDL particles should be smaller and deficient in cholesteryl esters.

Low HDL-Cholesterol

The fourth component of atherogenic dyslipidemia is a low concentration of HDL-cholesterol. In particular, there is a tight link between elevated triglycerides, small LDL particles, and low HDL-cholesterol (106). Prospective epidemiological studies reveal a strong inverse relation between low HDL-cholesterol levels and risk of CHD (110, 111, 112 and 113). This inverse correlation may have several explanations. First, HDL may directly retard atherogenesis by blocking the atherogenic action of LDL; second, a low HDL level can be a marker for the presence of other components of atherogenic dyslipidemia; and third, a low HDL commonly denotes the presence of the nonlipid risk factors in the metabolic syndrome (114). These several links may explain why low HDL levels have been reported to be such a strong predictor of CHD (110, 111, 112 and 113).

The underlying causes of low HDL-cholesterol are the same as those for other causes of atherogenic dyslipidemia: obesity, lack of exercise, aging, diet, and genetics.

Increasing obesity causes a progressive fall in HDL-cholesterol concentration (18, 19). Sedentary life habits lower HDL levels; these low levels can be reversed by regular and vigorous exercise (115). Both obesity and lack of exercise increase insulin resistance, and insulin resistance is reported to be common in patients with low HDL-cholesterol levels (116). One dietary pattern resulting in low HDL levels is a low-fat, high-carbohydrate diet (117, 118). Cigarette smoking also reduces serum HDL levels (119). Finally, genetic polymorphism accounts for about 50% of the variation in serum HDL-cholesterol levels in the general population (120, 121); therefore, genetic factors probably contribute to many cases of low serum HDL levels.

There is genetic control over a large number of key metabolic pathways affecting the level of HDL-cholesterol. For instance, multiple genetic factors contribute to higher serum triglyceride levels. Higher serum triglycerides, in turn, are accompanied by lower HDL-cholesterol concentrations (122). Triglycerides in TGRLP exchange for cholesteryl esters in HDL, thereby lowering HDL-cholesterol levels. One factor under genetic control that affects both triglyceride and HDL-cholesterol levels is LPL; patients with low HDL levels often have reduced LPL activity (123, 124). Another determinant of HDL levels is HTGL activity. Increased HTGL activity commonly accompanies reduced serum HDL-cholesterol levels (114, 124). Recent studies (121, 125) indicate that polymorphism in the HTGL gene accounts for about half of the genetic contribution to variation in HDL-cholesterol concentrations. Current evidence suggests that increased HTGL activity facilitates degradation of HDL particles and promotes HDL catabolism (126). Enhanced catabolism of HDL also may occur because of high CETP activity (127); this protein promotes transfer of cholesteryl ester from HDL to TGRLP (64). Genetic polymorphism of the CETP gene accounts for about 20% of the variability of CETP levels in plasma (128). Studies of apolipoprotein kinetics (129, 130) reveal that increased HDL catabolism is responsible for most cases of low serum HDL-cholesterol levels. Accelerated HDL catabolism may be secondary to increased serum triglycerides, reduced LPL activity, increased HTGL activity, and increased CETP activity. All of these changes can be influenced by genetic polymorphism, although acquired factors (e.g., insulin resistance) also may contribute (116). Finally, reduced production of apo-AI may be another cause of low HDL-cholesterol levels (130); production rates of apo-AI likewise appear to be under genetic control (121) (see Chapter 74). Thus, low HDL-cholesterol concentrations, which often are part of the syndrome of atherogenic dyslipidemia, appear to be determined in part by polymorphism in a few key genes that regulate HDL metabolism and in part by external influences on these genes. When patients become insulin resistant, the genetic influences on HDL metabolism are magnified.

Management of Atherogenic Dyslipidemia

The strategy for management of atherogenic dyslipidemia is based on its twofold origin. First, a generalized metabolic disorder—a state of insulin resistance—commonly is present in dyslipidemic patients. But since the severities of particular components of atherogenic dyslipidemia are modified by genetic factors, treatment must be directed toward (a) lessening insulin resistance and, when necessary, (b) direct therapeutic modification of individual components of the dyslipidemic pattern.

Treatment of Insulin Resistance

Insulin resistance is best reduced by caloric restriction and increased physical activity. Both changes in life habits will lower serum insulin levels and dampen the lipid abnormalities characteristic of atherogenic dyslipidemia. Therefore, weight control and increased physical activity are the foundation of management of atherogenic dyslipidemia.

In recent years, there has been a growing interest in the use of drugs designed specifically to reduce insulin resistance. One drug of this type is metformin. Its primary site of action appears to be the liver. The precise biochemical target of metformin action is not known. However, one consequence of its action is reduced hepatic glucose production, which leads to a decrease in peripheral insulin resistance (131). Associated with this change can be a reduction in plasma triglyceride levels (132). Unfortunately, metformin does not fully correct the metabolic abnormalities characteristic of the insulin-resistant state, and hence, dyslipidemia is only partially improved.

The thiazolidinediones are another class of drugs that can modify cellular metabolism and lessen insulin resistance. Among these, troglitazone is the one currently in clinical use. The thiazolidinediones appear to act by binding to the nuclear receptor, PPAR-g(133). The biochemical consequences of this action are not fully understood. One response, however, appears to be an inhibition of FFA release from adipose tissue. This action alone should reduce the availability of FFAs for accumulation as lipids in liver and skeletal muscle. Troglitazone also may act directly on liver and skeletal muscle to modify metabolism favorably. These actions result in decreased plasma insulin levels, indicating reduced insulin resistance (134). There are reports that treatment of patients with troglitazone improves atherogenic dyslipidemia (135). However, insulin resistance is only partially corrected by thiazolidinediones, and serum lipid patterns, although improved, usually remain abnormal.

Available data indicate that effective weight reduction and increased physical exercise correct insulin resistance as effectively as drugs (136, 137). In some patients, insulin “sensitizers” may be a useful adjunct, but current agents are too weak to normalize the serum lipid pattern in most patients. The foundation of treatment of atherogenic dyslipidemia, therefore, is weight reduction and physical activity. Unfortunately, in many patients, changes in life habits do not suffice to normalize serum lipids, and lipid-lowering drugs are necessary to normalize the lipoprotein profile.

Treatment of Lipoprotein Disorders of Atherogenic Dyslipidemia. The primary therapeutic target for lipid modification in atherogenic dyslipidemia is elevated serum LDL-cholesterol (100). Reducing the intake of fats containing cholesterol-raising fatty acids and cholesterol will produce some decrease in plasma LDL-cholesterol concentrations. The goals of LDL-lowering therapies depend on a patient's absolute risk for CHD (outlined above in the section “Management of Hypercholesterolemia”). Patients with a high or very high risk of CHD often require LDL-lowering drugs. The statins are the first line of therapy in higher-risk patients with atherogenic dyslipidemia. Many patients in the CARE study (4) had a lipoprotein pattern characteristic of

atherogenic dyslipidemia; the marked reduction in acute coronary events in CARE patients who received pravastatin therapy reveals the benefit of aggressively lowering LDL-cholesterol levels.

The second abnormality of atherogenic dyslipidemia is a high level of VLDL. Reduction in LDL-cholesterol concentrations with statin therapy typically is accompanied by a concomitant decrease in VLDL levels ([138](#), [139](#)), best reflected by decreased VLDL-cholesterol levels. Statin therapy causes similar percentage reductions in both LDL-cholesterol and VLDL-cholesterol levels ([138](#), [139](#)). Much of the reduction in VLDL levels during statin therapy reflects a fall in VLDL remnants. Thus, some of the CHD risk reduction accompanying treatment with statins in patients with atherogenic dyslipidemia probably is due to a decreased level of atherogenic VLDL remnants.

Nonetheless, even with statin therapy, many patients with mild-to-moderate hypertriglyceridemia maintain some elevation of VLDL levels. The question thus arises whether addition of a triglyceride-lowering drug, combined with statins, will provide further benefit. Available drugs to use in combination with statins are fibric acids and nicotinic acid. Their use is attractive because of reports that these drug combinations can normalize lipoprotein patterns ([140](#)). However, the incremental benefit of combined drug therapy over statins alone has never been documented in clinical trials designed to quantify CHD risk reduction. Until such trials are carried out, it remains uncertain whether combined-drug therapy, in spite of its theoretical benefits, is advantageous in patients with mild-to-moderate hypertriglyceridemia. Unfortunately, combined-drug therapy carries an increased risk for side effects; combining a fibric acid with a statin raises the likelihood for severe myopathy, whereas use of nicotinic acid in combination therapy increases the chances of hepatotoxicity.

The third component of atherogenic dyslipidemia consists of small dense LDL particles, discussed above. Treatment with statins certainly reduces the concentration of small LDL particles in the circulation, which itself should reduce atherogenic risk. Adding a triglyceride-lowering drug to statin therapy helps convert smaller dense LDL particles into larger particles with lower atherogenic potential ([141](#)). This is one theoretical benefit of combined drug therapy. Should future clinical trials show combined-drug therapy to be advantageous, one mechanism of benefit may involve a change in the particle size of LDLs.

The fourth component of atherogenic dyslipidemia is a low HDL-cholesterol level. Statins and fibric acids can elicit modest elevations in HDL-cholesterol levels, in combination they produce moderate increases in HDL-cholesterol ([138](#), [141](#)). However, the best available agent for raising HDL-cholesterol levels is nicotinic acid ([142](#), [143](#)). The combination of a statin and nicotinic acid leads to a particularly striking increase in HDL-cholesterol. In spite of this beneficial response, many patients cannot tolerate nicotinic acid because of its side effects (see above). Certainly, in very high risk patients, an effort can be made to lower LDL-cholesterol concentrations maximally and to raise HDL-cholesterol levels by combined drug therapy. Alternatively, if combining a triglyceride-lowering drug with a statin is unacceptable, the prudent approach may be to lower the LDL-cholesterol level more effectively with a higher dose of statin, thus

partially offsetting the risk of a low HDL-cholesterol level.

Abbreviations: **ACAT**—acyl-CoA cholesterol acyltransferase; **BMI**—body mass index; **CETP**—cholesteryl ester transfer protein; **CHD**—coronary heart disease; **FFA**—free (unesterified) fatty acid(s); **FDB**—familial defective apolipoprotein B; **FH**—familial hypercholesterolemia; **HDL**—high-density lipoprotein; **LDL**—low-density lipoprotein; **LPL**—lipoprotein lipase; **MTP**—microsomal lipid-transfer protein; **NCEP**—National Cholesterol Education Program; **NIDDM**—non-insulin-dependent diabetes mellitus; **SREBP**—sterol regulatory element-binding proteins; **TGRLP**—triglyceride-rich lipoproteins; **VLDL**—very low density lipoproteins.

[Chapter References](#)

Between 1971 and 1991, national health examination surveys document a downward trend of blood pressure levels and the prevalence of hypertension in the US (1). Adoption of healthier lifestyles may have contributed to this favorable trend. Nevertheless, hypertension continues to be a major risk factor for cardiovascular disease (1a). As many as 50 million people in the United States have elevated blood pressure (systolic blood pressure >140 mm Hg and/or diastolic blood pressure >90 mm Hg) or are taking antihypertensive medications (2). Blood pressure–associated risks ensue incrementally and progressively over a wide range of blood pressure levels, and a critical value of blood pressure above which individuals are classified as “hypertensive” is arbitrary. Furthermore, even among normotensive individuals, blood pressure level is predictive of morbidity and mortality from stroke, heart disease, and renal impairment (3). Although categorization of individuals as hypertensive or normotensive provides pragmatic guidelines for medical intervention, it insufficiently addresses blood pressure–related risks. Indeed, between 30 and 40% of all blood pressure–related cardiovascular disease events occur in individuals with average blood pressures below currently defined hypertensive levels but above 120/80 mm Hg. A recent consensus report recommended that the goal of treating hypertensive patients is to maintain blood pressure levels below 140/90 mm Hg, and possibly to levels of 130/85 mm Hg, while concurrently controlling other modifiable risk factors (2).

This chapter reviews evidence that specific nutrients and interactions among nutrients influence blood pressure. [Figure 76.1](#) presents a schematized, incomplete compilation of highly interrelated physiologic factors that contribute to regulation of arterial pressure. As discussed below, many of these factors have been implicated as potential mechanisms by which specific nutrients affect blood pressure. An understanding of the relationship between diet and blood pressure has important implications not only for the treatment of hypertension but also for developing population-based strategies to

decrease the long-term risk of cardiovascular disease.

Figure 76.1. Interrelated physiologic factors that contribute to the regulation of arterial pressure. Arterial pressure is determined by cardiac output and peripheral vascular resistance, and cardiac output is determined by stroke volume and heart rate. Cardiac contractility and vascular volume determine stroke volume. Structural and functional changes in the vasculature affect vascular resistance, and increased vascular resistance induces structural and functional changes in the vasculature. Factors that contribute to the regulation of myocardial contractility, vascular volume, and vascular structure and function are also noted.

SODIUM CHLORIDE

A high sodium chloride (NaCl) intake convincingly contributes to elevated arterial pressure in a number of genetic and acquired models of experimental hypertension. The chimpanzee is phylogenetically close to the human, and in a carefully controlled study, it was recently demonstrated that addition of NaCl to the usual diet of the chimpanzee (a fruit and vegetable diet that is low in sodium and high in potassium) over 20 months results in a significant elevation of blood pressure (4). Blood pressure did not increase in control animals maintained on their usual diets. Despite individual variation, blood pressures increased progressively with progressive increases in dietary NaCl, and at the highest NaCl intake studied, systolic and diastolic pressures increased by 33 mm Hg and 10 mm Hg, respectively. These increases were completely reversed within 6 months of cessation of the high NaCl intake. Animal studies (as well as limited epidemiologic and clinical observations) also suggest that diets high in NaCl may have deleterious cardiovascular consequences independent of blood pressure, e.g., cerebral arterial disease and stroke, left ventricular hypertrophy, renal vascular disease, and glomerular injury (5).

In the human, evidence for an association between NaCl intake and blood pressure is provided by both observational and intervention studies (6, 7, 8, 9 and 10). The effect of NaCl on blood pressure increases with age, with the height of the blood pressure, and,

in normotensive individuals, with a family history of hypertension (11). There may also be a modest association between higher NaCl intake and higher blood pressure in children and adolescents (11a), and results of a recently published randomized trial suggest that a high NaCl intake during the first 5 weeks of life is associated with higher blood pressures during adolescence (11b).

Among populations, the prevalence of hypertension is related to NaCl intake. The Intersalt study describes the relationship between blood pressure and 24-h urine sodium excretion in over 10,000 individuals at 52 centers around the world (12, 13). Two principal findings of this study are (a) a difference of 100 mEq/day in sodium intake is associated with a 3 to 6 mm Hg difference in systolic blood pressure, and (b) lowering the sodium intake by 100 mEq/day attenuates the rise of systolic blood pressure in those between the ages of 25 and 55 years by 10 mm Hg.

NaCl Sensitivity

Based on results of acute NaCl depletion or acute NaCl loading protocols (depending on criteria for the definition of NaCl sensitivity), approximately 30 to 50% of hypertensives and a smaller percentage of normotensives are estimated to be NaCl sensitive, i.e., arterial pressure is decreased by NaCl depletion and/or increased by NaCl loading (14, 15). In short-term intervention trials of the effects of moderate NaCl restriction on blood pressure, the overall reduction of blood pressure is relatively small. As reviewed in two recent metaanalyses, reduction of blood pressure by NaCl restriction is more prominent in hypertensive (4.9/2.9–3.7/0.9 mm Hg) than in normotensive (1.7/1.0–1.0/0.1 mm Hg) individuals (16, 17). These modest reductions of blood pressure in normotensives has led some to question recommendations for reducing NaCl intake in the general population (18). However, many of the trials included in the metaanalyses were of short duration (<2 weeks), and the full impact of NaCl reduction on blood pressure may increase over time. It has been estimated that these small reductions of blood pressure in the population would reduce risks of stroke by 15% and coronary heart disease by 6% (19).

The anion accompanying sodium is important in determining the magnitude of the blood pressure increase in response to high dietary intake of NaCl. The full expression of NaCl-sensitive hypertension depends on concomitant administration of both sodium and chloride (20). In both experimental models of NaCl-sensitive hypertension and in the human, blood pressure is not increased by high dietary sodium intake with anions other than chloride, and a high chloride intake without sodium has less effect on blood pressure than NaCl. The failure of nonchloride sodium salts to produce hypertension may be related to their failure to expand plasma volume. In usual diets, however, sodium is generally consumed as NaCl.

Blood pressure responses to sodium may be modified by other components of the diet. Both epidemiologic and clinical evidence suggest that dietary intake of potassium or calcium below the recommended daily allowances (RDA) potentiate NaCl sensitivity of blood pressure (21, 22). Conversely, high dietary intake of potassium or calcium prevents or attenuates development of NaCl-induced hypertension in several animal models. Increasing evidence, primarily in the rat, suggests that high intakes of sucrose

potentiate NaCl sensitivity of blood pressure (23); this may be related to an antinatriuretic effect of sucrose.

Within a population, overall blood pressure responses to NaCl restriction may mask individual variability. Experimental models of hypertension and increasing information in the human provide convincing evidence for a genetic susceptibility and a genetic resistance to the effects of dietary NaCl on arterial pressure. A familial resemblance in the change of blood pressure in response to salt restriction has been described, and a phenotype of haptoglobin may be a marker of NaCl sensitivity (24, 25). In the United States, compared with Caucasians, a larger proportion of both normotensive and hypertensive African Americans are NaCl sensitive. Reasons for this are not entirely clear but may in part be genetic. Clinically, there is evidence for heritability of sodium excretion, levels of hormones that regulate sodium excretion, and salt sensitivity of blood pressure in both Caucasians and African Americans. African Americans excrete sodium less efficiently than whites; plasma renin activity tends to be suppressed in African Americans, and low plasma renin may be a surrogate marker for salt sensitivity of blood pressure (26). It has been estimated that more than 50% of African American hypertensives in the U.S. are salt sensitive; the prevalence of diuretic-sensitive (and presumably salt-sensitive) blood pressures approaches 75% (27).

Physiologic Mechanisms of NaCl Sensitivity

Several interrelated blood-pressure control mechanisms may contribute to blood pressure elevations induced by NaCl (Fig. 76.1). Experimental and clinical evidence suggests that a genetically determined decreased capacity to excrete sodium contributes to NaCl-induced elevations of arterial pressure in the susceptible host (28). The Dahl salt-sensitive (Dahl-S) rat is a well-characterized genetic model of low-renin, NaCl-sensitive hypertension associated with insulin resistance (29). In this model, the pressure natriuresis curve (inflow pressure vs. sodium excretion) from the isolated kidney is shifted to the right, i.e., the kidney of the NaCl-sensitive animal requires a greater pressure to excrete sodium than the kidney from the salt-resistant (Dahl-R) rat. Similarly, in the human, several, but not all, investigators reported that NaCl-sensitive hypertensives retain more sodium in response to a NaCl load than NaCl-resistant patients (30).

Nitric oxide is a vascular endothelium-derived vasodilator. In the normal rat, nitric oxide activity increases in response to a high NaCl intake, perhaps facilitating natriuresis and blood pressure homeostasis, and impaired nitric oxide synthase activity may contribute to NaCl sensitivity of blood pressure (31). Pharmacologic inhibition of nitric oxide synthesis shifts the pressure/natriuresis relationship to higher levels of arterial pressure and produces hypertension (28); conversely, long-term treatment with arginine shifts the pressure/natriuresis relationship to lower pressures and prevents development of hypertension in the Dahl-S rat and the spontaneously hypertensive rat (SHR).

Increased sympathetic nervous system activity and impaired baroreflex function may also contribute to NaCl-sensitive hypertension in the experimental animal and in man (32, 33 and 34). In the Dahl-S rat, dietary NaCl loading potentiates the increment of vascular resistance in response to neural stimulation and increases the rate of basal

firing of the splanchnic nerve (32, 35). A high NaCl intake increases vascular reactivity to norepinephrine in the prehypertensive Dahl-S rat. A high NaCl diet also exacerbates impairment of baroreceptor reflex control of heart rate in the Dahl-S rat, whereas in the Dahl-R rat, a high NaCl diet enhances afferent discharge of aortic baroreceptors and augments sympathoinhibitory responses to volume expansion. In the normotensive rat, dog, and rabbit, impaired baroreflex function renders the animal susceptible to NaCl-induced blood pressure elevations.

NaCl sensitivity of blood pressure is also associated with alterations of ion transport in vascular smooth muscle that favor vasoconstriction (36). Based primarily on studies in circulating blood cells, most evidence suggests that active membrane Na⁺ transport is suppressed by high NaCl intake and that suppression of sodium transport by a high NaCl diet may be less prominent in circulating cells of hypertensives than of normotensives. Hypertension is also associated with increased red blood cell Li⁺Na⁺ countertransport and decreased Na⁺K⁺/2 Cl⁻ cotransport; increased red cell Li⁺Na⁺ countertransport may be a marker for NaCl sensitivity of blood pressure. Dietary NaCl loading has been reported to increase intracellular calcium in lymphocytes of NaCl-sensitive humans. Based on nuclear magnetic resonance spectroscopy studies of the intracellular ionic consequences of NaCl loading, patients with salt-sensitive hypertension have an exaggerated increase in intracellular sodium and, in contrast to non-salt-sensitive individuals, elevation of cytosolic free calcium, and suppression of intracellular pH and magnesium levels (37). These ionic alterations may contribute to increased peripheral resistance.

OBESITY

An association between obesity and hypertension has been amply documented. Data from cross-sectional studies indicate a direct linear correlation between body weight (or body mass index) and blood pressure (38, 39, 40, 41, 42 and 43). Centrally located body fat is a more important determinant of blood pressure elevation than peripherally located body fat in both women and men. In longitudinal studies, there is a direct correlation between change in weight and change in blood pressure over time, even when dietary salt intake is held constant (43). The proportion of the prevalence of hypertension attributable to obesity is an important public health question. It has been estimated that 60% of hypertensives are more than 20% overweight. The high prevalence of overweight combined with the corresponding increase in risk of developing high blood pressure has led to estimates that 20 to 30% of hypertension can be attributed to this exposure (44).

A reduction of blood pressure by weight loss has been clearly documented in short-term trials in both hypertensive and normotensive individuals. Based on pooling results of controlled dietary intervention trials, it has been estimated that a mean change in body weight of 9.2 kg is associated with a 6.3 mm Hg change in systolic blood pressure and 3.1 mm Hg change in diastolic blood pressure (43).

Obesity-related hypertension has been variously ascribed to hypervolemia and an increased cardiac output without an appropriate reduction of peripheral resistance, to

increased sympathetic nervous system activity, and to insulin resistance ([45](#), [46](#)).

INSULIN RESISTANCE

Obesity is associated with resistance to insulin-stimulated glucose uptake and hyperinsulinemia, and weight loss increases insulin sensitivity ([47](#)). Depending on the populations studied and methodologies for defining insulin resistance, approximately 25 to 40% of nonobese, nondiabetic hypertensives are also insulin resistant ([48](#)). The constellation of insulin resistance, reactive hyperinsulinemia, increased serum triglyceride concentrations, decreased HDL cholesterol, and hypertension has been designated "syndrome X." Independent of obesity, centripetal distribution of body fat is also associated with insulin resistance and elevated blood pressure. Insulin resistance is also associated with alterations in the blood clotting cascade that accentuate thrombosis by increasing coagulation and inhibiting fibrinolysis. In both women and men, centripetal obesity is predictive of coronary heart disease, independent of body mass index, and waist:hip ratio may be a better predictor of cardiovascular risk than body mass index ([48](#)).

Increasing evidence suggests that insulin resistance is associated with salt sensitivity of blood pressure in both normotensive and hypertensive individuals ([47](#), [48](#) and [49](#)). Like patients with salt-sensitive hypertension, even in the absence of hypertension, obese individuals and/or individuals with type II diabetes mellitus reportedly also have elevated intracellular calcium and suppressed intracellular magnesium levels, and these ionic alterations may contribute to insulin resistance.

Syndrome X may in part be heritable; however, in the rat, simple carbohydrate feeding (sucrose, glucose, or fructose) also results in insulin resistance, dyslipidemia, and increased blood pressure ([47](#)). Sucrose feeding also potentiates development of hypertension in the SHR, in a rat model of adrenal regeneration hypertension, and in normotensive rats fed high NaCl. Although a number of putative mechanisms have been proposed, it is unclear whether insulin resistance and/or hyperinsulinemia actually cause hypertension. Putative mechanisms include antinatriuretic effect of insulin, increased sympathetic nervous system activity, augmented vasoconstriction in response to norepinephrine and angiotensin, impaired endothelium-dependent vasodilatation, and stimulation of vascular smooth muscle growth by insulin.

POTASSIUM

Potassium loading prevents or ameliorates development of hypertension in several animal models of genetic and NaCl-induced hypertension ([21](#)). Conversely, in both Dahl-S and Dahl-R rats on a high NaCl diet, a low potassium intake results in blood pressure elevation and renal vascular remodeling (increased wall:lumen ratio), indicating increased renal vascular resistance ([50](#)).

In societies with high potassium intakes, both mean blood pressure and the prevalence of hypertension tend to be lower than in societies with low potassium intakes ([21](#), [51](#)). Several large surveys have demonstrated a significant inverse correlation between

potassium intake and blood pressure among individuals within a population; this inverse association is more prominent on a high NaCl diet (12, 21). However, in some studies, after adjusting for other variables (e.g., age, weight, consumption of alcohol, fiber, magnesium), dietary potassium was not found to be independently associated with blood pressure (52), and not all surveys have documented an association between potassium intake and either level of blood pressure or prevalence of hypertension. Failure to observe this association may be related to insufficient sample sizes. The urine sodium:potassium ratio appears to be a stronger correlate of blood pressure than either sodium or potassium alone (12, 21, 51, 53); in children, the rise of blood pressure with age is directly related to the urine sodium:potassium ratio (54).

Almost 70 years ago, Addison reported that a high potassium intake has an antihypertensive effect in humans (55). More recently, results of two metaanalyses of clinical trials concluded that oral potassium supplements significantly lower both systolic and diastolic blood pressures (56, 56a). The magnitude of the blood pressure lowering effect is greater in hypertensive, than in normotensive, individuals and is more pronounced with a longer duration of supplementation. The effect of a high potassium intake on blood pressure is also more pronounced in blacks than in whites and in individuals consuming a high NaCl diet (21). Increased intake of potassium has been reported not to affect blood pressure in hypertensive men on a low NaCl diet (57); however, reduced sodium and increased potassium and magnesium intake lowered blood pressure in men and women with mild-to-moderate hypertension (58). Conversely, potassium depletion induced either by a low-potassium diet or by diuretics is associated with blood pressure elevation (59, 60).

Proposed mechanisms by which a high dietary intake of potassium may lower blood pressure include a natriuretic effect of potassium, inhibition of renin release, antagonism of the pressor response to angiotensin II, direct vasodilatation, augmentation of endothelium-dependent vasodilatation, decreased production of the vasoconstrictor thromboxane, and increased production of the vasodilator kallidin (21).

Dietary potassium may affect morbidity and mortality, independent of an effect on blood pressure. Unrelated to changes of blood pressure, a high potassium diet was reported to decrease stroke mortality in the stroke-prone SHR and to decrease renal damage in several rat models of hypertension (61, 62 and 63). Similarly, in a prospective clinical study, the 12-year risk of stroke death was negatively associated with potassium intake, independent of blood pressure (54). In a prefecture in Japan, introducing a diet with a low sodium:potassium ratio was associated with a reduced 10-year stroke mortality rate (64).

CALCIUM

As recently reviewed, more than 80 studies have reported that blood pressure is lowered by increasing dietary calcium in experimental models of hypertension (65). This effect of calcium on blood pressure may be more pronounced in models of salt-sensitive hypertension (66).

Within and among human populations, like potassium, there is an inverse association

between dietary calcium intake and blood pressure, and low calcium intake is associated with an increased prevalence of hypertension (22, 67). Data from both epidemiologic reports and animal studies suggest a threshold for calcium intake below which arterial pressure increases (68), and a low calcium intake may amplify the effects of a high NaCl diet on blood pressure. In the human, diets with less than 600 mg calcium per day are most clearly associated with hypertension (65). Based on results of two published metaanalyses including 23 and 66 populations, weak but statistically significant inverse correlations were observed for association of dietary calcium with both systolic and diastolic blood pressures (69, 70). However, because of the size of the estimate, the heterogeneity among studies, the difficulty of assessing calcium intake, and the possibility of confounding and publication bias, the authors conclude that increasing calcium intake above the RDA is not recommended for the prevention or treatment of high blood pressure. Dietary calcium is also inversely related to systolic blood pressure in young children (71).

Most clinical trials evaluating the effect of increased dietary calcium on blood pressure have supplemented diets with 1000 to 1500 mg of elemental calcium per day. Reductions of blood pressure have been modest and inconsistent, and no gradient of calcium effect or threshold intake level has been identified. Two recently published metaanalyses of randomized clinical trials have shown a small, statistically significant reduction of systolic, but not diastolic, blood pressure (72, 73). Like the data in the observational studies, results of these clinical trials do not justify recommending calcium supplementation to the general population for prevention or treatment of hypertension.

Within a population, it may be possible to identify subgroups who are more likely to be responsive to calcium. For example, calcium supplementation may preferentially lower blood pressure in patients with NaCl-sensitive hypertension and low-renin hypertension, whereas calcium may actually increase blood pressure in patients with high-renin or renin-dependent hypertension (22). During pregnancy, calcium supplementation has been reported to reduce both systolic and diastolic blood pressure (74). Despite earlier evidence to the contrary (75), results of a recent, randomized, multicenter trial indicate that calcium supplementation during pregnancy does not prevent preeclampsia or pregnancy-associated hypertension (75a). Calcium supplementation more convincingly lowers blood pressure in individuals consuming low-calcium diets (68, 76).

There is considerable speculation about mechanisms by which dietary calcium may affect blood pressure (77). Calcium has a natriuretic effect, which may explain the apparent greater sensitivity of patients with NaCl-sensitive hypertension to the blood pressure-lowering effect of calcium. Conversely, in both the human and the intact rat, NaCl loading increases urinary calcium excretion and serum parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D concentrations. Hypercalcuria, decreased plasma ionized calcium concentrations, and increased plasma concentrations of PTH and 1,25-dihydroxyvitamin D have been observed in experimental models of NaCl-sensitive hypertension and in patients with low-renin hypertension (78, 79). It has been hypothesized that PTH results in vasoconstriction by influencing neural activity and/or vasoactive hormones either directly or indirectly via changes in serum calcium (77, 78 and 79). Other studies have emphasized a role for vitamin D, especially in NaCl-related

hypertension.

Conceivably, NaCl-sensitive hypertension may be a calcium-losing state, resulting in secondary hyperparathyroidism ([65](#), [77](#), [78](#) and [79](#)). Calcium supplementation may reduce blood pressure by correcting this calcium deficiency and the associated hyperparathyroidism. Alternatively, alterations of calcium metabolism and calcium-regulating hormones may be epiphenomena of NaCl loading that are not causally related to development of hypertension.

Other putative mechanisms by which high dietary calcium intake may lower blood pressure include decreased calcium influx into vascular smooth muscle cells and increased capacity of these cells to extrude calcium, potential vasoactive effects of calcium-regulating hormones (PTH, 1,25-dihydroxyvitamin D, calcitonin-gene-related peptide), and modulation of sympathetic nervous system activity.

MAGNESIUM

Relatively little information is available concerning dietary magnesium and blood pressure. Although magnesium is found in a variety of foods, it is not easily identified and quantified. High magnesium intakes lower blood pressure in rat models of hypertension, and in the rat, blood pressure increases in response to magnesium deprivation ([80](#), [81](#)).

In the human, as with calcium, there is suggestive evidence for an association between lower magnesium in the diet and higher blood pressures ([22](#)). Over the past century, the availability of magnesium-rich foods has declined, and consumption of processed foods that have lost magnesium has increased. It has been proposed that subclinical magnesium deficiency has developed in industrialized countries, and that this has paralleled the increased prevalence of hypertension ([82](#)). Conversely, persons consuming vegetarian diets, which are usually high in magnesium and fiber content, tend to have lower blood pressures than nonvegetarians, raising the possibility that dietary magnesium is inversely related to blood pressure. However, in one cross-sectional study of 9- to 10-year-old girls, after adjusting for dietary fiber, a significant inverse association between magnesium intake and blood pressure was no longer discerned ([83](#)). In older persons, diets high in both magnesium and potassium are associated with lower blood pressures ([58](#)). Limited evidence suggests that dietary intake of magnesium is lower in hypertensives than in normotensives; in one prospective study, lower calcium (<400 mg/day vs. >800 mg/day) and lower magnesium (<200 mg/day vs. >300 mg/day) intake predicted risk of subsequent hypertension ([84](#)). In another prospective study, dietary magnesium, potassium, and fiber were each significantly associated with lower risk of hypertension when considered separately; however, when these nutrients were considered simultaneously, only dietary fiber had an inverse association with hypertension ([85](#)).

Limited information is available about the effects of magnesium supplementation on blood pressure in hypertensives, and the results are inconsistent (see also [Chapter 9](#)). At best, the overall hypotensive response to magnesium supplementation is small and may become more apparent in trials of more than 6 months duration ([86](#), [87](#)). The

capacity of magnesium to lower blood pressure appears to be greater in hypertensives who are hypomagnesemic and/or are taking diuretics (88, 89).

There is a plausible physiologic rationale for an effect of magnesium on blood pressure. Magnesium decreases vascular tone and contractility, possibly by decreasing cellular uptake of calcium and thereby decreasing cytosolic calcium (22). In addition, magnesium administration in endothelial cells and in humans stimulates production of prostaglandin I₂, a vasodilator, when serum magnesium is raised acutely (90). Conversely, magnesium deficiency is associated with resistance to insulin-stimulated glucose uptake and enhanced vascular contractility.

ALCOHOL

Observational studies suggest a J-shaped relationship between alcohol consumption and blood pressure (91, 92, 93 and 94). Light drinkers (one to two drinks per day) have lower blood pressures than teetotalers (95), whereas in comparison to nondrinkers, there is a small but significant elevation of blood pressure in individuals consuming three or more drinks per day (a standard drink contains approximately 14 g of ethanol and is defined as a 12-ounce glass of beer, a 6-ounce glass of table wine, or 1.5 ounces of distilled spirits). These higher blood pressures are not related to potentially confounding variables such as age and body mass. The assumption is that alcohol is a vasodilator at low doses but a vasoconstrictor at higher doses.

The contribution to the prevalence of hypertension attributed to consuming more than two drinks of alcohol per day has been estimated to be 5 to 7%; the contribution in men is greater than in women, although in women the risk of hypertension increases progressively with alcohol intake in excess of 20 g/day. Several short-term studies suggest that decreasing alcohol consumption has therapeutic benefit to hypertensives (96). In controlled studies, reduction of alcohol consumption has been associated with a reduction of 4 to 8 mm Hg in systolic blood pressure and a lesser reduction of diastolic pressure. Blood pressure of normotensives may also decrease in response to a reduction of alcohol consumption.

The mechanism(s) by which alcohol may affect blood pressure has not been established. In both the rat and the human, alcohol ingestion augments sympathetic nervous system activity (95). Alcohol also stimulates corticotropin-releasing hormone (CRH) and cortisol secretion, and CRH appears to stimulate sympathetic neural activity. In normal subjects, it has recently been reported that dexamethasone inhibits both the augmented neural discharge and blood pressure increment in response to alcohol infusion (97). This observation suggests that the alcohol-induced elevation of blood pressure is related to CRH-mediated sympathetic activation. Additionally, short-term administration of alcohol results in an early rise in serum magnesium level followed by a transient decrease in PTH, associated with a transient hypocalcemia and hypercalcuria and followed by a late rise in PTH. What relation, if any, this may have to alcohol-induced increases of blood pressure is not clear.

LIPIDS

Both animal and human data suggest that polyunsaturated n-3 and n-6 fatty acids play a role in blood pressure regulation (99). In experimental models of hypertension, both linoleic acid (a long-chain n-6 polyunsaturated fatty acid) and fish oil (rich in eicosapentaenoic and docosahexaenoic acids, both n-3 fatty acids) attenuate development of renin-dependent hypertension (100). Limited epidemiologic evidence suggests a direct association between diets high in saturated fats and blood pressure, and many populations that have low mean blood pressure levels consume diets low in total fat and saturated fatty acids (101). Conversely, diets high in n-3 fatty acids may be associated with lower blood pressures (102). Several trials have failed to show a significant blood pressure effect by varying the dietary content of fat or by exchanging polyunsaturated fatty acids for saturated fatty acids, and there is ongoing debate as to whether reducing saturated fat and/or increasing polyunsaturated fat in the diet lowers blood pressure (103). Limited evidence suggests that linoleic acid-enriched diets reduce blood pressure in normotensive and hypertensive humans.

Results of a recent metaanalysis of 31 controlled trials showed a small, statistically significant reduction of blood pressure by fish oil (3.0/1.5 mm Hg) at an overall mean dose of 4.8 g of n-3 fatty acids (or approximately 10 capsules) per day (104). In these trials, there was little or no effect among healthy normotensive individuals; however, hypertensive patients showed a dose-response hypotensive effect of fish oil. Fish oil also had a moderate effect on blood pressure in hypercholesterolemic patients and patients with atherosclerotic cardiovascular disease. The authors concluded that fish oil is unlikely to benefit healthy subjects for the prevention or treatment of hypertension, given the uncertainty of response and the large dose required to elicit small changes in blood pressure. Despite some earlier evidence to the contrary, a recent randomized, controlled trial concluded that fish oil in doses that reduce blood pressure in hypertensive persons does not adversely affect insulin sensitivity or glucose metabolism (105).

In contrast to n-3 polyunsaturated fatty acids, results of clinical trials show little or no evidence that saturated fats and n-6 polyunsaturated fats have an independent effect on blood pressure beyond changing body weight (106, 107). The blood pressure reductions attributed to n-3 fatty acids may be related to alterations of prostaglandin metabolism, alterations of vascular endothelial function, increased vascular responsiveness to pressor agents, and inhibition of vascular smooth muscle proliferation.

PROTEIN

Several recent observational studies, including the Intersalt study, suggest that blood pressure level is inversely associated with dietary protein consumption (12, 108). However, limited clinical intervention trials show no evidence that amount or type of protein in the diet affects blood pressure (95, 96). Conceivably, specific amino acids could affect neurotransmitters or humoral substances that control blood pressure. For example, acute administration of tryptophan or tyrosine (either peripherally or directly

into the central nervous system) reduces blood pressure in experimental animals, possibly via effects on neuronal pathways involved in blood pressure control (108).

CARBOHYDRATE

As discussed above, simple carbohydrate feeding induces insulin resistance. In the rat, high dietary intake of glucose, sucrose, or fructose may increase arterial pressure in the normotensive animal, may augment NaCl sensitivity of blood pressure, and may potentiate development of hypertension in several experimental models (23, 47). However, in the human, there is no evidence that manipulating the carbohydrate content of the diet affects blood pressure.

VEGETARIAN DIET

In general, results of both observational and intervention studies demonstrate that lacto-ovo vegetarian diets consumed by acculturated individuals are associated with a decreased prevalence of hypertension and lower blood pressure levels than omnivorous diets (109, 110, 111 and 112). A strict lacto-ovo vegetarian diet consists of a relatively low intake of saturated fat, a high polyunsaturated:saturated fat ratio, and a high intake of fruits, vegetables, and other fiber. Dietary intakes of carbohydrate, potassium, magnesium, and calcium tend to be increased, and dietary protein is lower than that in omnivores.

The DASH Trial is a randomized multicenter study that evaluated the effects of three dietary patterns over 8 weeks on blood pressure in 459 adults with high-normal blood pressure or mild hypertension (112a). The dietary interventions were (a) control diet, with potassium, calcium, and magnesium levels close to the 25th percentile of U.S. consumption; (b) a diet rich in fruits and vegetables; and (c) a “combination” diet rich in fruits, vegetables, and low-fat dairy products. Sodium chloride content was equivalent in all three diets (8 g/day). Systolic and diastolic blood pressures were significantly reduced by the fruit and vegetable diet (−2.8 and −1 mm Hg, respectively) and, compared with controls, were reduced even more by the combination diet (−5.5 and −3.0 mm Hg, respectively).

The specific nutrients responsible for the blood pressure reduction associated with vegetarian diets have not been defined. Although vegetarians tend to be slimmer, the lower blood pressure appears not to be totally accounted for by body weight. Results of randomized controlled dietary trials suggest that the hypotensive effect of a vegetarian diet is also not due to the absence of meat protein per se (111). Substituting animal fat with starch and sugar appears not to lower blood pressure, whereas blood pressure is lowered by replacing fat with vegetable products, including vegetable oils (109). The effect of dietary fiber on blood pressure remains an unresolved issue (113); carefully controlled studies with different types of fiber are needed. Additionally, vegetables are a primary source of vitamin C, and several observational studies suggest an inverse correlation between plasma vitamin C levels and blood pressure; however, the limited available clinical trial data do not demonstrate a convincing blood pressure reduction

with increased consumption of vitamin C (114).

PRIMARY PREVENTION AND TREATMENT OF HYPERTENSION

In children, there is a strong correlation between obesity and blood pressure, and a direct association between changes in body weight and change in blood pressure (115). In addition, blood pressures in the young tend to track over time, and a large proportion of obese children become obese adults. Prevention of obesity, beginning in childhood, would seem important for the primary prevention of hypertension and cardiovascular disease.

Several recent trials have tested the efficacy of preventing hypertension in adults through altered dietary intake. In one trial, approximately 200 subjects with diastolic blood pressures in the high-normal ranges (80–89 mm Hg) were assigned to either a control group or a combined intervention consisting of weight loss, sodium restriction, moderate alcohol restriction, and moderate isotonic physical activity (116). Subjects were followed over a 5-year period. Nine percent of intervention subjects developed hypertension, compared with 19% of control subjects ($P = 0.027$). In a second prevention trial, 841 men and women between the ages of 25 and 49 years with diastolic blood pressures between 78 and 89 mm Hg were assigned to one of five groups: (a) control, (b) reduced calories, (c) reduced sodium, (d) reduced calories and sodium, and (e) reduced sodium and increased potassium (117). Calorie counseling reduced mean diastolic and systolic blood pressures at 6 months (2.8 and 5.1 mm Hg, respectively) and 3 years (1.8 and 2.4 mm Hg). Somewhat unexpectedly, the combination of calorie and sodium counseling was less effective than calorie counseling alone. The other interventions did not significantly affect blood pressure.

The Trial of Hypertension Prevention (TOPH) was designed to evaluate nonpharmacologic interventions in the primary prevention of hypertension in men and women with diastolic blood pressures ranging from 80 to 89 mm Hg. Different groups of subjects were exposed to different interventions. In phase I (which included 2182 subjects), stress management or dietary supplementation for 6 months with calcium, magnesium, potassium, or fish oil did not significantly reduce systolic or diastolic blood pressure, compared with controls; however, blood pressure was reduced by weight reduction and to a lesser extent by modest salt restriction over an 18-month period (118, 119 and 120). Phase II was designed to test the effects of weight loss and sodium restriction, alone and in combination, on blood pressure over 3 to 4 years in overweight adults with high normal blood pressures (120). Both weight loss and reduction of sodium intake, individually and in combination, lowered systolic and diastolic blood pressures in the short term (6 months), although the effects of the two interventions were not additive. Beyond 6 months, the interventions were less effective in maintaining both weight loss and sodium restriction, and although their impact on blood pressure (although still significant) lessened, hypertension incidence was reduced. Additional studies evaluating the impact of diet modification and the interaction of nutrients on blood pressure in adults with “high normal” blood pressures are in progress.

The impact of dietary intervention on blood pressure is most pronounced in individuals with hypertension. With appropriate dietary modifications, it may be possible to treat

hypertensive patients with fewer drugs and with lower doses; in a significant percentage of hypertensives, particularly patients with mild hypertension, dietary modifications may totally obviate the need for drug therapy ([121](#), [122](#), [123](#) and [124](#)). In hypertensives whose blood pressures have been controlled with medications, weight loss or NaCl restriction more than doubles the likelihood of maintaining normal blood pressure after withdrawal of drug therapy. The following lifestyle modifications have been recommended as adjunctive or definitive therapy for hypertension: weight reduction if overweight; aerobic exercise; limited NaCl and alcohol intake; maintenance of adequate dietary potassium, calcium, and magnesium intake; smoking cessation and reduced dietary saturated fat and cholesterol intake for overall cardiovascular health ([2](#)).

PUBLIC HEALTH IMPLICATIONS

Observational and interventional studies in humans, supported by findings from animal studies, provide a clear rationale for the following population-based recommendations to optimize the effect of diet on blood pressure: reduce NaCl intake; control body weight; consume adequate amounts of potassium, calcium, and magnesium; and moderate alcoholic beverage intake. Blood pressure–lowering interventions applied to the entire community would result in a small downward shift in the blood pressure distribution, which would have a substantial impact on preventing hypertension and reducing the burden of blood pressure–related cardiovascular disease ([44](#), [112](#), [125](#)). There is strong rationale for a population-based educational approach to blood pressure control through diet. A population-based approach reaches children during years when lifestyles and dietary preferences are established. It also reinforces recommended dietary changes for hypertensive individuals. We found that educational efforts directed to an entire community significantly decreased blood pressure levels and improved control of high blood pressure ([126](#)).

It is estimated that 20 to 30% of hypertension can be attributed to overweight ([43](#), [44](#)). The strength of the association between body weight and blood pressure and between change in weight and change in blood pressure over time indicates that weight reduction in overweight individuals and avoidance of obesity should be key strategies for both prevention and treatment of hypertension.

Opinion is divided concerning a recommendation on NaCl restriction for the entire population ([44](#), [127](#)). Arguments for this recommendation include the following: current NaCl intake exceeds the physiologic need; the tendency for blood pressure to increase with high NaCl intake occurs over the entire population; although relatively large differences in dietary NaCl have a relatively small impact on blood pressure within and across populations, these blood pressure differences may significantly affect the overall incidence of cardiovascular disease; within a population, a certain percentage of individuals may be particularly susceptible to the effect of dietary NaCl on blood pressure; and identification of NaCl-sensitive individuals is not practical. Arguments against the recommendation for reduction of NaCl consumption for the entire population include the following: limited or no proven blood pressure reduction for a large segment of the population; little evidence that reduction of NaCl intake affects cardiovascular disease endpoints (e.g., stroke, heart attack, and kidney disease); and potential adverse

health consequences of NaCl restriction.

Despite these reservations, it is generally recommended that excessively high intake of dietary NaCl be avoided. Current estimates of NaCl intake in the U.S. are in the range of 8 to 10 g/day. As an example of a specific guideline, the U.S. Dietary Guidelines Advisory Committee and the American Heart Association recommended that dietary NaCl be restricted to no more than 6.0 g/day, and more rigorous NaCl restriction may be recommended for hypertensive individuals. In the absence of blatant salt-losing disorders, there is no convincing evidence that this modest reduction in salt intake has any long-term, adverse health consequences; nevertheless, this concern has been raised. Alderman et al. reported increased incidence of myocardial infarction over an average 3.8-year follow-up in drug-treated hypertensive men with the lowest levels of sodium excretion (<4 g NaCl per day) at entry (18). The design of this observational study makes it impossible to exclude the influence of such potentially confounding variables as severity of underlying disease, presence of other cardiovascular disease risk factors, and usual long-term NaCl consumption.

Recommendations about other nutrients should also be considered. Because of the strong association of alcohol intake with blood pressure, a recommendation to restrict alcohol intake to two drinks per day would seem reasonable, particularly in individuals with hypertension. Low intake of potassium, calcium, or magnesium has been associated with higher levels of blood pressure, and the effects of a high NaCl intake on blood pressure may be amplified by diets low in both potassium and calcium. Furthermore, dietary deficiencies of these ions may be associated with other disorders such as calcium deficiency and osteoporosis. Recent National Academy of Science recommendations for calcium consumption are 1300 mg/day for adolescents (ages 9–18 years), 1000 mg/day for adults under 50 years of age, and 1200 mg/day for those over age 50 (see [Chapter 7](#) and Appendix [Table II-A-2-b-1](#)). Although serum cholesterol and hence cardiovascular disease risk may be modified by dietary fat intake, there is currently insufficient information to make recommendations about dietary intake of lipids or carbohydrates for the prevention or treatment of hypertension.

Strategies for the prevention and treatment of hypertension should address overall cardiovascular disease risk, not simply elevated blood pressure. Dietary recommendations should be incorporated into a comprehensive program that also addresses other cardiovascular disease risk factors such as elevated serum cholesterol concentrations, cigarette smoking, and a sedentary lifestyle. In developing recommendations, the potential impact of changing the intake of a single nutrient on the dietary content and/or bioavailability of a wide range of nutrients should also be considered.

Several population-based dietary education initiatives have recently been introduced in the U.S. The U.S. Department of Agriculture has released revised recommendations for dietary intake for Americans. Dietary intake recommendations are communicated by the “food pyramid,” which emphasizes a diet based on increased intake of complex carbohydrates and limited intake of calorically dense foods. In addition, the National Cancer Institute and others have promoted “Five a Day for Better Health,” the recommendation that Americans consume five fruits and vegetables a day as a tangible

way to improve dietary intake. Through federally published dietary guidelines, revised recommendations for sodium intake are being promoted. The U.S. Department of Agriculture has made major changes in nutritional standards for reimbursable school breakfasts and lunches (128). These changes require decreased salt and fat in the foods provided in schools. In addition, there is federal support for nutritional education programs in schools for children and for food service employees. Finally, federally mandated food labeling permits individuals to assess their nutritional intake accurately and modify it more readily.

[Chapter References](#)

Over the last 50 years, attempts to define heart failure have remained difficult. Paul Wood offered the classic definition in 1950 as “a state in which the heart fails to maintain an adequate circulation for the needs of the body.” This description does not provide clinically useful diagnostic criteria and ignores the fact that cardiac output may be maintained. Cohn has offered an operational definition. He describes heart failure as a syndrome in which cardiac dysfunction is associated with impaired left ventricular function, reduced exercise tolerance, a high incidence of ventricular arrhythmia, and a shortened life expectancy (1). Although this definition is operational, it is not absolute. First, symptoms may be present without demonstrable systolic dysfunction, and secondly, exercise tolerance may be normal with severe systolic impairment.

EPIDEMIOLOGY

Advances in treatment of cardiac disease has led to a significant decline in myocardial infarction and strokes in the United States. Paradoxically, the incidence and prevalence of congestive heart failure has increased.

ETIOLOGY

In the United States, two million patients have congestive heart failure, and 400,000 new cases occur each year (2). The age-adjusted death rate for heart failure increased from 3.8/1000 in 1968 to about 7.7 in 1984. The incidence of death increases exponentially with age in both sexes. Hospitalization rates for heart failure have increased sharply among people older than 55 in the United States and Western Europe (3). Given a mortality that varies from 15 to 50% per year and the high cost of hospitalization, congestive heart failure is a costly public health issue.

PATHOPHYSIOLOGY

Heart

Recent models suggest that heart failure results from the combined effect of positive feedback mechanisms. These mechanisms include aortic impedance, ventricular preload, myocardial hypertrophy, myocardial ischemia, and neurohormonal activation (sympathetic nervous system, renin-angiotensin system, antidiuretic system, and natriuretic peptide).

Neurohormones

Following myocardial injury, ventricular performance is impaired. As a result of the diminished ventricular function, neurohormonal activation occurs to support the declining cardiac output. The major response is an increase in norepinephrine, which induces vasoconstriction. This initial response of the sympathetic nervous system activation is beneficial, enhancing contractility and promoting diastolic relaxation. However, this may be countered by redistribution of blood and increased afterload on the left ventricle because of vasoconstriction, both of which are factors in the progression of heart failure (4).

The second major neuroendocrine response is activation of the renin-angiotensin-aldosterone system. Many stimuli exist for activation of the renin-angiotensin aldosterone system in heart failure. In addition to decreased renal perfusion, circulating norepinephrine increases renin activity. The elevated activity of the renin-angiotensin-aldosterone system leads to increased angiotensin and aldosterone production, intensifying vasoconstriction and fluid retention, respectively. The subsequent increase in ventricular afterload and fluid retention promotes ventricular dilatation. This combination leads to further impairment of ventricular function (5).

Although the neurohormonal activation associated with congestive heart failure has major hemodynamic effects, specifically vasoconstriction with a consequent reduction in ejection fraction, the cellular effects of the neurohormones must be considered as well. Neurohormones, especially norepinephrine and angiotensin II, have definite effects on cellular growth. Myocyte hypertrophy occurs in response to nonspecific loading conditions. Mechanical stretching causes an increase in messenger RNA (mRNA), leading to protein synthesis associated with cell growth (6). Studies of neonatal myocytes show that norepinephrine promotes myocardial cell growth independent of loading conditions (7).

Remodeling

Angiotensin II induces hypertrophy of the myocytes independent of elevated peripheral vascular resistance and altered afterload. Secondly, angiotensin II has mitogenic properties. Increased levels of angiotensin II induces fibroblast proliferation and collagen synthesis leading to increased myocardial collagen content. The fibroblast

stimulation may be more important than the hemodynamic effect of angiotensin II on myocytes because the myocardium contains more fibrocytes than myocytes (8). The excess collagen alters the filling characteristics of the left ventricle and impairs contractile function. The increase in chamber radius produces increased wall stress and accentuates myocardial oxygen requirements (9). The combined effect of neurohormones on both hemodynamics and cellular structure leads to remodeling of the heart.

Remodeling is an alteration in the geometry (volume and shape) of the ventricular cavity independent of alteration in distending pressures (10). Initially, it is a compensatory mechanism that preserves stroke volume. Although incompletely understood, it is apparent that remodeling results from the interaction between the infarcted and noninfarcted myocardium. Infarct expansion involves acute dilatation and thinning of the infarcted area. Several tissue changes are involved, including myocyte slippage and loss of intracellular space. Echocardiographically, the process is associated with lengthening of noncontractile elements in the noninfarcted area. Studies indicate progressive increase in end-diastolic length in the noninfarcted myocardium, with ventricular enlargement as early as 2 weeks after myocardial injury. The extent of wall motion abnormality correlates closely with the degree of ventricular cavity enlargement. As a result of the ventricular dilatation and inadequate hypertrophy, increased wall stress leads to self-perpetuating dysfunction of the noninfarcted ventricle. Remodeling is progressive and increases mortality by a factor of 3 (11, 12).

CLINICAL RECOGNITION

Hemodynamic changes associated with remodeling include a progressive increase in end-diastolic volume and a decrease in the ejection fraction of the ventricle. Left ventricular end-diastolic pressure rises initially and is transmitted to the left atrium, pulmonary wedge pressure, pulmonary artery, right ventricular pressure, and finally right atrial pressure. Over time, the decreased ejection fraction leads to diminished cardiac output.

The increased left atrial pressure produces exudation of fluid from the intravascular space to the pulmonary interstitium, leading to decreased pulmonary compliance or stiff lungs. When fluid exudes into the alveoli, there is a reduction in air space volume as well as decreased oxygen exchange. These changes are manifested clinically by dyspnea and orthopnea in the heart failure patient.

The reduced cardiac output is manifested clinically by fatigue and weakness. This effect results not only from absolute reduction of cardiac output but also from redistribution of flow, favoring the vital organs. The reduced blood flow to the kidneys leads to renin release, elaboration of angiotensin II, and finally elevated aldosterone levels. The increase in aldosterone levels produces significant fluid retention, manifested clinically by jugular venous distention, pulmonary rales or pleural fluid, S3 gallop, enlarged tender liver, hepatojugular reflux, ascites, and peripheral edema.

The routine laboratory procedures useful in evaluating heart failure include complete blood count, urinalysis, serum electrolytes, BUN, creatinine, liver function test, arterial

blood gases, and drug levels such as digoxin levels. The chest x-ray (cardiac size and shape) and electrocardiogram can be extremely useful in defining the cause of the cardiac problem. The echocardiogram defines chamber size and volume, valvular integrity, wall motion abnormalities, and presence or absence of pericardial fluid.

Exercise testing quantifies the degree of functional impairment, and prognostic and therapeutic information may also be obtained. It has become a standard method for evaluating the response to chronic drug therapy as well as detecting ST abnormalities associated with ischemic heart disease. It is inexpensive, repeatable, and safe (13).

As heart failure progresses, symptoms of dyspnea and fatigue increase. Weakness develops, and weight loss may occur in advanced cases. Development of weakness associated with loss of lean body mass in patients with heart failure constitutes a well-recognized syndrome known as cardiac cachexia. Cachexia involves primarily the depletion of metabolically active lean body mass, with subsequent declines in strength, performance status, and immune competence (14, 15 and 16). Nutritional surveys of hospitalized patients have revealed that between 50 and 68% of patients with CHF are significantly malnourished, based on anthropometric measurements, total body weight, and plasma protein status (16). Although Hippocrates was the first to observe the association of heart failure (dropsy) with cachexia, the mechanisms of this syndrome remain obscure (14). Multiple mechanisms include decreased caloric intake, increased metabolic needs, hypermetabolism, decreased energy and nutrient assimilation, and increased cytokine production (14).

Decreased caloric intake may be secondary to anorexia, directly related to the nausea, dyspnea, or fatigue of heart failure. Some investigators have reported inadequate intake of both calories and vitamins in heart failure. Others have shown that negative nitrogen and calorie balance could be reversed with voluntary improvement in food intake (15, 16 and 17). Although the exact mechanism of anorexia is unknown, visceral congestion, unpalatable diets (salt free), and severe depression may contribute to this problem. Drugs often prescribed to treat heart failure may inadvertently contribute to development of cardiac cachexia. Diuretics may deplete potassium and zinc stores, leading to hypomotility of the gastrointestinal tract and decreased taste acuity, respectively. Likewise, digitalis intoxication may cause nausea, vomiting, and anorexia. Quinidine may also decrease gastrointestinal tolerance to food (18). The loss of lean body mass, however, exceeds that expected from anorexia alone (15).

Steatorrhea is recognized clinically, and fat balance studies have demonstrated a rough correlation between fat malabsorption and the severity of CHF (19). Iodine-labeled triolein studies have confirmed steatorrhea in 30% of heart failure patients, compared with 2% of normal controls (20). Defective absorption of amino acids and protein-losing enteropathy have been reported, but the mechanism of protein loss has not been fully explained (21).

Hypermetabolism is an established state in chronic congestive heart failure. It may be divided into increased metabolic needs of specific tissues or a generalized calorogenic effect. Of the increased metabolic demands, dyspnea due to the increased work of breathing has been documented. Generalized factors involved in hypermetabolism

include low-grade fever and enhanced sympathetic nervous system (SNS) activity. Investigators reviewing records of 200 hospitalized heart failure patients found only 4 entirely free of fever. At autopsy of the 50 patients who expired, pulmonary infarction was found in half, and pneumonia was present in 40% of the patients (22).

Poehlman has compared 20 men with advanced heart failure and reduced ejection fractions with 40 age-matched healthy males (see Chapter 5). The patients had a lower fat-free mass than the controls. The two groups did not differ in fat mass. The measured metabolic mass had a higher resting metabolic rate (18%) in heart failure patients than in healthy volunteers. The difference was clinically significant and was felt to contribute to weight loss and musculoskeletal wasting. These investigators could not confirm that caloric expenditure associated with meals, deconditioned state, or voluntary reduction in caloric intake adequately explained the weight loss. A more likely explanation is the increase in SNS activity (23). Elevated SNS activity is established in heart failure and accounts for many other adverse aspects including tachycardia, sweating, and vasoconstriction.

Recently, there has been interest in tumor necrosis factor in heart failure and cardiac cachexia (23). Tumor necrosis factor- α (TNF- α) is a proinflammatory cytokine. It is a low-molecular-weight protein that acts at shorter distances than classic endocrine hormones. Classically, cytokines are released by monocytes and macrophages in response to viral and bacterial infection. In heart failure, TNF- α activity appears to respond to cardiac tissue injury and is produced by impaired myocytes and not the white cells of the immune system (24).

TNF- α has a moderate negative inotropic effect in humans. Prolonged infusion of TNF- α leads to irreversible cardiomyopathy. It may activate remodeling by activating a collagenase gene, leading to breakdown of the collagen framework of the heart (25). In addition, TNF- α produces fever and cachexia in experimental cardiac failure. Elevated circulating TNF- α levels have been noted in severe heart failure. Other studies comparing measured body weights reveal an inverse correlation between circulating TNF level and body weight. This continued loss of muscle tissue contributes to morbidity and mortality.

The clinical manifestations of cardiac cachexia are well described. Subclavicular and temporal wasting generally is evident, and the skin texture is like parchment. Measurements of triceps skin fold and midarm muscle circumference may be reduced to 60% of normal. Generally a 10% loss of lean body mass is recorded, which is more significant than loss of total body weight (14).

Several biochemical parameters are significant to the nutritional assessment of the patient with congestive heart failure: reduced serum albumin and transferrin levels, depressed total lymphocyte counts, elevated BUN and creatinine, and reduced potassium and magnesium levels. Creatinine-height index is generally a reliable indicator of protein stores in patients with cardiac failure. The ratio of blood urea nitrogen to blood creatinine may also be used as an accurate measure in stable patients. It is important to note that commonly used visceral protein markers such as serum albumin and transferrin may be artificially low because of dilutional effects of

excessive extracellular fluid rather than malnutrition per se (15). Cell-mediated immunity as assessed by delayed hypersensitivity has been observed to be reduced. Electrolyte imbalances may also result from diuretic medications and excess fluid restriction.

TREATMENT

Surgical

Once the cause of the heart failure has been established, the clinician must select the appropriate therapy. Medical therapy consists of elimination of precipitating causes such as pulmonary emboli, infection, anemia, dietary indiscretion, and medication noncompliance. Surgical therapy is a reasonable choice in selected cases. Revascularization may be helpful in patients with viable but hibernating myocardia. Current intervention includes coronary artery bypass or coronary angioplasty (13). Certain congenital and acquired valvular problems respond nicely to valve replacements. In view of the poor outlook (50% mortality/year), eligible patients with the most advanced congestive heart failure should be considered for cardiac transplantation. In the modern era of immunosuppression, survival rates for transplants exceed 80% at 1 year and 70% at 3 years. Quality of life is markedly improved by successful cardiac transplantation. At present, however, organ donation is low relative to the demand, and the cost is high.

Medical

Basic drug therapy in the current era includes the appropriate application of diuretics and the use of inotropics, specifically digoxin and vasodilators. More recently, angiotensin-converting enzyme (ACE) inhibition has been shown effective in increasing survival in patients with severe heart failure (26, 27). More controversial medical therapy includes the cautious use of b-blockers, which may have a role in selected cases. Calcium-channel blockers have not yet been shown beneficial in this syndrome. Current data suggest that the use of first-generation calcium-channel blockers is harmful in dilated cardiomyopathy.

Diuretics are used in heart failure to alleviate symptoms and prevent accumulation of fluid in both the central and peripheral circulations, preventing associated breathlessness and swelling. The major benefit of this therapy is reduction of edema. To date, no trials have demonstrated that diuretics improve prognosis in heart failure. They are, however, generally safe, although electrolyte abnormalities and metabolic disturbances may be noted. The most severe adverse effects include electrolyte abnormalities with abnormalities that are associated with cardiac arrhythmias, glucose intolerance, elevation of LDL cholesterol level, and hyperuricemia.

Digitalis is a mainstay in the treatment of chronic congestive heart failure. Digoxin is a mildly positive inotrope that increases ejection fraction as well as exercise tolerance in heart failure. It is apparently most effective in dilated forms of cardiomyopathy and usually is not indicated in patients with sinus rhythm and preserved systolic function. It may, however, be useful in this group when atrial arrhythmias become a problem.

Digitalis toxicity may occur in 10 to 12% of patients but rarely causes death. The interaction of digoxin compounds with other drugs such as quinidine, verapamil, and amiodarone must be carefully weighed, as these agents reduce digoxin binding and may enhance digoxin toxicity. Several studies are pending to clarify the effects of digoxin on survival.

In 1986, Cohn showed that the combination of digoxin, diuretics, and the vasodilators hydralazine and isordil was beneficial in prolonging the survival of patients with chronic congestive heart failure (26). In the V-HeFT I studies, there was a reduction of 34% in mortality over a 2-year period, compared with placebo. In 1991, the V-HeFT II and SOLVD groups assessed the efficacy of the ACE inhibitor enalapril in chronic congestive heart failure. Both groups showed a significant beneficial effect on survival when these agents were added to a fixed regimen of digoxin and diuretics. However, isordil and hydralazine induced greater hemodynamic improvements, e.g., increased both ejection fraction and exercise capacity, compared with the ACE inhibitors (27, 28).

Fatigue interferes with the activities of daily living in heart failure. The potential mechanisms include impaired arteriolar compliance, increased neurohormonal vasoconstriction, and endothelial dysfunction. Most studies have demonstrated a decline in the biochemical and ultrastructural indicators of oxidative capacity. Exercise training regimens are safe in compensated heart failure and improve both the endurance and strength of trained muscles (16, 29).

Nutritional Management

The basic objectives in nutritional management of congestive heart failure are (a) to reduce the workload of the heart as much as possible, (b) to maintain appropriate dry weight, and (c) to achieve and maintain overall optimal nutritional status. Nutritional management encompasses a threefold process of assessment, intervention, and education.

Nutritional Assessment

Accurate assessment of a wide spectrum of dietary, anthropometric, biochemical, and clinical indices provide the data upon which the clinician can implement appropriate therapy. Physical examination, medical history, and individual interview are all essential components of the nutritional assessment of the patient with congestive heart failure (see Chapter 55). Indications of nutrient deficiencies and imbalances may be identified by general examination, patient interview, and medical history. It is especially important to include the patient's family or caregivers in the interview process. Evaluation of the patient's usual weight, rate of weight change, reported dietary intake, and medication compliance as well as the rate of weight change will help not only in determining the presence and degree of malnutrition and fluid retention but also in assessing the patient's level of comprehension and compliance with therapeutic recommendations. Also, concomitant diseases such as diabetes, atherosclerotic coronary artery disease, and chronic renal failure may necessitate monitoring pertinent indices and integrating additional appropriate diet and clinical therapy. The diet should not be overly restricted,

especially since many of these patients are immunocompromised.

Nutrition Intervention

The goal of achieving and maintaining the patient at or slightly below dry weight while protecting and even improving overall nutritional status forms the basis for determination of the specific therapeutic diet prescription. Diet modification centers on sodium restriction and management of fluid intake. Although individual response to sodium restriction varies, most patients who have congestive heart failure with edema respond to a diet restricted to 1.5 to 2.0 g sodium per day (30, 31). A reasonable determination for effective sodium restriction should be based on individual assessment. A brief oral interview can delineate estimated sodium intake as well as medication compliance.

Ordinarily, fluid intake for patients with congestive heart failure need not be restricted. In fact, fluid intake up to 2500 to 3000 mL daily may enhance diuresis (31). However, with the progressive pump failure associated with cardiac cachexia, fluid restriction to about half the normal daily requirement, or 1500 mL, is advisable (32).

In advanced heart failure, especially when the patient's general and cardiac condition has deteriorated, significant edema—both pulmonary and peripheral—may appear to be refractory to treatment. Even with administration of potent diuretics, unusual retention of fluid can develop on a low-sodium diet and unrestricted fluid intake. This leads to dilutional hyponatremia in which there is a dilutional lowering of extracellular sodium concentration, although the total body sodium content is usually excessive. Administration of salt is useless and often dangerous. Since there is a refractoriness to diuretics, fluid restriction is urgently indicated along with appropriate treatment for the underlying causes of the aggravated circulatory failure. Restoration of serum sodium concentration after spontaneous water diuresis may then occur, with improvement in the patient's general status (31, 33).

In an acute CHF event, it is often difficult to ascertain the cause and best treatment approach. Asking patient and family about recent diet and medication compliance often provides the clinician the key to the appropriate treatment plan. Weight monitoring is fundamental in management of congestive heart failure. Laboratory indicators to monitor include serum urea nitrogen and serum creatinine levels. Elevated serum urea nitrogen and elevated creatinine usually reflect decreased renal flow due to pump failure or dehydration (34). If the patient presents with increased weight with elevated urea nitrogen and creatinine levels, sodium restriction should be intensified, fluid should be restricted, and diuretic therapy may require adjustment. Conversely, weight loss with elevated urea nitrogen and elevated creatinine levels indicates volume depletion, and thus treatment should consist of increased oral or intravenous fluids, suspension of diuretic therapy, and maintenance of moderate dietary sodium intake.

The clinician should be cautioned to maintain close observation of patients adhering to a low-sodium diet. Very low sodium diets can result in depletion of body sodium stores, particularly in those with chronic renal insufficiency. Excretion of urinary sodium exceeding intake accompanied by weight loss and decreased renal function indicates that more sodium is needed. Too little sodium in the diet can produce muscle cramps,

convulsions, hypovolemia, hypotension, and further deterioration of renal function (33). Elderly patients may be more vulnerable to abrupt sodium withdrawal than younger persons.

In addition to sodium and fluid considerations, other diet management factors should be integrated into the diet prescription and nutrition counseling. Total caloric needs may require adjustment to achieve and maintain the patient at a healthful weight. Emphasis in counseling should be placed on achieving the most nutrient-dense composition possible.

Protein needs of the well-nourished adult range between 0.75 and 1.0 g per kg body weight (35). However, patients with cardiac cachexia and those with loss of protein in the urine as a result of increased glomerular permeability or in the feces because of impaired digestion and absorption may have increased protein needs (18, 19, 32).

Dietary supplements of magnesium, potassium, folate, and thiamin are indicated to offset losses of water-soluble vitamins and electrolytes associated with high diuretic doses (36). Broad-range vitamin and mineral supplementation also may be indicated, depending on the patient's dietary intake and nutritional status. Also, problems with gastrointestinal absorption may interfere with adequate absorption of fat-soluble vitamins and minerals, especially calcium and magnesium. In addition, small frequent feedings are often better tolerated by these patients and may better help them meet their caloric requirements.

Education

The central objective of education of the patient with congestive heart failure is to increase long-term compliance to reduce episodes of acute congestive heart failure requiring hospitalization and to improve and maintain optimal overall nutritional status. Patients often fail to comply with prescribed treatment because (a) they do not understand what they are supposed to do and the rationale behind the recommendations; (b) they forget to follow the advised regimen or are not convinced that the treatment is beneficial; or (c) they cannot consistently adhere to the regimen because of financial, psychosocial, or other constraints. Therefore, the educational process must be designed to provide an interdisciplinary, patient- and family-centered, threefold approach encompassing needs assessment, instruction, and long-term support.

Needs assessment should address the critical self-management issues that affect the patient's ability to comply with recommendations. These include age, financial limitations, visual and physical impairments, dentition, literacy and language differences, other medical conditions, and family or social support. In addition, long-term psychologic and motivational factors related to depression and isolation, often seen in this population, have significant influence on long-term compliance.

Education should be individualized and reinforced by all members of the health care team. Patients and caregivers need to understand the rationale for each recommendation. Nutritional education should include instruction regarding basic

nutrition, sodium content of basic foods, nutrition labeling of packaged foods, and food preparation modifications.

Patients should be encouraged to keep a diet and medication diary plus a daily weight chart and to review them with health care providers on a regular basis. Involving the patient as an active member of his or her health care team fosters self-responsibility and communication, both of which are critical to achieving and maintaining long-term compliance. Group educational and support programs have proven to be cost-effective measures resulting in improved compliance and fewer hospitalizations (29).

SUMMARY

In summary, until the precise mechanism of cardiac cachexia is defined, one can only intensify therapy for the underlying heart failure and provide supportive therapy. Long-term compliance is significantly improved when the treatment is individualized and not only meets the patient's clinical needs, but also encompasses his or her capabilities and psychosocial influences. In clinical practice, it appears that patient-centered, interdisciplinary education of the patient and family or caregivers is the single most important factor in long-term compliance and management of the patient with congestive heart failure.

Current dogma in molecular oncology is built on the premise that cancer is the end result of an accumulation of genetic alterations, some that may be acquired, some that may be inherited. The genes that are altered are those involved in fundamental, normal cellular processes such as cell cycle regulation, signaling, and differentiation, many of which are discussed elsewhere in this book. Many environmental agents are felt to cause such genetic abnormalities. These include viruses, chemicals, dietary factors, and radiation; however, when focusing on a specific gene, specific abnormality, or a specific type of cancer, the list shortens considerably. This dogma—that cancer results from the accumulation of genetic abnormalities—unifies the current hypotheses of physical carcinogenesis (chemicals and radiation), viral carcinogenesis, and genetics, in that all of these can cause changes in a cell's DNA.

This tutorial describes the crucial classes, or families, of genes and genetic systems that are altered as part of the basic processes of carcinogenesis in which a normal cell is transformed into a malignant one. The promise for the future is that by better understanding the molecular basis of carcinogenesis, specific treatments or preventive measures can be undertaken that will be nontoxic to the normal cells and tissues of the patient, thus providing more effective cancer therapy.

ONCOGENES AND TUMOR SUPPRESSOR GENES (ANTIONCOGENES)

The homeostatic state of most cells results from a balance between opposing processes, akin to a car that is moving at constant speed on level ground with both the accelerator and brake pedals partially “on.” When a cell needs to adjust to a stimulus or new conditions, the “action” is often the result of a relative change in balance between opposing forces; using the model of the car, as it climbs a hill, it must either increase the accelerator, decrease the brake, or both to maintain a constant speed; once on level ground, the previous ratio is restored to again maintain the constant speed. Similarly, if there is a need to change the speed (e.g., to go slower), the accelerator:brake ratio

must change (decrease, favoring the braking mechanism).

Analogously, regulation of the cell cycle (which determines the replication rate of cells) is a balance between gene products that induce a cell to replicate and gene products that deter cells from replicating; in many cancers, defects in these regulatory systems have occurred, causing the cells to be driven into uncontrolled replication. Genes that can cause resting cells to divide are in a class of genes referred to as protooncogenes (i.e., the “accelerator” on the car model), whereas the genes that can prevent a cell from dividing are members of the family of tumor suppressor genes (i.e., the “brakes”) ([Table 78.1](#)). Cancer often results in part from a “lack of brakes” (absence of tumor suppressor activity), “too much accelerator” (overactivity of oncogenes), or both. Understanding how “the brakes fail” or “the accelerator gets stuck on the floor” forms the basis for understanding molecular oncogenesis.

Table 78.1 Examples of Oncogenes and Tumor Suppressor Genes

Oncogenes

As early as 1911 it was established that particular tumors (avian sarcomas) could be induced in healthy birds by an extract derived from established avian sarcomas (1); this was not the case for sarcomas in other species nor other tumors (at that time). Although neither viruses nor DNA were recognized, considerable information was gleaned from these initial observations, such as species specificity (only birds) and tumor reproducibility (always sarcomas). Not until many years later was a viral agent proven as causative, and not until the mid-1970s was the viral genome analyzed, and it was realized that the particular virus described in the 1911 paper (which bears the author's name—the Rous Sarcoma virus) contained extra genetic material and that this material alone could induce a malignant sarcoma in healthy birds. Intense studies on this “cancer gene,” or oncogene, yielded the following, unexpected revelations unprecedented for genetics theory and models at that time (2, 3):

- This oncogene was closely related to sequences found in normal, healthy cells

from *all* mammalian species (the normal counterpart gene is formally referred to as a protooncogene)

- The degree of similarity (homology) between species was quite high—higher than for any other genetic system studied
- Only a single copy of the (abnormal) oncogene was needed to transform a normal, healthy cell to a full-blown malignant one

Not until 1982, after a number of viral oncogenes had been isolated from virus-induced tumors in nonhuman mammals, was the first evidence obtained that oncogenes were involved in human malignancy. In this setting, the *c-myc protooncogene*, originally isolated as the cellular homolog to the avian leukemia virus oncogene VMYC (the avian myelocytosis virus, hence the name *myc*), was shown to be structurally altered in virtually all cases of a lymphoid tumor called Burkitt's lymphoma; furthermore, chromosomal abnormalities that were routinely and consistently seen on cytogenetic analysis of Burkitt's lymphoma (and felt to be “hallmark findings” unique to Burkitt's lymphoma) were found to have their molecular basis in rearrangement of the *c-myc* oncogene (4). It was soon determined that the consequence of *c-myc* rearrangement was constitutive (i.e., constant, unregulated) overproduction of the CMYC protein to hundreds of times normal levels, regardless of the cell-cycle phase the lymphoma cell was in. It was later established that (a) exposure of a normal resting cell to a mitogenic stimulus resulted in a “burst” of CMYC oncoprotein expression (lasting only 5–10 minutes), followed by subsequent decrease in CMYC protein levels to basal resting levels as a result of normal degradative processes and (b) the high levels of CMYC protein associated with the “burst” were associated with that cell's entry into the S-phase of the cell cycle and subsequently by cell division and the formation of two daughter cells. Thus, the evolving picture of Burkitt's lymphomagenesis is that of a B cell whose DNA is altered so that the cell is always producing an endogenous protein that drives it into S phase and cell division (Fig. 78.1). Clearly, uncontrolled replication alone does not explain all facets of Burkitt's lymphoma (or any other malignancy), but it does explain why these (lymphoid) cells replicate in the absence of exogenous growth factors, something not seen in normal lymphocytes.

Figure 78.1. Schematic demonstrating CMYC oncoprotein levels in a normal cell and a neoplastic Burkitt's lymphoma cell. In normal cells, the level of CMYC oncoprotein is tightly regulated and linked to the cell cycle; in Burkitt's lymphoma, because of the chromosomal translocation involving the *c-myc* protooncogene, the CMYC oncoprotein

is constitutively overexpressed, regardless of the phase of the cell cycle.

Today there are approximately 65 genes that are considered oncogenes or candidate oncogenes. Alteration of these protooncogenes to activated forms capable of inducing neoplastic transformation can occur via a variety of mechanisms, outlined below. One common feature of (activated) oncogenes is their *dominance*, in that only one of the two copies needs to be altered to induce neoplastic transformation. Furthermore, the biochemical activity of the oncoprotein is usually (but not always) more active than the normal gene product; referring to the car model, oncogene activity can, therefore, be viewed as having the gas pedal stuck to the floor in the “full open” position, accelerating the car out of control, beyond the capacity of the brakes to slow it down. It is important to realize that the abnormal oncoprotein activity (and the activated oncogene itself) are found only in tumor tissue—the remaining normal cells of the patient contain the normal protooncogene and normal gene product.

Protooncogenes can be activated to oncogenes by a variety of mechanisms; the common end result is aberrant activity of a protein that the cell cannot properly control and that ultimately drives the cell into replication. The commonly observed mechanisms are best highlighted by the following examples, in which a “normal DNA sequence” (presented as 3-letter words, akin to the triplet anticodon sequence that codes for the specific amino acid sequences of a protein) is altered in a pattern analogous to the alteration in protooncogenes:

—THE RED CAT ATE THE OLD RAT—

Point Mutations/Transversions

Point mutations/transversions frequently result from exposure to chemical carcinogens and radiation. There are two types of point mutations—sense mutations, in which the altered triplet codon is a legitimate codon (i.e., is “readable”), and nonsense mutations, in which the new codon does not code for anything. Activating sense mutations usually result in amino acid substitutions (a different amino acid replacing the correct one), although the codon can code for a “stop” signal, which would result in a shortened, truncated protein; activating nonsense mutations always result in a prematurely truncated product.

The following is an example of a sense mutation (i.e., the altered sequence can still be “read,” although its meaning is altered):

—THE RED CARATE THE OLD RAT—

below is an example of a nonsense mutation (i.e., the altered sequence cannot be “read”):

—THE RED CAXATE THE OLD RAT—

Protooncogenes whose activation occurs as the result of premature truncation are usually overactive, as the missing sequences are frequently the regulatory sequences that control the protein's activity. When the normal gene codes for a receptor, the deleted portion is often the ligand-binding portion, with the truncated product being the catalytic activity portion that performs the biochemical process. This truncated protein can now carry out its activity in the absence of the ligand, *as if the ligand were always present*; the presence or absence of the ligand now becomes irrelevant, and the protein activity is uncontrollable.

Frameshift Mutations

Frameshift mutations result from insertions or deletions; these alterations can involve a single nucleotide or large quantities of DNA. Such mutations can easily result in an unreadable sequence (such as deletion of the “D” of “red” illustrated below), which frequently results in premature truncation of the protein:

—THE REC ATA TET HEO LDR AT?—
(? denotes the next base in the DNA sequence)

Amplification

Amplification is a process whereby a protooncogene, instead of being present in two copies within a cell, is found in increased numbers—anywhere from 10 copies to hundreds of copies per cell. In this scenario, the cellular compensatory mechanisms simply are not strong enough to overcome a signal of such magnitude. This would be akin to a well-matched pair of arm wrestlers in which one player suddenly became hundreds of times stronger; the weaker of the two players would now lose consistently. In neuroblastomas and breast cancer, the copy number of the *Nmyc* and *c-erb-B2/HER2/neu* oncogenes, respectively, is of independent prognostic importance for survival. The mechanisms that cause amplification are not yet established, although some data suggest that errors in mismatch-repair may play a role. In the following example the sequence is amplified three times, in tandem:

—THE RED CAT ATE THE OLD RAT THE RED CAT
ATE THE OLD RAT THE RED CAT ATE
THE OLD RAT—

Translocations

Translocations result in the fusion of two genes—a protooncogene and another cellular gene—forming the transforming oncogene. The fusion gene often codes for a novel protein not found under any other circumstances. Alternatively, translocations can bring the intact protooncogene coding sequences under the regulatory control of a strong(er) promoter, resulting in overexpression of a normal protooncogene product (this end

result would be biologically indistinguishable from amplification). This latter case is the situation for Burkitt's lymphoma, in which the coding sequences of *c-myc* are translocated to the immunoglobulin genes in such a way that the *c-myc* coding sequences are under the control of the immunoglobulin gene regulatory sequences.

 becomes
 chromosome A*: — THE RED CAT SAW THE NEW FLY—
 chromosome B*: — THE DOG ATE THE OLD RAT—

With rare exceptions, there is nothing specific about a given oncogene abnormality and the type of tumor caused by that abnormality; rather, a normal cell can undergo transformation to a neoplastic (malignant) cell if a particular protooncogene within that cell becomes altered in a fashion that results in activation. For example, the *ras* protooncogene family has three members—*H-ras*, *N-ras*, and *Ki-ras*, which have unique locations within the genome. Each *ras* member can become activated by a point mutation at any of three particular codons (12, 13, or 61), which results in an amino acid substitution. As shown in [Table 78.2](#), the same abnormality of *H-ras* (i.e., Glu → Leu transversion of codon 61), for instance, has been identified in lung cancers and melanomas, while lung cancer has been reported to have abnormalities of either *H-ras*, *N-ras*, or *Ki-ras*, albeit not to equal extents. Thus, there is not a specific lung cancer abnormality within the *ras* system, nor does a specific *ras* abnormality cause a particular cancer. A notable exception is a specific abnormality of *Ki-ras* that is seen in over 95% of human pancreatic carcinomas; the high frequency of this association suggests that this alteration may be causative for this malignancy.

Oncogene Allele	Amino Acid Residue			Tumor Type
	12	13	61	
c [*] -H-ras ^a	Gly	Gly	Glu	(Normal)
			Leu	Melanoma
			Leu	Lung cancer Bladder cancer
c-Ki-ras	Gly	Gly	Val	Breast
			Asp	(Normal)
			Gly	Colon
c-N-ras	Gly	Gly	Cys	Lung
			Gly	(Normal)
			Lys	Neuroblastoma
			Arg	Lung
			Val or Asp	Acute myeloid leukemia

^ac₀ denotes cellular homologue.

Table 78.2 Alterations Associated with *ras* Activation and Tumor Types

A second example involves the *c-erb-B2/HER2/neu* oncogene (this gene has three names, reflecting the three different means by which it was independently studied and named prior to the realization that it was in fact one gene). In human breast cancers this

oncogene is amplified, with copy number having prognostic importance. This contrasts with this gene's first isolation from rat *neuro-* and glioblastomas, in which it is activated by point mutations.

Tumor Suppressor Genes

As alluded to above, tumor suppressor genes serve as “braking mechanisms,” preventing cells from undergoing uncontrolled growth; tumors may result, therefore, when such gene activity is *absent*. Since these genes are autosomal (i.e., cells contain two copies—one maternally derived and one paternally derived), tumor formation requires that *both* genes become defective (within a cell) to lose genetic (tumor suppressor) activity. Using our automobile analogy, this situation would arise when the brakes are suddenly lost, with the result being that the car accelerates uncontrollably, since the gas pedal is “on” (remember, “normal” is a balance in which the gas and brakes are both (partially) “on”). As with oncogenes, particular abnormalities of a tumor suppressor gene are not specific for tumor type, nor are particular tumor types associated with specific tumor suppressor abnormalities, although there are exceptions (much like the association of *Ki-ras* abnormalities with >95% of human pancreatic carcinomas). For example, alteration of codon 132 of *p53* has been reported for cancers of the ovary, breast, lung, and colon; ovarian cancers, on the other hand, have been associated with abnormalities of codons 132, 139, 151, 172, 237, and 242, to name only a few. A striking association exists between abnormalities involving codon 249 and hepatocellular carcinomas from individuals in high-risk regions (5). Most abnormalities of *p53* that have been associated with malignancies involve those regions of the gene with highly conserved sequences between the human and other mammals.

The tumor suppressor genes are the class of genes that are responsible for many, if not all, of the inherited cancer syndromes (6). These syndromes have variable penetrance (i.e., virtually all members of one family may develop cancer, while only a few members of another family may become victim to the disease). Such patterns of presentation would be predicted, since abnormalities of one allele would not be expected to give rise to malignancy, but such patients would be more susceptible to cancer development when exposed to other factors. This predisposition arises since all cells in these patients already have one of the two abnormalities (of a given suppressor gene) necessary for tumor development; furthermore, such predisposition would lead to earlier and more frequent tumor development than seen in the sporadic cases, since the sporadic cases require two abnormalities to be acquired within the same cell (against a normal background). Indeed, this is the situation a) in patients with hereditary retinoblastoma (who have a defect in *rb-1*) versus those with sporadic retinoblastoma, b) for development of neurofibrosarcomas in patients with hereditary neurofibromatosis (who have a defect in *nf-1*) versus those with sporadic neurofibrosarcoma, and c) for development of sarcomas and breast cancers in patients with the Li-Fraumeni syndrome (who have a defect in *p53*) versus the general population. These are a few of many cases. Although the responsible genes have not been definitively identified, the identification and inheritance pattern of approximately 20 to 30 familial cancer syndromes is consistent with their molecular etiology being an inherited defective tumor suppressor gene.

As with the oncogenes, many mechanisms can alter tumor suppressor genes. The most intuitive (to eliminate a gene's activity)—that of deleting or eliminating the gene itself—occurs frequently among these genes. The first indication of this was at the cytogenetic level, when a small percentage of retinoblastomas demonstrated a shortened chromosome 13, specifically a shortened long arm; a very rare patient's tumor demonstrated abnormalities of both chromosome 13s. As loss of function can occur with deletion or substitution of just a single critical base, the biologic significance of deletions of larger amounts of genetic material (sometimes the entire chromosome) is not clear. Base substitution (point mutation) is the other abnormality frequently seen in defective tumor suppressor genes. For unclear reasons, most tumors that have been analyzed have demonstrated a consistent pattern: one allele is completely deleted, while the other one contains small, intragenic deletions or point mutations. Which came first, or why both alleles are not altered by the same means to the same extent, is unclear.

The concept of cancer being a multistep process, likely involving multiple genetic defects, is best exemplified in the hereditary cancer syndromes, since these represent situations in which every cell in the body contains the identical (single) allelic defect. Were a tumor to arise from whatever cell acquired the second necessary defect (in the normal allele), then all types of cancers would be seen in affected families. Yet specific syndromes are identifiable because of the limited spectrum of tumor type(s) seen for a particular syndrome. For example, patients with hereditary retinoblastoma are predisposed to becoming homozygous with respect to *rb-1* (the retinoblastoma suppressor gene); to date, this gene has been implicated as having a central role in the cell cycle, which all living cells use. Yet patients with hereditary retinoblastoma only demonstrate increased incidences of retinoblastomas, osteosarcomas, and breast cancers; notably “absent” from this list are tumors from tissues that are very active and are always dividing and cycling—primarily skin and gastrointestinal tract but also the respiratory tract. Hence, as with the oncogenes, a given gene defect likely is necessary but not sufficient.

Some of the most intriguing experiments being conducted that hold promise for future treatments involve reintroduction of missing tumor suppressor genes into tumor cells. Such genetic manipulation in vitro has resulted in reversal of some (if not all) of the properties of malignant cells, with return of growth control (cessation of growth, inability to form a tumor mass), loss of metastatic capabilities (inability to spread), and even tumor cell death (7, 8). Such manipulations are still limited to in vitro conditions in which the missing gene, part of the chromosome containing the missing gene, or the entire chromosome on which the missing gene lies, is directly introduced into the cell by nuclear microinjection or by exposing cells in culture to nonphysiologic conditions (such as extremes in acidity, salt concentrations, or electrical fields) (9). Despite the inapplicability of such manipulations to the intact organism, these experiments form the basis and rationale for developing gene therapy as a treatment modality because they demonstrate that restoration of absent genetic function can arrest the natural progression of an established malignancy. Additionally, such experiments may ultimately lead to a better understanding of the exact function(s) of the missing gene(s), which could suggest an alternative means of compensating for the genetic deficiency, possibly by providing the protein itself or its product or by manipulating the affected

pathway farther downstream through conventional pharmacologic means.

Oncogenes, Growth Factors, Hormones, and Their Receptors

Recent studies have elucidated a system of growth factors, receptors, and transporters related to insulin and its receptors—the insulin-like growth factor superfamily. This system of ligands (insulin-like growth factors, or IGFs), receptors (insulin-like growth factor receptors [IGFRs]), and binding proteins (insulin-like growth factor–binding proteins [IGFBPs]) is abnormally expressed or regulated in malignant cells and may serve an autocrine or paracrine function in tumor cell proliferation.

Breast cancer is one of only a few malignancies that express estrogen and progesterone receptors (ER and PR, respectively) on the surface of the tumor cells. When these receptors are present, there is an (approximately) 80% likelihood the tumors will respond to hormonal blockade with antiestrogenic agents such as tamoxifen; interestingly, about one-third of patients whose tumors do not express hormone receptors also respond to hormonal manipulation, for previously unclear reasons.

Studies on breast cancer that have examined the IGFs have not only demonstrated abnormal expression of these growth factors, their receptors, and binding proteins but also suggested that an interaction may exist between the “classic” hormone/receptor system (i.e., estrogen, progesterone, and their receptors) and the IGF system of growth factors and receptors. Specifically, tissues from both receptor-positive and receptor-negative breast tumors express increased levels of IGFBPs (10), and tamoxifen decreases circulating levels of IGF-1 (11, 12); this lowering of circulating IGF-1 may explain why tamoxifen works in some breast cancer patients whose tumors are receptor negative. Analogously, all-*trans* retinoic acid, which induces differentiation of certain tumors in vivo and in vitro (see Chapter 17), inhibits breast cancer cells in vivo by altering expression and release of IGFBPs (13).

MISMATCH REPAIR

DNA replication is an imperfect system; it is estimated that one of every 100,000 bases (i.e., 10^{-5}) that is replicated is initially replicated erroneously. As the genome of each human cell contains approximately 1 billion (10^9) bases, 10,000 errors would be acquired within every cell with each division were there no mechanisms to correct these mistakes. Many mechanisms have been demonstrated in organisms as simple as bacteria and yeast that “proofread” the DNA as it is being replicated and correct these errors, so that the error rate in bacteria is estimated to be on the order of $1/10^{10}$ bases (10^{-10}). Although there are no estimates for mammalian (and particularly, human) cells, the rates are probably of the same order of magnitude. One of the most important mechanisms and the one with strong implications for human cancer is the mismatch-repair system, or the human homologue to the bacterial MutS system. This system reads the double helix as it is being replicated, and if an incorrect base has been inserted (creating a mismatch), this system excises the incorrect base, allowing insertion of another base (statistically, the correct one).

This system was first established as being important in human cancer when it was shown that the vast majority of patients with hereditary nonpolyposis colon cancer (HNPCC) had defective mismatch repair and that this defect was likely the heritable lesion (14); soon thereafter it was shown that (colon) tumors from most patients with sporadic colon cancer were also deficient in mismatch repair, whereas normal tissues from these patients were not.

Cancer cells have been noted to have a higher spontaneous mutation rate than their normal counterparts in vitro and in vivo. This is almost certainly requisite for solid tumor development if the current model, which predicts that tumors arise as the result of the accumulation of *multiple* genetic defects, is correct (see Fig. 78.2, for the model of colorectal carcinogenesis). Such a hypothesis is supported by recent observations that defects in mismatch repair result in higher mutation rates. Thus, errors in mismatch repair are likely early events in tumorigenesis; these errors then predispose the cells (deficient in mismatch repair) to even more errors and mutations, probably within critical oncogenes and tumor suppressors, leading to a growth advantage over the normal cells. The increased growth rate contributes to further errors in DNA replication, ultimately leading into a “vicious cycle” that would continue until either sufficient damage is acquired to be lethal or the “right combination” of errors occurs in critical genes to allow autonomous uncontrolled growth.

Figure 78.2. Schema of colorectal tumorigenesis, demonstrating accumulation of multiple genetic abnormalities required to achieve a malignant neoplastic cell. Note that the ability to metastasize requires acquisition of additional abnormalities that remain to be elucidated. (Adapted from Stanbridge EJ, et al., Science 1990;247:12–13.)

TELOMERES AND TELOMERASE

One of the latest discoveries in molecular oncology involves the regulation of telomeres—the “capping” sequences found at the ends of chromosomes. Structurally, telomeres are tandem repeat sequences whose length and integrity are maintained by

the enzyme telomerase. Every time a cell divides, the telomeres of the daughter cells are slightly shorter because of the way that DNA replication is initiated; furthermore, as a resting cell ages (chronologically), telomerase activity within that cell steadily decreases. The end result of these processes is progressively shorter telomeres, both as a result of endogenous, normal enzymatic degradation of the ends of the chromosomal DNA and by imperfect DNA replication.

At some critical point, the telomeres become so short that the genes at the ends of the somatic portion of the chromosomes become inactive, because of either altered regulation or actual structural degradation, and the cell undergoes apoptosis (programed cell death). In vitro, immortal cells (cells that can be passaged and propagated “indefinitely”) have constant, and sometimes increased, levels of telomerase, and their telomeres are often longer than those in the parental nonimmortalized cells ([Fig. 78.3](#)).

Figure 78.3. Effect of telomere length in normal and (some) neoplastic cells. In normal cells, the telomeres become progressively shorter with each replication of the cell or as part of normal turnover and DNA repair in some nondividing resting cells. In neoplastic cells, telomerase activity, normally absent in somatic cells, is present, often above the levels found in germ cells and fetal tissues. The telomeres do not shorten over time or with replication; thus the cells can potentially live “indefinitely.”

Analysis of tumor cells from certain malignancies in humans and other species revealed increased telomerase activity and telomere length in the tumor cells relative to the normal surrounding tissue. This “phenotype” (increased telomerase activity and long telomeres) is present in some human renal cell carcinoma cell lines. In renal cell carcinoma, the short arm of chromosome 3 is frequently lost, and occasionally the entire chromosome is lost. Cell lines derived from these tumors have longer telomeres than those found in normal renal cells and higher telomerase levels than normal renal cells; these cell lines are immortal. Reintroduction of a normal chromosome 3 into the nuclei of cells from these cell lines (by nuclear microinjection) results in decreased telomerase levels, progressive shortening of the telomeres, and eventual senescence of the cells

that were microinjected (15). How widespread this phenomenon is among human tumors has not yet been determined, but potential differences in telomere biology between normal and cancer tissue clearly provides a new avenue for investigation and intervention. To date, no hereditary disease or condition (other than cancer) is attributable to abnormal telomerase, although some premature aging syndromes (e.g., progeria) are candidates for investigation into this area.

CANCER AS A PUBLIC HEALTH PROBLEM

Following cardiovascular disease, cancer is the second leading cause of death in most affluent countries and also contributes importantly to mortality rates among adults in developing countries (1, 2). In the U.S., about one in three persons will be diagnosed with cancer during their lifetime, and about 60% of those diagnosed will die of cancer (3). Because rates of cardiovascular death have been declining rapidly and overall cancer mortality has not substantially changed, it is likely that cancer will become the most important cause of death in the U.S. (2, 4). Although overall cancer rates among adults vary only modestly around the world, the types of cancers are dramatically different (1, 2). In affluent countries cancers of the lung, colon, breast, and prostate contribute most to incidence and mortality (Fig. 79.1A and Fig. 79.1B). In poorer regions and the Far East, cancers of the stomach, liver, oral cavity, esophagus, and uterine cervix are most important. In Japan, for example, rates of breast cancer have until recently been only about one-fifth those of the U.S., and the differences in rates of colon and prostate cancers have been even greater (5). However, cancer incidence rates are very dynamic; many areas of the world are experiencing a transition from the cancer incidence patterns of poorer to those of affluent areas (1). In almost all countries, rates of breast cancer have been increasing.

Figure 79.1. A. Cancer incidence rates for men in several countries. Cumulative incidence 0–74 years (per 100,000 population). (U.S.-SEER-nationwide, Costa Rica-nationwide, Japan-Osaka, India-Bangalore, Mali-Bamako) (skin cancers not included) (2, 170) **B.** Cancer incidence rates for women in several countries. Cumulative incidence 0–74 years (per 100,000 population). (U.S.-SEER-nationwide, Costa Rica-nationwide, Japan-Osaka, India-Bangalore, Mali-Bamako) (skin cancers not included) (2, 170).

Although development of cancer is characterized by alterations in DNA and some of these changes can be inherited, inherited mutations cannot account for the dramatic differences in cancer rates seen around the world. Populations that move from countries with low rates of cancer to areas with high rates, or the reverse, almost invariably achieve the rates characteristic of the new homeland (6, 7 and 8). The rate of change can vary, though, from several decades in the case of colon cancer, to about three generations for breast cancer (8, 9, 10 and 11). The dramatic changes in cancer rates within countries provide further evidence for the importance of noninherited factors. For example, in Japan, rates of colon cancer mortality increased about 2.5-fold between 1950 and 1985 (5).

The dramatic variations in cancer rates around the world and changes over time imply that these malignancies are potentially avoidable if we knew and could alter the causal factors. For a few cancers, such as lung cancer, the primary causes are well known, in this case smoking, but for most others, the etiologic factors are less well established. However, there are strong reasons to suspect that dietary and nutritional factors may account for many of these variations in cancer rates. First, a role of diet has been suggested by observations that national rates of specific cancers are strongly correlated with aspects of diet such as per capita consumption of fat (12). Also, numerous studies in animals, including a series of detailed experiments conducted during the 1930s (13), clearly demonstrated that dietary manipulations could dramatically influence tumorigenesis.

Also, a multitude of steps in the pathogenesis of cancer have been identified in which dietary factors could plausibly act either to increase or decrease the probability that

clinical cancer will develop. For example, carcinogens in specific foods that can directly damage DNA are discussed in [Chapter 80](#), and other dietary factors may block endogenous synthesis of carcinogens or induce enzymes involved in the activation or deactivation of exogenous carcinogenic substances ([14](#)). Oxidative damage to DNA is likely to be an important cause of mutations and can potentially be enhanced by some dietary factors, such as polyunsaturated fats, or reduced by dietary antioxidants or nutrients that are cofactors for antioxidant enzymes, such as selenium or copper ([15](#)). Inadequate intake of dietary factors needed for DNA synthesis, such as folic acid, could also influence the risk of mutation. The rate of cell division influences whether DNA lesions are replicated and is thus likely to influence the probability of cancer developing ([15](#)). Thus, energy balance and growth rates, which can be influenced by a variety of essential nutrients, could affect cancer rates. Dietary factors can influence endogenous hormone levels, including estrogens and various growth factors, which can influence cell cycling and thus, potentially, cancer incidence. Estrogenic substances found in some plant foods can also interact with estrogen receptors and thus could either mimic or block the effects of endogenous estrogens ([14](#)). Many other aspects of diet can alter cell proliferation or differentiation, either by direct hormonal effects, such as by vitamins A or D, or indirectly by influencing inflammatory or irritative processes, such as specific fatty acids that are precursors of prostaglandins or that inhibit their synthesis. Many other examples can be given of how dietary factors could plausibly influence the development of cancer ([14](#), [15](#)).

EPIDEMIOLOGIC INVESTIGATION OF DIET AND CANCER RELATIONSHIPS

The strong suggestion from international comparisons, animal studies, and mechanistic investigations that various aspects of diet might importantly influence risk of cancer raises two critical sets of questions: Which dietary factors are actually important determinants of human cancer? and What is the nature of the dose-response relationships? The nature of the dose-response relationships is particularly important because a substance could be carcinogenic to humans, but there could be no important risk within the range of intakes actually consumed by humans. Alternatively, another factor could be critical for protection against cancer, but all persons in a population may already be consuming sufficient amounts to receive the maximal benefit. In either case, there is no potential for reduction in cancer rates by altering current intakes. The important factors to identify are those of which at least some part of the population is either consuming a toxic level or is not eating a sufficient amount for optimal health.

A variety of epidemiologic approaches can be used to investigate diet and human cancer relationships ([Table 79.1](#)). Relationships between diet, nutrition, and cancer incidence in epidemiologic studies can be evaluated by collecting data on dietary intake, by using biochemical indicators of dietary factors, or by measuring body size and composition. Food frequency questionnaires have been used to assess diet in most epidemiologic studies because they provide information on usual diet over an extended period of time and are sufficiently efficient to be used in large populations. Food frequency questionnaires have been shown to be sufficiently valid to detect important diet-disease relationships in comparisons with more detailed assessments of diet and biochemical indicators ([16](#)). Biochemical indicators of diet can be useful in some

situations, but for many dietary factors of interest, such as total fat, fiber, and sodium, no useful indicators exist. DNA specimens collected from participants in many studies allow examination of gene-diet interactions. Until now, most information on diet and cancer has been obtained from case-control studies. However, a number of large prospective cohort studies of diet and cancer in various countries are now ongoing and will be producing reliable data at an exponentially increasing rate as their populations age.

Study	Methods	Advantages/Disadvantages
Descriptive	Comparison of cancer rates in populations having different diets by assessing average intake of specific nutrients and determining cancer incidence or mortality	Diets in one or many variables that distinguish different populations; differing diets usually diets by average nutrient intake is difficult; these studies are probably best used to generate hypotheses
Case-control	Comparison of cancer diets reported by patients with a particular type of cancer with diets reported by matched controls without cancer	Selection bias can occur if controls do not accurately represent the population from which cases arose; recall bias likely since patients spontaneously offer their controls or diets to recall diets; memory of disease history can be faulty among patients with cancer; researchers must select an equal number of controls from an exposure
Cohort (prospective or follow-up)	Comparison of incidence of cancer in people whose diets and other potentially relevant facts are determined before following up over time	Selection bias and recall bias should not occur, but cohort studies must enroll thousands or even tens of thousands of people and monitor their health for many years before minimal cancer can be detected
Interventional	Comparison of incidence of cancer in two groups randomized to specific interventions or exposures to no intervention	Changes in diet and other lifestyle factors are difficult for many people; selection biases can occur; compliance often poor; Control groups may be difficult to maintain; duration of intervention required is generally unknown but may be decades

Table 79.1 Types of Studies That Address Effect of Diet on Human Cancer

Epidemiologic investigations should be viewed as complementary to animal studies, in vitro investigations, metabolic studies of diet in relation to intermediate endpoints, such as hormone levels, and randomized controlled studies. Although conditions can be controlled to a much greater degree in laboratory studies than in free-living human populations, the relevance of findings to humans will always be uncertain, particularly in regard to dose-response relationships. Ultimately, our knowledge is best based on a synthesis of epidemiologic, metabolic, animal, and mechanistic studies.

SPECIFIC ASPECTS OF DIET

Diet is a complex composite of various nutrients and nonnutritive food constituents, and there are many types of human cancer, each with its own pathogenetic mechanisms; thus, the combinations of specific dietary factors and cancer are almost limitless. This brief overview focuses primarily on the major cancers of affluent populations and aspects of diet for which there are strong hypotheses and substantial epidemiologic data. Several dietary factors that are thought to have preventive roles are discussed in detail in [Chapter 81](#).

Energy Balance, Growth Rate, and Body Size

Studies by Tannenbaum and colleagues (13, 17) during the first half of the 20th century

indicated that energy restriction could profoundly reduce development of mammary tumors in animals. This finding has been consistently replicated in a wide variety of mammary tumor models and has also been observed for a wide variety of other tumors (18, 19, 20, 21 and 22). For example, restricting energy intake by approximately 30% can reduce mammary tumors by as much as 90% (23). The possibility that this relationship, which is the most consistent and strong effect of diet in animal studies, might also apply to humans has received relatively little attention until recently.

In evaluating the effect of energy restriction on cancer rates in humans, it may be tempting to examine the association between energy intake and incidence of cancer. However, such an approach is likely to be completely misleading because in free-living populations, variation in energy intake is determined largely by energy expenditure in the form of physical activity (24). Thus, for example, energy intake is inversely associated with risk of coronary heart disease. This is attributed to the fact that increased exercise is actually the driving force for the increased food intake (16). The most sensitive indicators of the balance between energy intake and expenditure are growth rates and body size, which can be well measured in epidemiologic investigations, although they also reflect genetic and other nonnutritional factors. Adult height can provide an indirect indicator of preadult nutrition, and adult weight gain and obesity reflect positive energy balance later in life.

Internationally, the average national height of adult women is strongly associated with risk of breast cancer (25). Also, in case-control and cohort studies, greater height has generally been associated with an increased risk of breast cancer (26). For example, in a representative U.S. sample, taller women had nearly twice the risk of breast cancer of the shortest (27). Taller height has also been associated with risk of colon and other cancers (28, 29). In populations who were traditionally short, such as the Japanese, rapid gains in height during the last several decades (30) have corresponded to increases in breast cancer rates. Further support for an important role of growth rates comes from epidemiologic studies of age at menarche. Early menarche is a well-established risk factor for breast cancer. The difference in the late age in China, approximately 17 years (31), compared with 12 and 13 years of age in the U.S. (32), contributes importantly to differences in breast cancer rates between these populations. Body mass index, height, and weight have consistently been strong determinants of age at menstruation (33, 34 and 35), but the composition of diet appears to have little if any effect. Collectively, these studies provide strong evidence, consistent with animal experiments, that rapid growth rates prior to puberty play an important role in determining future risk of breast and probably other cancers. Whether the epidemiologic findings are due only to restriction of energy intake in relation to requirements for maximal growth or whether the limitation of other nutrients, such as essential amino acids, may also play a role cannot be determined from available data.

A positive energy balance during adult life and the resultant accumulation of body fat also contributes importantly to several human cancers. The best-established relationships are with cancers of the endometrium and gall bladder (36, 37, 38, 39 and 40). Greater adiposity also increases the risk of colon cancer in both women (41) and men, particularly when assessed as abdominal circumference (42). The relationship between body fatness and breast cancer is more complex. Prior to menopause, women with greater body fat have reduced risks of breast cancer (43, 44), and after menopause

a positive, but weak, association with adiposity is seen. These findings are probably the result of anovulatory menstrual cycles in fatter women prior to menopause (45), which should reduce risk, and the synthesis of endogenous estrogen by adipose tissue in postmenopausal women (46), which is presumed to increase risk of breast cancer.

Dietary Fat and Meat Intake

In the landmark 1982 National Academy of Sciences review of diet, nutrition, and cancer (47), reduction in fat intake to 30% of calories was the primary recommendation; this objective has been echoed in subsequent dietary recommendations as well (48, 49).

Interest in dietary fat as a cause of cancer began in the first half of the 20th century when studies by Tannenbaum and colleagues (13, 17) indicated that diets high in fat could promote tumor growth in animal models. In this early work, energy (caloric) restriction also profoundly reduced the incidence of tumors. A vast literature on dietary fat and cancer in animals has subsequently accumulated (reviewed elsewhere [22, 47, 50, 51 and 52]).

Dietary fat has a clear effect on tumor incidence in many models, although not in all (53, 54); however, a central issue has been whether this is independent of the effect of energy intake. An independent effect of fat has been seen in some animal models (22, 50, 51), but this has been either weak (55) or nonexistent (23) in some studies designed specifically to address this issue. A possible relationship of dietary fat intake to cancer incidence has also been hypothesized because the large international differences in rates of cancers of the breast, colon, prostate, and endometrium are strongly correlated with apparent per capita fat consumption (12, 56, 57). These correlations are limited to animal (not vegetable) fat (58)

Fat and Breast Cancer

Although a major rationale for the dietary fat hypothesis has been the international correlation between fat consumption and national breast cancer mortality (12), in a study of 65 Chinese counties (59) in which per capita fat intake varied from 6 to 25% of energy only a weak positive association was seen between fat intake and breast cancer mortality. Notably, five counties consumed approximately 25% of energy from fat, yet experienced rates of breast cancer far below those of U.S. women with similar fat intake (60), thus providing strong evidence that factors other than fat intake account for the large international differences. Breast cancer incidence rates have increased substantially in the United States during this century, as have the estimates of per capita fat consumption based on food disappearance data. However, surveys based on reports of individual actual intake, rather than food disappearance, indicate that consumption of energy from fat, either as absolute intake or as a percentage of energy, has actually declined in the last several decades (61, 62), a time during which breast cancer incidence has increased (63).

A number of case-control studies have investigated the effect of dietary fat on breast cancer risk. In the largest study so far (64), animal fat and total fat intake were not associated with breast cancer. The results from twelve smaller case-control studies

have been summarized in a metaanalysis by Howe et al. (65), which included 4312 cases and 5978 controls. The pooled relative risk was 1.35 ($P < .0001$) for a 100-g increase in daily total fat intake, and the risk was somewhat stronger for postmenopausal women (relative risk, 1.48; $P < .001$). This magnitude of association, however, could potentially be compatible with biases due to recall of diet or the selection of controls (66).

A substantial body of data from cohort studies is now available to assess the relationship between dietary fat intake and breast cancer in developed countries. In a pooled analysis of the prospective studies, which included nearly 5000 cases of breast cancer (67), no overall association was seen for overall fat intake ranging from below 20% to more than 45% of energy from fat (Fig. 79.2). A similar lack of association was seen among postmenopausal women only and for specific types of fat. Only among the small number of women consuming less than 15% of energy from fat was a significant association seen; breast cancer risk was twofold higher in this group. These cohort findings therefore do not support the results of the case-control studies cited above.

Figure 79.2. Pooled relative risks and 95% confidence intervals for various levels of energy from fat. A level of 30 to less than 35% of total energy from fat was designated as the reference category. N, number of cases in each category. (From Hunter DJ, Spiegelman D, Adami H-O, et al. N Engl J Med 1996;334:356, with permission.)

Although empirical evidence is limited, endogenous estrogen levels are thought to be related to risk of breast cancer. Thus, the effects of fat and other dietary factors on estrogen levels are of potential interest. Vegetarian women, who consume higher amounts of fiber and lower amounts of fat, have lower blood levels and reduced urinary excretion of estrogens, apparently due to increased fecal excretion (68). In studies without concurrent controls, estrone sulfate, but not other estrogens, decreased among women fed diets high in fiber and low in fat (69); among postmenopausal women, estradiol but not estrone sulfate decreased on a low-fat diet (70). These studies are difficult to interpret because of a lack of a concurrent control group.

Although total fat intake has been unrelated to breast cancer risk in prospective epidemiologic studies, some evidence suggests that the type of fat may be important. In animal mammary tumor models, the tumor-promoting effect of fat intake has been observed primarily for polyunsaturated fats fed in diets containing approximately 45% of energy from total fat (71, 72). However, in a metaanalysis of case-control studies (65), increased risk of breast cancer was somewhat greater for saturated (relative risk, 1.46) and monounsaturated fats (relative risk, 1.41) than for polyunsaturated fats (relative risk, 1.25). Data based on the detailed food frequency questionnaire administered in 1984 in the Nurses' Health Study, showed an inverse association between monounsaturated fat and breast cancer (60). This is an intriguing observation given the relatively low rates of breast cancer in Southern European countries that have high average intakes of monounsaturated fats because olive oil is the primary fat. In case-control studies in Spain and Greece, women who used more olive oil had reduced risks of breast cancer (73, 74). Furthermore, olive oil has been protective relative to other sources of fats in some animal studies (50).

Fat and Colon Cancer

In comparisons among countries, rates of colon cancer are strongly correlated with national per capita disappearance of animal fat and meat, with correlation coefficients ranging between 0.8 and 0.9 (12, 58). Based on these epidemiologic investigations and animal studies, a hypothesis has developed that dietary fat increases excretion of bile acids, which can be converted to carcinogens or promoters (75). However, recent evidence from many studies that higher levels of physical activity reduce risk of colon cancer means that at least part of the high rates in affluent countries previously attributed to fat intake are probably due to sedentary lifestyle.

With some exceptions (76, 77, 78 and 79), case-control studies have generally shown an association between risk of colon cancer and intake of fat (80, 81, 82, 83, 84, 85, 86 and 87) or red meat (88, 89, 90, 91, 92 and 93). However, in many of these studies, a positive association between total energy intake and risk of colon cancer has also been observed (80, 81, 82, 83 and 84, 86, 87), raising the question of whether it is general overconsumption of food or the fat composition of the diet that is etiologically important. A recent metaanalysis by Howe and colleagues of 13 case-control studies found a significant association between total energy and colon cancer, but saturated, monounsaturated, and polyunsaturated fat were not associated with colon cancer independently of total energy (94).

The relation between diet and colon cancer has been examined in several large prospective studies. These have not confirmed the positive association with total energy intake in case-control studies (95, 96, 97, 98 and 99), suggesting that the case-control studies were distorted by reporting bias. The Nurses' Health Study showed that women in the highest quintile of animal fat intake had about a 2-fold higher risk of colon cancer than those in the lowest quintile (95). In a multivariate analysis of these data, which included red meat and animal fat intakes in the same model, red meat intake remained significantly predictive of risk of colon cancer, whereas the association with animal fat was eliminated. A cohort study from the Netherlands showed a significant direct

association between intake of processed meats and risk of colon cancer, but no relationship was observed for fresh meats or overall fat intake (96). A cohort study in Iowa women also found a direct association with processed meats, although this was not statistically significant (97). Among a large cohort study of men, a direct association between red meat consumption and risk of colon cancer was seen, but no association was observed with other sources of fat (98). In this study, no overall relationship existed between total or saturated fat and colon cancer despite a substantial range in fat intake. A similar association was noted for colorectal adenomas in the same cohort of men. (75) In the large American Cancer Society Cohort (99), little relation was seen between either meat or fat intake and mortality due to colon cancer, but the dietary questionnaire was brief and of uncertain validity. The apparently stronger association with red meat than with fat in several recent cohort studies needs further confirmation but could result if the fatty acids or nonfat components of meat (e.g., the heme iron or carcinogens created by cooking) were the primary etiologic factors. This issue does have major practical implications, as current dietary recommendations (100) support daily consumption of red meat as long as it is lean.

Fat and Prostate Cancer

An association between fat intake and risk of prostate cancer has been seen in many case-control studies (101, 102, 103, 104, 105, 106, 107, 108, 109, 110 and 111), but sometimes only in subgroups. In a recent large case-control study among various ethnic groups within the U.S. (112), consistent associations with prostate cancer risk were seen for saturated fat, but not with other types of fat.

The association between fat intake and prostate cancer risk has been assessed in only a few cohort studies. In a cohort of 8000 Japanese men living in Hawaii, no association was seen with intake of total or unsaturated fat (113); however, diet was assessed with a single 24-h recall, so the lack of association may not be informative. In a study of 14,000 Seventh-Day Adventist men living in California, a positive association was seen between the percentage of calories from animal fat and prostate cancer risk was seen, but it was not statistically significant (114). More recently, two large prospective studies have been published. In the Health Professionals Follow-up Study of 51,000 men, a positive association seen with intake of red meat and total and animal fat was largely limited to aggressive prostate cancers (115). No association was seen with vegetable fats. In another cohort from Hawaii, increased risks of prostate cancer were seen with consumption of beef and animal fat (116).

Although further data are desirable, the evidence from international correlations, case-control, and cohort studies is reasonably consistent in supporting an association between consumption of fat-containing animal products and prostate cancer incidence. This evidence does not generally support a relation with intake of vegetable fat, which suggests that either the type of fat or other components of these animal products are responsible. Evidence also suggests that animal fat consumption may be most strongly associated with aggressive prostate cancer, which suggests an influence on the transition from the widespread indolent form to the more lethal form of this malignancy.

Other Cancers

Rates of other cancers that are common in affluent countries, including those of the endometrium and ovary, are also correlated with fat intake internationally. Although these have been studied in a small number of case-control investigations, consistent associations with fat intake have not been seen ([117](#), [118](#), [119](#), [120](#), [121](#), [122](#), [123](#), [124](#), [125](#) and [126](#)). In a prospective study among Iowa women ([127](#)), no evidence of relation between fat intake and risk of endometrial cancer was observed. Positive associations have been hypothesized between fat intake and risks of skin cancer ([128](#)) and lung cancer, but relevant data in humans are limited.

Assessment of Fat and Cancer

As the findings from large prospective studies have become available, support for a major relationship between fat intake and breast cancer risk has weakened considerably. For colon cancer, the associations seen with animal fat internationally have been supported in numerous case-control and cohort studies. However, more-recent evidence suggests that this might be explained by factors in red meat other than simply its fat content. Further, the importance of physical activity as a protective factor against colon cancer indicates that international correlations probably overstate the contribution of diet to differences in colon cancer incidence. The available evidence most strongly supports an association between animal fat consumption and risk of prostate cancer, particularly the aggressive form of this disease. As with colon cancer, however, the possibility remains that other factors in foods containing animal fat contribute to risk.

Fruits and Vegetables

A massive body of epidemiologic data indicates that higher consumption of fruits and vegetables is associated with a reduced risk of cancers at many sites. Inverse relationships with intake of these foods have been observed in over 200 case-control and prospective cohort studies ([129](#), [130](#)), and additional support comes from studies in which biochemical indicators of fruit and vegetable consumption, such as serum carotenoid levels, are also associated with reduced risks. The studies are particularly numerous and consistent for cancers of the lung ([131](#)) and stomach ([132](#)); inverse associations have also been observed in many case-control studies of colon cancer but prospective data are still limited. Somewhat fewer studies have also indicated inverse associations with cancers of the oral cavity, larynx, esophagus, endometrium, cervix, bladder, kidney, and breast ([133](#)). Although inverse associations have not been seen between fruit and vegetable consumption in general and risk of prostate cancer, inverse associations with tomato products, the primary source of the carotenoid lycopene, have been seen in several case-control and prospective studies ([105](#), [114](#), [134](#)).

Although the evidence that high consumption of fruits and vegetables can reduce the risk of many cancers is strong, which constituents of these foods are responsible for these reduced risks is less clear. These foods contain a myriad of biologically active chemicals, including both recognized nutrients and many more nonnutritive constituents

that could potentially play a role in protection against cancer (14). Among the potentially protective factors are various carotenoids, folic acid, vitamin C, phytoestrogens (see [Chapter 81](#)) and fiber (discussed below). Identification of the specific protective constituents, or combination thereof, is a daunting task and may never be completely possible. Further details on the types and amounts of fruits and vegetables that appear to be particularly protective could provide additional practical guidance for those wanting to select an optimally healthy diet.

Dietary Fiber

Interest in dietary fiber is largely the result of Dr. Denis Burkitt's observation of low rates of colon cancer in areas of Africa where fiber consumption and stool bulk were high (135). Fiber was originally seen simply as providing bulk to dilute potential carcinogens and speed their transit through the colon. Other hypotheses have suggested that fiber may act by binding carcinogenic substances (136), altering the colonic flora (137, 138, 139 and 140), reducing the pH (141), or serving as the substrate for the generation of short-chain fatty acids that are the preferred substrate for colonic epithelial cells (142).

As epidemiologic evidence has accrued, the importance of dietary fiber in reducing risk of colon cancer has become less clear. First, the populations with high fiber consumption and low rates of colon cancer are also typically those of poorer countries where meat consumption and obesity are low and physical activity is high. Evidence has become clearer that each of these factors reduces risk and thus is likely to explain at least part of the geographic associations between low intake of dietary fiber and colon cancer rates. Also, in case-control studies, intake of cereal products or fiber from grains has not usually been associated with reduced risks of colon cancer, in contrast to the abundant evidence for a protective effect of fruits and vegetables (143, 144). Indeed, in some studies higher consumption of grains has been associated with greater risks of colon cancer (76, 89, 145, 146). Also, in several large prospective studies, even overall fiber intake has not been clearly associated with lower risk of colon cancer after adjustment for other risk factors (95, 96, 97 and 98). Thus, fiber intake does not appear to account for the reduced risk of colon cancer associated with consumption of fruits and vegetables, and evidence supporting higher consumption of grain fiber to reduce risk of colon cancer is weak.

Higher intake of fiber has also been hypothesized to reduce risk of breast cancer by interrupting the enterohepatic circulation of estrogens (147). However, in prospective studies, little or no relationship has been observed between fiber intake and risk of breast cancer (60, 148, 149).

Alcoholic and Caffeinated Beverages

High consumption of alcohol, particularly in combination with cigarette smoking, is a well-established cause of cancer of the oral cavity, larynx, esophagus, and liver (150). More recently, substantial evidence from case-control and cohort studies indicates that amounts as low as one or two drinks per day increase risk of breast cancer (151, 152). Moderate alcohol consumption appears to increase endogenous estrogen levels, which may account for this effect (46, 153, 154). Moderate alcohol consumption also appears

to be associated with risk of cancers of the colon and rectum (144). Alcohol interferes with the availability of folic acid, which may account for its relationship with large bowel cancers (155, 156 and 157).

Coffee contains multiple mutagenic substances (15), and concern has thus existed that it might be an important cause of cancer in humans. Although early evidence suggested a possible positive association with pancreatic cancer, this has not been supported in most subsequent studies (158, 159 and 160). Similarly, for breast cancer, coffee consumption has been unassociated (161) or even weakly inversely associated with risk (162). Green tea contains polyphenolic compounds that inhibit tumors in experimental animals (163) and inverse associations between green tea consumption and risk of gastric cancer have been seen in case-control studies from Japan (164) and China (165). Notably, however, rates of gastric cancer in the U.S., where tea consumption is low, are among the lowest in the world; this has been attributed in part to relatively low salt intake (132).

Vitamin Supplements

Relatively few data are available on vitamin supplement use and cancer incidence. High-dose supplements of vitamins C and E have not been associated with reductions in breast cancer incidence (148, 166). In the study by Hunter, there was a suggestion that vitamin A supplements at the RDA level might be associated with reductions in breast cancer risk among women whose dietary intakes were relatively low, but higher intakes did not confer additional reductions in risk. Limited data suggest that folic acid contained in multiple vitamins might reduce risk of large bowel cancer (155, 156), but this needs confirmation. In a single case-control study, vitamin E supplements were associated with a reduced risk of oral cancer (167). In a randomized trial conducted in a region of China with low consumption of fruits and vegetables, a supplement containing b-carotene, vitamin E, and selenium reduced incidence of stomach cancer (168). Although further research is needed, on the basis of available evidence, the prevention of cancer does not provide justification for the use of vitamin supplements by most persons with a reasonable diet.

CONCLUSIONS

Evidence from both animal and epidemiologic studies indicate that throughout life, excessive energy intake in relation to requirements increases risk of human cancer. Rapid growth rates in childhood lead to earlier age at menarche, which in turn increases risk of breast cancer, and accumulation of body fat in adulthood is related to cancers of the colon, kidney, and endometrium as well as postmenopausal breast cancer. Higher intake of vegetables and fruits has been associated with lower risks of many cancers. The constituents responsible for these apparent protective effects remain uncertain, although evidence supports a contribution of folic acid. Recent evidence suggests that the percentage of energy from fat in the diet is not a major cause of cancers of the breast or colon. Higher intake of meat and dairy products has been associated with greater risk of prostate cancer, which may be related to their saturated fat content. Also, red meat consumption has been associated with risk of colon cancer in numerous studies, but this appears to be unrelated to its fat content. Excessive consumption of

alcohol increases risks of upper gastrointestinal tract cancer, and even moderate intake appears to increase cancers of the breast and large bowel. Although many details remain to be learned, evidence is strong that remaining physically active and lean throughout life, consuming an abundance of fruits and vegetables, and avoiding high intakes of red meat, foods high in animal fat, and excessive alcohol will substantially reduce risk of human cancer.

[Public Health Significance](#)

[Chapter References](#)

It is widely accepted that dietary factors are deeply involved in human neoplasia. Cancer is a disease of DNA, and genetic alterations are essential for its development. Individual cancers are caused by multiple factors, including both genotoxic substances and nongenotoxic tumor promoters. 12-O-Tetradecanoylphorbol-13-acetate (TPA), teleocidines, and aplysiatoxins are well known as typical tumor promoters (1, 2). However, human exposure to these typical tumor promoters is very limited. In contrast, major dietary components, salt and fat, may have a sizeable influence on cancer development as tumor promoters in our actual environment. Many reports indicate the presence in foodstuffs of various types of genotoxic carcinogens (i.e., mutagens/carcinogens), which can be divided into several groups. The first group comprises the naturally occurring mycotoxins and plant-origin mutagenic and carcinogenic compounds. The second includes the compounds produced during cooking, food storage, and food processing. The third group, which consists of food additives and pesticide residue contaminants, is the subject of rigorous control by regulatory agencies; thus this chapter is mainly concerned with the genotoxic carcinogens, mutagens/carcinogens classified into the first and second groups. Additionally, as examples of factors responsible for tumor promotion and progression, the effects of salt and fat are discussed.

AFLATOXINS AND OTHER MYCOTOXINS

Mycotoxins are toxic substances produced by fungi. A number of mycotoxins have been reported, and some of these have proven to be carcinogenic. In 1960, numerous

turkeys died of a disease syndrome called the “turkey X disease” in the United Kingdom. The etiologic factor appeared to be the diet, which was contaminated with a potent carcinogen subsequently identified as aflatoxin. Aflatoxins are very toxic metabolites produced by *Aspergillus flavus*. Among many derivatives, aflatoxin B₁ exerts the strongest carcinogenicity (3). Its structure is shown in [Figure 80.1](#). Aflatoxin B₁ induces hepatocarcinomas in many species of experimental animals such as rodents, monkeys, birds, and fishes. Male Fischer rats are the most sensitive among rodents, with a TD₅₀ of 1.3 µg/kg body weight/day (1). Aflatoxin B₁ has been classified as a group 1 human carcinogen by the International Agency for Research on Cancer (IARC) (4) and is found as a contaminant of foodstuffs consumed by inhabitants in several areas, mainly in Asia and Africa. Levels of aflatoxin B₁ as low as micrograms per kilogram of food may increase the incidence of liver cancer in man. The carcinogenicity of other derivatives of aflatoxins are much weaker, but aflatoxin M₁, a hydroxy derivative often found in milk, does produce hepatocellular carcinomas in rats (5). Aflatoxins G₁ and B₂ can also induce tumors in experimental animals.

Figure 80.1. Structure of aflatoxin B₁.

Induced Mutations

Aflatoxin B₁ induces gene mutations in mammalian cells as well as bacteria. In addition, it causes unscheduled DNA synthesis and cell transformation in mammalian cell lines including human fibroblasts in vitro and micronucleus formation in rats in vivo (6, 7). Aflatoxin B₁ is metabolically activated to its 8,9-epoxide, the ultimate carcinogen, by cytochrome P-450s including CYP1A2 and 3A4. This epoxide modifies DNA to form an adduct, 8,9-dihydro-8-(N⁷-guanyl)-9-hydroxyaflatoxin B₁ (8). The level of aflatoxin binding to hepatic DNA is correlated with hepatocarcinogenicity among different species (9). Several studies concerned with mutation spectra indicate that aflatoxin B₁ preferentially induces GC to TA transversions (10, 11). In addition, it has been

associated with a G to T transversion in codon 249 of the *p53* tumor suppressor gene in human hepatocytes (12). This mutation has been recognized as a mutational hotspot in human hepatocellular carcinomas (13). The frequency is more than 50% in Qidong, China, where the inhabitants are exposed to high levels of aflatoxins, but less than 5% in most developed countries (14, 15, 16 and 17). These findings suggest that aflatoxin B₁ ingested with contaminated foods is directly involved in hepatocarcinogenesis in humans by inducing G to T mutations in codon 249 of the *p53* gene.

Urine specimens have been used to estimate human exposure to aflatoxins, and a number of biomarkers including aflatoxin-DNA adducts and metabolites have been identified in human urine. The dose of aflatoxin B₁ correlates with the level of aflatoxin B–N⁷-guanine in rat urine (18). Moreover, a follow-up study in China suggested that persons demonstrating detectable amounts of aflatoxin-DNA adduct or other aflatoxin biomarkers in their urine have a significantly elevated risk of developing primary liver cancer (19). Aflatoxin-protein adducts in serum albumin can also be used as a biomarker of aflatoxin exposure, since the aflatoxin B₁ form binds to lysine residues in this protein (20).

Other Mycotoxins

Fumonisin, produced by the corn pathogen *Fusarium moniliforme*, is carcinogenic in rats (21, 22). It consists of fumonisin B₁, B₂, and other forms, which are all closely related structural analogues. Sterigmatocystin, generated by *Penicillium*, *Aspergillus*, and *Biopolaris*, also induces hepatocellular carcinomas in rats (23). Ochratoxin A, produced by *Aspergillus ochraceus* and other fungi, causes tubular cell carcinomas of the kidney in female rats (24).

PLANT-ORIGIN CARCINOGENS

Pyrrrolizidine Alkaloids

Pyrrrolizidine alkaloids are esters of amino alcohols derived from pyrrrolizidine, which exist in a wide range of Asteraceae and other plant species, often at more than 1% by weight. Some of the alkaloids are known to cause serious hepatic damage in humans and animals. Petasitenine, which has an otonecine moiety, is present in a kind of coltsfoot, *Petasites japonicus* Maxim, and induces hemangioendothelial sarcomas in rats (25). The young flower stalk of the plant has been used as a food and an herbal remedy in Japan. Senkirkine, which also has an otonecine moiety, is a main alkaloid component in another coltsfoot, *Tussilago farfara* L. The dried buds of coltsfoot are taken as an herbal remedy for coughs in China and Japan. Feeding *Tussilago farfara* L. also induces hemangioendothelial sarcomas in rats (26). Heliotrine, whose necine base is heliotridine, occurs in *Heliotropium* species and was the cause of an outbreak of venoocclusive disease in Afghanistan. Heliotrine and another alkaloid containing the same necine base, lasiocarpine, induce islet cell tumors and hepatocellular carcinomas, respectively, in rats (27, 28). Monocrotaline, which has a retronecine moiety, is also carcinogenic in the rat (29). The mutagenicity of some pyrrrolizidine alkaloids has been

shown in *Salmonella typhimurium* strain TA100 with S9 mix by the preincubation method.

Aquilide A/Ptaquiloside

Bracken fern, *Pteridium aquilinum*, is grown in many areas of the world and is eaten by residents of some countries, including Japan (Fig. 80.2). Cows allowed to graze in fields where bracken fern grows often develop hematuria with tumors of the urinary bladder. Moreover, feeding bracken fern induces adenocarcinomas and urinary bladder carcinomas in rats. (30, 31) The active principle of bracken fern was isolated as a mutagenic compound and termed aquilide A by van der Hoeven et al. (32). Aquilide A, a norsesquiterpene glucoside of the illudane type, itself is not mutagenic to *Salmonella*, but becomes so after alkaline treatment. Thus, an aglycone of aquilide A has been suggested as the mutagenic component. Hirono et al. isolated the same compound by monitoring the carcinogenicity of various fractions from bracken fern and named it ptaquiloside (33). Ptaquiloside was also found to induce multiple ileal adenocarcinomas and mammary cancers in rats (34). Thus aquilide A/ptaquiloside was concluded to be the carcinogenic component in bracken fern. Its structure is shown in Figure 80.2. Since the carcinogenic activity of bracken fern is essentially lost after boiling, exposure of humans to aquilide A/ptaquiloside in cooked bracken fern is probably small.

Figure 80.2. Structure of aquilide A/ptaquiloside.

Mushroom Hydrazines

The commonly cultivated edible mushroom, *Agaricus bisporus*, contains a hydrazine, *b-N*-[*g*-*S*(+)-glutamyl-4-hydroxymethylphenylhydrazine (agaritine) as well as derivatives that in some cases have been shown to be carcinogenic to experimental animals. Toth et al. demonstrated that the *N**c*-acetyl derivative of 4-hydroxymethylphenylhydrazine induces adenocarcinomas of the lung and angiosarcomas of the blood vessels in mice (35). Subcutaneous injection and intragastric instillation of 4-(hydroxymethyl)benzenediazonium ion, stabilized as the tetrafluoroborate salt, causes

subcutis and skin cancers, and glandular stomach cancers, respectively (36, 37). These results suggest that the edible mushroom may have carcinogenic potential in animals. In fact, uncooked cultivated *Agaricus bisporus* itself is carcinogenic in mice (38). The shiitake (*Lentinus edodes*), which is a popular edible mushroom in Japan, also contains agaritine. Another edible mushroom, false morel (*Gyromitra esculenta*), contains several hydrazine derivatives, including acetaldehyde methylformylhydrazone (gyromitrin), *N*-methyl-*N*-formylhydrazine, and methylhydrazine. *N*-Methyl-*N*-formylhydrazine induces malignant histiocytomas and liver cell carcinomas in hamsters (39).

Cycasin

Cycad is a plant classified as a gymnosperm that grows in tropical areas. Its nuts have been used as a source of starch for food by the inhabitants in some tropical areas including Guam and the Amami Oshima islands. Carcinogenicity of cycad nuts was first reported by Laqueur et al. (40). The b-D-glucoside of methylazoxymethanol, cycasin, is responsible for the carcinogenicity of cycad nuts. Cycasin itself is not an ultimate carcinogen; its hydrolysis is required to produce the aglycon methylazoxymethanol by intestinal microflora. Methylazoxymethanol acts as a methylating agent and is carcinogenic for the rat colon (41).

Alkenylbenzenes
