

Modern Nutrition in Health and Disease 9th edition (January 1999): by Maurice E. Shils (Editor), James A. Olson (Editor), Moshe Shike (Editor), A. Catherine Ross (Editor)
By Lippincott, Williams & Wilkins

By OkDoKeY

Modern Nutrition in Health and Disease

Contents

[Editors](#)

[Preface](#)

[Acknowledgments](#)

[Contributors](#)

PART I. SPECIFIC DIETARY COMPONENTS

Section A. Major Dietary Constituents and Energy Needs

[Chapter 1. Defining the Essentiality of Nutrients](#)

ALFRED E. HARPER

[Chapter 2. Proteins and Amino Acids](#)

DWIGHT E. MATTHEWS

[Chapter 3. Carbohydrates](#)

ROY J. LEVIN

[Chapter 4. Lipids, Sterols, and Their Metabolites](#)

PETER J.H. JONES AND STANLEY KUBOW

[Chapter 5. Energy Needs: Assessment and Requirements in Humans](#)

ERIC T. POEHLMAN AND EDWARD S. HORTON

Section B. Minerals

[Chapter 6. Electrolytes, Water, and Acid-Base Balance](#)

MAN S. OH AND JAIME URIBARRI

[Chapter 7. Calcium](#)

CONNIE M. WEAVER AND ROBERT P. HEANEY

[Chapter 8. Phosphorus](#)

JAMES P. KNOCHEL

[Chapter 9. Magnesium](#)

MAURICE E. SHILS

[Chapter 10. Iron in Medicine and Nutrition](#)

VIRGIL F. FAIRBANKS

[Chapter 11. Zinc](#)

JANET C. KING AND CARL L. KEEN

Chapter 12. Copper

JUDITH R. TURNLUND

Chapter 13. Iodine

BASIL S. HETZEL AND GRAEME A. CLUGSTON

Chapter 14. Selenium

RAYMOND F. BURK AND ORVILLE A. LEVANDER

Chapter 15. Chromium

BARBARA J. STOECKER

Chapter 16. Ultratrace Minerals

FORREST H. NIELSEN

Section C. Vitamins

Chapter 17. Vitamin A and Retinoids

A. CATHARINE ROSS

Chapter 18. Vitamin D

MICHAEL F. HOLICK

Chapter 19. Vitamin E

MARET G. TRABER

Chapter 20. Vitamin K

ROBERT E. OLSON

Chapter 21. Thiamin

VICHAI TANPHAICHITR

Chapter 22. Riboflavin

DONALD B. McCORMICK

Chapter 23. Niacin

DANIEL CERVANTES-LAUREAN, N. GERARD McELVANEY AND JOEL MOSS

Chapter 24. Vitamin B₆

JAMES E. LEKLEM

Chapter 25. Pantothenic Acid

NORA PLESOFKY-VIG

Chapter 26. Folic Acid

VICTOR HERBERT

Chapter 27. Vitamin B₁₂ "Cobalamin"

DONALD G. WEIR AND JOHN M. SCOTT

Chapter 28. Biotin

DONALD M. MOCK

Chapter 29. Vitamin C

ROBERT A. JACOB

Section D. Signs Of Clinical Deficiencies

Chapter 30. Clinical Manifestations of Human Vitamin and Mineral Disorders: A Resumé

DONALD S. McLAREN

Section E. Organic Compounds with Nutritional Relevance

Chapter 31. Carnitine

CHARLES J. REBOUCHE

Chapter 32. Choline and Phosphatidylcholine

STEVEN H. ZEISEL

Chapter 33. Carotenoids

JAMES ALLEN OLSON

Chapter 34. Homocysteine, Cysteine, and Taurine

MARTHA H. STIPANUK

Chapter 35. Glutamine and Arginine

STEVE F. ABCOUWER AND WILEY W. SOUBA

PART II. NUTRITION IN INTEGRATED BIOLOGIC SYSTEMS

Section A. Tutorials in Physiologic Regulation

Chapter 36. Nutritional Regulation of Gene Expression

ROBERT J. COUSINS

Chapter 37. Transmembrane Signaling

ROBERT A. GABBAY AND JEFFREY S. FLIER

Chapter 38. Membrane Channels and Transporters: Paths of Discovery

DAVID ERLIJ

Chapter 39. The Alimentary Tract in Nutrition

SAMUEL KLEIN, STEVEN M. COHN, AND DAVID H. ALPERS

Section B. Genetic, Physiologic, and Metabolic Considerations

Chapter 40. Control of Food Intake

GERARD P. SMITH

Chapter 41. Metabolic Consequences of Starvation

L. JOHN HOFFER

Chapter 42. Nutrition and the Chemical Senses

RICHARD D. MATTES

Chapter 43. Fiber and Other Dietary Factors Affecting Nutrient Absorption and Metabolism

DAVID J. A. JENKINS, THOMAS M. S. WOLEVER, AND ALEXANDRA L. JENKINS

Chapter 44. Hormone, Cytokine, and Nutrient Interactions

IRWIN G. BRODSKY

Chapter 45. Nutrition and the Immune System

STEVEN H. YOSHIDA, CARL L. KEEN, AFTAB A. ANSARI, AND M. ERIC GERSHWIN

Chapter 46. Oxidative Stress and Oxidant Defense

JAMES A. THOMAS

Chapter 47. Diet in Work and Exercise Performance

ERIC HULTMAN, ROGER C. HARRIS, AND LAWRENCE L. SPRIET

Chapter 48. Nutrition in Space

HELEN W. LANE AND SCOTT M. SMITH

Section C. Nutritional Needs During the Life Cycle

Chapter 49. Body Composition: Influence of Nutrition, Physical Activity, Growth, and Aging

GILBERT B. FORBES

Chapter 50. Maternal Nutrition

WILLIAM J. MCGANITY, EARL B. DAWSON, AND JAMES W. VAN HOOK

Chapter 51. Nutritional Requirements During Infancy

WILLIAM C. HEIRD

Chapter 52. Diet, Nutrition, and Adolescence

FELIX P. HEALD AND ELIZABETH J. GONG

Chapter 53. Nutrition in the Elderly

LYNNE M. AUSMAN AND ROBERT M. RUSSELL

PART III. DIETARY AND NUTRITIONAL ASSESSMENT OF THE INDIVIDUAL

Chapter 54. Clinical Nutrition Assessment of Infants and Children

VIRGINIA A. STALLINGS AND ELLEN B. FUNG

Chapter 55. Clinical and Functional Assessment of Adults

JEANETTE M. NEWTON AND CHARLES H. HALSTED

Chapter 56. Nutritional Assessment of Malnutrition by Anthropometric Methods

STEVEN B. HEYMSFIELD, RICHARD N. BAUMGARTNER, AND SHEAU-FANG PAN

Chapter 57. Laboratory Tests for Assessing Nutritional Status

NANCY W. ALCOCK

Chapter 58. Dietary Assessment

PART IV. PREVENTION AND MANAGEMENT OF DISEASE

Section A. Pediatric and Adolescent Disorders

[Chapter 59. Protein-Energy Malnutrition](#)
BENJAMIN TORUN AND FRANCISCO CHEW

[Chapter 60. Malnutrition among Children in the United States: The Impact of Poverty](#)
ROBERT KARP

[Chapter 61. Nutritional Support of Inherited Metabolic Disease](#)
LOUIS J. ELSAS II AND PHYLLIS B. ACOSTA

[Chapter 62. Inherited Metabolic Disease: Defects of \$\beta\$ -Oxidation](#)
JERRY VOCKLEY

[Chapter 63. Childhood Obesity](#)
WILLIAM H. DIETZ

[Chapter 64. Nutritional Management of Infants and Children with Specific Diseases and/or Conditions](#)
WILLIAM C. HEIRD AND ARTHUR COOPER

Section B. Disorders of the Alimentary Tract

[Chapter 65. Assessment of Malabsorption](#)
DARLENE G. KELLY

[Chapter 66. Nutrition in Relation to Dental Medicine](#)
DOMINICK P. DEPAOLA, MARY P. FAINE, AND CAROLE A. PALMER

[Chapter 67. The Esophagus and Stomach](#)
WILLIAM F. STENSON

[Chapter 68. Short Bowel Syndrome](#)
JAMES S. SCOLAPIO AND C. RICHARD FLEMING[†]

[Chapter 69. Inflammatory Bowel Disease](#)
ANNE M. GRIFFITHS

[Chapter 70. Diseases of the Small Bowel](#)
PENNY S. TURTEL AND MOSHE SHIKE

[Chapter 71. Celiac Disease](#)
J. JOSEPH CONNOR

[Chapter 72. Nutrition in Pancreatic Disorders](#)
MASSIMO RAIMONDO AND EUGENE P. DIMAGNO

[Chapter 73. Nutrition in Liver Disorders](#)
C. S. LIEBER

Section C. Prevention and Management of Cardiovascular Disorders

[Chapter 74. Nutrient and Genetic Regulation of Lipoprotein Metabolism](#)
CLAY F. SEMENKOVICH

[Chapter 75. Nutrition and Diet in the Management of Hyperlipidemia and Atherosclerosis](#)
SCOTT M. GRUNDY

[Chapter 76. Nutrition, Diet, and Hypertension](#)
THEODORE A. KOTCHEN AND JANE MORLEY KOTCHEN

[Chapter 77. Chronic Congestive Heart Failure](#)
CHARLES HUGHES AND PATRICIA KOSTKA

Section D. Prevention and Management of Cancer

[Chapter 78. Molecular Basis of Human Neoplasia](#)
PAUL D. SAVAGE

[Chapter 79. Diet, Nutrition, and the Prevention of Cancer](#)
WALTER C. WILLETT

[Chapter 80. Carcinogens in Foods](#)
TAKASHI SUGIMURA AND KEIJI WAKABAYASHI

[Chapter 81. Chemoprevention of Cancer](#)
DIANE F. BIRT, JAMES D. SHULL, AND ANN L. YAKTINE

[Chapter 82. Nutritional Support of the Cancer Patient](#)
MAURICE E. SHILS AND MOSHE SHIKE

Section E. Prevention and Management of Skeletal and Joint Disorders

[Chapter 83. Bone Biology in Health and Disease](#)
ROBERT P. HEANEY

[Chapter 84. Nutrition and Diet in Rheumatic Diseases](#)
CLAUDIO GALPERIN, BRUCE J. GERMAN, AND M. ERIC GERSHWIN

[Chapter 85. Osteoporosis](#)
ELIZABETH A. KRALL AND BESS DAWSON-HUGHES

Section F. Other Systemic Diseases and Disorders

[Chapter 86. Nutritional Management of Diabetes Mellitus](#)
JAMES W. ANDERSON

[Chapter 87. Obesity](#)
F. XAVIER PI-SUNYER

[Chapter 88. Nutritional Aspects of Hematologic Disorders](#)

ISRAEL CHANARIN

[Chapter 89. Renal Disorders and Nutrition](#)

JOEL D. KOPPLE

[Chapter 90. Nutrition, Respiratory Function, and Disease](#)

MARGARET M. JOHNSON, ROBERT CHIN, JR., AND EDWARD F. HAPONIK

[Chapter 91. Nutrition and Retinal Degenerations](#)

ELIOT L. BERSON

[Chapter 92. Diagnosis and Management of Food Allergies](#)

HUGH A. SAMPSON

Section G. Psychiatric, Behavioral, and Neurologic Disorders

[Chapter 93. Behavioral Disorders Affecting Food Intake: Anorexia Nervosa, Bulimia Nervosa, and Other Psychiatric Conditions](#)

DIANE M. HUSE AND ALEXANDER R. LUCAS

[Chapter 94. Nutrition and Diet in Alcoholism](#)

LAWRENCE FEINMAN AND CHARLES S. LIEBER

[Chapter 95. Nutrition and Diseases of the Nervous System](#)

DOUGLAS R. JEFFERY

Section H. Nutrition, Infection, and Trauma

[Chapter 96. The Hypercatabolic State](#)

MICHELLE K. SMITH AND STEPHEN F. LOWRY

[Chapter 97. Nutrition and Infection](#)

LUCAS WOLF AND GERALD T. KEUSCH

[Chapter 98. Diet and Nutrition in the Care of the Patient with Surgery, Trauma, and Sepsis](#)

WILEY W. SOUBA AND DOUGLAS W. WILMORE

[Chapter 99. Diet, Nutrition, and Drug Interactions](#)

VIRGINIA UTERMOHLEN

Section I. Systems of Nutritional Support

[Chapter 100. Enteral Feeding](#)

MOSHE SHIKE

[Chapter 101. Parenteral Nutrition](#)

MAURICE E. SHILS AND REX O. BROWN

[Chapter 102. Nutrition and Medical Ethics: The Interplay of Medical Decisions, Patients' Rights, and the Judicial System](#)

MAURICE E. SHILS

PART V. DIET AND NUTRITION IN HEALTH OF POPULATIONS

[Chapter 103. Recommended Dietary Intakes: Individuals and Populations](#)

GEORGE H. BEATON

[Chapter 104. Dietary Goals and Guidelines: National and International Perspectives](#)

A. STEWART TRUSWELL

[Chapter 105. Nutrition Monitoring in the United States](#)

MARIE FANELLI KUCZMARSKI AND ROBERT J. KUCZMARSKI

[Chapter 106. Nutritional Implications of Vegetarian Diets](#)

PATRICIA K. JOHNSTON

[Chapter 107. International Priorities for Clinical and Therapeutic Nutrition in the Context of Public Health Realities](#)

NOEL W. SOLOMONS

[Chapter 108. Social and Cultural Influences on Food Consumption and Nutritional Status](#)

SARA A. QUANDT

[Chapter 109. Fads, Frauds, and Quackery](#)

STEPHEN BARRETT AND VICTOR D. HERBERT

[Chapter 110. Alternative Nutrition Therapies](#)

VICTOR D. HERBERT AND STEPHEN BARRETT

PART VI. ADEQUACY, SAFETY, AND OVERSIGHT OF THE FOOD SUPPLY

[Chapter 111. Food Processing: Nutrition, Safety, and Quality Balances](#)

ALEXA W. WILLIAMS AND JOHN W. ERDMAN, JR.

[Chapter 112. Designing Functional Foods](#)

WAYNE R. BIDLACK AND WEI WANG

[Chapter 113. Food Additives, Contaminants, and Natural Toxins](#)

JOHN N. HATHCOCK AND JEANNE I. RADER

[Chapter 114. Risk Assessment of Environmental Chemicals in Food](#)

A. M. FAN AND R. S. TOMAR

[Chapter 115. Food Labeling, Health Claims, and Dietary Supplement Legislation](#)

ALLAN L. FORBES AND STEPHEN H. McNAMARA

PART VII. APPENDIX

ABBY S. BLOCH AND MAURICE E. SHILS

Appendix Contents

Section I. Conversion Factors, Weights and Measures, and Metabolic Water Formation

Section II. National and International Recommended Dietary Reference Values

Section III. Energy and Protein Needs and Anthropometric Data

Section IV. Nutrients, Lipids, and Other Organic Compounds in Beverages and Selected Foods

Section V. Exchange Lists and Therapeutic Diets

Section VI. Internet and Other Sources of Nutrition Information

Contributors

STEVE F. ABCOUWER, Ph.D.

Assistant Biochemist
Department of Surgical Oncology
Massachusetts General Hospital
Instructor, Department of Surgery
Harvard Medical School
Boston, Massachusetts

PHYLLIS B. ACOSTA, Dr.P.H.

Director, Metabolic Diseases
Department of Pediatric Nutrition Research and Development
Ross Products Division, Abbott Laboratories
Columbus, Ohio

NANCY W. ALCOCK, Ph.D.

Professor
Department of Preventive Medicine and Community Health
University of Texas Medical Branch
Galveston, Texas

DAVID H. ALPERS, M.D.

Professor and Chief
Division of Gastroenterology
Washington University School of Medicine
St. Louis, Missouri

JAMES ANDERSON, M.D.

Professor
Medicine and Clinical Nutrition
Department of Internal Medicine
University of Kentucky
Chief, Endocrine
Metabolic Section
VA Medical Center
Lexington, Kentucky

AFTAB A. ANSARI, Ph.D.

Department of Pathology
Emory University School of Medicine
Atlanta, Georgia

LYNNE M. AUSMAN, D.Sc.

Scientist
Jean Mayer USDA Human Nutrition Research Center on Aging
Tufts University

Boston, Massachusetts
Professor, School of Nutrition Science and Policy
Tufts University
Medford, Massachusetts

STEPHEN BARRETT, M.D.

Consumer Advocate
Member, Board of Directors
National Council Against Health Fraud, Inc.
Allentown, Pennsylvania

RICHARD BAUMGARTNER, Ph.D.

Associate Professor
Division of Epidemiology
Department of Medicine
University of New Mexico
Albuquerque, New Mexico

GEORGE H. BEATON, Ph.D.

Professor Emeritus
Department of Nutritional Sciences
University of Toronto
Toronto, Ontario, Canada

ELIOT L. BERSON, M.D.

William F. Chatlos Professor of Ophthalmology
Harvard Medical School
Director, Berman-Gund Laboratory for the Study of Retinal Degenerations
Massachusetts Eye and Ear Infirmary
Boston, Massachusetts

WAYNE R. BIDLACK, Ph.D.

Dean
College of Agriculture
California State Polytechnic University, Pomona
Pomona, California

DIANE F. BIRT, Ph.D.

Professor
Eppley Institute for Research in Cancer and Department of Biochemistry and Molecular
Biology
College of Medicine
University of Nebraska Medical Center
Omaha, Nebraska
Current address:
Department of Food Science and Human Nutrition
Iowa State University

Ames, Iowa

ABBY S. BLOCH, Ph.D., R.D.

Coordinator of Clinical Nutrition Research
Gastroenterology/Nutrition Service
Department of Medicine
Memorial Sloan-Kettering Cancer Center
New York City, New York

IRWIN G. BRODSKY, M.D., M.P.H.

Assistant Professor of Medicine and Nutrition
Department of Medicine
Endocrinology and Metabolism Section
University of Illinois at Chicago
Chicago, Illinois

REX O. BROWN, Pharm.D., BCNSP, FACN

Professor
Department of Clinical Pharmacy
University of Tennessee
Nutrition Support Pharmacist
Department of Pharmacy
Regional Medical Center at Memphis
University of Tennessee Medical Center
Memphis, Tennessee

RAYMOND F. BURK, M.D.

Professor of Medicine
Director
Division of Gastroenterology
Department of Medicine
Vanderbilt University
Nashville, Tennessee

DANIEL CERVANTES-LAUREAN, M.D.

Pulmonary-Critical Care Medicine Branch
National Heart, Lung, and Blood Institute
National Institutes of Health
Bethesda, Maryland

ISRAEL CHANARIN, M.D., F.R.C.Path.

Formerly, Chief
Division of Hematology
Medical Research Council
Northwick Park Hospital Centre
Harrow, Middlesex, United Kingdom

FRANCISCO CHEW, M.D.

Head
Maternal and Child Health Unit
Instituto de Nutricion de Centro America y Panama (INCAP)
Guatemala City, Guatemala

ROBERT CHIN, Jr., M.D.

Associate Professor of Medicine
Section on Pulmonary and Critical Care Medicine
Wake Forest University School of Medicine
Winston-Salem, North Carolina

GRAEME A. CLUGSTON, M.B., D.C.H., Ph.D.

Chief
Nutrition Section
World Health Organization
Geneva, Switzerland

STEVEN COHN, M.D.

Assistant Professor of Medicine
Division of Gastroenterology
Washington University School of Medicine
St. Louis, Missouri

J. JOSEPH CONNON, M.D., F.R.C.P. (Lond), F.R.C.P.C.

Professor of Medicine
Department of Medicine
University of Toronto
Toronto, Ontario, Canada

ARTHUR COOPER, M.D., M.S.

Associate Professor
Chief
Pediatric Surgical Critical Care
College of Physicians and Surgeons of Columbia University
Harlem Hospital Center
New York City, New York

ROBERT J. COUSINS, Ph.D.

Boston Family Professor of Nutrition
Food Science and Human Nutrition Department and Center for Nutritional Sciences
University of Florida
Gainesville, Florida

EARL B. DAWSON, Ph.D.

Associate Professor

Department of Obstetrics and Gynecology
University of Texas Medical Branch
Galveston, Texas

BESS DAWSON-HUGHES, M.D.

Chief
Calcium and Bone Metabolism Laboratory
Jean Mayer USDA Human Nutrition Research Center on Aging
Associate Professor of Medicine
Tufts University
Boston, Massachusetts

DOMINICK P. DEPAOLA, D.D.S., Ph.D.

President and Dean
College of Dentistry
Texas A&M University
Dallas, Texas
Current address:
President and Chief Executive Officer, Forsyth Dental Center
Boston, Massachusetts

WILLIAM H. DIETZ, M.D., Ph.D.

Director of Clinical Nutrition
New England Medical Center
Boston, Massachusetts
Current address:
Director, Division of Nutrition and Physical Activity
Centers for Disease Control and Prevention
Atlanta, Georgia

EUGENE P. DIMAGNO, M.D.

Professor of Medicine
Department of Internal Medicine
Director, Department of Gastroenterology Research Unit
Mayo Clinic
Rochester, Minnesota

JOHANNA DWYER, D.Sc., R.D.

Professor of Medicine and Community Health
Tufts University Schools of Medicine and Nutrition
Senior Scientist
Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University
Director, Frances Stern Nutrition Center
New England Medical Center
Boston, Massachusetts

LOUIS JACOB ELSAS II, M.D.

Professor and Director

Division of Medical Genetics
Pediatrics/Medicine/Biochemistry
School of Medicine
Emory University
Atlanta, Georgia

JOHN W. ERDMAN, Jr., M.D.

Professor
Department of Food Science and Human Nutrition
Director of Nutritional Sciences
University of Illinois
Urbana, Illinois

DAVID ERLIJ, M.D., Ph.D.

Professor of Physiology
State University of New York Health Science Center at Brooklyn
Brooklyn, New York

MARY P. FAINE, M.S., R.D.

Associate Professor and Director of Nutrition Education
Department of Prosthodontics
School of Dentistry
University of Washington
Seattle, Washington

VIRGIL F. FAIRBANKS, M.D.

Consultant
Mayo Clinic
Professor of Medicine and Laboratory Medicine
Mayo Clinic and Mayo Foundation
Rochester, Minnesota

ANNA M. FAN, Ph.D.

Chief
Pesticide and Environmental Toxicology Section
Office of Environmental Health Hazard Assessment
California Environmental Protection Agency
Berkeley, California

LAWRENCE FEINMAN, M.D.

Associate Professor
Department of Medicine
Mount Sinai School of Medicine (CUNY)
New York City, New York
Chief, Section of Gastroenterology
Veterans Affairs Medical Center

Bronx, New York

C. RICHARD FLEMING, M.D.[†]

David Murdoch Professor of Nutrition Science
Mayo Medical School
Chair, Division of Gastroenterology
Mayo Clinic
Jacksonville, Florida

JEFFREY S. FLIER, M.D.

Professor of Medicine
Harvard Medical School
Chief, Division of Endocrinology and Metabolism
Beth Israel Deaconess Medical Center
Boston, Massachusetts

ALLAN L. FORBES, M.D.

Medical Consultant (Foods and Nutrition)
Formerly, Director
Office of Nutrition and Food Sciences
Food and Drug Administration
Old Farm
Rockville, Maryland

GILBERT B. FORBES, M.D.

Professor of Pediatrics and Biophysics
Emeritus
School of Medicine and Dentistry
University of Rochester
Rochester, New York

ELLEN B. FUNG, Ph.D.

Postdoctoral Fellow
Division of Gastroenterology and Nutrition
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

ROBERT A. GABBAY, M.D., Ph.D.

Instructor
Harvard Medical School
Endocrine Division
Beth Israel Deaconess Medical Center
Boston, Massachusetts

CLAUDIO GALPERIN, M.D.

Postdoctoral Scholar
Division of Rheumatology/Allergy and Clinical Immunology

University of California at Davis
Davis, California
Current address:
Rua Albuquerque Lins
São Paulo, Brazil

J. BRUCE GERMAN, Ph.D.

The John Kinsella Endowed Chair of Food Science
University of California at Davis
Davis, California

M. ERIC GERSHWIN, M.D.

The Jack and Donald Chia Professor of Medicine
Chief
Division of Rheumatology/Allergy and Clinical Immunology
University of California at Davis
Davis, California

ELIZABETH J. GONG, M.Ph., M.S, R.D.

Nutrition Research Associate
Department of Nutrition
University of California at Davis
Davis, California

ANNE M. GRIFFITHS, M.D., F.R.C.P.C.

Associate Professor of Pediatrics
Faculty of Medicine
University of Toronto
Director, Inflammatory Bowel Diseases Program
Division of Gastroenterology and Clinical Nutrition
The Hospital for Sick Children
Toronto, Ontario, Canada

SCOTT M. GRUNDY, M.D., Ph.D.

Chairman
Department of Clinical Nutrition
Professor of Internal Medicine
Director, Center for Human Nutrition
University of Texas Southwestern Medical Center at Dallas
Dallas, Texas

CHARLES H. HALSTED, M.D.

Professor
Department of Internal Medicine and Nutrition
University of California at Davis
Davis, California

EDWARD F. HAPONIK, M.D.

Professor of Internal Medicine
Chief
Section of Pulmonary and Critical Care Medicine
Wake Forest University School of Medicine
Winston-Salem, North Carolina

ALFRED E. HARPER, Ph.D.

Professor Emeritus
Department of Nutritional Sciences
Biochemistry
University of Wisconsin
Madison, Wisconsin

ROGER C. HARRIS, Ph.D.

Senior Research Fellow
Royal Veterinary College
University of London
London, England

JOHN N. HATHCOCK, Ph.D.

Director
Nutritional and Regulatory Science
Council for Responsible Nutrition
Washington, DC

FELIX P. HEALD, M.D.

Professor Emeritus of Pediatrics
University of Maryland School of Medicine
Baltimore, Maryland

ROBERT P. HEANEY, M.D.

John A. Creighton University Professor
Creighton University
Omaha, Nebraska

WILLIAM C. HEIRD, M.D.

Professor
Children's Nutrition Research Center
Department of Pediatrics
Baylor College of Medicine
Houston, Texas

VICTOR D. HERBERT, M.D., J.D.

Professor of Medicine
Mount Sinai School of Medicine

Chief of Hematology and The Nutrition Laboratory
Bronx Veteran Affairs Medical Center
New York City, New York

BASIL S. HETZEL, M.D.

Chairman
International Council for Control of Iodine Deficiency Disorders
Woman's and Children's Hospital
North Adelaide, Australia

STEVEN B. HEYMSFIELD, M.D.

Professor of Medicine
College of Physicians and Surgeons
Columbia University
Deputy Director, Obesity Research Center
Saint Lukes-Roosevelt Hospital
New York City, New York

L. JOHN HOFFER, M.D., C.M., Ph.D.

Associate Professor
Department of Medicine and Dietetics and Human Nutrition
McGill University
Senior Physician, Division of Endocrinology
Department of General Internal Medicine
Sir Mortimer B. Davis-Jewish General Hospital
Montreal, Quebec, Canada

MICHAEL F. HOLICK, M.D., Ph.D.

Professor of Medicine, Dermatology, and Physiology
Section of Endocrinology, Diabetes, and Metabolism in the Department of Medicine
Boston University School of Medicine
Boston, Massachusetts

EDWARD S. HORTON, M.D.

Professor
Department of Medicine
Harvard Medical School
Medical Director, Joslin Diabetes Center
Boston, Massachusetts

CHARLES HUGHES, M.D.

Professor of Medicine
Medical College of Wisconsin
Department of Cardiology
Department of Veteran Affairs
Clement J. Zablocki Medical Center

Milwaukee, Wisconsin

ERIC HULTMAN, M.D., Ph.D.

Professor Emeritus
Department of Medical Laboratory Sciences and Technology
Karolinska Institute, Division of Clinical Chemistry
Huddinge Hospital
Huddinge, Sweden

DIANE M. HUSE, R.D., M.S.

Assistant Professor of Nutrition
Mayo Medical School
Clinical Dietitian, Mayo Clinic
Rochester, Minnesota

ROBERT A. JACOB, Ph.D.

Research Chemist
USDA Western Research Center
Western Human Nutrition Research Center
Presidio of San Francisco, California

DOUGLAS R. JEFFERY, M.D., Ph.D.

Assistant Professor of Neurology
Department of Neurology
Wake Forest University School of Medicine
Winston-Salem, North Carolina

ALEXANDRA L. JENKINS

Research Associate
Department of Nutrition Sciences
University of Toronto
Toronto, Ontario, Canada

DAVID J. A. JENKINS, M.D., Ph.D.

Professor
Department of Nutrition Sciences
University of Toronto
Toronto, Ontario, Canada

MARGARET M. JOHNSON, M.D.

Senior Associate Consultant
Mayo Clinic at Jacksonville
Jacksonville, Florida

PATRICIA K. JOHNSTON, M.S., R.D., Dr.P.H.

Professor
Department of Nutrition

School of Public Health, Loma Linda University
Associate Dean
Loma Linda University
Loma Linda, California

PETER J. H. JONES, Ph.D.

Associate Professor of Human Nutrition
Director
School of Dietetics and Human Nutrition
McGill University
Montreal, Quebec

ROBERT KARP, M.D.

Medical Director
Pediatric Resource Center of Kings County Hospital Center
Professor of Pediatrics
State University of New York Health Science Center at Brooklyn
Brooklyn, New York

CARL L. KEEN, Ph.D.

Professor and Chair
Department of Nutrition
University of California at Davis
Davis, California

DARLENE G. KELLY, M.D., Ph.D.

Assistant Professor
Mayo Medical School
Consultant in Gastroenterology
Department of Internal Medicine
Mayo Foundation
Rochester, Minnesota

GERALD T. KEUSCH, M.D.

Professor of Medicine
Tufts University School of Medicine
New England Medical Center
Boston, Massachusetts

JANET C. KING, Ph.D.

Professor
Department of Nutritional Sciences
University of California at Berkeley
Berkeley, California
Director, Western Human Nutrition Research Center
USDA, ARS

San Francisco, California

SAMUEL KLEIN, M.D.

Professor of Medicine
Director
Center for Human Nutrition
Washington University School of Medicine
St. Louis, Missouri

JAMES P. KNOCHEL, M.D.

Chairman
Department of Internal Medicine
Presbyterian Hospital
Clinical Professor, Department of Internal Medicine
University of Texas Southwestern Medical School
Dallas, Texas

JOEL D. KOPPLE, M.D.

Professor of Medicine and Public Health
Schools of Medicine and Public Health
University of California at Los Angeles
Los Angeles, California
Chief, Division of Nephrology and Hypertension
Harbor-UCLA Medical Center
Torrance, California

PATRICIA KOSTKA, M.S., R.D.

Clinical Specialist Dietitian
Cardiopulmonary Rehabilitation Center
Department of Veteran Affairs
Clement J. Zablocki Medical Center
Milwaukee, Wisconsin

JANE M. KOTCHEN, M.D., M.P.H.

Professor
Department of Epidemiology/Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin

THEODORE A. KOTCHEN, M.D.

Professor and Chairman
Department of Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin

ELIZABETH A. KRALL, Ph.D.

Assistant Professor

School of Nutrition
Scientist II
Jean Mayer USDA Human Nutrition Research Center on Aging
Tufts University
Boston, Massachusetts

STANLEY KUBOW, Ph.D.

Associate Professor
School of Dietetics and Human Nutrition
McGill University
Montreal, Quebec

MARIE FANELLI KUCZMARSKI, Ph.D., R.D., L.D.

Associate Professor
Department of Nutrition and Dietetics
University of Delaware
Newark, Delaware

ROBERT J. KUCZMARSKI, Dr.P.H., R.D., L.D.

Nutrition Analyst
National Center for Health Statistics
Centers for Disease Control and Prevention
United States Public Health Service
Hyattsville, Maryland

HELEN W. LANE, R.D., Ph.D.

Chief
Biomedical Operations Research Branch
NASA Chief Nutritionist
Johnson Space Center, NASA
Houston, Texas

JAMES E. LEKLEM, Ph.D.

Professor
Department of Nutrition and Food Management
Oregon State University
Corvallis, Oregon

ORVILLE A. LEVANDER, Ph.D.

Nutrient Requirements and Functions Laboratory
Human Nutrition Research Center
Agricultural Research Services
United States Department of Agriculture
Beltsville, Maryland

ROY J. LEVIN

Reader in Physiology

Department of Biomedical Science
University of Sheffield
Sheffield, England

CHARLES S. LIEBER, M.D.

Professor of Medicine and Pathology
Mount Sinai School of Medicine (CUNY)
New York City, New York
Chief, Section of Liver Disease and Nutrition
Director, Alcohol Research and Treatment Center and GI-Liver-Nutrition Training
Program
Veterans Affairs Medical Center
Bronx, New York

STEPHEN F. LOWRY, M.D., F.A.C.S.

Professor of Surgery
Cornell University Medical College
New York City, New York
Current address:
Professor and Chairman, Department of Surgery
University of Medicine and Dentistry of New Jersey
New Brunswick, New Jersey

ALEXANDER R. LUCAS, M.D.

Professor of Psychiatry
Mayo Medical School
Division of Child and Adolescent Psychiatry
Mayo Clinic
Rochester, Minnesota

RICHARD D. MATTES, R.D., M.P.H., Ph.D.

Professor
Department of Foods and Nutrition
Purdue University
Lafayette, Indiana
Adjunct Associate Professor of Medicine, Division of Endocrinology and Metabolism
Indiana University School of Medicine
Indianapolis, Indiana

DWIGHT E. MATTHEWS, Ph.D.

Professor of Medicine and Chemistry
University of Vermont
Burlington, Vermont

DONALD B. McCORMICK, Ph.D.

Fuller E. Callaway Professor
Department of Biochemistry
Emory University

Atlanta, Georgia

N. GERALD McELVANEY, M.D.

Professor of Medicine
Clinical Investigation Unit
Beaumont Hospital
Dublin, Ireland

WILLIAM J. MCGANITY, M.D., F.R.C.S. (Canada)

Ashbel Smith Professor Emeritus of Obstetrics and Gynecology
Department of Obstetrics and Gynecology
University of Texas Medical Branch
Galveston, Texas

DONALD S. McLAREN, M.D., Ph.D., D.T.M. and H., F.R.C.P.E.

Honorary Head
Nutritional Blindness Prevention Programme
Department of Preventive Ophthalmology
Institute of Ophthalmology
London, United Kingdom

STEPHEN H. McNAMARA, Esq.

Senior Partner

Preface

The immediate predecessor of *Modern Nutrition in Health and Disease* was *Dietotherapy*, published in 1945 and edited by Drs. Michael Wohl and Robert Goodhart. With the same editors, its successor, the first edition of *Modern Nutrition in Health and Disease*, appeared in 1955. Its original objective has remained in succeeding editions: to serve as a comprehensive authoritative text and reference source reviewing the history, scientific base, and practice of nutrition for students, practitioners, and educators. The broad scope of nutritional sciences has relevance to all basic and applied biologic sciences, medicine, dentistry, dietetics, nursing, pharmacy, public health, and public policy.

This edition has 115 chapters and multiple sections of an Appendix, updated by 169 authors in 10 countries and from many scientific disciplines. To these authors we express our deep appreciation.

Thirty-five chapters review specific dietary components in depth; 18 others are concerned with the role of nutrition in integrated biologic systems; 5 review aspects of nutrition assessment; 41 cover a variety of clinical disorders; and 13 discuss public health and policy issues.

Thirty-six new chapters have been introduced designed to provide better understanding of the role of nutrition in integrated biologic systems and in other areas. These include general and specific aspects of molecular biology and genetics, ion channels, transmembrane signaling, and other topics—all in tutorial form. The matter of essential and conditionally essential nutrients is reviewed historically in the opening chapter and considered in separate chapters on individual essential nutrients and in those on taurine, homocysteine, glutamine, arginine, choline, and carnitine.

There are added chapters on nutritional issues in pediatrics, cardiovascular disorders, gastroenterology, cancer, hematology, and rheumatology. In the field of public health, new chapters address vegetarian diets, anthropology, “alternative” nutritional therapies, nutritional priorities in less industrialized countries, and risk assessment of nutrition-related environmental chemicals.

An extensive Appendix includes dietary reference recommendations from various national (including the new 1997 and 1998 U.S. Dietary Reference Intakes) and international agencies, multiple anthropometric tables, nutrient and nonnutrient contents of foods and beverages, numerous therapeutic diets and exchange lists, and other sources of nutritional information.

Relevant quantitative data have been expressed both in conventional and in international system (SI) units. The widespread use of the SI units in major publications in the United States and especially in other countries makes dual unitage useful to our readers.

We have endeavored to provide the breadth of coverage and quality of content required

by this ever-changing discipline in its basic and clinical dimensions. We invite the comments and suggestions of our readers.

Acknowledgments

The preparation, editing, and production of this extensive work has succeeded because of the expertise, effort, and dedication of many individuals in addition to the authors. The editors have worked with some personally, while others have been involved “behind the scenes” at the editorial, publication, and distribution stages.

At Williams and Wilkins, our interactions were primarily with Donna Balado, acquisitions editor; Victoria Vaughn, formerly senior managing editor; Jennifer Schmidt, managing editor; Jennifer Weir, production editor; and Anne K. Schwartz, copy editor. We express our appreciation to them for their guidance, knowledge, and cooperation in solving the numerous issues arising at various stages of planning, executing, and producing this work.

We are particularly indebted to Betty Shils, Beverly Satchell, Maggie Wheelock, and Denise Kowalski for enabling us to manage the enormous number of communications, records, manuscripts, and page proofs involved in the editing process.

To our respective spouses, Betty, Giovanna, Sherry, and Alex, we extend appreciation and thanks for their understanding and support of the increased demands on our time.

Chapter 1. Defining the Essentiality of Nutrients

THE CONCEPT OF NUTRITIONAL ESSENTIALITY

The concept of nutritional essentiality was firmly established less than 100 years ago. It arose from observations that certain diseases observed in human populations consuming poor diets could be prevented by including other foods in the diet and that failure of animals fed on diets composed of purified components or restricted to one or a few foodstuffs to grow and survive could similarly be corrected by including another food or an extract of the food in the diet. The food constituents that were found to prevent these problems were classified as indispensable (or essential) nutrients. Nutrients that could be deleted from the diet without causing growth failure or specific signs of disease were classified as dispensable (or nonessential).

This classification of nutrients served well through the 1950s as the basis of recommendations for treating dietary deficiency diseases, offering dietary advice to the public, and establishing food regulations and policy. As information about nutrients accrued, however, some essential nutrients were found to be synthesized from precursors, interactions among some nutrients in the diet were found to influence the need for others, and later, in some conditions, such as prematurity, certain pathologic states, and genetic defects, the ability of the body to synthesize several nutrients not ordinarily required was found to be so impaired that a dietary source was needed. As a result, the system of classifying nutrients simply as indispensable or dispensable has been modified to include a category of conditional essentiality ([1](#)).

Recently, associations observed between the risk of developing certain chronic and degenerative diseases and the consumption of some dispensable nutrients and nonnutrient components of foods, as well as the beneficial effects sometimes observed with high intakes of some essential nutrients, have raised questions about the adequacy of the present system of nutritional classification of food constituents ([2](#), [3](#), [4](#), [5](#) and [6](#)). In this chapter evolution of the concept of nutritional essentiality is outlined and

problems encountered in classifying food constituents on the basis of their effects on health and disease are identified.

Evolution of the Concept

Differences in the physical properties of foods and in their content of medicinal and toxic substances were considered to be important in the prevention and treatment of diseases in ancient times, but knowledge that foods contain many substances essential for life has been acquired only during the past two centuries (7, 8, 9, 10 and 11). Although the Hippocratic physicians in Greece practiced a form of dietetic medicine some 2400 years ago, they had no understanding of the chemical nature of foods and believed that foods contained only a single nutritional principle—aliment (9). This belief persisted until the 19th century, but a few earlier observations presaged the concept of nutritional essentiality (11). During the 1670s, Sydenham, a British physician, observed that a tonic of iron filings in wine improved the condition of chlorotic (anemic) patients, and in the 1740s, Lind, a British naval surgeon, found that consumption of citrus fruits, but not typical shipboard foods and medicines, cured scurvy in sailors. McCollum (9) cites Sydenham's report as the first evidence of essentiality of a specific nutrient, but it was not recognized as such at the time.

Between 1770 and 1794, through experiments on the nature of respiration in guinea pigs and human subjects, Lavoisier and Laplace discovered that oxidation of carbon compounds in tissues was the source of energy for bodily functions (7). For the first time, a specific function of foods had been identified in chemical terms. Lavoisier and his colleagues also established the basic concepts of organic chemistry, thus opening the way for understanding the chemical nature of foods.

Scientists interested in animal production then began to examine food components as nutrients. The first evidence of nutritional essentiality of an organic food component—protein—was the observation of Magendie in 1816 that dogs fed only carbohydrate or fat lost considerable body protein and died within a few weeks, whereas dogs fed on foods containing protein remained healthy. A few years later, in 1827, Prout, a physician and scientist in London, proposed that the nutrition of higher animals could be explained by their need for the three major constituents of foods—proteins, carbohydrates, and fats—and the changes these undergo in the body. This explanation, which was widely accepted, sounded the death knell of the single aliment hypothesis of the Hippocratic physicians.

During the next two decades, knowledge of the needs of animals for several mineral elements advanced. Chossat found that a calcium supplement prevented the mineral loss observed in birds fed a diet of wheat; Boussingault, using the balance technique, showed that pigs required calcium and phosphorus for skeletal development and also noted that cattle deteriorated when deprived of salt for a prolonged period. Liebig, a leading German chemist with a major interest in agricultural problems, found that sodium was the major cation of blood and potassium of tissues. Thus, by 1850, at least six mineral elements (Ca, P, Na, K, Cl, and Fe) had been established as essential for higher animals (11).

During this time also, Liebig postulated that energy-yielding substances (carbohydrates, fats) and proteins together with a few minerals were the principles of a nutritionally adequate diet. Liebig's hypothesis, however, was questioned by Pereira (1847), who noted that diets restricted to a small number of foods were associated with development of diseases such as scurvy, and by Dumas, who observed that feeding children artificial milk containing the known dietary constituents had failed to prevent deterioration of their health during the siege of Paris (1870–71). Still, owing to his great prestige, Liebig's concept continued to dominate thinking throughout the 19th century (9).

In 1881, Lunin in Dorpat, and 10 years later, Socin in Basel, found that mice fed on diets composed of purified proteins, fats, carbohydrates, and a mineral mixture survived less than 32 days. Mice that received milk or egg yolk in addition remained healthy throughout the 60-day experiments. Lunin and Socin concluded that these foods must contain small amounts of unknown substances essential for life. Their observations, nonetheless, did not stimulate a vigorous search for essential nutrients in foods, probably because of the skepticism of prominent scientists. Von Bunge, in whose laboratories Lunin and Socin worked, attributed inadequacies of purified diets to mineral imbalances or failure to supply minerals as organic complexes. Voit, a colleague of Liebig, assumed that purified diets would be adequate if they could be made palatable.

During the early 1880s, Takaki, director general of the Japanese Navy, noted that about 30% of Japanese sailors developed beriberi, although this disease was not prevalent among British sailors, whose rations were higher in protein. When evaporated milk and meat were included in the rations of the Japanese Navy, the incidence of beriberi declined remarkably. He concluded correctly that beriberi was a dietary deficiency disease, but incorrectly that it was caused by an inadequate intake of protein. In the 1890s, Eijkman, an army physician in the Dutch East Indies who was concerned with the high incidence of beriberi in the prisons in Java (Indonesia), where polished rice was a staple, discovered that chickens fed on a military hospital diet consisting mainly of polished rice developed a neurologic disease resembling beriberi, whereas those fed rice with the pericarp intact remained healthy. He proposed that accumulation of starch in the intestine favored formation of a substance that acted as a nerve poison and that rice hulls contained an antidote.

Grijns extended Eijkman's investigations and showed through feeding trials with chickens that the protective substance in rice hulls could be extracted with water. In 1901, he concluded that beriberi was caused by the absence from polished rice of an essential nutrient present mainly in the hulls. He provided, for the first time, a clear concept of a dietary deficiency disease, but the broad implications of his discovery were not appreciated. The authors of a British report (8) noted that facts brought to light by research done between 1880 and 1901 had "little or no effect on orthodox views and teaching concerning human nutrition." Another 15 years of research was required before the concept that foods contained a variety of unidentified essential nutrients gained widespread acceptance.

Establishing the Concept

The first evidence of essentiality of a specific organic molecule was the discovery by Willcock and Hopkins (12) in 1906 that a supplement of the amino acid tryptophan prolonged the survival of mice fed on a diet in which the protein source was the tryptophan-deficient protein zein. The following year, Holst and Frölich in Norway reported that guinea pigs fed on dry diets with no fresh vegetables developed a disease resembling scurvy, which was prevented by feeding them fresh vegetables or citrus juices. This was further evidence that foods contained unidentified substances that protected against specific diseases (9, 10).

Also, in 1907, Hart and associates at Wisconsin initiated a direct test of the validity of Liebig's hypothesis that the nutritive value of foods and feeds could be predicted from measurements of their gross composition by chemical analysis. They fed heifers on different rations designed to contain essentially the same amounts of major nutrients and minerals, each composed of a single plant source—wheat, oats, or corn—using all parts of the plant. The study lasted 3 years and included two reproductive periods. Animals that ate the wheat plant ration failed to thrive and did not produce viable calves; those fed the corn plant ration grew well and reproduced successfully. The results of this study, published in 1911, demonstrated that Liebig's hypothesis was untenable and stimulated intensive investigation in the United States of nutritional defects in diets (13).

In experiments undertaken between 1909 and 1913 to compare the nutritional value of proteins, Osborne and Mendel at Yale had initially been unable to obtain satisfactory rates of growth of rats fed on purified diets. They solved this problem by including a protein-free milk preparation in the diets. They then demonstrated that proteins from different sources differed in nutritive value and discovered that lysine, sulfur-containing amino acids, and histidine were essential for the rat (14).

During this time, Hopkins also observed that including small amounts of protein-free extracts of milk in nutritionally inadequate, purified diets converted them into diets that supported growth (10). In 1912 he commented: "It is possible that what is absent from artificial diets...is of the nature of an organic complex...which the animal body cannot synthesize." In 1912 also, in a review of the literature on beriberi, scurvy, and pellagra, Funk in London, who had been trying to purify the antiberiberi principle from rice polishings, proposed that these diseases were caused by a lack in the diet of "special substances which are in the nature of organic bases, which we will call vitamins" (9).

In studies of the nutritional inadequacies of purified diets McCollum and Davis, at Wisconsin, noted that when part of the carbohydrate was supplied as unpurified lactose, growth of rats was satisfactory if the fat was supplied as butterfat. When butterfat was replaced by lard or olive oil, growth failure occurred. In 1913 they concluded that butterfat contained an unidentified substance essential for growth. Meanwhile, Osborne and Mendel observed that if they purified the protein-free milk included in their diets, growth failure of rats again occurred, but if they substituted milk fat for the lard in their diets, growth was restored. They also concluded in 1913 that milk fat contained an unidentified substance essential for life.

McCollum and Davis extracted the active substance from butterfat and transferred it to

olive oil, which then promoted growth. They called this substance “fat-soluble A.” They then tested their active extracts in a polished rice diet of the type used by Eijkman and Grijns and found that even though the diet contained fat-soluble A, it failed to support growth. The problem was remedied when they added water extracts of wheat germ or boiled eggs. They concluded that animals consuming purified diets required two unidentified factors—fat-soluble A and water-soluble B (presumably Grijns' antiberiberi factor) (9, 10). Thus, by 1915, six minerals, four amino acids, and three vitamins—A, B, and the antiscorbutic factor—had been identified as essential nutrients.

The concept that foods contained several organic substances that were essential for growth, health, and survival was by then generally accepted. By 1918, the importance of consuming a wide variety of foods to ensure that diets provided adequate quantities of these substances was being emphasized in health programs for the public in Great Britain and the United States, and by the League of Nations.

NUTRITIONAL CLASSIFICATION OF FOOD CONSTITUENTS

As discoveries of other unidentified nutrients in foods or feeds continued to be reported after the 1920s, sometimes on the basis of limited evidence, criteria were needed, both on scientific grounds and for regulatory purposes, for establishing the validity of such claims.

Criteria of Essentiality

Criteria for establishing whether or not a dietary constituent is an essential nutrient were implicit in the types of investigations that had provided the basis for the concept of nutritional essentiality. Later they were elaborated in more detail as follows:

1. The substance is required in the diet for growth, health, and survival
2. Its absence from the diet or inadequate intake results in characteristic signs of a deficiency disease and, ultimately, death
3. Growth failure and characteristic signs of deficiency are prevented only by the nutrient or a specific precursor of it, not by other substances
4. Below some critical level of intake of the nutrient, growth response and severity of signs of deficiency are proportional to the amount consumed
5. The substance is not synthesized in the body and is, therefore, required for some critical function throughout life

By 1950 some 35 nutrients had been shown to meet these criteria. Nutrients presently accepted as essential for humans and for which there are recommended dietary intakes (RDIs) or allowances (RDAs) are listed in [Table 1.1](#).

Water	Energy sources
Amino acids	Fatty acids
Histidine	Linoleic
Isoleucine	α -Linolenic
Leucine	Minerals
Lysine	Calcium
Methionine	Phosphorus
Phenylalanine	Magnesium
Threonine	Iron
Tryptophan	Trace minerals
Valine	Zinc
Vitamins	Copper
Ascorbic acid	Manganese
Vitamins A, D, E, K	Iodine
Thiamin	Selenium
Riboflavin	Molybdenum
Niacin	Chromium
Vitamin B ₆ (pyridoxine)	Electrolytes
Pantothenic acid	Sodium
Folic acid	Potassium
Biotin	Chloride
Vitamin B ₁₂ (cobalamin)	Ultratraces elements ^a

^aSee chapter 18

Table 1.1 Nutrients Essential for Humans

Classification According to Essentiality

As knowledge of nutritional needs expanded, nutrients were classified according to their essentiality. This type of classification was applied initially to amino acids. In the early 1920s, Mendel used the term *indispensable* for amino acids that are not synthesized in the body. The term *nonessential* was used widely for those that are not required in the diet. This term was not considered satisfactory because these amino acids, although not required in the diet, are physiologically essential. Block and Bolling used the term *indispensable* for organic nutrients with carbon skeletons that are not synthesized in the body, and *dispensable*, which does not carry the broad implication of the term *nonessential*, for those with carbon skeletons that can be synthesized ([15](#), [16](#)).

Nutritional essentiality is characteristic of the species, not the nutrient. Arginine is required by cats and birds but not by humans. Also, it is not synthesized by the young of most species in amounts sufficient for rapid growth. It may, therefore, be either dispensable or indispensable depending on the species and stage of growth. Ascorbic acid (vitamin C), which is required by humans and guinea pigs, is not required by most species.

The Concept of Conditional Essentiality

Snyderman ([17](#)) found that premature infants, in whom many enzymes of amino acid metabolism develop late during gestation, required cystine and tyrosine (which are dispensable for most full-term infants) to ensure nitrogen retention and maintain their normal plasma levels. Cystine and tyrosine were thus essential for premature infants. Rudman and associates ([18](#), [19](#)) subsequently proposed the term *conditionally essential* for nutrients not ordinarily required in the diet but which must be supplied exogenously to specific populations that do not synthesize them in adequate amounts. They applied the term initially to dispensable nutrients needed by seriously ill patients maintained on total parenteral nutrition (TPN). The term now is used for similar needs that result from

developmental immaturity, pathologic states, or genetic defects.

Developmental Immaturity. Cystine and tyrosine, as mentioned above, are conditionally essential for premature infants (17). McCormick (3) has suggested that because preterm infants lack the enzymes for elongation and desaturation of linoleic and α -linolenic acids, elongated derivatives of these fatty acids, which are precursors of eicosanoids and membrane phospholipids, should be considered conditionally essential for them.

Damage to the cones of the eye and decline in weight gain of infant monkeys fed a taurine-free diet were prevented by supplements of taurine. In premature infants maintained on TPN without taurine, plasma taurine concentration declined, and the b-wave of the electroretinogram was attenuated. Gaul (20) suggests that taurine becomes conditionally essential for children maintained on TPN because they cannot synthesize enough to meet the body's need.

Plasma and tissue carnitine concentrations are lower in newborn infants than in adults, but this condition has not been associated with any physiologic defect. In infants maintained on TPN without carnitine, however, plasma and tissue carnitine levels are low, and in one study, this was associated with impaired fat metabolism and reduced nitrogen retention, both corrected by carnitine supplementation. Hoppel (21) concluded from a comprehensive review of the evidence that carnitine may be conditionally essential for premature infants maintained on TPN but is not conditionally essential for adults.

Pathologic States. Some patients with cirrhosis of the liver require supplements of cysteine and tyrosine to maintain nitrogen balance and normal plasma levels of these amino acids. Plasma taurine concentration also declines in adults with low plasma cystine levels. Insufficient synthesis of these nutrients in cirrhotic patients has been attributed to impairment of the synthetic pathway in the diseased liver. In some cancer patients, plasma choline concentrations declined by 50% when they were maintained on TPN. This was attributed to precursors of choline bypassing the liver during feeding by TPN (18).

In human subjects suffering severe illness, trauma, or infections, muscle and plasma glutamine concentrations decrease, generally in proportion to the severity of the illness or injury. In animals, decreased glutamine concentrations are associated with negative nitrogen balance, decreased tissue protein synthesis, and increased protein degradation. In clinical trials, nitrogen balance and clinical responses of surgical patients were improved by provision of glutamine in parenteral fluids following surgery. These findings support the conclusion that glutamine utilization exceeds its synthesis in patients in hypercatabolic states, and thus glutamine becomes conditionally essential for them (22).

Genetic Defects. Conditional essentiality of nutrients is also observed in individuals with genetic defects in pathways for synthesis of biologically essential but nutritionally dispensable substances. Genetic defects of carnitine synthesis result in myopathies that can be corrected by carnitine supplements (3). Genetic defects in the synthesis of

tetrahydrobiopterin, the cofactor for aromatic amino acid hydroxylases, result in phenylketonuria and impaired synthesis of some of the neurotransmitters for which aromatic amino acids are precursors (3). Tetrahydrobiopterin is thus conditionally essential for such individuals.

Criteria for Conditional Essentiality

Rudman and Feller (18) proposed three criteria for establishing conditional essentiality of nutrients: (a) decline in the plasma level of the nutrient into the subnormal range; (b) appearance of chemical, structural, or functional abnormalities; and (c) correction of both of these by a dietary supplement of the nutrient. All these criteria must be met to establish unequivocally that a nutrient is conditionally essential.

Conditional essentiality represents a qualitative change in requirements, i.e., the need for a nutrient that is ordinarily dispensable. Alterations in the need for an essential nutrient, from whatever cause, and health benefits from consumption of nonnutrients, dispensable nutrients, or essential nutrients in excess of amounts needed for normal physiologic function do not fit this category. Such situations should be dealt with separately.

MODIFICATION OF ESSENTIAL NUTRIENT NEEDS

Needs for essential nutrients may be influenced by (a) the presence in the diet of substances for which the nutrient is a precursor, that are precursors of the nutrient, or that interfere with the absorption or utilization of the nutrient; (b) imbalances and disproportions of other related nutrients; (c) some genetic defects; and (d) use of drugs that impair utilization of nutrients. These conditions do not alter basic requirements; they just increase or decrease the amounts that must be consumed to meet requirements. A few examples below illustrate the general characteristics of such effects.

Nutrient Interactions

Precursor-Product Relationships. Many substances that are physiologically, but not nutritionally, essential are synthesized from specific essential nutrients. If the products of the synthetic reactions are present in the diet, they may exert sparing effects that reduce the need for the precursor nutrients. Less phenylalanine and methionine are required, particularly by adults, when the diet includes tyrosine and cystine, for which they are, respectively, specific precursors. Birds, which do not synthesize arginine, have a high requirement for this amino acid. Inclusion in the diet of creatine, for which arginine is a precursor, reduces the need for arginine. Effects of this type, however, have not been explored extensively (23).

Precursors of Essential Nutrients. Tryptophan is a precursor of niacin. The need for niacin is therefore reduced by dietary tryptophan, but the efficiency of conversion differs for different species. The cat has an absolute requirement for niacin, but the rat converts tryptophan to niacin very efficiently. Human requirements for niacin are expressed as niacin-equivalents: 60 mg of dietary tryptophan equals 1 mg of niacin. b-Carotene, and

to a lesser extent other carotenoids, are precursors of retinol (vitamin A). Human requirements for vitamin A are expressed as retinol-equivalents: 1 µg retinol-equivalent equals 1 µg of retinol or 6 µg of b-carotene. These are examples of interactions that alter the dietary need for essential nutrients (24). They are not examples of conditional essentiality.

Imbalances and Disproportions of Nutrients. High proportions of some nutrients in the diet can influence the need for others. This phenomenon was first recognized when additions of amino acids that stimulated growth of young rats fed on diets low in tryptophan and niacin were found to precipitate niacin deficiency—an example of a vitamin deficiency induced by an amino acid imbalance. With diets that contain adequate niacin but are low in tryptophan, amino acid disproportions increased the need for tryptophan and depressed growth (25). Many examples of this type of imbalance, involving a variety of amino acids, have been observed in young animals. The growth-depressing effects result from depressed food intake mediated through alterations in brain neurotransmitter concentrations (26).

Dietary imbalances can also increase needs for some mineral elements (23, 27). Disproportionate amounts of molybdenum and sulfate in the diet increase the dietary need for copper and precipitate copper deficiency in animals consuming an otherwise adequate amount of copper. Extra manganese in the diets of sheep or pigs increases the need for iron to prevent anemia, and excess iron reduces the absorption of manganese. The presence in the diet of phytic acid, which binds zinc as well as other multivalent cations, impairs zinc absorption and increases the need for zinc. Thus, phytic acid can precipitate zinc deficiency in both humans and animals.

Dietary needs for some essential nutrients are influenced by the proportions of macronutrients in the diet. The need for vitamin E in the diet increases as the amount of fat rich in polyunsaturated fatty acids is increased (28). Thiamin functions mainly as part of the cofactor for decarboxylation of the α -ketoacids arising from metabolism of carbohydrates and branched-chain amino acids; hence, the need for thiamin depends upon the relative proportions of fat, carbohydrate, and protein in the diet. Fat has long been known to exert a “thiamin-sparing” effect (29).

Genetic Defects

Individuals with genetic defects that limit conversion of a vitamin to its coenzyme form develop severe deficiency diseases. Defects in the utilization of biotin, cobalamin, folate, niacin, pyridoxine, and thiamin are known. Effects of some of these diseases are relieved by large doses of the vitamin, but the degree of response varies with the disease and among patients with the same defect (30). Intakes required to relieve or correct these conditions are well above the RDA. In the genetic disease acrodermatitis enteropathica, which impairs zinc absorption, the need for zinc is three to four times the RDI level (see Chapter 11).

Drug-Nutrient Interactions

Many types of drug-nutrient interactions increase the need for a nutrient. The drug may

cause malabsorption, act as a vitamin antagonist, or impair mineral absorption (see [Chapter 99](#)). These and other conditions that alter the amounts of essential nutrients needed because of either interactions among dietary constituents or impairment of a metabolic function are not examples of conditional essentiality.

HEALTH BENEFITS NOT RELATED TO NUTRITIONAL ESSENTIALITY

For several decades after the concept of nutritional essentiality was established in the early 1900s, foods were primarily considered to be sources of essential nutrients required for critical physiologic functions that, if impaired by dietary deficiencies, caused specific diseases. Except for the debilitating effects of malnutrition, little consideration was given during this time to the idea that the type of diet consumed might influence development of diseases other than those caused by inadequate intakes of essential nutrients. By the 1950s, dietary deficiency diseases were virtually eliminated in industrialized nations. Improvements in nutrition, sanitation, and control of infectious diseases had resulted in immense improvements in health; life expectancy had lengthened, and chronic and degenerative diseases had become the major causes of death. This aroused interest in the possibility that susceptibility to such diseases might be influenced by the type of diet consumed.

Associations observed subsequently between diet composition, intakes of various individual diet components, and the incidence of heart disease and cancer have implicated food constituents such as fatty acids, fiber, carotenoids, various nonnutrient substances in plants, and high intakes of some essential nutrients (especially vitamins E and C, which can function as antioxidants) as factors influencing the risk of developing these diseases ([6](#)) (see [Chapter 76](#), [Chapter 80](#) and [Chapter 81](#)). This has led to proposals for modifying the criteria for essentiality or conditional essentiality to include dietary constituents reported to reduce the risk of chronic and degenerative diseases or to improve immune function, and for considering such effects of high intakes of essential nutrients as part of the basis for establishing RDIs ([2](#), [3](#), [4](#), [5](#) and [6](#)).

The definitions for *essential* and *conditionally essential* nutrients are clear from the criteria used to establish them. If the definitions were broadened to include substances that provide some desirable effect on health but do not fit these criteria, the specificity of the current definitions would be lost. Providing a health benefit, as for example is the case with fiber, is obviously not an adequate criterion for classifying a food constituent as essential or conditionally essential. Altering the criteria for establishing RDIs on the basis of effects of intakes of essential nutrients that greatly exceed physiologic needs or amounts obtainable from usual diets would have similar consequences—the specificity of the term *RDI* would be lost.

Food Constituents Desirable for Health. A straightforward way of avoiding these problems is to treat food constituents that exert desirable or beneficial effects on health, but do not fit the criteria established for essentiality or conditional essentiality, as a separate category of food constituents termed *desirable (or beneficial) for health* ([1](#)). Another more general term for such substances, which embraces both beneficial and adverse effects, is *physiological modulators* ([31](#)). A dietary guideline for including plenty of fresh vegetables and fruits in diets as sources of both known and unidentified

substances that may have desirable effects on health or in preventing disease has been readily accepted. Individual food constituents that may confer health benefits different from those of physiologically required quantities of essential nutrients, whether they are nonnutrients, dispensable nutrients, or essential nutrients in quantities exceeding those obtainable from diets, are more appropriately included in guidelines for health than in the RDI. Some nutrients and other food constituents that have prophylactic actions are presently dealt with in essentially this manner. Fiber and fluoride are discussed in dietary guideline publications, and this has been suggested as the most appropriate way of dealing with the potential beneficial effects of high intakes of antioxidant nutrients (32).

Fluoride, in appropriate dose, reduces susceptibility to dental caries without exerting a toxic effect. Whether fluoride meets criteria for essentiality, whether it is essential for tooth and bone development, or even if it should be considered a nutrient is controversial. Nonetheless, in low doses it acts as a prophylactic agent in protecting teeth against the action of bacteria. It is discussed in RDI and dietary guidelines publications on this basis, and it is certainly classified appropriately as a dietary constituent that provides a desirable health benefit.

Fiber has been long recognized to be beneficial for gastrointestinal function, to prevent constipation, and to relieve signs of diverticulosis. There is no basis for classifying fiber as an essential nutrient, but some forms of fiber that are transformed in the gastrointestinal tract into products that can be oxidized to yield energy fit the definition of nutrients. Without question it is a food constituent that provides a desirable health benefit when ingested in moderate amounts (33). Fiber is discussed with carbohydrates in RDI publications and with plant foods in dietary guidelines. A recommendation for inclusion of fiber in diets is appropriate, but recommended intakes should not be considered as RDIs, which are reference values for intakes of essential nutrients.

To develop a separate category of food constituents of this type (substances with desirable effects on health that are different from effects attributable to the physiologic functions of essential nutrients), specific criteria must be established to identify those to be included. Establishing appropriate criteria for assessing the validity of health claims for a category of food constituents that will include a variety of unrelated substances with different types of effects, many of which apply to only segments of the population, will be more complex than establishing criteria for assessing the validity of claims for essentiality of food constituents. The latter criteria apply uniformly to all substances proposed for inclusion and can be measured objectively. Assessing the effects of food constituents on health or in preventing disease involves a greater element of judgment and is more subjective than evaluating the essentiality of nutrients. Thus, claims for such effects must be evaluated especially critically.

In establishing criteria for assessing claims for desirable health benefits, consideration must be given to the need for subcategories of substances having different effects. Susceptibility to chronic and degenerative diseases is highly variable and may be influenced by many factors, including genetic differences among individuals or between populations, lifestyle, and diet-genetic interactions that can influence expression of genetic traits. Among questions that require answers are, Does the effect result from

alteration of a basic mechanism that prevents a disease from developing or is it due to modulation of the disease process? Does the benefit apply to the entire population or only to individuals at risk? This has been a source of controversy in relation to dietary recommendations for reducing the risk of developing heart disease (34). The effects of dietary constituents on immunocompetence should be analyzed in a similar manner: Are they of general significance or of consequence only if the immune system is impaired? When is stimulation of the immune system beneficial and when might it have adverse effects?

An immense number of plant constituents with anticarcinogenic actions are currently under investigation. These constituents differ in both their effects on cells and the stage of tumor development at which they act, and some have both adverse and beneficial effects (35). A number of subcategories would seem to be needed for which specific criteria will be required.

Pharmacologic Effects of Nutrients. Nutrients that function in large doses as drugs fall logically into a separate category of pharmacologic agents (36). Nicotinic acid in large doses is used to lower serum cholesterol. This represents use of a nutrient as a drug (see Chapter 23). The effect is unrelated to its function as a vitamin required for oxidation of energy-yielding nutrients and can be achieved only by quantities that far exceed nutritional requirements or usual dietary amounts. Use of tryptophan as a sleep inducer (37) and of continuous intravenous infusions of magnesium in the treatment of preeclampsia or myocardial infarction fall into this category (38). Essential nutrients that fit this pattern are functioning as pharmacologic agents not as nutritional supplements, as are substances, such as aspirin or quinine, originally isolated from plants, that are used as medicines.

With the current state of knowledge, it is undoubtedly premature to try to resolve definitively the problems encountered in classifying food constituents that have desirable effects on health or have been implicated in disease prevention. Such actions are not related to the physiologic functions of essential nutrients. Nonetheless, even though solutions proposed at this stage must be considered tentative, an orderly resolution of questions relating to health effects of food constituents that do not fit current nutritional concepts must be started. The confusion that would be created by accommodating them through modifying the criteria for essentiality or conditional essentiality is to be avoided at all costs. They should be considered within the context of dietary guidelines for health, not as part of the scientifically based RDIs.

Proteins are associated with all forms of life, and much of the effort to determine how life began has centered on how proteins were first produced. Amino acids joined together in long strings by peptide bonds form proteins, which twist and fold in three-dimensional space, producing centers to facilitate the biochemical reactions of life that either would run out of control or not run at all without them. Life could not have begun without enzymes, of which there are thousands of different types in the body. Proteins are prepared and secreted to act as cell-cell signals in the form of hormones and cytokines. Plasma proteins produced and secreted by the liver stabilize the blood by forming a solution of the appropriate viscosity and osmolarity. These secreted proteins also transport a variety of compounds through the blood.

The largest source of protein in higher animals is muscle. Through complex interactions, entire sheets of proteins slide back and forth to form the basis of muscle contraction and all aspects of our mobility. Muscle contraction provides for pumping oxygen and nutrients throughout the body, inhalation and exhalation in our lungs, and movement.

Many of the underlying causes of noninfectious diseases are due to derangements in proteins. Molecular biology has provided much information about DNA and RNA, not so much to understand DNA per se, but to understand the purpose and function of the proteins that are translated from the genetic code.

Three major classes of substrates are used for energy: carbohydrate, fat, and protein. The amino acids in protein differ from the other two primary sources of dietary energy by inclusion of nitrogen (N) in their structures. Amino acids contain at least one N in the form of an amino group, and when amino acids are oxidized to CO₂ and water to produce energy, waste N is produced that must be eliminated. Conversely, when the body synthesizes amino acids, N must be available. The synthetic pathways of other N-containing compounds in the body usually require donation of N from amino acids or incorporation of amino acids per se into the compound being synthesized. Amino acids provide the N for DNA and RNA synthesis. Therefore, when we think of amino acid metabolism, we must think of N metabolism.

Protein and amino acids are also important to the energy metabolism of the body. As Cahill pointed out (1), protein is the second largest store of energy in the body after adipose tissue fat stores (Table 2.1). Carbohydrate is stored as glycogen, and while important for short-term energy needs, has very limited capacity for meeting energy needs beyond a few hours. Amino acids from protein are converted to glucose by the process called gluconeogenesis, to provide a continuing supply of glucose after the glycogen is consumed during fasting. Yet, protein stores must be conserved for numerous critical roles in the body. Loss of more than about 30% of body protein results in such reduced muscle strength for breathing, reduced immune function, and reduced organ function that death results. Hence, the body must adapt to fasting by conserving protein, as is seen by a dramatic decrease in N excretion within the first week of starvation.

Component	Mass (kg)	Energy (kcal)	Availability ^a (days)
Body water and minerals	49	0	0
Protein	6	24,000	13
Glycogen	0.2	800	0.4
Fat	15	140,000	78
Total:	70	164,800	91.4

Data adapted from Cahill GE. *N Engl J Med* 1970;282:668-75.

^aAvailability is the duration for which the energy supply would last based upon an 1800 kcal/day resting energy consumption.

Table 2.1 Body Composition of a Normal Man in Terms of Energy Components

Body protein is made up of 20 amino acids, each with different metabolic fates in the

body, different activities in different metabolic pathways in different organs, and differing compositions in different proteins. When amino acids are released after absorption of dietary protein, the body makes a complex series of decisions concerning the fate of those amino acids: to oxidize them for energy, to incorporate them into proteins, or to use them in the formation of a number of other N-containing compounds. This chapter elucidates the complex pathways and roles amino acids play in the body, with a focus on nutrition. Since the inception of this book, this chapter has been authored by the late Hamish Munro, an excellent teacher who spent much of his life refining complex biochemical concepts into understandable terms. Professor Munro brought order into the apparently chaotic world of amino acid and protein metabolism through his classic four-volume series (2, 3, 4 and 5). Readers familiar with former versions of this chapter will find many of his views carried forward into the present chapter.

AMINO ACIDS

Basic Definitions

The amino acids that we are familiar with and all of those incorporated into mammalian protein are “alpha”-amino acids. By definition, they have a carboxyl-carbon group and an amino nitrogen group attached to a central α -carbon (Fig. 2.1). Amino acids differ in structure by substitution of one of the two hydrogens on the α -carbon with another functional group. Amino acids can be characterized by their functional groups, which are often classified at neutral pH as (a) nonpolar, (b) uncharged but polar, (c) acidic (negatively charged), and (d) basic (positively charged) groups.

Figure 2.1. Structural formulas of the 21 common α -amino acids. The α -amino acids all have (a) a carboxyl group, (b) an amino group, and (c) a differentiating functional group attached to the α -carbon. The generic structure of amino acids is shown in the upper left corner with the differentiating functional marked R . The functional group for each amino acid is shown below. Amino acids have been grouped by functional class. Proline is the only amino acid whose entire structure is shown because of its “cyclic” nature.

Within any class there are considerable differences in shape and physical properties. Thus, amino acids are often arranged in other functional subgroups. For example, amino acids with an aromatic group—phenylalanine, tyrosine, tryptophan, and histidine—are often grouped, although tyrosine is clearly polar and histidine is also basic. Other common groupings are the aliphatic or neutral amino acids (glycine, alanine, isoleucine, leucine, valine, serine, threonine and proline). Proline differs in that its functional group is also attached to the amino group, forming a five-member ring. Serine and threonine contain hydroxy groups. The branched-chain amino acids (BCAAs: isoleucine, leucine, and valine) share common enzymes for the first two steps of their degradation. The acidic amino acids, aspartic acid and glutamic acid, are often referred to as their ionized, salt forms: *aspartate* and *glutamate*. These amino acids become *asparagine* and *glutamine* when an amino group is added in the form of an amide group to their carboxyl tails.

The sulfur-containing amino acids are methionine and cysteine. Cysteine is often found in the body as an amino acid dimer, *cystine*, in which the thiol groups (the two sulfur atoms) are connected to form a disulfide bond. Note the distinction between *cysteine* and *cystine*; the former is a single amino acid, and the latter is a dimer with different properties. Other amino acids that contain sulfur, such as homocysteine, are not incorporated into protein.

All amino acids are charged in solution: in water, the carboxyl group rapidly loses a hydrogen to form a carboxyl anion (negatively charged), while the amino group gains a hydrogen to become positively charged. An amino acid, therefore, becomes “bipolar” (often called a *zwitterion*) in solution, but without a net charge (the positive and negative charges cancel). However, the functional group may distort that balance. Acidic amino acids lose the hydrogen on the second carboxyl group in solution. In contrast, basic amino acids accept a hydrogen on the second N and form a molecule with a net positive charge. Although the other amino acids do not specifically accept or donate additional hydrogens in neutral solution, their functional groups do influence the relative polarity and acid-base nature of their bipolar portion, giving each amino acid different properties in solution.

The functional groups of amino acids also vary in size. The molecular weights of the amino acids are given in [Table 2.2](#). Amino acids range from the smallest, glycine, to large and bulky molecules (e.g., tryptophan). Most amino acids crystallize as uncharged molecules when purified and dried. The molecular weights given in [Table 2.2](#) reflect their molecular weights as crystalline amino acids. However, basic and acidic amino acids tend to form much more stable crystals as salts, rather than as free amino acids. Glutamic acid can be obtained as the free amino acid with a molecular weight of 147 and as its sodium salt, monosodium glutamate (MSG), which has a crystalline weight of 169. Lysine is typically found as a hydrogen chloride–containing salt. Therefore, when amino acids are represented by weight, it is important to know whether the weight is based on the free amino acid or on its salt.

Amino acid	Molecular weight (kDa)		Molecular weight (kDa)
	3-letter	1-letter	
Essential amino acids			
Phenylalanine	Phe	F	146.15
Valine	Val	V	99.09
Leucine	Leu	L	133.07
Alanine	Ala	A	89.09
Proteinogenic amino acids			
Alanine	Ala	A	89.09
Arginine	Arg	R	174.20
Asparagine	Asn	N	132.12
Aspartic acid	Asp	D	133.07
Cysteine	Cys	C	121.16
Glycine	Gly	G	75.07
Glutamic acid	Glu	E	146.15
Glutamine	Gln	Q	146.15
Non-proteinogenic amino acids			
Hydroxyproline	HyP	H	133.07
Hydroxylysine	HyL	K	146.15

Table 2.2 Common Amino Acids in the Body

Another important property of amino acids is optical activity. Except for glycine, which has a single hydrogen as its functional group, all amino acids have at least one chiral center: the α -carbon. The term *chiral* comes from Greek for *hand* in that these molecules have a left (*levo* or L) and right (*dextro* or D) handedness around the α -carbon atom. The tetrahedral structure of the carbon bonds allows two possible arrangements of a carbon center with the same four different groups bonded to it, which are not superimposable; the two configurations, called *stereoisomers*, are mirror images of each other. The body recognizes only the L form of amino acids for most reactions in the body, although some enzymatic reactions will operate with lower efficiency when given the D form. Because we do encounter some D amino acids in the foods we eat, the body has mechanisms for clearing these amino acids (e.g., renal filtration).

Any number of molecules could be designed that meet the basic definition of an amino acid: a molecule with a central carbon to which are attached an amino group, a carboxyl group, and a functional group. However, a relatively limited variety appear in nature, of which only 20 are incorporated directly into mammalian protein. Amino acids are selected for protein synthesis by binding with transfer RNA (tRNA). To synthesize protein, strands of DNA are transcribed into messenger RNA (mRNA). Different tRNA molecules bind to specific triplets of bases in mRNA. Different combinations of the 3 bases found in mRNA code for different tRNA molecules. However, the 3-base combinations of mRNA are recognized by only 20 different tRNA molecules, and 20 different amino acids are incorporated into protein during protein synthesis.

Of the 20 amino acids in proteins, some are synthesized *de novo* in the body from either other amino acids or simpler precursors. These amino acids may be deleted from our diet without impairing health or blocking growth; they are *nonessential* and *dispensable* from the diet. However, several amino acids have no synthetic pathways in humans; hence these amino acids are *essential* or *indispensable* to the diet. [Table 2.2](#) lists the amino acids as essential or nonessential for humans. Both the standard 3-letter abbreviation and the 1-letter abbreviation used in representing amino acid sequences in proteins are also presented in [Table 2.2](#) for each amino acid. Some nonessential amino

acids may become *conditionally essential* under conditions when synthesis becomes limited or when adequate amounts of precursors are unavailable to meet the needs of the body (6, 7 and 8). The history and rationale of the classification of amino acids in [Table 2.2](#) is discussed in greater detail below.

Beside the 20 amino acids that are recognized by, and bind to, tRNA for incorporation into protein, other amino acids appear commonly in the body. These amino acids have important metabolic functions. For example, ornithine and citrulline are linked to arginine through the urea cycle. Other amino acids appear as modifications after incorporation into proteins; for example, hydroxy-proline, produced when proline residues in collagen protein are hydroxylated, and 3-methylhistidine, produced by posttranslational methylation of select histidine residues of actin and myosin. Because no tRNA codes for these amino acids, they cannot be reused when a protein containing them is broken down (hydrolyzed) to its individual amino acids.

Amino Acid Pools and Distribution

The distribution of amino acids is complex. Not only are there 20 different amino acids incorporated into a variety of different proteins in a variety of different organs in the body, but amino acids are consumed in the diet from a variety of protein sources. In addition, each amino acid is maintained in part as a free amino acid in solution in blood and inside cells. Overall, a wide range of concentrations of amino acids exists across the various protein and free pools. Dietary protein is enzymatically hydrolyzed in the alimentary tract, releasing free individual amino acids that are then absorbed by the gut lumen and transported into the portal blood. Amino acids then pass into the systemic circulation and are extracted by different tissues. Although the concentrations of individual amino acids vary among different free pools such as plasma and intracellular muscle, the abundance of individual amino acids is relatively constant in a variety of proteins throughout the body and nature. [Table 2.3](#) shows the amino acid composition of egg protein and muscle and liver proteins (9). The data are expressed as *moles* of amino acid. The historical expression of amino acids is on a weight basis (e.g., *grams* of amino acid). Comparing amino acids by weight skews the comparison toward the heaviest amino acids, making them appear more abundant than they are. For example, tryptophan (molecular weight, 204) appears almost three times as abundant as glycine (molecular weight, 75) when quoted in terms of weight.

Amino Acid	Composition (μmole/g protein)		
	Hen Egg	Mammalian	
		Muscle	Liver
Alanine	810	730	750
Arginine	360	380	328
Aspartate + asparagine	530	600	600
Cysteine	190	120	140
Glutamate + glutamine	810	990	800
Glycine	450	670	610
Histidine	150	180	170
Isoleucine	490	360	380
Leucine	650	610	600
Lysine	425	580	510
Methionine	200	170	170
Phenylalanine	340	270	310
Proline	350	430	430
Serine	770	480	510
Threonine	410	390	390
Tryptophan	80	55	80
Tyrosine	270	170	200
Valine	600	470	520

(Data taken from Tables 2 and 3 (pp. 343-4) of Block BJ, Wooley RW. Amino acid nutrition: methods and results of analysis. Springfield, IL: Charles C. Thomas, 1966.)

Table 2.3 Amino Acid Concentrations in Muscle and Liver Protein and in High-Quality Egg Protein

An even distribution of all 20 amino acids would be 5% per amino acid, and the median distribution of individual amino acids centers around this figure for the proteins shown in [Table 2.3](#). Tryptophan is the least common amino acid in many proteins, but considering the effect of its large size on protein configuration, this is not surprising. Amino acids of modest size and limited polarity such as alanine, leucine, serine, and valine are relatively abundant in protein (8–10% each). While the abundance of the essential amino acids is similar across the protein sources in [Table 2.3](#), a variety of vegetable proteins are deficient or low in some essential amino acids. In the body, a variety of proteins are particularly rich in specific amino acids that confer specific attributes to the protein. For example, collagen is a fibrous protein abundant in connective tissues and tendons, bone, and muscle. Collagen fibrils are arranged differently depending on the functional type of collagen. Glycine makes up about one-third of collagen, and there is also considerable proline and hydroxyproline (proline converted after it has been incorporated into collagen). The glycine and proline residues allow the collagen protein chain to turn tightly and intertwine, and the hydroxyproline residues provide for hydrogen-bond cross-linking. Generally, the alterations in amino acid concentrations do not vary so dramatically among proteins as they do in collagen, but such examples demonstrate the diversity and functionality of the different amino acids in proteins.

The abundance of different amino acids varies over a far wider range in the free pools of extracellular and intracellular compartments. Typical values for free amino acid concentrations in plasma and intracellular muscle are given in [Table 2.4](#), which shows that amino acid concentrations vary widely in a given tissue and that free amino acids are generally inside cells. Although there is a significant correlation between free amino acid levels in plasma and muscle, the relationship is not linear ([10](#)). Amino acid concentrations range from a low of »20 μM for aspartic acid and methionine to a high of »500 μM for glutamine. The median level for plasma amino acids is 100 μM . There is no defined relationship between the nature of amino acids (essential vs. nonessential) and amino acid concentrations or type of amino acids (e.g., plasma concentrations of the three BCAAs range from 50 to 250 μM). Notably, the concentration of the acidic amino acids, aspartate and glutamate, is very low outside cells in plasma. In contrast, the concentration of glutamate is among the highest inside cells, such as muscle ([Table 2.4](#)).

Amino acid ^a		Concentration (mM)		Gradient Intracellular/ Plasma
		Plasma	Intracellular Muscle	
Aspartic acid	NE	0.07		
Phenylalanine	E	0.05	0.07	1.4
Tyrosine	CE	0.05	0.10	2.0
Methionine	E	0.02	0.11	5.5
Isoleucine	E	0.06	0.11	1.8
Leucine	E	0.12	0.15	1.3
Cysteine	CE	0.11	0.18	1.6
Valine	E	0.22	0.26	1.2
Ornithine		0.06	0.30	5.0
Histidine	E	0.08	0.37	4.6
Asparagine	NE	0.05	0.47	9.4
Arginine	NE	0.08	0.51	6.4
Proline	NE	0.17	0.83	4.9
Serine	NE	0.12	0.98	8.2
Threonine	E	0.15	1.03	6.9
Lysine	E	0.18	1.15	6.4
Glycine	NE	0.21	1.33	6.3
Alanine	NE	0.33	2.34	7.1
Glutamic acid	NE	0.06	4.38	73.0
Glutamine	NE	0.57	19.45	34.1
Saureine ^b		0.07	15.44	221.0

Data from Borgstrom A, Furst P, Nicoll LD, et al. J Appl Physiol 1974; 36:690-4.
^aE, essential; NE, nonessential; CE, conditionally essential.
^bSaureine is not an amino acid per se but is highly concentrated in free form in muscle.

Table 2.4 Typical Concentrations of Free Amino Acids in the Body

It is important to bear in mind the differences in the relative amounts of N contained in extracellular and intracellular amino acid pools and in protein itself. A normal person has about 55 mg amino acid N/L outside cells in extracellular space and about 800 mg amino acid N/L inside cells, which means that free amino acids are about 15 times more abundant inside cells than outside (10). Furthermore, the total pool of free amino acid N is small compared with protein-bound amino acids. Multiplying the free pools by estimates of extracellular water (0.2 L/g) and intracellular water (0.4 L/g) provides a measure of the total amount of N present in free amino acids: 0.33 g N/kg body weight. In contrast, body composition studies show that the N content of the body is 24 g N/kg body weight (11, 12). Thus, free amino acids make up only about 1% of the total amino N pool, with 99% of the amino N being protein bound.

Amino Acid Transport

The gradient of amino acids within and outside cells is maintained by active transport. Simple inspection of Table 2.4 shows that different transport mechanisms must exist for different amino acids to produce the range of concentration gradients observed. A variety of different transporters exist for different types and groups of amino acids (13, 14, 15 and 16). Amino acid transport is probably one of the more difficult areas of amino acid metabolism to quantify and characterize. The affinities of the transporters and their mechanisms of transport determine the intracellular levels of the amino acids. Generally, the essential amino acids have lower intracellular/extracellular gradients than do the nonessential amino acids (Table 2.4), and they are transported by different carriers. Amino acid transporters are membrane-bound proteins that recognize different amino acid shapes and chemical properties (e.g., neutral, basic, or anionic). Transport occurs both into and out of cells. Transport may be thought of as a process that sets the intracellular/extracellular gradient, or the transporters may be thought of as processes that set the rates of amino acid cellular influx and efflux, which then define the intracellular/extracellular gradients (13). Perhaps the more dynamic concept of transport defining flows of amino acids is more appropriate, but the gradient (e.g., intracellular

muscle amino acid levels) is measurable, not the rates.

The transporters fall into two classes: sodium-independent and sodium-dependent carriers. The sodium-dependent carriers cotransport a sodium atom into the cell with the amino acid. The high extracellular/intracellular sodium gradient (140 mEq outside and 10 mEq inside) facilitates inward transport of amino acids by the sodium-dependent carriers. These transporters generally produce larger gradients and accumulations of amino acids inside cells than outside. The sodium entering the cell may be transported out via the sodium-potassium pump, which transports a potassium ion in for the removal of a sodium ion.

Few transporter proteins have been identified; most information concerning transport results from kinetic studies of membranes using amino acids and competitive inhibitors or amino acid analogues to define and characterize individual systems. [Table 2.5](#) lists the amino acid transporters characterized to date and the amino acids they transport. The neutral and bulky amino acids (the BCAAs, phenylalanine, methionine, and histidine) are transported by system *L*. System *L* is sodium independent, operates with a high rate of exchange, and produces small gradients. Other important transporters are systems *ASC* and *A*, which use the energy available from the sodium ion gradient as a driving force to maintain a steep gradient for the various amino acids transported (e.g., glycine, alanine, threonine, serine, and proline) ([13](#), [14](#)). The anionic transporter (X_{AG-}) also produces a steep gradient for the dicarboxylic amino acids, glutamate and aspartate. Other important carriers are systems *N* and N^m for glutamine, asparagine, and histidine. System y^+ handles much of the transport of the basic amino acids. Some overall generalizations can be made in terms of the type of amino acid transported by a given carrier, but the system is not readily simplified because individual carrier systems transport several different amino acids, and individual amino acids are often transported by several different carriers with different efficiencies. Thus, amino acid gradients are formed and amino acids are transported into and out of cells via a complex system of overlapping carriers.

System	Amino Acid Transported	Tissue Location	pH Dependence
Sodium dependent			
A	Most neutrals (Ala, Ser)	Ubiquitous	Yes
ASC	Most neutrals	Ubiquitous	No
B	Most neutrals	Intestinal brush border	Yes
N	Gln, Asn, His	Hepatocytes	Yes
N^m	Gln, Asn	Muscle	No
Gly	Gly, sarcosine	Ubiquitous	
X_{AG-}	Glu, Asp	Ubiquitous	
Sodium independent			
L	Leu, Ile, Val, Met, Phe, Tyr, Trp, His	Ubiquitous	Yes
T	Trp, Phe, Tyr	Red blood cells, hepatocytes	No
y^+	Arg, Lys, Orn	Ubiquitous	No
asc	Ala, Ser, Cys, Thr	Ubiquitous	Yes

Data taken from compilations in refs. 13-15.

Table 2.5 Amino Acid Transporters

PATHWAYS OF AMINO ACID SYNTHESIS AND DEGRADATION

Several amino acids have their metabolic pathways linked to the metabolism of other amino acids. These codependencies become important when nutrient intake is limited or when metabolic requirements are increased. Two aspects of metabolism are reviewed here: the synthesis only of nonessential amino acids and the degradation of all amino acids. Degradation serves two useful purposes: (a) production of energy from the oxidation of individual amino acids (≈ 4 kcal/g protein, almost the same energy production as for carbohydrate) and (b) conversion of amino acids into other products. The latter is also related to amino acid synthesis; the degradation pathway of one amino acid may be the synthetic pathway of another amino acid. Amino acid degradation also produces other non-amino acid, N-containing compounds in the body. The need for synthesis of these compounds may also drain the pools of their amino acid precursors, increasing the need for these amino acids in the diet. When amino acids are degraded for energy rather than converted to other compounds, the ultimate products are CO_2 , water, and urea. The CO_2 and water are produced through classical pathways of intermediary metabolism involving the tricarboxylic acid cycle (TCA cycle). Urea is produced because other forms of waste N, such as ammonia, are toxic if their levels rise in the blood and inside cells. For mammals, urea production is a means of removing waste N from the oxidation of amino acids in the form of a nontoxic, water-soluble compound.

This section discusses the pathways of amino acid metabolism. In all cases, much better and more detailed descriptions of the pathways can be found in standard textbooks of biochemistry. One caveat to the reader consulting such texts for reference information: mammals are not the only form of life. Several texts cover subject matter beyond mammalian systems and present material for pathways that are of little importance to human biochemistry. When consulting reference material, the reader needs to be aware of what organism contains the metabolic pathways and enzymes being discussed. The discussion below concerns human biochemistry. First, the routes of degradation of each amino acid when the pathway is directed toward oxidation of the amino acid for energy are discussed, then pathways of amino acid synthesis, and finally use of amino acids for other important compounds in the body.

Amino Acid Degradation Pathways

Complete amino acid degradation produces nitrogen, which is removed by incorporation into urea. Carbon skeletons are eventually oxidized to CO_2 via the TCA cycle. The TCA cycle (also known as the Krebs cycle or the citric acid cycle) oxidizes carbon for energy, producing CO_2 and water. The inputs to the cycle are acetyl-CoA and oxaloacetate forming citrate, which is degraded to α -ketoglutarate and then to oxaloacetate. Carbon skeletons from amino acids may enter the Krebs cycle via acetate as acetyl-CoA or via oxaloacetate/ α -ketoglutarate, direct metabolites of the amino acids aspartate and glutamate, respectively. An alternative to complete oxidation of the carbon skeletons to CO_2 is the use of these carbon skeletons for formation of fat and carbohydrate. Fat is formed from elongation of acetyl units, and so amino acids whose carbon skeletons

degrade to acetyl-CoA and ketones may alternatively be used for synthesis of fatty acids. Glucose is split in glycolysis to pyruvate, the immediate product of alanine. Pyruvate may be converted back to glucose by elongation to oxaloacetate. Amino acids whose degradation pathways go toward formation of pyruvate, oxaloacetate, or α -ketoglutarate may be used for glucose synthesis. Thus, the degradation pathways of many amino acids can be partitioned into two groups with respect to the disposal of their carbon: amino acids whose carbon skeleton may be used for synthesis of glucose (gluconeogenic amino acids) and those whose carbon skeletons degrade for potential use for fatty acid synthesis.

The amino acids that degrade directly to the primary gluconeogenic and TCA cycle precursors, pyruvate, oxaloacetate, and α -ketoglutarate, do so by rapid and reversible transamination reactions:

(catalyzed by the enzyme aspartate aminotransferase) which of course is also

is catalyzed by the enzyme alanine aminotransferase. Clearly, the amino N of these three amino acids can be rapidly exchanged, and each amino acid can be rapidly converted to/from a primary compound of gluconeogenesis and the TCA cycle. As shown below, compartmentation among different organ pools is the only limiting factor for complete and rapid exchange of the N of these amino acids.

The essential amino acids leucine, isoleucine, and valine are grouped together as the BCAAs because the first two steps in their degradation are common to all three amino acids:

The reversible transamination to keto acids is followed by irreversible decarboxylation of the carboxyl group to liberate CO_2 . The BCAAs are the only essential amino acids that undergo transamination and thus are unique among essential amino acids.

Together, the BCAAs, alanine, aspartate, and glutamate make up the pool of amino N that can move among amino acids via reversible transamination. As shown in [Figure 2.2](#), glutamic acid is central to the transamination process. In addition, N can leave the transaminating pool via removal of the glutamate N by glutamate dehydrogenase or enter by the reverse process. The amino acid glutamine is intimately tied to glutamate as well; all glutamine is made from amidation of glutamate, and glutamine is degraded by removal of the amide N to form ammonia and glutamate. A similar process links

asparagine and aspartate. [Figure 2.2](#) shows that the center of N flow in the body is through glutamate. This role becomes even clearer when we look at how urea is synthesized in the liver. CO_2 , ATP, and NH_3 enter the urea cycle to form carbamoyl phosphate, which condenses with ornithine to form citrulline ([Fig. 2.3](#)). The second N enters via aspartate to form arginosuccinate, which is then cleaved into arginine and fumarate. The arginine is hydrolyzed by arginase to ornithine, liberating urea. The resulting ornithine can reenter the urea cycle. As is mentioned briefly below, some amino acids may release ammonia directly (e.g., glutamine, asparagine, and glycine), but most transfer through glutamate first, which is then degraded to α -ketoglutarate and ammonia. The pool of aspartate in the body is small, and aspartate cannot be the primary transporter of the second N into urea synthesis. Rather, aspartate must act as arginine and ornithine do, as a vehicle for the introduction of the second N. If so, the second N is delivered by transamination via glutamate, which places glutamate at another integral point in the degradative disposal of amino acid N.

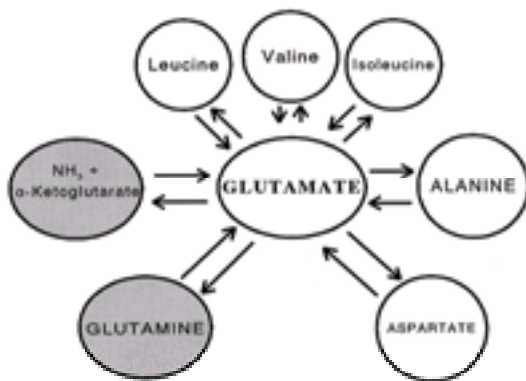

Figure 2.2. Movement of amino N around glutamic acid. Glutamate undergoes reversible transamination with several amino acids. Nitrogen is also removed from glutamate by glutamate dehydrogenase, producing α -ketoglutarate and ammonia. In contrast, the enzyme glutamine synthetase adds ammonia to glutamate to produce glutamine. Glutamine is degraded to glutamate by liberation of the amide N to release ammonia by a different enzymatic pathway (glutaminase).

Figure 2.3. Urea cycle disposal of amino acid N. Urea synthesis incorporates one N from ammonia and another from aspartate. Ornithine, citrulline, and arginine sit in the middle of the cycle. Glutamate is the primary source for the aspartate N; glutamate is also an important source of the ammonia in the cycle.

An outline of the degradative pathways of the various amino acids is presented in [Table 2.6](#). Rather than show individual reaction steps, the major pathways for degradation, including the primary endproducts, are presented. The individual steps may be found in textbooks of biochemistry or in reviews of the subject such as the very good chapter by Krebs ([17](#)). Because of the importance of transamination, most of the N from amino acid degradation appears via N transfer to α -ketoglutarate to form glutamate. In some cases, the aminotransferase catalyzes the transamination reaction with glutamate bidirectionally, as indicated in [Figure 2.2](#), and these enzymes are distributed in many tissues. In other cases, the transamination reactions are liver specific and compartmentalized and specifically degrade, rather than reversibly exchange, nitrogen. For example, when leucine labeled with the stable isotopic tracer ^{15}N was infused into dogs for 9 hours, considerable amounts of ^{15}N were found in circulating glutamine, glutamate, alanine, the other two BCAAs, but not tyrosine ([18](#), [19](#)), indicating that the transamination of tyrosine was minimal.

Metabolic Pathway	Important Enzymes	Nitrogen End Products	Carbon End Products
<i>Amino acids converted to other amino acids</i>			
Asparagine	Asparaginase	Aspartate	+ NH_3
Glutamine	Glutaminase	Glutamate	+ NH_3
Arginine	Arginase	Ornithine	+ NH_3
Phenylalanine	Phenylalanine hydroxylase	Tyrosine	+ NH_3
Proline		Glutamate	
Cysteine		Sauren	
<i>Bidirectional transamination to form glutamate</i>			
Alanine		Glutamate	Pyruvate
Aspartate		Glutamate	Chondrochondrate
Leucine		Glutamate	Pteroyl
Isoleucine		Glutamate	Succinyl
Valine		Glutamate	Succinyl
Ornithine		β -Glutamyl	α -Ketoglutarate
Tyrosine		Glutamate	Relaxin + Formate
Cysteine		Glutamate	Pyruvate + SO_3^{2-}
<i>Other pathways</i>			
Serine	Serine dehydratase	NH_3	Pyruvate
Threonine	Serine dehydratase	NH_3	Acetylacetyl
Methionine	Methionine	NH_3	Homocysteine
Tryptophan		NH_3	Indole
Arginine		NH_3	CO_2
Glutamine		NH_3	Glutamate
Urea		β -Glutamyl	Acetate

Table 2.6 Pathways of Amino Acid Degradation

Another reason why the entries in [Table 2.6](#) do not show individual steps is that the specific metabolic pathways of all the amino acids are not clearly defined. For example, two pathways for cysteine are shown. Both are active, but how much cysteine is metabolized by which pathway is not as clear. Methionine is metabolized by conversion to homocysteine. The homocysteine is not directly converted to cysteine; rather, homocysteine condenses with a serine to form cystathionine, which is then split into

cysteine, ammonia, and ketobutyrate. However, the original methionine molecule appears as ammonia and ketobutyrate; the cysteine carbon skeleton comes from the serine. So the entry in [Table 2.6](#) shows methionine degraded to ammonia, yet this degradation pathway is the major synthetic pathway for cysteine. Because of the importance of the sulfur-containing amino acids ([20](#)), a more extensive discussion of the metabolic pathways of these amino acids may be found in [Chapter 27](#) and [Chapter 34](#).

Glycine is degraded by more than one possible pathway, depending upon the text you consult. However, the primary pathway appears to be the glycine cleavage enzyme system that breaks glycine into CO₂ and ammonia and transfers a methylene group to tetrahydrofolate ([21](#)). This is the predominant pathway in rat liver and in other vertebrate species ([22](#)). Although this reaction degrades glycine, its importance is the production of a methylene group that can be used in other metabolic reactions.

Synthesis of Nonessential Amino Acids

The essential amino acids are those that cannot be synthesized in sufficient amounts in the body and so must be supplied in the diet in sufficient amounts to meet the body's needs. Therefore, discussion of amino acid synthesis applies only to the nonessential amino acids. Nonessential amino acids fall into two groups on the basis of their synthesis: (a) amino acids that are synthesized by transferring a nitrogen to a carbon skeleton precursor that has come from the TCA cycle or from glycolysis of glucose and (b) amino acids synthesized specifically from other amino acids. Because this latter group of amino acids depends upon the availability of other specific amino acids, they are particularly vulnerable to becoming essential if the dietary supply of a precursor amino acid becomes limiting. In contrast, the former group is rarely rate limited in synthesis because of the ample precursor availability of carbon skeletons from the TCA cycle and from the labile amino-N pool of transaminating amino acids.

The pathways of nonessential amino acid synthesis are shown in [Figure 2.4](#). As with amino acid degradation, glutamate is central to the synthesis of several amino acids by providing the N. Glutamate, alanine, and aspartate may share amino-N transaminating back and forth among them ([Fig. 2.2](#)). As [Figure 2.4](#) is drawn, glutamate derives its N from ammonia with α -ketoglutarate, and that glutamate goes on to promote the synthesis of other amino acids. Under most circumstances, the transaminating amino acids shown in [Figure 2.2](#) supply more than adequate amino N to glutamate. The transaminating amino acids provide a buffer pool of N that can absorb an increase in N from increased degradation or supply N when there is a drain. From this pool, glutamate provides material to maintain synthesis of ornithine and proline, the latter particularly important in synthesis of collagen and related proteins.

Figure 2.4. Pathways of synthesis of nonessential amino acids. Glutamate is produced from ammonia and α-ketoglutarate. That glutamate becomes the N source added to carbon precursors (pyruvate, oxaloacetate, glycolysis products of glucose, and glycerol) to form most of the other nonessential amino acids. Cysteine and tyrosine are different in that they require essential amino acid input for their production.

Serine may be produced from hydroxypyruvate derived either from glycolysis of glucose or from glycerol. Serine may then be used to produce glycine through a process that transfers a methylene group to tetrahydrofolate. This pathway could (and probably should) have been listed in [Table 2.6](#) as a degradative pathway for serine. However, it is not usually considered an important means of degrading serine but as a source of glycine and one-carbon-unit generation ([21](#), [22](#)). On the other hand, the pathway backward from glycine to serine is also quite active in humans. When [¹⁵N]glycine is given orally, the primary transfer of ¹⁵N is to serine ([23](#)). Therefore, there is significant reverse synthesis of serine from glycine. The other major place where ¹⁵N appeared was in glutamate and glutamine, indicating that the ammonia released by glycine oxidation is immediately picked up and incorporated into glutamate and the transaminating-N pool.

All of the amino acids shown in [Figure 2.4](#) have *active* routes of synthesis in the body ([17](#)), in contrast to the essential amino acids for which no routes of synthesis exist in humans. This statement should be a simple definition of “essential” versus “nonessential.” However, in nutrition, we define a “nonessential” amino acid as an amino acid that is *dispensable* from the diet ([7](#)). This definition is different from defining the presence or absence of enzymatic pathways for an amino acid's synthesis. For example, two of the nonessential amino acids depend upon degradation of essential amino acids for their production: cysteine and tyrosine. Although serine provides the carbon skeleton and amino group of cysteine, methionine provides the sulfur through condensation of homocysteine and serine to form cystathionine ([20](#)). The above discussion explains why neither the carbon skeleton nor amino group of serine are likely to be in short supply, but provision of sulfur from methionine may become limiting. Therefore, cysteine synthesis depends heavily upon the availability of the essential amino acid methionine. The same is true for tyrosine. Tyrosine is produced by

hydroxylation of phenylalanine, which is also *the* degradative pathway of phenylalanine. The availability of tyrosine is strictly dependent upon the availability of phenylalanine and the liver's ability to perform the hydroxylation.

Incorporation of Amino Acids into Other Compounds

[Table 2.7](#) lists some of the important products made from amino acids, directly or in part. The list is not inclusive and is meant to highlight important compounds in the body that depend upon amino acids for their synthesis. Amino acids are also used for the synthesis of taurine ([20](#), [24](#), [25](#)), the “amino acid–like” 2-aminoethanesulfonate found in far higher concentrations inside skeletal muscle than any amino acid ([10](#)). Glutathione, another important sulfur-containing compound ([26](#), [27](#)), is composed of glycine, cysteine, and glutamate.

Amino Acid	Incorporated into
Arginine	Creatine
Aspartate	Purines and pyrimidines
Cysteine	Glutathione Taurine
Glutamate	Neurotransmitters
Glutamine	Purines and pyrimidines
Glycine	Creatine Porphyrins (hemoglobin and cytochromes) Purines
Histidine	Histamine
Lysine	Carnitine
Methionine	One-carbon methylation/transfer reactions Creatine Choline
Serine	One-carbon methylation/transfer reactions Ethanolamine and choline
Tyrosine	Neurotransmitters
Tryptophan	Neurotransmitters

Table 2.7 Important Products Synthesized from Amino Acids

Carnitine ([28](#), [29](#)) is important in the transport of long-chain fatty acids across the mitochondrial membrane before fatty acids can be oxidized. Carnitine is synthesized from *ε-N,N,N*-trimethyllysine (TML) ([30](#)). TML synthesis from free lysine has not been demonstrated in mammalian systems; rather TML appears to arise from methylation of peptide-linked lysine. The TML is released when proteins containing the TML are broken down ([30](#)). TML can also arise from hydrolysis of ingested meats. In contrast to 3-methylhistidine, TML can be found in proteins of both muscle and other organs such as liver ([31](#)). In rat muscle, TML is about one-eighth as abundant as 3-methylhistidine. Using comparisons of 3-methylhistidine to TML concentration in muscle protein and rates of 3-methylhistidine release in the rat ([32](#)), Rebouche estimated that protein breakdown in a rat would release about 2 μmol/day of TML, which could be used for the estimated 3 μmol/day of carnitine synthesized ([30](#)). These calculations suggest that carnitine requirements can be met from synthesis from TML from protein plus the carnitine from dietary intake.

Amino acids are the precursors for a variety of neurotransmitters that contain N.

Glutamate may be an exception in that it is both a precursor for neurotransmitter production and is a primary neurotransmitter itself (33). Glutamate appears important in a variety of neurologic disorders from amyotrophic lateral sclerosis to Alzheimer's disease (34). Tyrosine is the precursor for catecholamine synthesis. Tryptophan is the precursor for serotonin synthesis. A variety of studies have reported the importance of plasma concentrations of these and other amino acids upon the synthesis of their neurotransmitter products; most commonly cited relationship is the increase in brain serotonin levels with administration of tryptophan.

Creatine and Creatinine

Most of the creatine in the body is found in muscle, where it exists primarily as creatine phosphate. When muscular work is performed, creatine phosphate provides the energy through hydrolysis of its "high-energy" phosphate bond, forming creatine with transferal of the phosphate to form an ATP. The reaction is reversible and catalyzed by the enzyme ATP-creatine transphosphorylase (also known as creatine phosphokinase).

The original pathways of creatine synthesis from amino acid precursors were defined by Bloch and Schoenheimer in an elegant series of experiments using ¹⁵N-labeled compounds (35). Creatine is synthesized outside muscle in a two-step process (Fig. 2.5). The first step occurs in the kidney and involves transfer of the guanidino group of arginine onto the amino group of glycine to form ornithine and guanidinoacetate. Methylation of the guanidinoacetate occurs in the liver via S-adenosylmethionine to create creatine. Although glycine donates a nitrogen and carbon backbone to creatine, arginine must be available to provide the guanidino group, as well as methionine to donate the methyl group. Creatine is then transferred to muscle where it is phosphorylated. When creatine phosphate is hydrolyzed to creatine in muscle, most of the creatine is rephosphorylated when ATP requirements are reduced, to restore the creatine phosphate supply. However, some of the muscle creatine pool is continually dehydrated by a nonenzymatic process forming creatinine. Creatinine is not retained by muscle but is released into body water, removed by the kidney from blood, and excreted into urine (36).

Figure 2.5. Synthesis of creatine and creatinine. Creatine is synthesized in the liver from guanidinoacetic acid synthesized in the kidney. Creatine taken up by muscle is

primarily converted to phosphocreatine. Although there is some, limited direct dehydration of creatine directly to creatinine, most creatinine comes from dehydration of phosphocreatine. Creatinine is rapidly filtered by the kidney into urine.

The daily rate of creatinine formation is remarkably constant (»1.7% of the total creatine pool per day) and dependent upon the size of the creatine/creatine-phosphate pool, which is proportional to muscle mass (37). Thus, daily urinary output of creatinine has been used as a measure of total muscle mass in the body. Urinary creatinine excretion increases within a few days after a dietary creatine load, and several more days are required after removal of creatine from the diet before urinary creatinine excretion returns to baseline, indicating that creatine in the diet per se affects creatinine production (38). Therefore, consumption of creatine and creatinine in meat-containing foods increases urinary creatinine measurements. Although urinary creatinine measurements have been used primarily to estimate the adequacy of 24-hour urine collections, with adequate control of food composition and intake, creatinine excretion measurements are useful and accurate indices of body muscle mass (39, 40), especially when the alternatives are much more difficult and expensive radiometric approaches.

Purine and Pyrimidine Biosynthesis

The purines (adenine and guanine) and the pyrimidines (uracil and cytosine) are involved in many intracellular reactions when high-energy di- and triphosphates have been added. These compounds also form the building blocks of DNA and RNA. Purines are heterocyclic double-ring compounds synthesized with phosphoribosylpyrophosphate (PRPP) sugar as a base to which the amide N of glutamine is added, followed by attachment of a glycine molecule, a methylene group from tetrahydrofolate, and an amide N from another glutamine to form the imidazole ring. Then CO_2 is added, followed by the amino N of aspartic acid and another carbon to form the final ring to produce inosine monophosphate (IMP)—a purine attached to a ribose phosphate sugar. The other purines, adenine and guanine, are formed from inosine monophosphate by addition of a glutamine amide N or aspartate amino N to make guanosine monophosphate (GMP) or adenosine monophosphate (AMP), respectively. These compounds can be phosphorylated to high-energy di- and triphosphate forms: ADP, ATP, GDP, and GTP.

In contrast to purines, pyrimidines are not synthesized after attachment to a ribose sugar. The amide N of glutamine is condensed with CO_2 to form carbamoyl phosphate, which is further condensed with aspartic acid to make orotic acid—the pyrimidine's heterocyclic 6-member ring. The enzyme forming carbamoyl phosphate is present in many tissues for pyrimidine synthesis but is not the hepatic enzyme that makes urea (Fig. 2.3). However, a block in the urea cycle causing a lack of adequate amounts of arginine to prime the urea synthesis cycle in the liver will result in diversion of unused carbamoyl phosphate to orotic acid and pyrimidine synthesis (41). Uracil is synthesized as uridine monophosphate by forming orotidine monophosphate from orotic acid followed by decarboxylation. Cytosine is formed by adding the amide group of glutamine

to uridine triphosphate to form cytidine triphosphate.

TURNOVER OF PROTEINS IN THE BODY

As indicated above, proteins in the body are not static. Just as every protein is synthesized, it is also degraded. Schoenheimer and Rittenberg first applied isotopically labeled tracers to the study of amino acid metabolism and protein turnover in the 1930s and first suggested that proteins are continually made and degraded in the body at different rates. We now know that the rate of turnover of proteins varies widely and that the rate of turnover of individual proteins tends to follow their function in the body, i.e., proteins whose concentrations must be regulated (e.g., enzymes) or that act as signals (e.g., peptide hormones) have relatively high rates of synthesis and degradation as a means of regulating concentrations. On the other hand, structural proteins such as collagen and myofibrillar proteins or secreted plasma proteins have relatively long lifetimes. However, there must be an overall balance between synthesis and breakdown of proteins. Balance in healthy adults who are neither gaining nor losing weight means that the amount of N consumed as protein in the diet will match the amount of N lost in urine, feces, and other routes. However, considerably more protein is mobilized in the body every day than is consumed ([Fig. 2.6](#)).

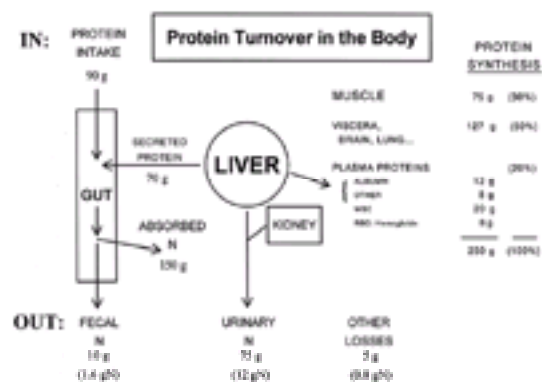

Figure 2.6. Relative rates of protein turnover and intake in a healthy 70-kg human. Under normal circumstances, dietary intake (IN = 90 g) matches N losses (OUT = 90 g). Protein breakdown then matches synthesis. Protein intake is only $90/(90 + 250) \approx 25\%$ of total turnover of N in the body per day. (Redrawn from Hellerstein MK, Munro HN. Interaction of liver and muscle in the regulation of metabolism in response to nutritional and other factors. In: Arias IM, Jakoby WB, Popper H, et al., eds. *The liver: biology and pathobiology*. 2nd ed. New York: Raven Press, 1988;965–83.)

Although there is no definable entity such as “whole-body protein,” the term is useful for understanding the amount of energy and resources spent in producing and breaking down protein in the body. Several methods using isotopically labeled tracers have been developed to quantitate the whole-body turnover of proteins. The concept and definition

of whole-body protein turnover and these methods have been the subject of entire books (e.g., [42]). An important point of [Figure 2.6](#) is that the overall turnover of protein in the body is several fold greater than the input of new dietary amino acids (43). A normal adult may consume 90 g of protein that is hydrolyzed and absorbed as free amino acids. Those amino acids mix with amino acids entering from protein breakdown from a variety of proteins. Approximately a third of the amino acids appear from the large, but slowly turning over, pool of muscle protein. In contrast, considerably more amino acids appear and disappear from proteins in the visceral and internal organs. These proteins make up a much smaller proportion of the total mass of protein in the body but have rapid synthesis and degradation rates. The overall result is that approximately 340 g of amino acids enter the free pool daily, of which only 90 g come from dietary amino acids. The question is how to assess the turnover of protein in the human body? As noted from [Figure 2.6](#), the issue quickly becomes complex. Much effort has been spent in devising methods to quantify various aspects of protein metabolism in humans in meaningful terms. The methods that have been developed and applied with success to date are listed in [Table 2.8](#). These methods, which range from simple and noninvasive to expensive and complicated, are described below.

-
- Nitrogen balance
 - Arteriovenous measurement of amino acids and/or tracer across a tissue bed
 - End-product method
 - Turnover of individual components:
 - Essential amino acids (index of protein breakdown)
 - Nonessential amino acids (de novo synthesis and gluconeogenesis)
 - Urea (amino acid oxidation)
 - Tracer into a specific protein to measure protein synthesis
 - Tracer out to a specific protein to measure protein degradation
-

Table 2.8 Methods of Measuring Protein Metabolism in Humans

METHODS OF MEASURING PROTEIN TURNOVER AND AMINO ACID KINETICS

Nitrogen Balance

The oldest (and most widely used) method of following changes in body N is the N balance method. Because of its simplicity, the N balance technique is the standard of reference for defining minimum levels of dietary protein and essential amino acid intakes in humans of all ages (44, 45). Subjects are placed for several days on a specific level of amino acid and/or protein intake and their urine and feces are collected over a 24-h period to measure their N excretion. A week or more may be required before collection reflects adaptation to a dietary change. A dramatic example of

adaption involves placing healthy subjects on a diet containing a minimal amount of protein. As shown in [Figure 2.7](#), urinary N excretion drops dramatically in response to the protein-deficient diet over the first 3 days and stabilizes at a new lower level of N excretion by day 8 ([46](#)).

Figure 2.7. Time required for urinary N excretion to stabilize after changing from an adequate to a deficient protein intake in young men. *Horizontal solid and broken lines* are mean \pm 1 standard deviation for N excretion at the end of the measurement period. (Data from NS Scrimshaw, Hussein MA, Murray E, et al., J Nutr 1972;102:1595–604.)

The N end-products excreted in the urine are not only end products of amino acid oxidation (urea and ammonia) but also other species such as uric acid from nucleotide degradation and creatinine ([Table 2.9](#)). Fortunately, most of the nonurea, nonammonia N is relatively constant over a variety of situations and is a relatively small proportion of the total N in the urine. Most of the N is excreted as urea, but ammonia N excretion increases significantly when subjects become acidotic, as is apparent in [Table 2.9](#) when subjects have fasted for 2 days ([47](#)). [Table 2.9](#) also illustrates how urea production is related to N intake and how the body adapts its oxidation of amino acids to follow amino acid supply (i.e., with ample supply, excess amino acids are oxidized and urea production is high, but with insufficient dietary amino acids, amino acids are conserved and urea production is greatly decreased).

N Species	Low-Protein Diet		
	High-Protein Diet	(g N/day)	Fasting (day 2)
Urea	14.7 (87%)	2.2 (61%)	6.6 (75%)
Ammonia	0.5 (3%)	0.4 (11%)	1.0 (12%)
Uric acid	0.2 (1%)	0.1 (3%)	0.2 (2%)
Creatinine	0.6 (4%)	0.6 (17%)	0.4 (5%)
Undetermined	<u>0.8 (5%)</u>	<u>0.3 (8%)</u>	<u>0.5 (6%)</u>
Total	16.8 (100%)	3.6 (100%)	8.7 (100%)

Data compiled from reports by Folin (1905) and Cathcart (1907) cited in ref. 47.

Table 2.9 Composition of the Major Nitrogen-Containing Species in Urine

Nitrogen appears in the feces because the gut does not completely absorb all dietary protein and reabsorb all N secreted into the gastrointestinal tract (Fig. 2.6). In addition, N is lost from skin via sweat as well as via shedding of dead skin cells. There are also additional losses through hair, menstrual fluid, nasal secretions, and so forth. As N excretion in the urine decreases in the case of subjects on a minimal-protein diet (Fig. 2.7), it becomes increasingly important to account for N losses through nonurinary, nonfecal routes (48). The loss of N by these various routes is shown in Table 2.10. Most of the losses that are not readily measurable are minimal (<10% of total N loss under conditions of a protein-free diet when adaptation has greatly reduced urinary N excretion) and can be discounted by use of a simple offset factor for nonurinary, nonfecal N losses. The assessment of losses comes into play in the finer definition of zero balance as a function of dietary protein intake for the purpose of determining amino acid and protein requirements. As we shall see below, small changes in N balance corrections make significant changes in the assessment of protein requirements using N balance.

	Daily Nitrogen Loss	
	As Nitrogen (mg N/kg/day)	As Protein Equivalent (g protein/kg/day)
Urine	37	0.23
Feces	12	0.08
Cutaneous	3	0.02
Other	<u>2</u>	<u>0.01</u>
Total	54	0.34
Upper limit (+2 standard deviations)	70	0.44

Table 2.10 Obligatory Nitrogen Losses by Adult Men on a Protein-Free Diet

Although the N balance technique is very useful and easy to apply, it provides no information about the inner workings of the system. An interesting analogy for the N balance technique is illustrated in [Figure 2.8](#) where the simple model of N balance is represented by a gumball machine. Balance is taken between “coins in” and “gumballs out.” However, we should not conclude that the machine turns coins into gum, although that conclusion is easy to reach with the N balance method. What the N balance technique fails to provide is information about what occurs *within* the system (i.e., inside the gumball machine). Inside the system is where the changes in whole-body protein synthesis and breakdown actually occur (shown as the smaller arrows into and out of the *Body N Pool* in [Fig. 2.8](#)). A further illustration of this point is made at the bottom of [Figure 2.8](#) where a positive increase in N balance has been observed going from zero (case 0) to positive balance (cases A–D). A positive N balance could be obtained with identical increases in N balance by any of four different alterations in protein synthesis and breakdown: a simple increase in protein synthesis (case A), a decrease in protein breakdown (case C), an increase in both protein synthesis and breakdown (case B), or a decrease in both (case D). The effect is the same positive N balance for all four cases, but the energy implications are considerably different. Because protein synthesis costs energy, cases A and B are more expensive, while cases C and D require less energy than the starting case, 0. To resolve these four cases, we have to look directly at rates of protein turnover (breakdown and synthesis) using a labeled tracer.

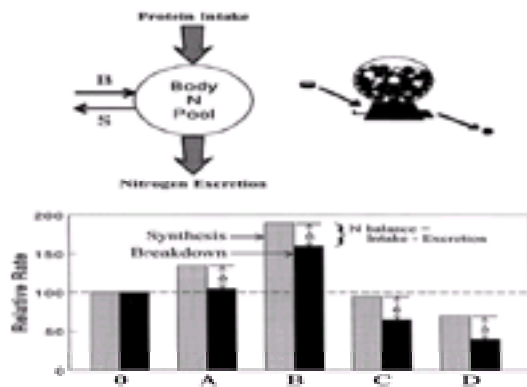

Figure 2.8. Illustration of the N balance technique. Nitrogen balance is simply the difference between input and output, which is similar to the introduction of a coin into a gumball machine resulting in a gumball being released. The perception of only the “in” and “out” observations is that the machine changed the coin directly into a gumball or that the dietary intake becomes directly the N excreted without consideration of amino acid entry from protein breakdown (B) or uptake for protein synthesis (S). This point is further illustrated with four different hypothetical responses to a change from a zero N balance (case 0) to a positive N balance (cases A–D). A positive N balance can be obtained by increasing protein synthesis (A), by increasing synthesis more than breakdown (B), by decreasing breakdown (C), or by decreasing breakdown more than synthesis (D). The N balance method does not distinguish among the four possibilities.

Using Arteriovenous Differences to Define Organ Balances

Just as the N balance technique can be applied across the whole body, so can the balance technique be applied across a whole organ or tissue bed. These measurements are made from the blood delivered to the tissue and from the blood emerging from the tissue via catheters placed in an artery to define arterial blood levels and the vein draining the tissue to measure venous blood levels. The latter catheter makes the procedure particularly invasive when applied to organs such as gut, liver, kidney, or brain ([49](#), [50](#), [51](#) and [52](#)). Less invasive are measures of muscle metabolism inferred from measurement of arteriovenous (A-V) differences across the leg or arm ([51](#)). Measurements have even been made across fat depots ([53](#)). However, the A-V difference provides no information about the mechanism in the tissue that causes the uptake or release that is observed. More information is gleaned from measurement of amino acids that are not metabolized within the tissue, such as the release of essential amino acids tyrosine or lysine, which are not metabolized by muscle. Their A-V differences across muscle should reflect the difference between net amino acid uptake for muscle protein synthesis and release from muscle protein breakdown. 3-Methylhistidine, an amino acid produced by posttranslational methylation of selected histidine residues in myofibrillar protein, which cannot be reused for protein synthesis when it is released from myofibrillar protein breakdown, is quantitatively released from muscle tissue when myofibrillar protein is degraded ([32](#), [54](#)). Its A-V difference can be used as a specific marker of myofibrillar protein breakdown ([55](#), [56](#) and [57](#)).

The limited data set of simple balance values across an organ bed is greatly enhanced when a tracer is administered and its balance is also measured across an organ bed. This approach allows a complete solution of the various pathways operating in the tissue for each amino acid tracer used. In some cases the measurement of tracer can become very complicated, requiring measurement of multiple metabolites to provide a true metabolite balance across the organ bed ([58](#)). Another approach using a tracer of a nonmetabolized essential amino acid has been described by Barrett et al. ([59](#)). This method requires a limited set of measurements with simplified equations to define specifically rates of protein synthesis and breakdown in muscle tissue. The conceptual simplicity of this approach with a limited set of measurements required makes it extremely useful for defining muscle-specific changes in response to a variety of perturbations (e.g., local infusion of insulin into the same muscle bed [[60](#)]). This approach has been expanded by others ([61](#), [62](#) and [63](#)).

Tracer Methods Defining Amino Acid Kinetics

Isotopically labeled tracers are used to follow flows of *endogenous* metabolites in the body. The labeled tracers are identical to the endogenous metabolites in terms of chemical structure with substitution of one or more atoms with isotopes different from those usually present. The isotopes are substituted to make the tracers distinguishable (measurable) from the normal metabolites. We usually think first of the radioactive isotopes (e.g., ^3H for hydrogen and ^{14}C for carbon) as tracers that can be measured by

the particles they emit when they decay, but there are also non-radioactive, stable isotopes that can be used. Because isotopes of the same atom only differ in the number of neutrons that are contained, they can be distinguished in a compound by mass spectrometry, which determines the abundance of compounds by mass. Most of the lighter elements have one *abundant* stable isotope and one or two isotopes of higher mass of *minor abundance*. The major and minor isotopes are ^1H and ^2H for hydrogen, ^{14}N and ^{15}N for nitrogen, ^{12}C and ^{13}C for carbon, and ^{16}O , ^{17}O , and ^{18}O for oxygen. Except for some isotope effects, which can be significant for both the radioactive (^3H) and nonradioactive (^2H) hydrogen isotopes, a compound that is isotopically labeled is essentially indistinguishable from the corresponding unlabeled endogenous compound in the body. Because they do not exist in nature and so little of the radioactive material is administered, radioisotopes are considered “weightless” tracers that do not add material to the system. Radioactive tracer data are expressed as counts or disintegrations per minute per unit compound. Because the stable isotopes are naturally occurring (e.g., »1% of all carbon in the body is ^{13}C), the stable isotope tracers are administered and measured as the “excess above the naturally occurring abundance” of the isotope in the body as either the *mole ratio* of the amount of tracer isotope divided by the amount of unlabeled material or the *mole fraction* (usually expressed as a percentage: *mole % excess* or *atom % excess*, the latter being an older, less appropriate term in the literature) (64).

The basis of most tracer measurements to determine amino acid kinetics is the simple concept of tracer dilution. This concept is illustrated in [Figure 2.9](#) for the determination of the flow of water in a stream. If you infuse a dye of known concentration (enrichment) into the stream, go downstream after the dye has mixed well with the stream water, and take a sample of the dye, then you can calculate from the measured dilution of the dye the rate at which water must be flowing in the stream to make that dilution. The necessary information required is infusion rate of dye (tracer infusion rate) and measured concentration of the dye (enrichment or specific activity of the tracer). The calculated value is the flow of water through the stream (flux of unlabeled metabolite) causing the dilution. This simple dye-dilution analogy is the basis for almost all kinetic calculations in a wide range of formats for a wide range of applications. A few of the more important approaches are discussed below.

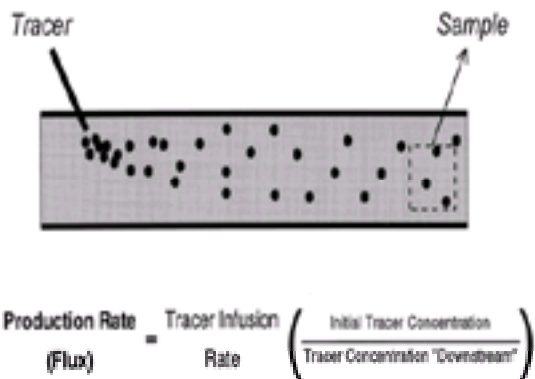

Figure 2.9. Basic principal of the “dye-dilution” method of determining tracer kinetics.

Models for Whole-Body Amino Acid and Protein Metabolism

The limitations to using tracers to define amino acid and protein metabolism are largely driven by how the tracer is administered and where it is sampled. The simplest method of tracer administration is orally, but intravenous administration is preferred to deliver the tracer *systemically* (to the whole body) into the free pool of amino acids. The simplest site of sampling of the tracer dilution is also from the free pool of amino acids via blood. Therefore, most approaches to measuring amino acid and protein kinetics in the whole body using amino acid tracers assume a single, free pool of amino N, as shown in [Figure 2.10](#). Amino acids enter the free pool from dietary amino acid intake (enteral or parenteral) and by amino acids released from protein breakdown. Amino acids leave the free pool by amino acid oxidation to end products (CO_2 , urea, and ammonia) and from amino acid uptake for protein synthesis. The free amino acid pool can be viewed from the standpoint of all of the amino acids together (as discussed for the end-product method) or from the viewpoint of a single amino acid and its metabolism per se. The model in [Figure 2.10](#) is called a “single-pool model” because protein is not viewed as a pool per se, but rather as a source of entry of unlabeled amino acids into the free pool, on the one hand, and a route of amino acid removal for protein synthesis on the other. Only a small portion of the proteins in the body are assumed to turn over during the time course of the experiment. Obviously, these assumptions are not true: many proteins in the body are turning over rapidly (e.g., most enzymes). Proteins that do turn over during the time course of the experiment will become labeled and appear as part of the free amino acid pool. However, these proteins make up only a fraction of the total protein; the remainder turn over slowly (e.g., muscle protein). Most amino acids entering via protein breakdown and leaving for new protein synthesis are coming from slowly turning over proteins. These flows are the *B* and *S* arrows of the traditional single-pool model of whole-body protein metabolism shown in [Figure 2.10](#).

Figure 2.10. Single-pool model of whole-body protein metabolism measured with a labeled amino acid tracer. Amino acid enters the free pool from dietary intake (*I*) and amino acid released from protein breakdown (*B*) and leaves the free pool via amino acid oxidation (*C*) to urea, ammonia, and CO₂ and uptake for protein synthesis (*S*).

End-Product Approach

The earliest model of whole-body protein metabolism in humans was applied by San Pietro and Rittenberg in 1953 using [¹⁵N]glycine (65). Glycine was used as the first tracer because glycine is the only amino acid without an optically active α -carbon center and therefore is easy to synthesize with a ¹⁵N label. At that time, measurement of the tracer in plasma glycine was very difficult. Thus, San Pietro and Rittenberg proposed a model based upon something that could be readily measured, urinary urea and ammonia. The assumption was that the urinary N end-products reflected the average enrichment in ¹⁵N of all of the free amino acids being oxidized. Although glycine ¹⁵N was the tracer, the tracee was assumed to be *all* free amino acids (assumed to be a single pool). However, it quickly became obvious that the system was more complicated and that a more complicated model and solution were required.

In essence, the method languished until 1969, when Picou and Taylor-Roberts (66) proposed a simpler method that also followed the glycine ¹⁵N tracer into urinary N. Their method dealt only with the effect of the dilution of the ¹⁵N tracer in the free amino acid pool as a whole, rather than invoking solution of tracer-specific equations of a specific model. Their assumptions were similar to those of the earlier Rittenberg approach in that they assumed that the ¹⁵N tracer mixes (scatters) among the free amino acids in some distribution that is not required to be known but that represents amino acid metabolism per se. This distribution of ¹⁵N tracer could be measured in the end products of amino acid metabolism, urea and ammonia. These assumptions allow the model to become “fuzzy” as shown in Figure 2.11, in that an explicit definition of the inner workings is not required. The [¹⁵N]glycine tracer is administered (usually orally), and urine samples are obtained to measure the ¹⁵N dilution in the free amino acid pool (67). The ¹⁵N in the free amino acid pool is diluted with unlabeled amino acid entering from protein breakdown and from dietary intake. The turnover of the free pool (*Q*, typically expressed as mg N/kg/day) is calculated from the measured dilution of ¹⁵N in the end products via the same approach illustrated in Figure 2.9:

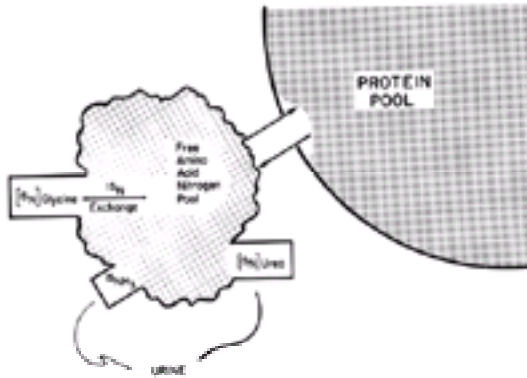

Figure 2.11. Model for measurement of protein turnover using [^{15}N]glycine as the tracer and measurement of the dilution of the ^{15}N tracer in urinary endproducts, urea and ammonia. (From Bier DM, Matthews DE. Fed Proc 1982;41:2679–85, with permission.)

$$Q = i/E_{UN}$$

where i is the rate of [^{15}N]glycine infusion (mg ^{15}N /kg/day), and E_{UN} is the ^{15}N enrichment in atom % excess ^{15}N in urinary N (urea and/or ammonia). The free pool is assumed to be in steady state (neither increasing or decreasing over time), and therefore, the turnover of amino acid will be equal to the rate of amino acids entering via whole-body protein breakdown (B) and dietary intake (I) and also equal to the rate of amino acids leaving via uptake for protein synthesis (S) and via amino acid oxidation to the end products urea and ammonia (C):

$$Q = I + B = C + S$$

Because dietary intake should be known and urinary N excretion is measured, the rate of whole-body protein breakdown can be determined: $B = Q - I$, as well as the rate of whole-body synthesis: $S = Q - C$. In these calculations, the standard value of 6.25 g protein = 1 g N is used to interconvert protein and urinary N. Attention to the units (g of protein vs. g of N) is important, as both units are often used concurrently in the same report.

Occasionally in the literature a term called “net protein balance” or “net protein gain” appears in papers. Net protein balance is defined as the difference between the measured protein synthesis and breakdown rates ($S - B$), which can be determined from whole-body protein breakdown and synthesis measured as shown above. However, as can be seen by rearranging the balance equation for Q above: $S - B = I - C$, which is simply the difference between intake and excretion, i.e., nitrogen balance. The $S - B$ term is a misnomer, in that it is based solely upon the N balance measurement, not upon the administration of the ^{15}N tracer.

There is no question that the end-product method of Picou and Taylor-Roberts is a

cornerstone method for protein metabolic research in humans and is especially well suited for studies of infants and children because it is noninvasive, requiring only oral administration of tracer and collection only of urine. However, the end-product method is not without its problems; the most serious of which are mentioned below.

When the [¹⁵N]glycine tracer is given orally at short intervals (e.g., every 3 h) the time required to reach a plateau in urinary urea ¹⁵N is about 60 h regardless of whether adults (23, 68), children, or infants (69, 70) are studied. The delay in attaining a plateau is due to the time required for the ¹⁵N tracer to equilibrate within the free glycine, serine, and urea pools (23, 67). An additional problem is plateau definition. Often the urinary urea ¹⁵N time course does not show by either visual inspection or curve-fitting regression the anticipated single exponential rise to plateau. To avoid this problem, Waterlow et al. (71) suggested measuring the ¹⁵N in ammonia after a *single dose* of [¹⁵N]glycine. The advantage is that the ¹⁵N tracer passes through the body ammonia pool within 24 hours. Tracer administration and urine collection are greatly simplified, and the modification does not depend on defining a plateau in urinary urea ¹⁵N. The caveat here is the dependence of the single-dose end-product method upon *ammonia* metabolism. Urinary ammonia ¹⁵N enrichment usually differs from urinary urea ¹⁵N enrichment (72) because the amino-¹⁵N precursor for ammonia synthesis is of renal origin, while the amino-¹⁵N precursor for urea synthesis is of hepatic origin. Which enrichment should be used? Probably the urea ¹⁵N, but it is difficult to prove either way (42).

The primary difficulty with the end-product method is highlighted from a report in which several different ¹⁵N-labeled amino acid tracers, including ¹⁵N-glycine and some ¹⁵N-labeled proteins, were compared as tracers for the end-product method. Widely divergent results were determined for protein turnover (from 2.6 to 17.8 g/kg/day), depending upon the ¹⁵N label administered (73). The differences reflect differences in the metabolism and distribution of the ¹⁵N label when placed into different amino acids and illustrate how dependent the end-product approach is on the metabolism of the amino acid tracer. Therefore, it is difficult to determine whether a change in end-product ¹⁵N enrichment may be attributable either to a change in protein turnover *or* to a change in the distribution of ¹⁵N due to changes in tracer metabolism *that may be independent* of changes in protein metabolism. To make these distinctions, the kinetics of the amino acid tracer in the body must be measured as well.

Measurement of the Kinetics of Individual Amino Acids

As an alternative to measuring the turnover of the whole amino-N pool per se, the kinetics of an individual amino acid can be followed from the dilution of an infused tracer of that amino acid. The simplest models consider only essential amino acids that have no de novo synthesis. The kinetics of essential amino acids mimic the kinetics of protein turnover as shown in Figure 2.10. The same type of model can be constructed but cast specifically in terms of a single essential amino acid, and the same steady-state balance equation can be defined:

$$Q_{aa} = I_{aa} + B_{aa} = C_{aa} + S_{aa}$$

where Q_{aa} is the turnover rate (or flux) of the essential amino acid, I_{aa} is the rate at which the amino acid is entering the free pool from dietary intake, B_{aa} is the rate of amino acid entry from protein breakdown, C_{aa} is the rate of amino acid oxidation, and S_{aa} is the rate of amino acid uptake for protein synthesis. The most common method for defining amino acid kinetics has been a primed infusion of an amino acid tracer until isotopic steady state (constant dilution) is reached in blood. The flux for the amino acid is measured from the dilution of the tracer in the free pool. Knowing the tracer enrichment and infusion rate and measuring the tracer dilution in blood samples taken at plateau, the rate of unlabeled metabolite appearance is determined (64, 74, 75):

$$Q_{aa} = I_{aa} \cdot (E_i/E_p - 1)$$

where I_{aa} is the infusion rate of tracer with enrichment E_i (mole % excess) and E_p is the blood amino acid enrichment.

For a carbon-labeled tracer, the amino acid oxidation rate can be measured from the rate of $^{13}\text{CO}_2$ or $^{14}\text{CO}_2$ excretion (42, 64, 74). The choice of a carbon label that is quantitatively oxidized is critical. For example, the ^{13}C of an L-[1- ^{13}C]leucine tracer is quantitatively released at the first irreversible step of leucine catabolism. In contrast, a ^{13}C -label in the leucine tail will end up in acetoacetate or acetyl-CoA, which may or may not be quantitatively oxidized. Other amino acids, such as lysine, have even more nebulous oxidation pathways.

Before the oxidized carbon-label is recovered in exhaled air, it must pass through the body bicarbonate pool. Therefore, information about body bicarbonate kinetics is required (76). To complete the oxidation rate calculation based upon the measured recovery of the administered carbon-label as CO_2 , we must know what fraction of bicarbonate pool turnover is the release of CO_2 into exhaled air versus retention for alternative fates in the body. In general only about 80% of the bicarbonate produced is released immediately as expired CO_2 , as determined from infusion of labeled bicarbonate and measurement of the fraction infused that is recovered in exhaled CO_2 (77). The other approximately 20% is retained in bone and metabolic pathways that “fix” carbon. The amount of bicarbonate retained is somewhat variable (ranging from 0 to 40% of its production) and needs to be determined when different metabolic situations are investigated. In cases in which the retention of bicarbonate in the body may change with metabolic perturbation, parallel studies measuring the recovery of an administered dose of ^{13}C - or ^{14}C -labeled bicarbonate are essential to interpretation of the oxidation results (78, 79).

The rate of amino acid release from protein breakdown and uptake for protein synthesis is calculated by subtracting dietary intake and oxidation from the flux of an essential amino acid—just as is done with the end-product method. The primary distinction is that the measurements are specific to a single amino acid's kinetics (μmol of amino acid per unit time) rather than in terms of N per se. Flux components can be extrapolated to

whole-body protein kinetics by dividing the amino acid rates by the assumed concentration of the amino acid in body protein (as shown in [Table 2.3](#)).

The principal advantages to measuring the kinetics of an individual metabolite are that (a) the results are specific to *that* metabolite, improving the confidence of the measurement, and (b) the measurements can be performed quickly because turnover time of the free pool is usually rapid (a tracer infusion study can be completed in less than 4 hours using a priming dose to reduce the time required to come to isotopic steady state). Drawbacks to measuring the kinetics of an individual amino acid are that (a) an appropriately labeled tracer may not be available to follow the pathways of the amino acid being studied, especially with regard to amino acid oxidation, and (b) metabolism of amino acids occurs within cells, but the tracers are typically administered into and sampled from the blood outside cells. Amino acids do not freely pass through cells; they are transported. For the neutral amino acids (leucine, isoleucine, valine, phenylalanine, and tyrosine), transport in and out of cells may be rapid, and only a small concentration gradient between plasma and intracellular milieu exists ([Table 2.4](#)). However, even that small gradient limits exchange of intracellular and extracellular amino acids. For leucine, this phenomenon can be defined using α -ketoisocaproate (KIC), which is formed from leucine inside cells by transamination. Some of the KIC formed is then decarboxylated, but most of it is either reaminated to reform leucine ([80](#)) or released from cells into plasma. Thus, plasma KIC enrichment can be used as a marker of intracellular leucine enrichment from which it came ([81](#)).

Previous workers have shown that generally, plasma KIC enrichment is about 25% lower than plasma leucine enrichment ([75](#), [81](#), [82](#)). If plasma KIC enrichment is substituted for the plasma leucine tracer enrichment in the calculation of leucine kinetics, then the measured leucine flux and oxidation and, likewise, estimates of protein breakdown and synthesis are increased by about 25%. However, when protein metabolism is studied under two different conditions and the resulting leucine kinetics are compared, the same relative response is obtained regardless of whether leucine or KIC enrichment is used for the calculation of kinetics ([81](#)). The prudent approach is to measure both species and to note occasions when the KIC/leucine enrichment ratio has changed, to signal a possible change in the partitioning of amino acids between intracellular and extracellular spaces ([83](#)).

Use of KIC to represent intracellular leucine is an application of a *concept* that adds definition to the model shown in [Figure 2.12](#) but does not require a more rigorous *model* to describe leucine kinetics. Because of confusion over a suitable model to describe leucine kinetics, a series of experiments were performed to develop a true multicompartmental model for the leucine-KIC system ([84](#)). Four leucine and three KIC pools were required to account for leucine kinetics. Clearly the kinetics of individual metabolites are far more complex than one- or two-compartment models. However, the conventional model using KIC as the precursor enrichment for calculating leucine kinetics as shown in [Figure 2.12](#) agreed well with the multi-compartmental model, which means that under many metabolic circumstances, the simpler approaches should accurately follow directional changes without requiring introduction of complicated compartmental models. These and intermediate models have been reviewed ([75](#), [85](#)), and the various assumptions, limitations, strengths, and weaknesses have been discussed. The leucine/KIC tracer system remains the single most applied measure of

whole-body amino acid kinetics used to reflect changes in protein metabolism (83).

Figure 2.12. Two-pool model of leucine kinetics. The leucine tracer is administered to the plasma pool (*large arrow*) and sampled from plasma and/or from exhaled CO_2 (*circles with sticks*). Plasma leucine exchanges with intracellular leucine where metabolism occurs: uptake for protein synthesis (*S*) or conversion to a-ketoisocaproate (*KIC*). Oxidation (*C*) occurs from KIC. Unlabeled leucine enters into the free pool via dietary intake (*I*) or protein breakdown (*B*) into intracellular pools.

Most amino acids do not have a convenient metabolite that can be readily measured in plasma to define aspects of their intracellular metabolism, but an intracellular marker for leucine does not necessarily authenticate leucine as the tracer for defining whole-body protein metabolism. A variety of investigators have measured the turnover rate of many of the amino acids, both essential and nonessential, in humans, to define aspects of the metabolism of these amino acids. The general trend of these amino acid kinetic data has been reviewed by Bier (75). The fluxes of essential amino acids should represent their release rates from whole-body protein breakdown for postabsorptive humans in whom there is no dietary intake. Therefore, if the Waterlow model of Figure 2.10 is a reasonable representation of whole-body protein turnover, the individual rates of essential amino acid turnover should be proportional to each amino acid's content in body protein, and a linear relationship of amino acid flux and amino acid abundance in body protein should exist. That relationship is shown in Figure 2.13 for data gleaned from a variety of studies in humans measured in the postabsorptive state (without dietary intake during the infusion studies) previously consuming diets of adequate N and energy intake. Amino acid flux is correlated with amino acid composition in protein across a variety of amino acid tracers and studies. This correlation suggests that even if there are problems in defining intracellular/extracellular concentration gradients of tracers to assess true intracellular events, changes in fluxes measured for the various essential amino acids reflect changes in breakdown in general.

Figure 2.13. Fluxes of individual amino acids measured in postabsorptive humans are plotted against amino acid concentration in protein. *Closed circles* represent nonessential amino acids, and *open circles* represent essential amino acids. The *regression line* is for the flux of the essential amino acids versus their content in protein. *Error bars* represent the range of reported values that were taken from various reports in the literature of studies of amino acid kinetics in healthy humans eating adequate diets of N and energy intake studied in the postabsorptive state. The amino acid content of protein data are taken for muscle values from [Table 2.3](#). The regression line slope of 4.1 g protein/kg/day is similar to other estimates of whole body protein turnover. (Redrawn from Bier DM. *Diabetes Metab Rev* 1989;5:111–32, with additional data added.)

Because nonessential amino acids are synthesized in the body, their fluxes are expected to exceed their expected flux based upon the regression line in [Figure 2.13](#) by the amount of de novo synthesis that occurs. Because de novo synthesis and disposal of the nonessential amino acids would be expected to be based upon the metabolic pathways of individual amino acids, the degree to which individual nonessential amino acids lie above the line should also vary. For example, tyrosine is a nonessential amino acid because it is made by hydroxylation of phenylalanine, which is also the pathway of phenylalanine disposal. The rate of tyrosine de novo synthesis is the rate of phenylalanine disposal. In the postabsorptive state, 10 to 20% of an essential amino acid's turnover goes to oxidative disposal. For phenylalanine, with a flux of about 40 $\mu\text{mol/kg/h}$, phenylalanine disposal produces about 6 $\mu\text{mol/kg/h}$ of tyrosine. We would predict from the tyrosine content of body protein that tyrosine release from protein breakdown would be 21 $\mu\text{mol/kg/h}$ and that the flux of tyrosine (tyrosine release from protein breakdown plus tyrosine production from phenylalanine) would be $21 + 6 = 27$ $\mu\text{mol/kg/h}$. The measured tyrosine flux approximates this prediction ([Fig. 2.13](#)) (86).

Compared with tyrosine, which has a de novo synthesis component limited by phenylalanine oxidation, most nonessential amino acids have very large de novo synthesis components because of the metabolic pathways they are involved in. For example, arginine is at the center of the urea cycle ([Fig. 2.3](#)). Normal synthesis for urea is 8–12 g of N per day. That amount of urea production translates into an arginine de novo synthesis of approximately 250 $\mu\text{mol/kg/h}$, which is four times the expected 60

$\mu\text{mol/kg/h}$ of arginine released from protein breakdown. As can be seen in [Figure 2.13](#), however, the *measured* arginine flux approximates the arginine release from protein breakdown (87). The large *de novo* synthesis component does not exist in the measured flux. The explanation for this low flux is that the arginine involved in urea synthesis is very highly compartmentalized in the liver, and this arginine does not exchange with the tracer arginine infused intravenously.

Similar disparities are seen between the measured fluxes of glutamine and glutamate determined with intravenously infused tracers and their anticipated fluxes from their expected *de novo* synthesis components. The predicted flux for glutamate should include transamination with the BCAAs, alanine, and aspartate, as well as glutamate's contribution to the production and degradation of glutamine. However, the glutamate flux measured in postabsorptive adult subjects infused with $[^{15}\text{N}]$ glutamate is $80 \mu\text{mol/kg/h}$, barely above the anticipated rate of glutamate release from protein breakdown ([Fig. 2.13](#)). The size of the free glutamate pool was also determined in this study from the tracer dilution. The tracer-determined pool of glutamate was very small and approximated only the pool size predicted for extracellular water. The much larger intracellular pool that exists in muscle ([Table 2.4](#)) was not seen with the intravenously administered tracer. The flux measured for glutamine is considerably larger ($350 \mu\text{mol/kg/h}$), reflecting a large *de novo* synthesis component ([Fig. 2.13](#)). However, the pool size determined with the $[^{15}\text{N}]$ glutamine tracer also was small—not much larger than glutamine in extracellular water. The large intracellular-muscle free pool of glutamine was not found (88). The results of this study showed that glutamine and glutamate tracers administered intravenously define pools of glutamine and glutamate that reflect primarily extracellular free glutamine and glutamate. The large intracellular pools (especially those in muscle) are tightly compartmentalized and do not readily mix with extracellular glutamine and glutamate. Intracellular events such as glutamate transamination are not detected by the glutamate tracer. The same is true of the glutamine tracer. However, the prominent role of glutamine in the body is *interorgan transport*, i.e., production by muscle and release for use by other tissues (89, 90), and that event is measured by the glutamine tracer (as is obvious from [Fig. 2.13](#) in which the tracer-determined glutamine flux shows the highest measured flux of any amino acid).

The model in [Figure 2.10](#) does not consider the potential first-pass effect that the splanchnic bed (gut and liver) has on regulating the delivery of nutrients from the oral route. Under normal circumstances, the amino acid tracer is infused intravenously to measure whole-body systemic kinetics. However, enterally delivered amino acids pass through the gut and liver before entering the systemic circulation. Any metabolism of these amino acids by gut or liver on the first pass during absorption will not be “seen” by an intravenously infused tracer in terms of systemic kinetics. Therefore, another pool with a second arrow showing the first-pass removal by gut and liver should precede the input arrow for I ([Fig. 2.14](#)) to indicate the role of the splanchnic bed. A fraction f of the dietary intake ($I \cdot f$) is sequestered on the first-pass, and only $I \cdot (1 - f)$ enters the systemic circulation.

Figure 2.14. Model of whole-body protein metabolism for the fed state when first-pass uptake of dietary intake is considered. A labeled amino acid tracer is administered by the gastrointestinal route (i_g) to follow dietary amino acid intake (I). The fraction of dietary amino acid sequestered on first pass by the splanchnic bed (f) can be determined by administering the tracer by both the gastrointestinal and the intravenous routes (i_{iv}) and comparing the enrichments in blood for the two tracers (E_g and E_{iv} , respectively).

There are two ways to address this problem. The first does not evaluate the fraction sequestered explicitly but builds the tracer administration scheme into the first-pass losses. One simply adds the amino acid tracer to the dietary intake so that the tracer administration is the oral route (i_g) and enrichments in blood (E_g) come after any first-pass metabolism by the splanchnic bed (91, 92). This approach is especially useful for studying the effect of varying levels of amino acid intake, but it does not evaluate per se the amount of material sequestered by the splanchnic bed.

The second approach applies the tracer by both the intravenous route and the enteral route. The intravenous tracer infusion (i_{iv}) and plasma enrichment (E_{iv}) are used to determine systemic kinetics, and the enteral tracer infusion and its plasma enrichment determine systemic kinetics plus the effect of the first pass. By difference, the fraction, f , is readily calculated (93). This approach can be applied even in the postabsorptive state to determine basal uptake of amino acid tracers by the splanchnic bed. As shown in Table 2.11, a number of amino acids have been studied, and first-pass fractional uptake values for these different amino acids have been determined (93, 94, 95, 96, 97, 98, 99, 100 and 101). In general, the splanchnic bed removes less of the essential amino acids but more than half of the nonessential amino acids on the first-pass—especially glutamate, which is almost entirely removed.

Amino Acid	Fraction Sequestered (f, %)	Reference
Leucine	17-21	(93, 94)
Phenylalanine	29-78	(93-95)
Alanine	70	(96)
Arginine	31-49	(97)
Glutamate	88-96	(98,99)
Glutamine	54-74	(98,100)
α -Ketoglutarate	25-32	(101)

Table 2.11 First-Pass Sequestration of Enteral Amino and Keto Acid Tracers by the Gut and Liver in Humans

Synthesis of Specific Proteins

The above methods deal with measurements at the whole-body level but do not address specific proteins and their rates of synthesis and degradation. To do so requires obtaining samples of the proteins for purification. Some proteins are readily sampled (e.g., proteins in blood such as the lipoproteins, albumin, fibrinogen, and other secreted proteins). Other proteins require tissue sampling (e.g., muscle biopsy). If a protein (or group of proteins) can be sampled and purified, then its (their) synthetic rate can be determined directly from the rate of tracer incorporation. Proteins that turn over slowly (e.g., muscle protein or albumin) incorporate only a small amount of tracer during a tracer infusion. Because the incorporation rate of tracer is approximately linear during this time, protein synthesis can be measured by obtaining only two samples. This technique has been especially useful for evaluating protein synthesis of myofibrillar protein with a limited number of muscle biopsies ([102](#), [103](#)). For proteins that turn over at a faster rate, the tracer concentration rises exponentially in the protein toward a plateau value of enrichment that matches that of the precursor amino acids used for its synthesis (i.e., the intracellular amino acid enrichment). The types of protein that have been measured under these conditions have been the lipoproteins, especially apolipoprotein-B (apo-B) in very low density lipoprotein (VLDL) ([104](#), [105](#) and [106](#)).

Determination of the protein fractional synthetic rate is a “precursor-product” method that requires knowledge of both the rate of tracer incorporation into the protein being synthesized and the enrichment of the amino acid precursor used for synthesis. For muscle, L-[1-¹³C]leucine is often used as the tracer, and plasma KIC ¹³C enrichment is used to approximate the intracellular muscle leucine enrichment ([102](#)). Various other schemes have been used to estimate intracellular liver amino acid tracer enrichment. Hippuric acid is excreted in urine after formation in the liver by conjugation of benzoic acid and glycine. Therefore, urinary hippuric acid can be used as an index of hepatic intracellular glycine ¹⁵N enrichment ([107](#), [108](#)). Although the evidence is not specific, suggestions have been made that the hippuric acid does not accurately reflect the

glycine precursor pool from which the export proteins are synthesized. However, in the absence of better approach, using the hippuric acid ^{15}N enrichment is clearly better than using another tracer where the hepatic intracellular enrichment is completely unknown. For proteins such as VLDL apo-B that turn over quickly (typically 4–8 hours), tracer incorporation into the protein will approach a plateau within the period of tracer infusion. If the tracer enrichment in the protein does not reach a plateau during the time course of the tracer infusion, curve fitting can usually predict the plateau. When the standard precursor-product relationship holds (i.e., the product is made only from the precursor), the protein plateau amino acid enrichment will reflect the precursor enrichment, simplifying the kinetic calculation ([106](#)). Cryer et al. ([104](#)) were able to use the plateau in VLDL apo-B to measure the precursor enrichment in normal subjects but still had to use urinary hippurate in hyperlipemic subjects who had large, slow-turnover VLDL pools that did not approach plateau during the course of the 8-h infusion.

Degradation of Specific Proteins

Measurement of protein degradation is much more limited in terms of the methods available. To measure protein degradation, the protein must be pre-labeled. Three methods have been used: (a) removal of the protein from the body, followed by iodination with radioactive iodine, and reinjection into the body to follow the disappearance of the labeled protein; (b) administration of a labeled amino acid to label proteins via incorporation of the tracer during protein synthesis, followed by measurement of labeled amino acid release from degradation of the protein; and (c) use of posttranslational amino acids such as 3-methylhistidine.

The use of iodination limits this methodology to readily removable and reinjectable proteins (i.e., proteins in plasma). Therefore, the applications of this method are limited but it has found use in lipoprotein metabolism ([109](#), [110](#) and [111](#)). The method is not without problems: proteins that are iodinated do not have the same structure after removal and iodination as they had before removal from the body, and the iodination process may cause untoward effects. However, properly applied, the method can be very specific for measuring the kinetics of select proteins.

Alternatively, proteins may be labeled by long infusions of amino acid tracer. After the tracer infusion is stopped, the tracer enrichment disappears quickly from plasma. At that point, serial sampling of the protein and measuring the decrease in tracer enrichment with time will give its degradation rate. However, another problem occurs: 80% or more of the amino acids released from protein breakdown are reused for synthesis of new proteins. Therefore the amino acid tracer from protein degradation is recycled into new proteins. Because there is generally not a large starting enrichment in the proteins being measured, recycling of low enrichments of tracer greatly complicates interpretation of the labeled protein data obtained by this method.

3-Methylhistidine and Other Posttranslational Amino Acids. In the body, a number of enzymes can modify the structure of proteins after they have been synthesized. The changes are generally modest, occur to specific amino acids, and are either the addition of a hydroxyl group (e.g., conversion of proline to hydroxyproline in collagen [[112](#)]) or methylation of N moieties of amino acid residues such as histidine or lysine. Because

t-RNAs do not code for these hydroxylated or methylated amino acids, they are not reused for protein synthesis once the protein containing them is degraded. Of posttranslationally modified amino acids, 3-methylhistidine has found the most extensive application: the measurement of muscle myofibrillar protein breakdown (32, 113).

Because of the quantitative importance of muscle to whole-body protein metabolism, measurement of the release of 3-methylhistidine is an important tool for following breakdown of myosin and actin, which are both primary proteins in skeletal muscle and the primary proteins containing 3-methylhistidine (Fig. 2.15). Analyses of rat carcasses demonstrated that muscle accounts for three-quarters of the 3-methylhistidine pool in body proteins (32), and administered ^{14}C -3-methylhistidine has been shown to be quantitatively recovered in the urine of rats (114) and humans (115). There are caveats, however, to the use of 3-methylhistidine excretion for measurement of myofibrillar protein breakdown. Dietary meat will distort urinary 3-methylhistidine collection (116). As much as 5% of the 3-methylhistidine released in the urine may be acetylated in the liver first (a pathway that is much more predominant in the rat), and urinary samples may have to be hydrolyzed before measurement of 3-methylhistidine. Conversion of 3-methylhistidine to balenine (the dipeptide 3-methylhistidine-b-alanine) is of less importance in humans than in other species (117).

Figure 2.15. Schematic depiction of the formation and disposal of 3-methylhistidine in myofibrillar protein in humans. Because 3-methylhistidine is not reused for protein synthesis or oxidized/metabolized, its release into blood represents degradation of myofibrillar protein from tissues containing myosin and actin (muscle, smooth muscle such as gut, skin). In man, 3-methylhistidine is quantitatively excreted into urine; in rat, 3-methylhistidine is also acetylated in the liver before excretion in urine. Dietary intake of meat adds another source of 3-methylhistidine. (Figure drawn from previous descriptions of the metabolism of 3-methylhistidine (32).)

Myofibrillar protein and 3-methylhistidine are not specific to skeletal muscle, which means that urinary 3-methylhistidine measurement may not be specific to skeletal muscle protein breakdown (118, 119). The primary argument has been that even though

skin and gut may have a small pool of myofibrillar protein compared to the large mass of protein found in skeletal muscle, skin and gut protein turn over rapidly by comparison and, therefore, continually contribute a significant amount of 3-methylhistidine to the urine. More-recent work suggests that skin and gut contributions, while noticeable, can be accommodated in the calculation of human skeletal muscle turnover from urinary 3-methylhistidine excretion ([113](#), [117](#), [120](#)).

A more specific approach to 3-methylhistidine measurement of skeletal muscle myofibrillar protein breakdown measures release of 3-methylhistidine from skeletal muscle via A-V blood measurements across a muscle bed, such as leg or arm ([121](#)). This measurement of protein breakdown from the 3-methylhistidine A-V difference can be combined with the A-V difference measurement of an essential amino acid that is not metabolized in muscle, such as tyrosine. In contrast to 3-methylhistidine, tyrosine released by protein breakdown is reused for protein synthesis. The A-V difference of tyrosine across an arm or leg defines net protein balance (i.e., the difference between protein breakdown and synthesis). Protein synthesis is, therefore, the difference of the 3-methylhistidine and tyrosine A-V difference measurements ([56](#), [122](#)). The results by this technique should be similar to those obtained by the tracer method of Barrett et al. ([59](#)).

CONTRIBUTION OF SPECIFIC ORGANS TO PROTEIN METABOLISM

Whole-Body Metabolism of Protein and Contributions of Individual Organs

From the above discussion of tracers of amino acid and protein metabolism, it is clear that the body is not static and that all compounds are being made and degraded over time. A general balance of the processes occurring is shown in [Figure 2.6](#) for an average adult. In diabetics treated with insulin, Nair et al. measured leucine and phenylalanine kinetics in the whole body as well as leucine and phenylalanine tracer balances across a leg and across the splanchnic bed ([123](#)). This work measured directly in humans what has been assumed from a composite of the measurements shown in [Figure 2.6](#). They found that approximately 250 g of protein turns over in a day on the basis of the leucine and phenylalanine fluxes. Muscle protein turnover accounted for 65 g/day, and splanchnic protein turnover accounted for 62 g/day. If secreted proteins are synthesized at a rate of 48 g/day, then nonsplanchnic, nonmuscle organs account for another 75 g/day. The proportion of skeletal muscle mass in the body is consistent with skeletal muscle's contribution to whole-body protein turnover: skeletal muscle comprises about one-third of the protein in the body ([11](#)) and accounts for about one-quarter of the turnover.

If amino acids could be completely conserved (i.e., if none were oxidized for energy or synthesized into other compounds), then all amino acids released from proteolysis could be completely reincorporated into new protein synthesis. Obviously, that is not the case, and when there is no dietary intake, whole-body protein breakdown must exceed protein synthesis by an amount equal to net disposal of amino acids by oxidative and other routes. Therefore, we need to consume enough amino acids during the day to make up for the losses that occur both during this period and during the nonfed period. This concept becomes the basis for methods defining amino acid and protein requirements

discussed below.

As shown in [Figure 2.6A](#), if about 90 g of protein are eaten in a day, of which 10 g are lost in feces, the net absorption will be 80 g. In the process, considerably more protein is made and broken down. The total turnover of protein in the body, including both dietary intake and endogenous metabolism, is $90 + 250 = 340$ g/day, of which oxidation of dietary protein accounts for $(75 + 5)/340 = 24\%$ of the turnover of protein in the body per day. When dietary protein intake is restricted, adaptation occurs whereby the body reduces N losses ([Fig. 2.7](#)), and protein intake/oxidation becomes a much smaller proportion of total protein turnover.

The preceding discussion defines turnover of protein in various parts of the body but does not integrate flows of material per se or highlight the relationship of amino acids to metabolites that are used for energy, such as glucose and fatty acids. Clearly, there must be interorgan cooperation to maintain protein homeostasis, simply because some tissues such as muscle have large amino acid reservoirs, yet all tissues have amino acid needs. A regular feeding schedule means that part of the day is a fasting period in which endogenous protein is used for energy and gluconeogenesis. The fed period then supplies amino acids from dietary protein to replenish these losses and provide additional amino acids that can be used for energy during the feeding portion as well. Such a normal diurnal feeding and fasting pattern causes movement of amino acids among organs, which takes on particular importance in situations of trauma and stress in which adaptation, or rather lack of adaptation, of amino acid metabolism to physiologic insults or pathophysiologic states occurs.

As Cahill and Aoki has emphasized ([124](#)), the first consideration of the body is to maintain and distribute energy supplies (oxygen and oxidative substrates). The caloric needs of different tissues in the body are shown in [Table 2.12](#). As can be seen from the table, the brain makes up only about 2% of body weight yet has 20% of the energy needs ([125](#)). The brain also lacks the ability to store energy (e.g., glycogen depots), so it depends continually on delivery of energy substrates via the blood from other organs ([Fig. 2.16](#)). In the postabsorptive state, the primary energy substrate for the brain is glucose. In infancy and early childhood, when the brain makes up a significantly greater proportion of body mass, glucose production and use rates are proportionately higher ([126](#)). The pioneering studies of Cahill, Felig, and Wahren have provided us with a wealth of data concerning flows of amino acids and glucose from organ balance studies in humans studied over a range of nutritional states ([50](#), [51](#), [127](#), [128](#) and [129](#)). Some basic concepts may be derived from these studies.

Organ or Tissue	Weight		Metabolic Rate	
	kg	(% of total)	kcal/kg/day	(% of total)
Kidneys	0.3	(0.5)	440	(8)
Brain	1.4	(2.0)	240	(20)
Liver	1.8	(2.6)	200	(21)
Heart	0.3	(0.5)	440	(9)
Muscle	28.0	(40.0)	13	(22)
Adipose tissue	15.0	(21.4)	4	(4)
Other (skin, gut, bone, etc.)	23.2	(33.0)	12	(16)
Total:	70.0	(100)		(100)

Data taken from Elia M. Organ and tissue contribution to metabolic rate. In: Kinney JM, Tucker HN, eds. Energy metabolism: determinants and cellular correlates. New York: Raven Press, 1992:61-70.

Table 2.12 Contribution of Different Organs and Tissues to Energy Expenditure

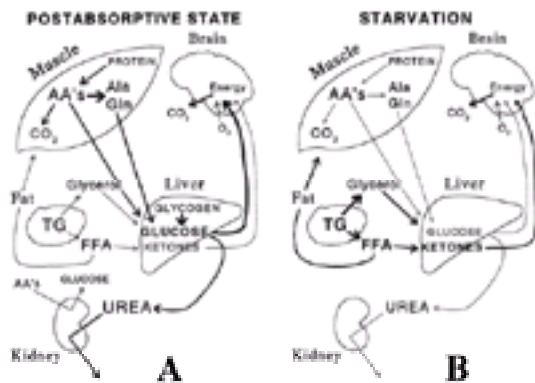

Figure 2.16. Interorgan flow of substrates in the body to maintain energy balance in the postabsorptive state (panel A) and after adaptation to starvation (panel B). The schematic diagrams are patterned after the work of Cahill. In all states, energy needs of the brain must be satisfied. In the postabsorptive state, glucose from liver glycogenolysis provides most of the glucose needed by the brain. After liver glycogen stores have been depleted (fasting state), gluconeogenesis from amino acids from muscle stores predominates as the glucose source. Eventually the body adapts to starvation by production and use of ketone bodies instead of glucose, thus sparing amino acid loss for gluconeogenesis. AAs, amino acids; Ala, alanine; Gln, glutamine; TG, triglycerides; FFA, free fatty acids, respectively. (Redrawn from Cahill GF Jr, Aoki TT. Partial and total starvation. In: Kinney JM, ed. Assessment of energy metabolism in health and disease, report of the first Ross conference on medical research. Columbus, Ohio: Ross Laboratories, 1980;129-34.)

As shown in [Figure 2.16A](#), in the postabsorptive state, the body provides energy for the brain in the form of glucose primarily from hepatic glycogenolysis and secondarily from

glucose synthesis (gluconeogenesis) from amino acids. Other substrates (e.g., glycerol released from triglyceride lipolysis) may also be used for gluconeogenesis, but amino acids provide the bulk of the gluconeogenic substrate. The pathways of conversion are discussed above for those amino acids whose carbon skeletons can be easily rearranged to form gluconeogenic precursors. The remaining amino acids released from protein breakdown and not used for gluconeogenesis may be oxidized. The amino acid N released by this process is removed from the body by incorporation into urea via synthesis in the liver and excretion into urine via the kidney. Gluconeogenesis also occurs in the kidney, but the effect and magnitude are masked from A-V measurements because the kidney is also a glucose consumer. With respect to amino acids, the net effect of the kidney is the uptake and use of amino acids for gluconeogenesis ([130](#), [131](#)).

Role of Skeletal Muscle in Whole-Body Amino Acid Metabolism

Early A-V difference studies across the human leg or arm revealed that more than 50% of the amino acids released from skeletal muscle are in the form of alanine and glutamine ([132](#)), yet alanine and glutamine comprise less than 20% of amino acids in protein ([Table 2.3](#)). The specific purpose of the alanine and glutamine release is still not well defined. Several possible reasons exist. First, skeletal muscle will oxidize nonessential amino acids and the BCAAs in situ for energy. Because amino acid oxidation produces waste N and because ammonia is neurotoxic, release of waste N as ammonia must be avoided. Because both alanine and glutamine are readily synthesized from intermediates derived from glucose (alanine from transamination of pyruvate from glycolysis, and glutamine from α -ketoglutarate), they are excellent vehicles to remove waste N from muscle while avoiding ammonia release. Alanine removes one and glutamine removes two Ns per amino acid. These observations have led to the proposal of a glucose-alanine cycle in which glucose made by the liver is taken up by muscle, where glycolysis liberates pyruvate. The pyruvate is then transaminated to alanine and released from muscle. That alanine is extracted by the liver and transaminated to pyruvate that is then used for glucose synthesis ([132](#)). This scheme has been expanded to explain the use of BCAAs by muscle for energy and the disposal through alanine of their amino-N groups. Such a scheme resolves a problem related to the BCAAs. In contrast to the other essential amino acids, which are metabolized only in liver, the BCAAs are readily oxidized in other tissues, especially muscle. Thus, if the BCAAs, which comprise about 20% of amino acids in muscle protein, are oxidized for energy by the muscle, then the glucose-alanine cycle could provide a means of removal of the N that is generated in the process.

Whole-Body Adaptation to Fasting and Starvation

As indicated in [Figure 2.16A](#), lipolysis (breakdown of adipose triglyceride to free fatty acids and glycerol) plays a lesser role in postabsorptive energy supply, especially to the brain. However, glycogen stores are limited and become depleted in less than 24 hours. That point in time when liver glycogen stores are exhausted is, by definition, the beginning of the *fasting* state. Now the glucose needs of the brain must be met completely by gluconeogenesis, which means sacrificing amino acids from protein. Because protein is critical to body function, from enzyme activity to muscle function

related to breathing and circulation, unrestrained use of amino acids for glucose production would rapidly deplete protein, causing death in a matter of days. Clearly, this does not occur, because people may survive without food and obese subjects may be fasted for weeks without protein intake (1). Adaptation occurs in starvation by the brain's switching from a glucose-based to a ketone-based fuel supply. Free fatty acids released from lipolysis are converted in the liver into ketone bodies that can then be used by the brain and other tissues for energy. That conversion begins in the fasting state and is complete during long-term fasting periods (Fig. 2.16B). In starvation, tissues such as muscle may use free fatty acids directly for energy, and the brain uses ketone bodies. The body's dependence upon glucose as a fuel has been greatly reduced, thereby conserving protein. This adaptation process is complete within a week of onset of starvation (124).

The Fed State

Although the body can accommodate to starvation, it is not a normal occurrence. The adaptations seen in everyday life evolve around the postabsorptive period and the fed period. Basically, we go through our nights after completing absorption of the last meal using nutrient stores of glycogen and protein as depicted in Figure 2.16A. During the fed portion of the day the dietary intake of amino acids and glucose is used to replete protein and glycogen that were lost during the postabsorptive period; intake that exceeds amounts needed to replete nighttime losses are either oxidized or stored to increase protein, glycogen, or fat for growth or storage of excess calories. Although muscle contains the bulk of body protein, all organs are expected to lose protein during the postabsorptive period and, therefore, need repletion during the fed period. What is poorly understood is how the individual amino acids that enter through the diet are distributed among the various tissues in the amounts needed for each tissue. Just as each amino acid has its own separate metabolic pathways, the rates and fates of absorption and use are expected to differ among amino acids. Thus, dietary protein requirements cannot be discussed without also considering the requirements for individual amino acids.

Digestion and Absorption of Protein

Two organs have particular, potentially important, regulatory roles during feeding: the gut and liver. All dietary intake passes first through the gut and then through the liver via portal blood flow. Digestion of protein begins with pepsin secretion in gastric juice and with proteolytic enzymes secreted from the pancreas and the mucosa of the small intestine (133). These enzymes are secreted in their "pro" (or zymogen) form and become activated by cleavage of a small peptide portion. Pancreatic proenzymes become activated by intestinal enterokinase secreted into the intestinal juice to cleave trypsinogen to trypsin. The presence of dietary protein in the gut appears to signal secretion of the enzymes. As trypsin becomes activated, it binds to proteins to initiate hydrolysis. An excess of trypsin occurs when either more trypsin is secreted than there is protein present or when most of the dietary protein has been hydrolyzed. At this point the presence of unbound trypsin appears to signal a feedback regulation system to the pancreatic acinar cells to inhibit synthesis and secretion of trypsinogen. Some plants, such as soybeans, contain protein inhibitors of proteolytic enzymes such as trypsin.

These proteins may often be denatured by heating (i.e., by cooking). Feeding unheated soybeans to rats results in hypertrophy of the pancreas, presumably caused by hypersecretion of pancreatic juices. The presumed mechanism is that the trypsin inhibitor in soy binds trypsin, which, in the free state, serves as a feedback inhibitor of pancreatic secretion ([134](#)).

The events of protein digestion and absorption as shown in [Figure 2.17](#) are well established ([133](#), [135](#), [136](#), [137](#) and [138](#)). Proteins are successively broken down into smaller peptides on the basis of the amino acid residues targeted by the proteolytic enzymes. For example, pepsin has a relatively low specificity for neutral amino acids such as leucine or phenylalanine, whereas trypsin shows specificity for a basic target (lysine or arginine). In addition, exopeptidases attack the free ends of the peptide chains: pancreatic carboxypeptidases at the carboxyl terminus, and aminopeptidases secreted in intestinal juice at the amino terminus.

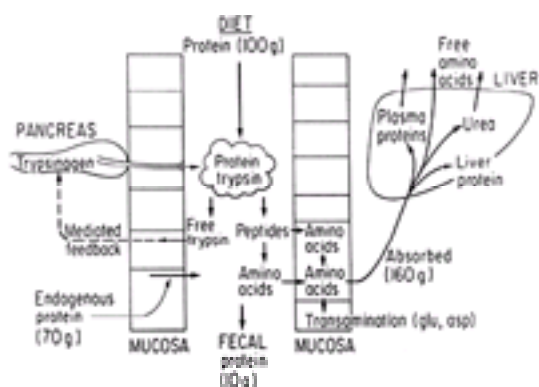

Figure 2.17. Digestion and absorption of dietary protein in the intestine. The secretion and feedback system of the pancreatic trypsinogen/trypsin is shown. In addition to the assumed dietary protein load of 100 g, an additional protein load of about 70 g occurs from secretion of protein and sloughing of mucosal cells. Under normal conditions, almost all of the protein is recovered by hydrolysis and absorption. Amino acids are absorbed by active transport through the mucosal cells into the portal blood system. Some amino acids are immediately metabolized by gut and liver during absorption. (From Crim MC, Munro HN. Protein and amino acid requirements and metabolism in relation to defined formula diets. In: Shils ME, ed. Defined formula diets for medical purposes. Chicago: American Medical Association, 1977;5–15, with permission.)

The free amino acids are absorbed by active transport into the mucosa by transporters specific to different types of amino acids ([136](#), [137](#)). At the same time, peptides, in particular di- and tripeptides, are assimilated on the luminal side intact. Peptide hydrolases present in the brush border and cytosol of the mucosal cells complete the hydrolysis of these peptides prior to their release into the portal blood system. There are specific transport systems for peptide uptake into mucosal cells, separate from the

transporters for amino acids. It is thought that a quarter of dietary protein is absorbed as di- and tripeptides (139). For example, patients with the rare genetic Hartnup disease with a defect in renal and gut transport of selected amino acids cannot transport free tryptophan into mucosal cells but do indeed absorb tryptophan when it is administered as a dipeptide (140, 141).

Figure 2.17 shows that in addition to dietary protein, protein is added directly to the lumen in the form of secreted proteins and sloughed cells. Because the small intestine is continually being remodeled with cells formed in the crypts migrating toward the villus tips, epithelial and other cells are continuously being sloughed off the tips of the villi. Although the exact amounts of protein secreted and cells sloughed are unknown, a reasonable estimate is that of the 70 g of protein added to the lumen, 20 g may come from secreted proteins and 50 g may come from sloughed cells (135). As indicated in Figure 2.17, most of this protein is efficiently reabsorbed.

To a limited but important extent, some proteins and large peptides enter intact directly from the gut into the basolateral blood. Absorption of intact proteins or large portions of proteins is a tenable physiologic explanation for numerous diseases involving food allergies and idiosyncrasies. The gut is generally viewed as an impermeable barrier that nutrients cross by active transport or where a break in the barrier occurs through cell injury. Small amounts of some proteins may pass this barrier by several possible mechanisms, such as through “leaks” between epithelial cell junctions or possibly by transport through uptake into vesicles from the lumen to the submucosal side of the epithelial cells (142). Again, the amount of protein entering intact is small, but it may be important in situations of immune response to the proteins or in delivery of some peptide drugs.

Gut and Liver as Metabolic Organs

The gut and liver facilitate absorption and delivery of dietary amino acids to the systemic blood and other tissues in the body. During this process, the gut and liver see all nutrients being absorbed and may sequester on the first pass during absorption any fraction of the dietary amino acids before these amino acid ever enter the systemic circulation. The liver has a natural role in this process as it is the organ that inactivates/modifies toxic substances in the blood. Therefore, the liver would be expected to regulate the flow of dietary amino acids into the systemic circulation following a meal. In addition, the liver is the only site in the body for metabolizing essential amino acids, except the BCAAs (which are metabolized by several tissues, most notably muscle). As mentioned above and discussed below, in terms of determining amino acid requirements, amino acids consumed during feeding in excess of the body's current needs would be expected to be oxidized. Therefore, a potential role for the liver is removal of excess amino acids, especially essential amino acids that cannot be oxidized in other tissues, on the first pass during amino acid absorption. The role of the gut and liver as active metabolic organs that metabolize dietary amino acids was shown in catheterized dogs by Elwyn et al. in 1968 (143). They demonstrated the active metabolism of the key nonessential amino acids, alanine, glutamine, and glutamate, and described how the BCAAs passed intact through the splanchnic bed. Several groups have shown similar results with respect to passage of amino acids

following meal feeding in humans, using splanchnic bed and/or leg/arm A-V catheterization ([51](#), [144](#), [145](#) and [146](#)). These studies have made several consistent observations.

As discussed above, the first observation was that most of the BCAAs in a meal pass through the splanchnic bed to be extracted and used by peripheral tissues. Later studies using labeled amino acid tracers administered enterally and intravenously ([Fig. 2.14](#)) showed that the BCAA leucine has the lowest fractional extraction by the gut and liver on the first pass when delivered enterally ([Table 2.11](#)). The amount of leucine oxidized by liver in the postabsorptive state is minimal (<2%) ([93](#)). Under conditions of feeding, the amount of enteral leucine extracted by the gut and liver on the first pass rose only slightly ([94](#)). However, the liver was shown to be a significant producer of KIC, indicating that the first step in BCAA metabolism is active, i.e., transamination. This step does not irreversibly remove leucine, rather it only forms a ketoacid that can be reconverted into leucine in a peripheral tissue such as muscle. Alternatively, the KIC produced by liver and released can be oxidized.

Of particular interest is the observation that the gut extracts glutamate and glutamine and releases alanine and ammonia ([143](#)). Early experiments with enteral glutamate infusion in dogs suggested that the glutamate sequestered is converted directly to alanine on the basis of glutamate uptake with resulting alanine release ([147](#)). Unfortunately, any interpretation of such an observation without proof from isotopic tracer studies would fall under the “gumball machine” analogy of [Figure 2.8](#). Nonetheless, the observation is intriguing, especially in light of the consistent observation of a large A-V gradient for glutamine across the gut, indicating uptake ([148](#), [149](#), [150](#) and [151](#)).

PROTEIN AND AMINO ACID REQUIREMENTS

The most fundamental question in nutrition concerning protein and amino acids is simply, what amount of protein is required in the diets of humans to maintain health? This question has several parts. First, we must evaluate the intake of both protein and the amounts of the individual amino acids in that protein. Second, this question must be answered in humans (*a*) over the complete range of life and development, (*b*) in sickness and in health, and (*c*) under different conditions of work and environment. These questions and the methods used to answer them are discussed below in terms of their individual components.

When we discuss the amino acid composition of a specific protein source, we generally focus upon the amount of essential acids contained in it because these are the amino acids that are *indispensable* to our diet. Which amino acids are dispensable and which are indispensable was originally determined by testing whether a diet deficient in a particular amino acid would support growth in a rat. However, there are important species differences between rats and humans that limit the comparison of rat to man. Furthermore, the growth retardation model, which is effective with the rat, is not applicable to humans. An alternative for studying amino acid requirements in humans is the N balance technique. A diet that is adequate in total N but deficient in an essential (indispensable) amino acid cannot produce a positive N balance because protein can be

synthesized only if each amino acid is present in adequate amounts. The nonessential amino acids can be synthesized if protein intake is adequate, but limited intake of an essential amino acid limits the amount of protein that can be synthesized. The body is then faced with a dietary excess of the other *nonlimiting* essential and nonessential amino acids that it cannot put into protein. Therefore, these amino acids must be oxidized to urea, and a negative N balance results.

The classic studies of Rose and colleagues measured N balance in humans fed diets deficient in individual amino acids. They determined that eight amino acids produced a negative N balance when they were deficient in the diet of adult humans (152, 153 and 154). Although the enzymatic pathways are missing for synthesis of these essential amino acids, several of these amino acids (such as the BCAAs) have a catabolic pathway whose first step is reversible (i.e., transamination to form branched-chain keto acids). The rat growth model was used to show that growth can be supported by supplying the keto acids of these essential amino acids. Various formulations have been proposed for supplying the carbon skeleton of several essential amino acids (e.g., the BCAAs) without adding N, which is detrimental in disease states such as renal disease (155).

Another related question is whether dispensable, nonessential amino acids ever become indispensable. If a nonessential amino acid is used in the body faster than it is made, it becomes essential for that *condition* (6). Tyrosine and cysteine are made from phenylalanine and methionine, respectively, but if insufficient phenylalanine or methionine is consumed, tyrosine and cysteine also become deficient and *essential*. This question must be answered across the range of life from infancy to the elderly as well as in sickness and health. For example, enzymes for amino acid metabolism mature at different rates in the growing fetus and newborn infant. Histidine is essential in infants but not necessarily in healthy children or adults. Therefore, the classification of “essential” or “nonessential” depends upon species, maturation (i.e., infant, growing child, or adult), diet, nutritional status, and pathophysiologic condition. Also to be considered is whether a particular amino acid *given in excess of requirement* has properties that may ameliorate or improve a clinical condition. These considerations must somehow be evaluated for each population group in which they are important.

Protein Requirements

Determination of the protein requirement must consider both the amount of amino acid N and its quality (i.e., its ability to be digested and absorbed and its essential amino acid content). The simplest approach to measuring the nutritional quality of a protein is to measure the ability of that protein to promote growth in young growing animals, such as rats. Their growth depends on synthesis of new protein, which depends on essential amino acid intake. Because alterations in rat growth can be measured in several days, the growing rat is often used to compare differences in quality (composition) of protein/amino acid diets. Because this approach cannot ethically be applied to humans, other approaches for assessing *human* requirements have been applied: the *factorial method* and the *balance method*.

Factorial Method

When a person is placed on a protein-free diet, rates of amino acid oxidation and urea production decrease over several days as the body tries to conserve its resources, but amino acid oxidation and urea production do not drop to zero ([Fig. 2.7](#)). There is always some *obligatory* oxidation of amino acids and urea formation and miscellaneous losses of N ([Table 2.10](#)). The factorial method assesses all routes of loss possible for adult humans on an N-free diet. The minimum daily requirement of protein is assumed to be the amount that matches the sum of the various obligatory N losses.

Whereas nonurinary nonfecal N losses are often ignored in N balance studies of adequate protein intake, they are of critical importance in the assessment of protein requirements by the factorial method. A variety of studies have been performed to assess these losses, and the results are tabulated in a World Health Organization/Food and Agriculture Organization/ United Nations University (WHO/FAO/UNU) panel publication ([156](#)) and summarized again in a U.S. National Research Council report ([157](#)). The obligatory N losses include (a) urinary N, estimated to be 38 mg/kg/day of N; (b) fecal loss of enzymes and desquamated intestinal cells that cannot be fully reabsorbed, estimated to be 12 mg/kg/day; and (c) loss of N through sweat, hair, skin, and nail turnover and growth, menstrual flow, seminal fluid, ammonia in breath, nasal secretions, etc., estimated to be 2 to 3 mg/kg/day on a protein-free diet and 5 to 8 mg/kg/day with a normal protein intake ([48](#)). Summation of these directly measurable losses gives a total obligatory minimum daily loss of N of 54 mg/kg/day (range, 41–69 mg/kg/day), corresponding to a protein intake of 0.34 g/kg/day (where 1 g N = 6.25 g protein) ([157](#)).

This value of 54 mg/kg/day of N is an “average value,” which must be raised if it is to indicate a requirement that will apply to most adults in the population. The 1973 WHO/FAO report ([158](#)) suggested a coefficient of variability among individuals of 15%. Adding twice this amount (+2 standard deviations) gives a protein requirement that includes 97.5% of the adult population; thus, the 0.34 g/kg/day protein becomes 0.44 g/kg/day after rounding off ([45](#)). For adults, the *dietary protein requirement* is considered to be this amount *plus* an adjustment for the inefficiency of use of dietary protein and for the quality (amino acid composition and digestibility) of the protein source consumed. For children and pregnant or lactating women, an additional (theoretically determined) amount of protein is added to this recommendation to account for growth and milk formation ([157](#)). Clearly this approach is based upon extrapolation of N losses from protein-starvation conditions and may reflect an adaptation to N deprivation, which may not reflect normal metabolism and N requirements of healthy humans near the actual requirement level. Hence, another method is needed to produce an alternative assessment of protein requirements.

Balance Method

In the balance method, subjects are fed varying amounts of protein or amino acids and the *balance* of a particular parameter—usually *N balance*—is measured. An adequate amount of dietary protein is that level of intake that will maintain a neutral or slightly

positive N balance. The balance method can be used to titrate N intake in infants, children, and women during pregnancy, when the end point is a balance positive enough to allow appropriate accretion of new tissue. The balance method is also useful for testing the validity of the factorial method estimates. In general, N balance studies in which dietary protein intake is titrated give higher protein requirements than predicted by the factorial method.

There are several reasons for this result. The N balance method has important errors associated with it that are not minor (48, 158). Urine collections tend to underestimate N losses, and intake tends to be overestimated. Miscellaneous cutaneous and hair losses, which are “best guesses,” may have small but substantial errors. However, these factors affect both methods. In the balance method, which “titrates” dietary intake to determine zero balance, the response to increasing protein intake is nonlinear. As protein intake is increased from a grossly deficient status toward an adequate status, the improvement in N balance is at first proportional to the amount of protein added to the diet. As the balance point is approached, however, the slope of the N balance–protein intake curve progressively decreases, i.e., more protein is required to achieve a zero N balance than is predicted by linear extrapolation (158). This refractoriness in reaching N equilibrium has been estimated to add 30% to the intake needed to equal output. As a result, the factorial method estimate of 0.44 g/kg/day is increased to a recommended intake of 0.57 g/kg/day (45).

Most studies of N balance have been performed at presumably adequate levels of energy intake. However, N balance is affected by energy intake. Energy intake below requirements causes the N balance measurement to become negative when protein intake is near the requirement. Most recommendations are based, nonetheless, on the assumption that energy intake is adequate (159). Another factor affecting N balance indirectly is the quality and digestibility of the protein being consumed. Generally it is assumed that protein of lesser quality and digestibility than egg white will be consumed. A correction factor that increases protein requirements by 25 to 30% is added to compensate for consumption of lesser-quality protein (156).

Recommended Dietary Allowances for Protein

In 1989, the Food and Nutrition Board subcommittee of the U.S. National Research Council updated their recommended dietary allowances (RDAs) for protein and amino acids (157). The RDAs are largely based upon the 1985 FAO/WHO/UNU committee report (156). The RDA values for protein shown in [Table 2.13](#) were based largely upon N balance data (rather than factorial method data) from studies using a high-quality, highly digestible source of protein. The protein intake values that produced zero N balance were then increased by two standard deviations to encompass 97.5% of the population to get the RDA for the reference protein. For example, from studies of young adult men, the value of 0.6 g/kg/day was increased to 0.75 g/kg/day.

Age (years)	Weight (kg)		Recommended Dietary Allowance of Protein (g/kg/day)	
0-0.5	6		2.2	
0.5-1	9		1.6	
1-3	13		1.2	
4-6	20		1.1	
7-10	28		1.0	
11-14	Male: 45	Female: 46	Male: 1.0	Female: 1.0
15-18	66	55	0.9	0.8
19+	72-79	58-65	0.8	0.8
			(g/day)	
Pregnancy add			+10	
Lactation, 1st 6 months add			+15	
Lactation, 2nd 6 months add			+12	

Data from Food and Nutrition Board, National Research Council. Recommended dietary allowances, 10th ed. Washington, DC: National Academy Press, 1989.

Table 2.13 Recommended Intakes of High-Quality Reference Protein for Normal Humans

The types of protein consumed in the United States were reviewed to determine both essential amino acid composition (see below) and digestibility. The RDA for the reference protein was then adjusted for imbalances in essential acids and protein digestibility where deemed important to produce the values shown in [Table 2.13](#). (The reader is referred to ref. [157](#) for details.)

Special cases are cited in [Table 2.13](#) in which growth and accretion of tissue must be accounted for in the RDAs: during pregnancy, during lactation, and in infants and children. In pregnancy, total protein deposited was estimated to be 925 g on the basis of maternal weight gain and an average birth weight at term. The rates of protein accretion were then divided by trimesters, with adjustments for variation in birth weight (+15%) and an assumed efficiency of conversion of dietary protein to fetal, placental, and maternal tissues (+70%) to produce increments in reference protein intake of +1.3, +6.1, and +10.7 g protein/day for the 1st, 2nd, and 3rd trimesters, respectively. These values were rounded to 10 g/day of additional protein for all trimesters to compensate for uncertainties about rates of tissue deposition and maintenance of those increases ([Table 2.13](#)) ([157](#)).

A factor to account for the additional protein intake required by women who are lactating was also added to values in [Table 2.13](#). This addition was based upon the composition of human milk, the volume of milk produced, an adjustment for the estimated 70% conversion efficiency of dietary protein into newly synthesized milk protein, and a 25% increase to account for a two standard deviation variance among women. This value was also adjusted for duration of lactation.

Protein requirements for newborn infants include additional intake to account for the approximate 3.3 g protein/day accretion of growth of infants fed human milk (which includes a 25% increase to account for a two standard deviation variance). The RDA for older infants and children is based upon the 1985 WHO report ([156](#)), which used a modified factorial method. Rates of protein accretion due to growth were calculated by

age group, increased by 50% to account for variability among children, and adjusted by a 70% conversion efficiency factor of dietary protein to body protein synthesis. This estimate was then increased by 25% (to account for a two standard deviation variance) to give the RDA.

Amino Acid Requirements

Recommendations for the intake of individual amino acids are largely based upon the pioneering work of W. C. Rose and his colleagues in the 1950s (152, 153). Irwin and Hegsted have reviewed these and other studies of amino acid requirement levels published before 1971 (160). Rose's studies are all N balance studies in which young male subjects were placed upon diets whose N intake consisted of a mixture of crystalline amino acids. The intake of a single amino acid could be altered, and the N balance measured. Because of the expense of the amino acid diets and the great difficulty in performing serial N balance studies at different intakes, Rose and colleagues were only able to study a very limited number of subjects per amino acid. Problems with interpreting the N balance data for a limited number of subjects cloud the extrapolation of these data to populations (161, 162 and 163); yet these N-balance data remain the basis for the present amino acid recommendations in adults (Table 2.14). Rose's data have been confirmed in the more recent study of Inoue et al., also using the N balance technique (164), but the data set for requirements for individual amino acids is extremely slim.

Amino Acid	Infants 3-4 months	Children 3-5 years	Children 10-12 years	Adults	Proposed by Young Adult ¹
Alanine	28	7	7	6-12 ²	
Isoleucine	10	11	28	10	10
Leucine	167	11	42	14	39
Lysine	103	94	44	12	30
Methionine - cysteine	58	11	22	13	15
Phenylalanine - tyrosine	125	88	22	14	39
Threonine	87	11	28	7	15
Tryptophan	17	12	3	4	6
Valine	83	38	25	10	20

¹ Data in the first 4 columns were taken from ref. 157. Data in the last column are based upon amounts of amino acids consumed to meet N balance in a protein-spared growth study (164). Data for infants are based upon human or cow milk consumption need to gain weight.

² Data from Young and Elmsley (160) are based upon nitrogen balance studies determined in peritoneal dialysis patients.

³ Amounts in parentheses for infants have been calculated based on 10-12 mg/kg/day but have been rounded to whole values.

Table 2.14 Estimates of Dietary Amino Acid Requirements (mg/kg/day) by Age Group

An alternative approach has been taken by Young and colleagues (162, 165, 166), based upon the method of Harper and others to assess amino acid requirements in growing animals by using amino acid oxidation as an index of dietary sufficiency. Animals fed an insufficient amount of a specific individual amino acid reduce their oxidation of the deficient amino acid to obligatory levels. Oxidation of the dietary-deficient amino acid will remain at obligatory oxidation levels until the requirement level is met. Then, as dietary amino acid intake rises above requirement,

the excess amino acid is oxidized. Therefore, a two-line curve should appear when amino acid oxidation is plotted against amino acid intake: a flat line below requirement (indicating obligatory oxidation) and a rising curve above the requirement (indicating oxidation of excess amino acid intake). The requirement level for the amino acid should be the intersection of the two curves, i.e., where oxidation of excess amino acid begins (167).

The amino acid oxidation curve has been assessed in growing animals placed on diets in which the intake of one amino acid is manipulated. A ^{14}C -labeled amino acid tracer of the manipulated amino acid is added to a test meal to measure oxidation as a function of dietary amino acid intake (168). This approach has been applied by Young and coworkers to assessing human amino acid requirements using *nonradioactive*, stable, isotopically labeled amino acid tracers. From the results of these studies, Young proposed that the present recommended essential amino acid requirements for isoleucine, leucine, lysine, phenylalanine/tyrosine, and valine be increased in healthy adults (165, 166). These estimates, which are 2 to 3 times the RDAs for adults (Table 2.14), have been challenged on methodologic and theoretical grounds by Millward et al. (169). Both Young (165, 166, 170) and Millward (171) have provided experimental data from stable isotope tracer studies in humans to support their arguments for and against increasing the recommended intakes of essential amino acids.

Zello et al. (172) have taken a different approach to the measurement of amino acid requirements using the oxidation of an amino acid tracer as an index. Rather than administer and measure the oxidation of an amino acid tracer of the amino acid that is being reduced in the diet, they use another essential amino acid tracer as the *indicator* of N balance. Nitrogen balance becomes negative when a single amino acid is deficient in the diet because the excess amino acids that cannot be incorporated into protein when one amino acid is deficient are oxidized, which increases urea production. As discussed above, measurement of the increase in urea production is fraught with problems, which is why direct oxidation of the indicator amino acid is measured using an amino acid tracer. When dietary intake of the test amino acid is below requirement levels, oxidation of the indicator amino acid increases as excess amino acids are wasted. The key to this method is the availability of an indicator amino acid tracer whose oxidation can be accurately and precisely measured, which differs from the test amino acid being manipulated in the diet. Using this approach and [1- ^{13}C]phenylalanine as the indicator amino acid, Zello et al. determined a requirement level for dietary lysine of 37 mg/kg/day (173), which supports Young's higher estimate of lysine requirements (Table 2.14).

Histidine, which is essential to the diet of the rat, has been hard to define as essential to the diet of adult humans (160). In the 1973 FAO/WHO report, no requirement for histidine was given for adults (158), but the 1985 WHO/FAO/UNU report (156) listed a requirement for histidine of 8–12 mg/kg/day (Table 2.14). This requirement in adults is based upon extrapolation of data from infants (157). The limited studies of adults indicate that the requirement for histidine may be less than 2 mg/kg/day (174). However, this requirement has not been clearly documented in normal subjects (154). Proving that histidine is essential in adults has largely been restricted to studies of renal failure (8). Why is it so difficult to determine whether histidine is essential in adults, using conventional dietary techniques, when there is little evidence that a metabolic pathway

for histidine synthesis exists in humans (17)? The difficulties occur because the requirement for histidine is small and the stores of histidine in the body are large (8, 154). Histidine is particularly abundant in hemoglobin and carnosine (the dipeptide β -alanylhistidine, which is present in large quantities in muscle). Furthermore, gut flora synthesize an unknown amount of histidine, which may be absorbed and used. Histidine must be removed from the diet for more than a month to observe effects, and those effects are indirect measures of histidine insufficiency (a fall in hemoglobin and rise in serum iron) rather than alterations in conventional indices (N balance). Thus, even though little direct evidence for histidine synthesis in humans exists, our estimates for the necessity of dietary histidine intake in adults are still largely inferential.

In contrast to histidine, arginine is synthesized in large amounts in the body for the production of urea. However, like that of cysteine and tyrosine, synthesis of arginine depends upon the availability of precursors, ornithine and citrulline. Although adequate amounts of arginine, ornithine, and citrulline are normally present in the liver to operate the urea cycle, the synthesis of ornithine, from which arginine and citrulline are produced, may be limited (17). Because arginine is synthesized in the body from ornithine, it is *not* an essential amino acid, but it is *indispensable* for optimal growth in several species of young mammals (154).

Rose et al. observed an adequate N balance in adult subjects fed an arginine-free diet, and Snyderman et al. found no health problems or lack of weight gain in infants fed an arginine-free diet (8). Carey et al. (175) placed adult subjects on a diet devoid of arginine for 5 days. They measured indices of urea cycle activity: plasma ammonia concentration, daily urinary excretion of orotic acid, and urinary N excretion. They found no alterations due to the arginine-free diet. These results would lead to the conclusion that arginine is nonessential to the diet of humans; yet, there is little evidence that the body synthesizes ornithine from glutamate in substantial amounts (Fig. 2.4).

Castillo et al. simultaneously measured arginine, ornithine, and citrulline kinetics in healthy adults, using stable isotopically labeled tracers (87). Their studies show that the fluxes of all three amino acids are very low in blood and do not reflect the active urea cycle component, which appears to be highly compartmentalized in the liver. Ornithine and citrulline fluxes were comparable, but were only one-third the rate of arginine turnover, and a relatively small fraction of the ornithine tracer appeared in plasma arginine or citrulline. The low flux of ornithine suggests that very little synthesis occurs, but direct measurements of ornithine synthesis are lacking. Inferential measurements do suggest ornithine synthesis. For example, ^{15}N tracer is transferred from glycine into glutamate and into the metabolic products of glutamate, including ornithine and proline (23).

Assessment of Protein Quality

The quality of a protein is defined by its ability to support growth in animals. Higher-quality protein produces a faster growth rate. Such growth rate measurements evaluate the actual factors important in a protein: (a) pattern and abundance of essential amino acids, (b) relative amounts of nonessential and essential amino acids in the mixture, (c) digestibility when eaten, and (d) presence of toxic materials such as

trypsin inhibitors or allergenic stimuli. Methods of determining the quality of a formula or protein source have generally fallen into two categories: empiric biologic assays and scoring systems.

Biologic Assays

It is assumed that the “highest quality protein” is protein that supports maximal growth of a young animal. Because rats grow quickly and have limited protein stores and a high metabolic rate, deficiencies and imbalances in amino acid patterns in young growing rats can be easily detected in a short period of time. The *protein efficiency ratio (PER)* is defined as the weight gained (in grams) divided by the amount of test protein consumed (in grams) by a young growing rat over several days. Obviously, duration of diet, age, starting body weight, and species of rat used are important variables. Typically, 21-day-old male rats fed 9 to 10% protein (by weight) for 10 days to 4 weeks are used. In one series of tests, casein produced a PER of 2.8; soy protein, 2.4; and wheat gluten, 0.4. Clearly, a casein diet produced much better growth (2.8 g of carcass weight increase for every gram of casein consumed) than gluten (0.4 g of carcass weight increase for every gram of gluten consumed). Such an approach has been useful in defining the relative efficacies of clinical formulas used in enteral and parenteral nutrition (176). The formula that provides the optimal mixture of essential and nonessential amino acids should induce the most rapid growth. Results from this method will be skewed in application to humans, depending upon the extent that human requirements for individual amino acids differ from those of the rat. However, the method has been very useful in comparing a new protein source against reference proteins, such as egg protein, and does evaluate other factors such as relative digestibility.

Scoring Systems

Rather than using growth in an animal species to indicate protein quality, a variety of methods have been developed to assign a quantitative value to the pattern of amino acids in a nutritional formula or to a particular dietary protein source. Thus, assignment is based on the amounts and importance of the individual amino acids in a formula. These “scoring” methods can be used to define protein quality in terms of amino acid content for any species. Block and Mitchell pointed out in 1946 that all amino acids have to be provided simultaneously at the sites of protein synthesis in the body in the same proportions that go into the protein (177). Assuming that any nonessential amino acid would not be limiting, they proposed that the value of a protein could be determined from the essential amino acid most limiting in abundance relative to the optimum amount needed. From this idea of “most limiting amino acid” came the concept of chemical scoring, which has been incorporated into the important reports assessing dietary needs of humans (157, 158, 178). The key to the method is that the test protein is defined “against” a reference protein, deemed to be of the “highest quality” in terms of amino acid composition. Historically, proteins that support maximal growth in animals were considered the proteins of “highest” quality. Those proteins from the most available sources for human consumption—eggs and cow milk—were consequently used as reference proteins. In 1973, the FAO/WHO adopted the amino acid requirement pattern recommended for various age groups (Table 2.14) as the basis for calculating chemical scores (158, 179). Some of the scoring patterns that have been used are

shown in [Table 2.15](#). Typically, data for the 2- to 5-year-old child are taken as most representative.

Amino Acid	Infant 1-yr	Child 1-4 yrs (by amino acid g protein)	Child 5-7 yrs	Adult	Hen Egg Protein	Body Protein
Histidine	16	15	19	11	22	
Isoleucine	40	28	29	13	54	38
Leucine	53	36	44	18	66	55
Lysine	60	38	44	16	70	59
Methionine - cysteine	33	25	22	17	57	25
Phenylalanine - tyrosine	72	53	52	18	89	65
Threonine	50	34	28	8	47	25
Tryptophan	16	11	9	5	17	10
Valine	54	35	25	13	66	38

On the basis of egg protein for 100, each value is given for 100.

Table 2.15 Scoring Patterns of Amino Acid Requirements in Humans and of Egg and Body Proteins

The scoring system is easy to apply because no animal studies or clinical studies are required to compare different nutritional formulations. The *chemical score* of a protein is calculated in two steps. First a score is calculated for each essential amino acid (EAA) in the protein against the reference protein:

$$\text{EAA score} = \frac{(\text{content of the EAA in the test protein/mixture})}{(\text{content of the EAA in reference protein/mixture})} \cdot 100$$

Next the lowest score is selected; the amino acid with the lowest score is defined as the *limiting amino acid*. The chemical score of the limiting amino acid is the protein's score. Typically, the limiting amino acids in dietary proteins are lysine, the sulfur-containing amino acids, threonine, and/or tryptophan. The BCAAs and phenylalanine/tyrosine are not usually limiting. The scoring method points out the obvious: proteins not balanced among the essential amino acids are not as good as those that are.

Ratio of Essential to Nonessential Amino Acids in Protein

Protein requirements diminish from infancy on ([Table 2.13](#)) because rates of accretion of new protein diminish with maturity. However, when the changes in requirements for essential amino acids in [Table 2.14](#) are compared with the total protein requirements in [Table 2.13](#) with age, a greater drop with age is seen in essential amino acid requirements than in protein requirements. Essential amino acids make up more than 30% of protein requirements in infancy and early childhood and drop to 20% in later childhood and 11% in adulthood. As essential amino acids become a decreasingly

important part of the amino acid requirements with age, nonessential amino acid intake could increase and become an increasingly greater proportion of our intake. However, such substitution does not necessarily happen. Except for possibly changing the type of protein eaten (e.g., decreased intake of milk proteins), we continue to eat protein presumably at or above the RDA. If that protein is of high quality, such as egg protein, it provides almost half of its amino acids as essential amino acids. Therefore, consumption of high-quality protein by adults at levels that meet the RDA for protein provide a severalfold excess of individual essential amino acids beyond requirements. In general, it is not hard for adults to meet the minimum for essential amino acid intake, as recommended or as proposed by Young (165), when protein is consumed at or above requirement.

Amino Acid Availability from Dietary Protein Sources

The above methods provide schemes for determining protein quality based upon either animal growth or amino acid composition using scoring. A particular drawback with the scoring system is that it does not consider other factors inherent in the test protein or the effect of how the protein is prepared for consumption. How food is prepared may significantly affect the bioavailability of individual amino acids. As discussed above, some plants contain protein inhibitors of proteolytic digestive enzymes. Although soy protein is limiting in terms of its methionine content (180), rats fed soy protein grow poorly because of trypsin inhibition (134). Heat processing of the soy protein inactivates these inhibitors and improves growth (180).

However, heat processing itself may damage amino acids. For example, heat treatment of protein in the presence of reducing sugars can promote reactions altering the lysine amino groups in the protein. This reaction, called the Maillard, or “browning,” reaction, can be seen in milk processing in which lactose reacts with lysine at high temperatures. Oxidative or alkaline processing conditions may alter other essential and nonessential amino acids, inducing loss of methionine or formation of amino acid products that have toxic properties. Likewise, storage conditions may affect the nutritional quality of the protein. Thus, processing or “cooking” the protein source as well as storage conditions and other factors must be considered in evaluating the quality of the protein.

Protein and Amino Acid Needs in Disease

Most of the discussion to this point has centered around amino acid and protein metabolism in normal individuals. Although the effect of disease on amino acid and protein requirements is beyond the limits of this introductory chapter, a few important general points need to be made. The first is that energy and protein needs are tied together, as illustrated in Figure 2.16. When metabolic rate rises, body protein is mobilized for use as a fuel (amino acid oxidation) and for supply of carbon for gluconeogenesis. Several disease states increase metabolic rate. The first is infection, in which the onset of fever is a hallmark of increased metabolic rate. The second is injury, be it trauma, burn injury, or surgery per se. Along with onset of a hypermetabolic state comes a characteristic increase in the loss of protein measured by increased urea production. Sir David Cuthbertson observed over 60 years ago that a simple bone fracture causes significant loss of N in the urine (181). Since then, numerous studies of

the hypermetabolic state of injury and infection have been performed. For most people, the injuries suffered are minimal and self-limiting, i.e., the fever goes away in a couple of days or the injury heals. In normal, healthy people the impact of the injury on overall protein metabolism is as minimal as a bout of fasting. However, in chronic, long-term illness or in patients otherwise weakened by age or other factors, onset of a hypermetabolic state may produce a significant and dangerous loss of body N.

The second point is that while the diagnosis of a metabolic condition that needs correcting may be straightforward (e.g., finding an increased loss of N and wasting of body protein), correcting the problem by administration of nutritional support is not as simple. The underlying illness usually resists or complicates simple nutritional replacement of amino acids. Trauma and infection are classic problems in which prevention of N loss is very difficult. Supplying additional nutrients either enterally (by mouth or feeding tube) or parenterally (by intravenous administration) may blunt, but will not reverse, the N loss seen in injury ([182](#), [183](#)).

Simple tools have been used to identify the hypermetabolic state: indirect calorimetry to measure energy expenditure, and N balance to follow protein loss. These measurements have shown that blunting the N loss in such patients is not as simple as supplying more calories, more amino acids, or different formulations of amino acids. What becomes clear is that although a nutritional problem exists, nutritional replacement will not correct the problem; instead, the metabolic factors that cause the condition must be identified and corrected. Wilmore has categorized the factors that produce the hypermetabolic state into three groups: stress hormones (cortisol, catecholamines, glucagon), cytokines (tumor necrosis factor, interleukins, etc.), and lipid mediators (prostaglandins, thromboxanes, etc.) ([182](#)). Strategies have been developed to address these various components. For example, insulin and growth hormone have been administered to provide anabolic hormonal stimuli to improve N balance. Alternatively, studies have been conducted in healthy individuals in which one or more of the potential mediators are administered to determine its effect on amino acid and protein metabolism ([183](#), [184](#)). For example, studies of the infusion of individual hormones while isotopically labeled amino acid tracers are also infused have given us some insight into the mechanisms of hormone action upon the regulation of amino acid oxidation and protein breakdown and synthesis in humans ([184](#)).

There are areas in which administration of a specific amino acid may produce a pharmacologic effect in ameliorating the disease state; for example, administration of glutamine and arginine or limiting sulfur amino acid intake. Glutamine is the most highly concentrated amino acid in muscle cells and plasma ([89](#)). Glutamine is an important nutrient to many cells, especially the gut and white cells, where it may be used both as a source of energy and for such critical processes as the synthesis of nucleotides ([185](#)). Glutamine is an essential nutrient for cell culture media. Because a hallmark of injury is a drop in the intracellular level of muscle glutamine, presumably because of increased use by other tissues, glutamine has been proposed as a nutrient that becomes conditionally essential in trauma and infection ([182](#)).

Arginine is another nonessential amino acid with important properties for promoting immune system function. Arginine is the precursor for nitric oxide synthesis ([186](#)) and

has been proposed as a nutrient for altering immune function and improving wound healing (187, 188). We believe that adequate ornithine is synthesized to maintain arginine supplies under normal conditions, but we do not know whether additional demands for arginine can be met endogenously or whether arginine becomes a conditionally indispensable nutrient. For example, Yu et al. (189) used stable isotope tracers to measure arginine kinetics in pediatric burn patients and determined little net de novo arginine synthesis, suggesting that under conditions of burn injury, insufficient arginine is made to meet the body's presumed increased need when the immune system is under challenge.

Elevated plasma homocysteine is an independent risk factor for vascular disease (190). Homocysteine is produced by hydrolysis of *S*-adenosylhomocysteine, which is derived from *S*-adenosylmethionine, a major methyl group donor (e.g., in creatine synthesis in Fig. 2.5). Homocysteine may be "remethylated" to methionine or degraded via condensation with serine to form cystathionine, which then goes on to form cysteine (Fig. 2.4). High concentrations of homocysteine occur when either or both of the disposal pathways of homocysteine are impaired. Because these reactions of homocysteine metabolism depend upon vitamin B₆ (pyridoxal 5'-phosphate) and folate, supplementation of the diet with vitamin B₆ and folate often is effective in lowering plasma homocysteine levels (190). Alternatively, the dietary intake of sulfur amino acids may be reduced by ingesting relatively more of a sulfur amino acid-poor dietary protein, such as soy protein.

While supplementation of specific amino acids or cofactors may produce beneficial responses, there may be occasions when supplementation produces undesirable effects on the disease state. Supplementing glutamine in the diets of cancer patients may be counterproductive because the glutamine (which is essential for fast-growing cell lines in culture) may promote accelerated tumor growth (191). Similarly, arginine supplementation may stimulate nitric oxide synthesis because of the increased availability of the precursor for its formation. However, nitric oxide production produces both helpful and detrimental effects (186). In these and other applications of specific nutrients, the use of isotopically labeled tracers is particularly helpful because the metabolic fate of the administered nutrient may be followed (labeled nitrate production from nitric oxide synthesis from ¹⁵N-labeled arginine) as well as measurement of the promotion or suppression of protein synthesis and proteolysis in specific tissues. Amino acid and protein requirements in various diseases are quite difficult to assess and require a multifactorial approach. These are the real challenges facing us in nutrition today and in the days ahead.

Abbreviations: **ADP**—adenosine diphosphate; **AMP**—adenosine monophosphate; **ATP**—adenosine triphosphate; **A-V**—arteriovenous; **BCAA**—branched-chain amino acid; **GMP**—guanosine monophosphate; **IMP**—inosine monophosphate; **KIC**— α -ketoisocaproate; **mRNA**—messenger RNA; **N**—nitrogen; **PER**—protein efficiency ratio; **PRPP**—phosphoribosylpyrophosphate; **RDA**—recommended dietary allowance; **TCA**—cycle, tricarboxylic acid cycle; **TML**—trimethyllysine; **tRNA**—transfer RNA; **WHO/FAO/UNU**—World Health Organization/Food and Agriculture Organization/ United Nations University.

HISTORICAL HIGHLIGHTS

The initial history of carbohydrates is the story of sugar cane and the human passion for sweetness. Although there is some dissension, sugar cane's origin is thought to be Papua New Guinea. It was probably cultivated from wild plants (still in existence) about 10,000 years ago at the time of the global Neolithic agricultural revolution. The slow diffusion of migrants carried it to India, Southeast Asia, and China. Sugar was mentioned by an Indian author in 325 BC. After the Arabs defeated the Romans, they brought the sugar cane from Persia to Europe and the Mediterranean where it failed to thrive, apart from the Moroccan coast. The returning Crusaders brought sugar to the European courts where it became an important and desirable luxury dietary constituent. Sugar cane was introduced to the Caribbean by Christopher Columbus on his second voyage, in 1493. The plants came from his father-in-law's plantation established in

Madeira in 1492 (Canary Islands). They thrived and were dispersed to Central and South America and throughout the Caribbean. By the early 17th century, raw sugar was being handled by refineries in England and France. Beets (unlike sugar cane, which needed a tropical or semitropical climate) could be grown in temperate climates and were first recognized as a source of sugar by Marggraf in 1747. Napoleon used beets to bypass the British sugar blockade of the French Caribbean Islands; by 1813, approximately 35,000,000 kg (35,000 tonnes) were being produced. Sugar from beets now represents 40% of the world sugar market. Kirchoff, a Russian chemist, reported in 1812 that starch, the plant storage form of carbohydrate, when boiled with dilute acid gave rise to a sugar identical with that of grapes (glucose). Schmidt, in 1844, designated carbohydrates as compounds that contained C, H, and O and showed that sugar was found in the blood. Liver glycogen, the animal storage form of carbohydrate, was discovered by the outstanding French physiologist Claude Bernard in 1856. Sugar is now cultivated in practically every country in the world and is consumed as a basic or staple food.

DEFINITION

What are carbohydrates? The formal definition is a class of substances having the formula $C_n(H_2O)_n$, i.e., the molar ratio of C:H:O is 1:2:1. This definition, however, fails for oligosaccharides, polysaccharides, and sugar alcohols (viz., sorbitol, maltitol, mannitol, galactitol, and lactitol). Of the complex carbohydrate macromolecules known, the main member is plant starch (and the animal polymer glycogen), but the group includes pectins, cellulose, and gums. Simple carbohydrates include the hexose monosaccharides (glucose, galactose, and fructose) and the disaccharides maltose (glucose-glucose), sucrose (glucose-fructose), and lactose (glucose-galactose). Other carbohydrates include trioses (glycerose, $C_3H_6O_3$), tetroses (erythrose, $C_4H_8O_4$), and pentoses (ribose, $C_5H_{10}O_5$). The latter are important constituents of nucleic acids. In general, oligosaccharides yield two to ten monosaccharides on hydrolysis, while polysaccharides yield more than ten. The polysaccharides serve storage and structural functions. Starch is the storage carbohydrate of plants; glycogen is that of animals (liver contains up to 6% and muscle about 1%) and is often called animal starch. There are many different types of starch, depending on the plant source. Inulin, for example, is a starch found in the tubers and roots of dahlias, artichokes, and dandelions and when hydrolyzed yields only fructose; hence it is a fructosan. The oligosaccharide cellulose consists of glucose units linked by $\beta(1-4)$ bonds to form long straight chains strengthened by hydrogen bonding. It is the chief structural framework of plants and cannot be easily digested by humans because they do not secrete an intestinal carbohydrase that attacks the $\beta(1-4)$ linkage. It is often thought of as a dietary fiber that gives bulk to food. Bacterial enzymes, however, can break down cellulose. A small amount is probably hydrolyzed by this process in the colons of humans, but it has little nutritive value.

Dietary Carbohydrates

Carbohydrates ([Fig. 3.1](#)) thus exist as a vast family of naturally occurring compounds and derivatives of these compounds. Fortunately, only a small number of them are

commercially significant and used in the food industry, while a similar number are of metabolic importance. Dietary carbohydrate is a major nutrient for both man and omnivorous animals. Human adults in the Western world obtain approximately half their daily caloric requirements from dietary carbohydrates; in the developing countries, it is the major source. Of this ingested carbohydrate, some 60% is in the form of polysaccharides, mainly starch and glycogen, but the disaccharides sucrose and lactose represent 30% and 10%, respectively (Table 3.1). More recently, in a few Western countries, a significant intake of monosaccharide sugars (glucose and fructose) can be obtained from manufactured foods and drinks. Some oligosaccharides, such as raffinose and stachyose, are found in small amounts in various legumes. They cannot be broken down by the enzymes of the pancreas and small intestine, but they are digested by bacterial enzymes, especially in the colon.

Figure 3.1. Structures of the common dietary monosaccharides and disaccharides in perspective, Haworth representation.

Table 3.1 Principal Dietary Carbohydrates

The important dietary polysaccharides, starch and glycogen, have to be broken down into their constituent monosaccharides before they can be used for metabolic purposes. This breakdown is initially carried out by the carbohydrase α -amylase secreted by the salivary glands and the pancreas and completed by the barrier of disaccharidases in the brush border membrane of the mature enterocytes covering the villi of the small intestine (see [Table 3.2](#) for the major intestinal glycosidases) (1).

Glycosidase	Enzyme Complex	Enzyme Activity
Maltase-sucrase	Sucrase-isomaltase	80% of maltase; some α -limit dextrinase; all of sucrase; most of isomaltase
Maltase-isomaltase Maltase-glucoamylase (2)	Glucoamylase	All glucoamylase; most of α -limit dextrinase; 20% maltase; small % isomaltase
Trehalase Lactase	β -glycosidase	All trehalase All neutral lactase and cellobiose
Glycosyl-ceramidase (phlorizin hydrolase)		Most of aryl β -glycosidase

Adapted from Dahlqvist A, Semenza G. *J Pediatr Gastroenterol* 1988;4:837-837.

Table 3.2 Major Glycosidases of the Mammalian Enterocyte Brush Border

Starch

Starch, by far the most important dietary polysaccharide, consists only of glucose units and is thus a homopolysaccharide and is designated a glucosan or glucan. It is actually composed of two such homopolymers ([Fig. 3.2](#)): amylose, which has linear (1-4) linked α -D-glucose, and amylopectin, a highly branched form containing both (1-4) and (1-6) linkages at the branch points. Plants have both forms as insoluble, semicrystalline granules and differing ratios of amylopectin and amylose, depending on the plant source ([Table 3.3](#)). The salivary and pancreatic amylases act on the interior (1-4) linkages but cannot break the outer glucose-glucose links. Thus, the final breakdown products formed by the amylases are α (1-4)-linked disaccharides (maltose) and trisaccharides (maltotriose).

Figure 3.2. Starch is composed of amylose (15–20%) and amylopectin (80–85%). Amylose is a nonbranching helical chain structure of glucose residues, while amylopectin (a portion shown above) has branched chains of 24–30 glucose residues (*solid black*) joined by (1@4) glucosidic linkages with (1-6) linkages creating the branching points.

	Amylose (%)	Amylopectin (%)
Maize (standard)	24	76
Potato	20	80
Rice	18.5	81.5
Tapioca	16.7	83.3
Wheat	25	75

Table 3.3 Amylose and Amylopectin Content of Various Plant Starches

Starch Breakdown

The breakdown of starch begins in the mouth, with salivary amylase. It is often assumed that as this is swallowed into an acid stomach the enzymic carbohydrate breakdown is then stopped (although acid hydrolysis may still occur) because salivary amylase is inhibited by a pH below 4. However, starch and its end products and the proteins and amino acids present in a mixed meal all buffer the acid of the stomach, allowing hydrolysis to continue. The quantitative involvement of salivary amylase in the breakdown of starch is thus probably underestimated. Pancreatic α -amylase added to the emptying gastric contents (chyle) in the duodenum cannot hydrolyze the (1-6)

branching links and has little specificity for the (1-4) links adjacent to the branching points. Amylase action thus produces large oligosaccharides (α-limit dextrins) containing on average about eight glucose units with one or more (1-6) links. These α-limit dextrins are split by the enzymic action of glucoamylase (α-limit dextrinase), which sequentially removes a single glucose unit from the nonreducing end of a linear α(1-4)-glucosyl oligosaccharide. Maltose and maltotriose are then broken down by secreted and brush border disaccharidases, especially sucrase-isomaltase, into free glucose, which is then transported into and across the enterocytes by hexose transporters ([Table 3.4](#)).

Type	Amino Acids (kD)	Chromosome Location	K_m (mmol/L) or Hexose (μmol/L)	Major Expression Sites
GLUT 1 (vertical)	460	1	1-2 (red cells)	Placenta, brain, kidney, colon
GLUT 2 (liver)	524	3	15-20 (hepatocytes)	Liver, β-cell/colony small intestine
GLUT 3 (brain)	498	12	10 (Kempes astrocytes)	Brain, testis
GLUT 4 (muscle)	520	17	5 (adipocytes)	Skeletal & heart muscle, brown & white fat
GLUT 5 (small intestine)	501	1	6-11* *fructose (Kempes astrocytes)	Small intestine, sperm

*The approximate K_m values refer to the uptake of glucose/fructose in the case of GLUT 5 in the designated tissue or cell in parentheses and are shown to give an approximate idea of the affinity of the transporter for glucose.

Table 3.4 Human Facilitated-Diffusion Glucose Transporter Family, GLUT 1–5

The initial breakdown of starch into α-limit dextrins, the intraluminal or cavital digestion phase, occurs mainly in the bulk fluid phase of the intestinal contents. In man, there appears to be little of the so-called contact or membrane digestion in which adsorption of amylase onto the brush border surface of enterocytes facilitates its enzymatic activity ([2](#)).

Normally α-amylase is not a limiting factor in the assimilation of starches in humans, but newborn babies and especially premature ones cannot assimilate starch because the pancreas secretes insufficient α-amylase to digest it. However, after a month, the secretion of α-amylase is satisfactory for full digestion ([3](#)).

Resistant Starch

Starch is usually eaten cooked. The heat of cooking gelatinizes the starch granules, increasing their susceptibility to enzymic (α-amylase) breakdown. However, a proportion of the starch, called resistant starch (RS), is undigestible even after prolonged incubation with the enzyme. In cereals, RS represents 0.4 to 2% of the dry matter; in potatoes, 1 to 3.5%; and in legumes, 3.5 to 5.7%. RS has been categorized as the sum of the starch and degradation products not absorbed in the small intestine of a healthy person ([3a](#)). There are three main categories: RS1, physically enclosed starch (partially milled grains and seeds); RS2, ungelatinized crystallite granules of the B-type x-ray

pattern (as found in bananas and potatoes); and RS3, retrograded amylose (formed during the cooling of starch gelatinized by moist heating). Resistant starch escapes digestion in the small intestine, but it then enters the colon, where it can be fermented by the local resident bacteria (of which there are over 400 different types). In this respect, RS is somewhat similar to dietary fiber. Estimates of the RS and unabsorbed starch represent about 2 to 5% of the total starch ingested in the average Western diet. This approximates to less than 10 g carbohydrate/day (4). The end products of the fermentation of the RS in the colon are short-chain fatty acids (e.g., acetic, butyric, propionic), carbon dioxide, hydrogen, and methane (expelled as flatus).

Refractory starches stimulate bacterial growth in the colon. While the short-chain fatty acids stimulate crypt cell mitosis in animals, it is not known whether they do the same in the human colon (5). However, if the human colon is removed from the mainstream of foodstuffs flowing down the lumen of the gastrointestinal tract, then the colonocytes become defunctionalized and ionic absorption is reduced. Luminal short-chain fatty acids from bacterial fermentation are used by colonocytes as metabolic substrates and appear essential for normal colonic function (6).

Dietary Fiber

Dietary fiber was originally defined as “the remnants of plant cell walls not hydrolyzed by the alimentary enzymes of man” but the definition was subsequently modified to include “all plant polysaccharides and lignin which are resistant to hydrolysis by the digestive enzymes of man” (7). The fiber, both soluble and insoluble, is fermented by the luminal bacteria of the colon. High-fiber diets maintained for the long term reduce the incidence of colon cancer, but the mechanism(s) involved rest on speculation, viz., its bulking action speeding colonic transit and reducing the absorption of luminal chemicals or the fiber absorbing the carcinogenic agents (5). (See also [Chapter 43.](#))

Sugar Functions and Properties

Sugars, unlike starch, have an obvious impact on human taste—they are sweet. The classic view of taste recognizes four: sweet, sour, salty, and bitter, with all other taste sensations considered mixtures of these. A more modern concept is that sweetness is not a unitary quality, and individuals “taste” different sweetness qualities for different sweeteners. Human neonates recognize and like sweetness, which is not surprising since the lactose in their major food, human milk, gives it a sweet taste. Estimates of relative sweetness of various carbohydrates by humans are usually made against the standard, sucrose (100%). On this scale, glucose (sweet with a bitter side taste) is 61 to 70, fructose (sweet, fruity) 130 to 180, maltose (sweet, syrupy) 43 to 50, and lactose 15 to 40. It is speculated that during mankind's evolution, the quest for food, hence, energy, made primitive man recognize that sweetness indicated safety and energy. Hence, sweetness became a desirable quality.

Today, sugar (especially sucrose) is used extensively in foods to give sweetness, energy, texture, and bulk and also for appearance, preservation (by raising the osmotic pressure), and fermentation (in bread, alcoholic beverages). The palatability, appearance, and shelf life of a huge variety of foods and drinks are enhanced by adding

sucrose, e.g., breads, cakes, and biscuits; preserves and jellies; confectionery; dairy products; cured, dried, and preserved meats; breakfast cereals; and frozen and canned vegetables. This “hidden sugar” makes the assessment of dietary sucrose intakes difficult.

GETTING GLUCOSE INTO CELLS—THE TRANSPORTERS

A major source of metabolic energy for most, if not all, mammalian cells is the oxidation of D-glucose. The lipid-rich membranes of such cells, however, are relatively impermeable to hydrophilic polar molecules such as glucose. Special transport processes have been developed to allow the cellular entry and exit of glucose. Carrier proteins located in the plasma membranes of cells can bind glucose and allow it to traverse the lipid membrane barrier, releasing the hexose into the cellular cytoplasm or body fluids.

Two distinct classes have been described: (a) a family of facilitative glucose transporters ([Table 3.4](#)) and (b) Na⁺-glucose cotransporters (symporters). The former class are membrane integral proteins found on the surface of all cells. They transport D-glucose down its concentration gradient (from high to low), a process described as *facilitative diffusion*. The energy for the transfer comes from dissipation of the concentration difference of the glucose. Such glucose transporters allow glucose to enter cells readily, but they can also allow it to exit from cells according to the prevailing concentration difference. In contrast, the Na⁺-glucose cotransporters participate in the uphill movement of D-glucose against its concentration difference, that is, they perform *active transport*. They are especially expressed in the specialized brush borders of the enterocytes of the small intestine and the epithelial cells of the kidney (proximal) tubule. They occur at lower levels in the epithelial cells lining the lung and in the liver ([8](#)). Cooperation between the two classes of glucose transporters, together with the hormones involved in carbohydrate metabolism, allows a fine control of glucose concentration in the plasma, maintaining a continuous supply of the body's main source of cellular energy.

The Human Facilitative-Diffusion Glucose Transporter Family

Five major hexose transporters have been identified and cloned since the characterization of the first, GLUT 1, by molecular cloning ([9](#)). They are numbered GLUT 1 to 5 in the order of their discovery and are all proteins with similar molecular structures containing between 492 and 524 amino acid residues. Mueckler et al. ([9](#)), using hydropathic and secondary structure predictions, proposed a two-dimensional orientation model of GLUT 1 in the plasma membrane ([Fig. 3.3](#)). The molecule has three major domains: (a) 12 α -helices spanning the membrane with the N and C termini of the protein on the cytoplasmic side of the cell membrane, (b) an intracellular domain of 65 hydrophilic amino acids (between M6 and M7), and (c) an extracellular 33-amino-acid segment (between M1 and M2) containing the site for an asparagine-linked oligosaccharide at asparagine 45.

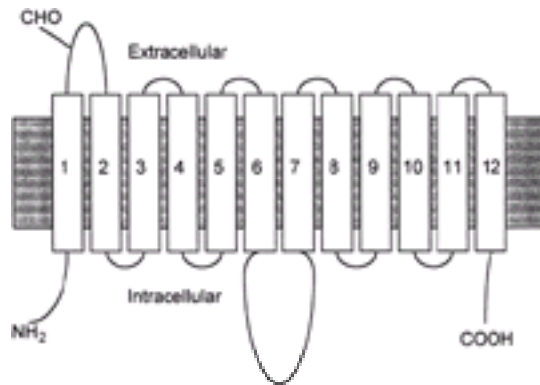

Figure 3.3. Highly schematic diagram illustrating the predicted secondary structure model of the glucose transporter molecule (GLUT 1) in the cell membrane (*shaded*). The putative membrane-spanning α -helices are shown as rectangles numbered 1–12 connected by chains (*lines*) of linked amino acids. (Adapted from Mueckler M, Caruso C, Baldwin SA, et al. *Science* 1985;229:941–5.)

The prediction was that the polypeptide backbone of the molecule traverses or spans the plasma membrane 12 times. Both the amino- and carboxy-terminal ends of the molecule are on the cytoplasmic side of the membrane, while an N-glycosylation site is present on the first extracytoplasmic loop (M1 and M2). These basic topologic features have been confirmed by studies using proteolytic digestion and sequence-specific antibodies. GLUT 1, purified from human red cells and reconstituted in liposomes, appears to be predominantly in the α -helical form, and the transmembrane segments form α -helices at right angles to the plane of the lipid membrane (10). The molecular structure of GLUT 1, shown in [Figure 3.3](#), is, of course, a two-dimensional model. At present, the three-dimensional structure of the carrier in the membrane is not known. Studies using radiation inactivation of the carrier in intact red cells have indicated that GLUT 1 probably exists as homotetramer (11).

The structures, properties, expression sites, and roles of each of the five facilitative glucose transporter isoforms are briefly described below and summarized in [Table 3.4](#). Because of the recognized importance of these transporters in health and disease, there have been numerous reviews (12, 13, 14 and 16), which should be consulted for greater detail.

GLUT 1 (Erythroid-Brain Carrier)

GLUT 1 is the glucose transporter in the human red cell. The first to be characterized by molecular cloning (9), it consists of 492 amino acid residues ([Table 3.4](#)). The gene for its expression is located on chromosome 1. GLUT 1 is widely distributed in many tissues including heart, kidney, adipose cells, fibroblasts, placenta, retina, and brain, but little is expressed in muscle or liver. Since there is particularly high expression in the endothelial cells of the microvessels of the brain, it forms part of the blood-brain barrier

(17). The transport process for D-glucose in the red cell is asymmetrical, as the affinity (K_m) for D-glucose uptake is approximately 1 to 2 mmol/L while the K_m for the exit of glucose is 20 to 30 mmol/L. This asymmetry appears to be allosterically regulated by the binding of intracellular metabolites and inhibited by adenosine triphosphate (ATP) (18). The asymmetry allows the transporter to be effective when the extracellular glucose is low and the intracellular demand high.

GLUT 2 (Liver Glucose Transporter)

Many biochemical studies indicated that the glucose transporter in liver cells was distinct from that of the red cells. Moreover, adult liver cells had only very low levels of GLUT 1 mRNA. Cloning of the second glucose carrier, GLUT 2, was accomplished by screening rat and human cDNA libraries with a cDNA probe for GLUT 1. GLUT 2 has 55% identity in amino acid sequence with GLUT 1, and it displays the same topologic organization in the cell membrane as predicted for GLUT 1. Human GLUT 2 contains 524 amino acids (Table 3.4), compared with rat GLUT 1 of 522 residues, and they show 82% identity in amino acid sequences, an excellent example of conservation of structure between species. GLUT 2 is preferentially expressed in liver (sinusoidal membranes), kidney (tubule cells), small intestine (enterocytes), and the insulin-secreting β cells of the pancreas.

In the liver cell, GLUT 2 has a low affinity for glucose ($K_m = 17$ mmol/L) and shows symmetric transport, i.e., a similar K_m for influx and efflux. This high-capacity, low-affinity transporter is useful for rapid glucose efflux following gluconeogenesis. GLUT 2 can also transport galactose, mannose, and fructose (19). The ability to transport fructose is only seen with GLUT 2 and GLUT 5 (see below).

GLUT 3 (Brain Glucose Transporter)

GLUT 3 was originally cloned from a human fetal muscle cDNA library (20). It contains 496 amino acid residues (Table 3.4) and shows 64% identity with GLUT 1 and 52% identity with GLUT 2. Its amino acid sequence again suggests that its membrane topology is similar to that of GLUT 1 (Fig. 3.3). GLUT 3 mRNA appears to be present in all tissues, but its highest expression is in adult brain, kidney, and placenta. Adult muscle, however, shows only very low levels. In the brain, it is mainly expressed in neurons. A GLUT 3 mRNA is found in fibroblasts and in smooth muscle. Since both of these cell types are found in practically all tissues, the ubiquitous expression of GLUT 3 is understandable. Its affinity for glucose transport is relatively low ($K_m \gg 10$ mmol/L) but significantly higher than that of GLUT 1 (17 mmol/L). A GLUT 3 is also found in spermatozoa. Such cells undertake glycolysis in the male genital tract, taking up glucose from epididymal fluid.

GLUT 4 (Insulin-Responsive Glucose Transporter)

Glucose is transported across the cell membranes of adipocytes (fat cells), and its rate of transport can be speeded up 20- to 30-fold within 2 or 3 minutes by addition of insulin, without evidence of protein synthesis. Studies showed that this stimulation of

glucose transport was due in part to translocation of GLUT 1 from an intracellular pool into the membrane. Careful quantitative measurements showed, however, that this could account for only a 12- to 15-fold increase in glucose transport. It became obvious that another transporter would have to be involved to account for the much larger insulin-stimulated transport. This new transporter, GLUT 4, was first identified in rat adipocytes by use of a monoclonal antibody. Subsequently, it has been cloned from rat, mouse, and human DNA (19). It is a protein with 509 amino acid residues (Table 3.4), with 65% identity with GLUT 1, 54% identity with GLUT 2, and 58% identity with GLUT 3. Rat and mouse GLUT 4s have 95 and 96% identity, respectively, with human GLUT 4. As with the previous GLUT transporters, the two-dimensional orientation of the structure in the cell membrane is similar to that proposed for GLUT 1 (Fig. 3.3).

GLUT 4 is the major glucose transporter of the insulin-sensitive tissues, brown and white fat, and skeletal and cardiac muscle. It occurs primarily in intracellular vesicles in the cells of these tissues. Insulin stimulation causes a rapid increase in the number of glucose transporters on the membranes of these cells because the vesicles are translocated toward the membrane and then fuse with it, releasing the molecule. This process ensures a high density of glucose transporters, enhancing the ability to move glucose from the surrounding cellular fluid into the interior of the cell, i.e., increased V_{\max} for glucose uptake. Because of this mechanism, the position of GLUT 4 and its regulation are important components of glucose homeostasis and its role in diabetes has been much studied.

Glut 5 (The Fructose Transporter?)

GLUT 5 was isolated from human (21), rat, and rabbit enterocyte cDNA libraries. It consists of 501 amino acid residues (Table 3.4), and has only 42%, 40%, 39%, and 42% identity with GLUTs 1, 2, 3, and 4, respectively. It is said to be primarily expressed in the jejunum (both in the brush border and basolateral membrane), but its mRNA has been detected, albeit at low levels, in human kidney, skeletal muscle, and adipocytes, microglial cells, and the blood-brain barrier. GLUT 5 appears to transport glucose poorly and is really the transporter for fructose. It is found in high concentrations in mature human spermatozoa (22), which are known to use fructose as an energy source (human seminal fluid contains high concentrations of fructose, which is manufactured by the seminal vesicles). In oocytes injected with GLUT 5 mRNA to effect GLUT 5 expression, the K_m for fructose uptake was 6 to 11 mmol/L.

Other Transporters

The major glucose transporters in cells have been the identified and cloned GLUTs 1–5. There are reports, however, of a possible GLUT 6 and GLUT 7.

GLUT 6 (Pseudogene-like Sequence)

A cDNA clone isolated from a human jejunum cDNA library hybridized to an approximately 11-kb transcript expressed at variable levels in all normal and tumor cells examined (22). The sequence of a partial-length GLUT 6 cDNA revealed approximately

80% identity with the human brain GLUT 3 transporter. However, because of multiple stop codons and frame shifts, the sequence could not encode a functional glucose transporter protein. The GLUT 6 gene was located on the long arm of human chromosome 5.

GLUT 7 (Hepatic Microsomal Glucose Transporter)

The existence of GLUT 7 has been reported. Unlike the others, it is an internal or intracellular transporter, possibly involved in the glucose-6-phosphatase complex found in the endoplasmic reticulum of hepatocytes. Glucose is produced in the liver by glycogenolysis and gluconeogenesis. The last stage of each of these processes is the removal of a phosphate group from glucose by the multicomponent enzyme glucose-6-phosphatase; the resultant free glucose is liberated into the lumen of the endoplasmic reticulum. To export the glucose into the bloodstream it must be transferred across the endoplasmic reticulum membrane. The transporter that does this job is called GLUT 7 (23). It has 65% identity of amino acids with GLUT 2. There is a unique sequence of 6 amino acids at the C terminus of GLUT 7 that appears to be involved in keeping the transporter in the endoplasmic reticulum membrane (19).

Study of Glucose Transporters by Use of Transgenic and Knock-Out Mice

Although a host of metabolic inhibitors are available for use in examining metabolic pathways, their specificities are often questionable. With molecular biologic techniques, however, metabolic pathways can be changed in quite specific ways, even in the intact animal. A protein (e.g., enzyme/carrier) can be overexpressed, expressed in a tissue that normally does not contain it, or eliminated in any particular cell type. Site-directed mutations allow a molecule to be dissected and particular component groups removed or altered so that their role in the molecule's functioning can be studied. Application of these techniques to the investigation of metabolic pathways and their regulation is just beginning (24). Recent examples involve the study of GLUT 1 and GLUT 4, which are responsible for transporting the bulk of the glucose from the blood, and investigating the role of GLUT 2 in glucose sensing in the insulin-secreting β cells of the pancreas. GLUTs 1 and 4 were altered in skeletal muscle and adipose tissue, respectively, (24) and the gene for GLUT 4 inactivated (25). In the case of GLUT 2, mice were created that did not express this transporter in the insulin-secreting cells of the pancreas (26). Brief comments about these studies show the new approaches fostered by molecular biologic techniques.

Transgenic mice were established that expressed high levels of human GLUT 1, and it was properly located in the muscle sarcolemma. The increase in the transporter created a 3- to 4-fold increase in glucose transport into specific tested muscles, confirming that GLUT 1 plays a major role in controlling glucose entry into resting muscle. Strangely, insulin did not increase the entry of glucose into the transgenic mice muscles despite the fact that GLUT 4 levels in these mice were the same as those of control mice. Possibly, the GLUT 1 levels are so high in the transgenic set that glucose is not limited any longer by transporter activity. Muscle glucose was 4- to 5-fold and glycogen 10-fold higher in the transgenic mice, even though they showed an 18 (fed) to 30% (fasted) decrease in plasma glucose concentration. Oral glucose loads did not increase plasma

levels as much as in normal mice and glucose was more rapidly disposed of. Thus, changing the level of GLUT 1 transporters affected not only muscle metabolism but also whole animal responses.

Because increases in the insulin-responsive transporter GLUT 4 occur in human and rodent adipocytes and are associated with obesity, the question arises as to whether increasing the GLUT 4 levels in adipocytes plays a role in obesity. Transgenic mice were made that expressed human GLUT 4 in their adipocytes. Basal-level glucose transport into their adipocytes increased approximately 20-fold compared with controls, but insulin only stimulated glucose uptake by a factor of 2.5, rather than the 15-fold increase of controls. Again, the possible explanation is that glucose transport is so high in the transgenic adipocytes that the number of transporters activated by insulin makes little difference to the overall transport. While the fat cell size was unchanged in the transgenic mice, their number more than doubled, and body lipid nearly tripled, matching the increase in cell number. The results suggest that a specific increase in GLUT 4 in adipocytes plays a role in generating obesity.

Remarkably, mice created with an absence of GLUT 4 have nearly normal glucose homeostasis (25). Clearly, while GLUT 4 is critical to the handling of glucose in insulin-sensitive tissues, it does not appear to be essential for survival. Presumably, other mechanisms can substitute for the absence of GLUT 4.

The β cells of the pancreas first sense, then respond to, elevated blood glucose levels by secreting insulin. The glucose transporter in their cell membranes is GLUT 2; circumstantial evidence suggests that it may be involved in the glucose-sensing mechanism. However, studies in transgenic mice created to express a transforming ras protein in the β cells showed that these animals respond normally to a glucose load, even though their β cells do not express GLUT 2 (26). It is thus difficult to consider GLUT 2 part of the sensing apparatus.

One major difficulty in using transgenic and “knock-out” mice is that the induced changes occur early on in the developing animal. Thus, the changes observed can be due to the presence or absence of the trans-gene at the time of the laboratory measurements or the genetic change could have initiated a plethora of events that caused the observed phenotype. Techniques are being developed, however, to overcome this serious problem.

BLOOD GLUCOSE—METABOLIC AND HORMONAL REGULATION

Metabolic

The concentration of glucose in the blood, set within the normal adult range of 3.9 to 5.8 mmol/L (70–105 mg/100 mL), is probably the most regulated of all substances. When a carbohydrate meal is ingested, the level may temporarily rise to 6.5 to 7.2 mmol/L, and during fasting it can fall to 3.3 to 3.9 mmol/L. One of the major reasons for closely regulating blood glucose levels is that the brain normally depends on a continuous supply, although it can adapt to lower levels or even use ketone bodies from fat

breakdown (27) if adaptation occurs slowly. This becomes essential during starvation, since the adult human brain uses about 140 g/day of glucose (28), and only about 130 g/day of glucose can be obtained from noncarbohydrate sources. Injection of a hormone, such as insulin, that rapidly lowers the blood glucose level can lead to convulsions and even death if left uncorrected.

Glucose enters the blood pool (about 16 g) from a number of sources. In normal postabsorptive man, the plasma appearance rate is 8 to 10 g/h, the blood pool being replaced every 2 hours. At normal blood glucose levels, the liver is a net producer of glucose.

When the dietary carbohydrates in a meal are finally hydrolyzed to glucose, galactose, and fructose, after absorption these are transported by the portal blood flow into the liver and kidney. The rising level of glucose to the liver decreases the liver output of glucose. In the rat, uptake and output are equal at about 8.3 mmol/L. The glucose entering the blood during a meal is handled by the liver and peripheral tissues, the first step being phosphorylation. In the tissues, phosphorylation is by hexokinase, an enzyme subject to feedback inhibition by the product, glucose-6-phosphate. The liver enzyme, glucokinase, is not so affected, has a lower affinity for glucose, and can increase its activity over the normal range of glucose found in the portal blood. It thus appears to be ideal for handling the high levels of glucose that enter the portal blood during a carbohydrate meal. Both galactose and fructose can be converted into glucose by the hepatic cells, so little of either hexose is found in the peripheral circulation, and more than 95% of all circulating hexoses is glucose.

Cori Cycle

Glucose can be formed in the liver and kidney from two other groups of compounds that undergo gluconeogenesis. Those in the first group, such as some amino acids (especially alanine during starvation) and propionate, are converted into glucose without being recycled; those in the second group are formed from glucose during its partial metabolism in various tissues. Both muscle and red blood cells oxidize glucose to form lactate, which on entering the liver is resynthesized into glucose. This newly formed glucose is then available for recirculation back to the tissue, a process known as the Cori, or lactic acid, cycle. The Cori cycle may account for approximately 40% of the normal plasma glucose turnover.

In the case of adipose tissue, the cells hydrolyze fats (acylglycerols) and form glycerol that cannot be metabolized by the adipocytes. The glycerol diffuses from the cells, enters the blood, and is transported to the liver and kidneys where it is converted back into glucose. Finally, glucose is also released into the blood by glycogenolysis of the large store of glycogen in the liver.

Hormonal

The level of glucose in the blood is regulated by both hormonal and metabolic mechanisms. The major hormones controlling the glucose level are (a) insulin, (b) glucagon, and (c) epinephrine (adrenaline), but others such as (d) thyroid hormone, (e)

glucocorticoids, and (f) growth hormone also play a role.

Insulin

Diabetes Mellitus—IDDM (Type I) and NIDDM (Type II). Insulin has a central role in regulating blood glucose. It is secreted by the β cells in the islets of Langerhans in the human pancreas; the daily output is some 40 to 50 units, which is about 15 to 20% of the amount stored in the gland. The glucose level in the blood controls insulin release; high blood glucose levels (hyperglycemia) cause secretion of insulin, low levels (hypoglycemia) inhibit. When the pancreas is unable to secrete insulin or secretes too little, the medical condition is known as diabetes mellitus. This disease, the third most prevalent in the Western world, is normally classified as type I, or insulin-dependent (IDDM), or type II, non-insulin-dependent (NIDDM). NIDDM accounts for approximately 90% of all diabetic patients. IDDM patients have an autoimmune disease of the β cells—they cannot make insulin and need daily injections of the hormone. IDDM affects children and younger adults predominantly and becomes manifest when about 80% of the β cells are destroyed. Those with NIDDM are mature adults. They have reduced secretion of the hormone and reduced metabolic response to it (peripheral insulin resistance). The cause(s) of this insulin resistance is still to be identified. There are conflicting findings about the role of GLUT 4 in the insensitivity. One group of workers has reported that there are no changes in GLUT 4 mRNA or protein (29), but others have found a small (18%) decrease (30). The insulin resistance may be due to a defect in translocation of GLUT 4 to the muscle membrane (19).

Mechanism of Insulin Secretion. The mechanism of the regulation of insulin secretion by the external glucose level has been studied using patch clamp techniques to control the ionic channels (see Chapter 38) in the β -cell membrane. The resting membrane potential of the β cells is maintained by the Na^+ - K^+ ATPase and ATP-sensitive K^+ channels (K_{ATP} channels). Normally these are open, but they close following glucose metabolism, when there is a concomitant increase in the ATP:ADP ratio (31). This depolarizes the cell membrane and opens voltage-gated Ca^{2+} channels. The resulting increase in the intracellular free Ca^{2+} concentration activates secretion of insulin through exocytosis—the fusion of insulin-containing granules with the plasma membrane and the release of their contents (32). A number of drugs (sulfonylureas), such as tolbutamide and glibenclamide, cause insulin secretion by inhibiting the K_{ATP} channels of the β cells and are used medically to treat NIDDM. K_{ATP} channels are a heteromultimeric complex of the inward rectifier K^+ channel (K_{IR} 6.2) and a receptor for sulfonylureas, SUR1, a member of the ABC or traffic family of plasma membrane proteins (33).

Apart from a high level of glucose in the blood, a variety of compounds increase insulin secretion, including amino acids, free fatty acids, ketone bodies, and the hormones glucagon and secretin. In human pregnancy, the hormones placental lactogen, estrogens, and progesterin all increase insulin secretion. Hence, insulin levels are higher in the pregnant than in the nonpregnant. Other hormones, such as epinephrine and norepinephrine (noradrenaline), inhibit its release. Inhibitory mechanisms are important as they protect individual β cells from overresponding and exhausting themselves (e.g.,

effects of chronic administration of growth hormone). Local controls by a host of autocrine, paracrine, and neurocrine substances (34) are thought to be involved in the inhibition of insulin secretion; these include the peptide pancreastatin, neuropeptide Y (NPY), somatostatin, calcitonin gene-related peptide (CGRP), galanin, and amylin (islet amyloid polypeptide or IAPP).

Insulin acts to lower blood glucose levels by facilitating its entrance into insulin-sensitive tissues and the liver. It does this by increasing the level of transporters in tissues such as muscle. In the liver, however, insulin stimulates storage of glucose as glycogen or enhances its metabolism via the glycolytic pathway. Surprisingly, glucose entry into liver cells is not mediated by changes in glucose transporter function, despite the fact that hepatocytes have these transporters present in their sinusoidal membranes (35). There is a functional specialization in the liver in regard to the disposition of GLUTs 1 and 2. GLUT 2 has higher expression in the periportal hepatocytes than in the perivenous hepatocytes. In the perivenous region, however, GLUT 1 is also present in the sinusoidal membranes of the hepatocytes, which form rows around the terminal hepatic venules. Periportal hepatocytes are more gluconeogenic than the more glycolytic perivenous cells (36). Why hepatocytes have GLUT 2 in their membranes is an enigma, as it is certainly not necessary for the ingress or egress of glucose. It has been suggested that GLUT 2 may be transporting fructose, since GLUT 5, the fructose transporter, is not expressed in the liver. However, GLUT 1 expression correlates well with the glycolytic activity of cells; in general, the higher the activity, the greater the concentration of GLUT 1. Thus, the presence of GLUT 1 in the perivenous liver cells may aid the efficient functioning of their glycolytic pathway.

While insulin has a primary influence on glucose homeostasis, it also influences many other cellular functions (Table 3.5). Glucose has a profound effect on the secretion of insulin, and insulin strongly affects the normal storage of ingested fuels and cellular growth and differentiation (as exemplified in Table 3.5). Thus, indirectly, glucose also influences these cellular events, which underscores the crucial role of glucose in influencing metabolism and catabolism, both directly and indirectly.

Positive Effects	Negative Effects
Glucose uptake	Pyruvate → glucose
Amino acid uptake	Apoptosis
Acetyl-CoA → fatty acid	Gene expression
Glucose → glycogen	
Protein synthesis	
DNA synthesis	
Na ⁺ K ⁺ pump	
Gene expression	

Table 3.5 Influence of Glucose via Insulin

Glucagon

Glucagon is secreted by the a cells of the islets of Langerhans in the pancreas. A major stimulus for its secretion is hypoglycemia (low blood glucose levels). Glucagon acts on the hepatic cells of the liver to cause glycogenolysis, the breakdown of glycogen, by activating the enzyme phosphorylase. It also enhances gluconeogenesis (formation of glucose) from amino acids and lactate. Thus, the major actions of glucagon oppose those of insulin. The a and b cells in the islets have a close functional relationship with one another; there is intraislet regulation of glucagon by insulin and of insulin by glucagon (37). Because of this, it is claimed that it is difficult to separate the direct effects of changes in plasma glucose levels on glucagon secretion from the a cells from control of glucagon secretion by insulin. When plasma glucose levels increase about twofold, glucagon secretion is inhibited by concurrent changes in b cell activity rather than by the direct effects of glucose or insulin on the a cells (38).

Glucagon must attach to its specific receptor in the plasma membrane to activate cellular responses. This specific glucagon receptor is a member of a superfamily of guanine nucleotide-binding protein-coupled receptors, and it is also a member of a smaller subfamily of homologous receptors for peptides structurally related to glucagon: GLP-1 (glucagon-like peptide-1), GIP (gastric inhibitory peptide), VIP (vasoactive intestinal peptide), secretin, GRF (growth hormone-releasing factor), and PACAP (pituitary adenylate cyclase-activating polypeptide). Using specific glucagon receptor mRNA expression in rat tissues, glucagon receptor mRNA was observed to be relatively abundant in liver, adipose tissue, and pancreatic islets, as expected, but also in heart, kidney, spleen, thymus, and stomach. Low levels were found in adrenal glands, small intestine, thyroid, and skeletal muscle. No expression was observed in testes, lung, large intestine, or brain (39).

Epinephrine

Epinephrine is secreted by the chromaffin cells of the adrenal medulla. It is often called the “fight or flight” hormone because stresses, such as fear, excitement, hypoglycemia, and blood loss, cause increased epinephrine output. It acts on liver and muscle to bring about glycogenolysis by stimulating phosphorylase, thus releasing glucose for muscle metabolism.

Thyroid

In humans, fasting blood glucose levels are elevated in hyperthyroid patients and lowered in hypothyroid patients. Thyroid hormones enhance the action of epinephrine in increasing glycolysis and gluconeogenesis and can potentiate the actions of insulin on glycogen synthesis and glucose utilization. They have a biphasic action in animals; at low doses they enhance glycogen synthesis in the presence of insulin, but at large doses they increase glycogenolysis.

Glucocorticoids

Glucocorticoids (11-oxysteroids) are secreted by the adrenal cortex. They increase gluconeogenesis and inhibit the utilization of glucose in the extrahepatic tissues; they are thus antagonistic to insulin's actions. The increased gluconeogenesis activated by the glucocorticoids involves increased protein catabolism in the tissues, enhanced uptake of amino acids by the liver, and increased activity of transaminases and other enzymes involved with hepatic gluconeogenesis.

Growth Hormone

Growth hormone is secreted by the anterior pituitary. Its secretion is enhanced by hypoglycemia. It has direct and indirect effects on decreasing glucose uptake in specific tissues such as muscle. Part of this effect may be due to the liberation of fatty acids from adipose tissue, which then inhibit glucose metabolism. If growth hormone is chronically administered, it causes persistent hyperglycemia, which stimulates the insulin secretion. The β cells, however, finally become exhausted, and diabetes ensues.

TRANSEPITHELIAL HEXOSE TRANSPORT—INTESTINE AND KIDNEY

Na⁺-Glucose Cotransporters (SGLTs)

The intestine and the kidney are two major organs that have epithelia with the specific function of vectorially transferring hexoses across their cells into the bloodstream. In the intestine, the transporters of the mature enterocytes capture the hexoses from the lumen after breakdown of dietary polysaccharides into simple hexoses, D-glucose, D-galactose, and D-fructose. In the kidney, the cells of the proximal tubule capture the glucose from the glomerular filtrate to return it to the blood. These glucose transporters, localized in the brush border membranes of the epithelial cells, differ from the GLUT 1–5 type and share no sequence homology. They are thus members of quite a different protein family.

Moreover, they transport glucose across the cell membrane by having both hexose and Na⁺ binding sites; thus the name Na⁺-glucose cotransporters. They couple cellular glucose transfer to the inwardly directed electrochemical gradient of Na⁺. The low intracellular concentration of Na⁺ ions, maintained by Na⁺-K⁺ ATPase or the Na⁺ pump at the basolateral borders of the cells, powers the uphill transfer of glucose through the agency of the cotransporter. The affinity of the sugar molecule for its cotransporter binding site is greater when the Na⁺ ions are attached to the transporter than when they are removed. Thus the external binding of Na⁺ and its subsequent intracellular debinding (because of the lower intracellular Na⁺ ion concentration) causes the binding, then release, of glucose, allowing it to be transported uphill against its concentration gradient. It is then transported across the basolateral membranes of the cells of the small intestine and kidney, usually by GLUT 2, but in the S3 segments of straight kidney tubules GLUT 1 is found. In this part of the kidney, GLUT 1 is probably involved both in the transepithelial transfer of glucose and in its uptake from the blood to provide energy

from cellular glycolysis.

The low concentration of the cotransporters in cell membranes (0.05–0.7%), their hydrophobic nature, and their sensitivity to proteolysis and denaturation made them nearly impossible to prepare by normal biochemical extraction and purification techniques. The first to be cloned and sequenced, by the technique known as functional expression cloning, was SGLT-1, the form found in the rabbit small intestine (40). Amphibian eggs of the toad *Xenopus laevis* can express almost any RNA that is injected into them and make the corresponding protein. Poly(A)*mRNA isolated from the rabbit small intestinal mucosa and microinjected into *Xenopus* oocytes stimulated Na⁺-dependent uptake of the hexose analogue α -methyl glucoside that could be blocked by the plant glycoside phlorizin, a high-affinity competitor for the sugar site of the transporter (15). Phlorizin has no effect on the GLUT 1–5 transporters; they are inhibited by the mold metabolite phloretin, which is the aglycone of phlorizin. Phloretin has no effect on the Na⁺-glucose transporter but blocks the GLUT 1–5 transporters. The predicted topologic organization of SGLT-1 in the cell membranes was surmised from its amino acids and, like the glucose transporter family, it is a large polypeptide with 12 putative membrane-spanning α -helices (Fig. 3.4). The polypeptide is glycosylated at one site, but this has little effect on its function (41). Radiation inactivation analysis of SGLT-1 suggests that the functional form in the membrane is a tetramer. Human SGLT-1 cDNA encodes a transporter with 84% amino acid sequence identity to the rabbit SGLT-1. It is composed of 664 amino acids. The gene for human SGLT-1 is located on chromosome 22 at q11.2@qter.

Figure 3.4. Highly schematic diagram illustrating the predicted secondary structure model of the Na⁺-glucose-cotransporter (SGLT-1) molecule in the cell membrane (solid). The putative membrane-spanning α -helices are shown as rectangles numbered 1–12 connected by linked amino-acid chains (lines). An outer glycosylation site is shown (CHO). It has little effect on carrier function. (Adapted from Wright EM, Turk E, Zabel B, et al. J Clin Invest 1991;88:1435–40.)

More recently, it has been shown that there are three different isoforms of the SGLT

cotransporters, designated SGLT-1, SGLT-2 (672 amino acids), and SGLT-3 (16). The cotransporters SGLT-1 and -2 have different glucose- Na^+ coupling ratios, the former high-affinity cotransporter ($K_m \gg 0.8$ mmol/L), primarily expressed in the small intestine, transports each glucose molecule with two Na^+ ions, while the latter, lower-affinity ($K_m \gg 1.6$ mmol/L) cotransporter, expressed in the kidney tubules, transports glucose with one Na^+ . SGLT-3, isolated from pig intestine, is a low-affinity cotransporter. It has approximately 60% homology in amino acid sequence to SGLT-2 (42).

Glucose-Galactose Malabsorption

The importance of human SGLT-1 for intestinal glucose absorption is exemplified in glucose-galactose malabsorption, a rare inborn error of glucose transport. This condition gives rise to a severe watery diarrhea in neonates, which is lethal unless glucose- and galactose-containing foods are removed from the diet. The diarrhea occurs because the unabsorbed hexoses enter the colon and are fermented into diarrheogenic compounds. The lack of hexose absorption in two sisters with the condition appears to be due to a single base change at nucleotide position 92, where a guanine is replaced by adenine. The mutation changed amino acid 28 of their SGLT-1 from aspartate to asparagine, making the SGLT-1 cotransporter defective and inactive. A single amino-acid alteration in the 664 that make up the molecule makes it unable to function as a cotransporter (43). Thus in humans who lack a functional SGLT-1, it appears that absorption of glucose and galactose cannot proceed normally. Experimental studies measuring the absorption of glucose in human jejunum in vivo showed that more than 95% of glucose absorption occurred by a carrier-mediated process, which agrees with the described pathophysiology of glucose-galactose malabsorption (44, 45).

Electrogenic Glucose-Linked Na^+ Transfer

Because SGLT cotransporters carry both glucose and Na^+ ions across the cell membrane without counterions, movement of the charged Na^+ ions creates an electrical potential difference across the cell membrane and subsequently across the epithelium. The transfer of glucose (or galactose) across the intestine or kidney tubule is called electrogenic (potential generating) or rheogenic (current generating). This electrical activity has been of inestimable value in the assessment of the kinetics of active hexose transport in native tissues and injected *Xenopus* eggs. This linking of the electrogenic Na^+ ion transfer with the hexose also enhances the net absorption of fluid across the small intestine. It is so effective that it overcomes the terrible excessive fluid secretory consequences of cholera toxin action in the small bowel and is a highly effective and cheap treatment to keep patients hydrated and alive. A simple solution of NaCl and glucose (or even rice water) has probably saved more lives than any drug!

Galactose

Metabolism and Transport. Galactose is a hexose monosaccharide whose dietary intake is usually in the form of the disaccharide lactose (milk sugar). Lactose is split by the digestive enzyme lactase into its hexose moieties, glucose and galactose. Galactose shares the same transport mechanisms as glucose in the enterocytes, namely apical

SGLT cotransporters and the basolateral GLUT 2. It enters the portal blood and is practically cleared in its passage through the liver, so that little or no galactose is seen in the systemic blood above 1 mmol/L, even after ingesting as much as 100 g of lactose. Ingestion of galactose without glucose, however, induces higher plasma concentrations. Alcohol is said to depress galactose uptake and metabolism by the liver, leading to an increased level in the blood (galactosemia). In the liver cells, it is converted by the enzyme galactokinase into galactose-1-phosphate. This, in turn, is converted by a two-stage enzymic transformation into glucose-1-phosphate, which is converted into glycogen. Although in theory glucose-1-phosphate can enter the glycolytic pathway, it does not normally do so to any great extent. Most tissues have enzymes that can metabolize galactose. However, even in the complete absence of dietary galactose, glucose can be converted into galactose and supply cellular needs for galactose if required. Many structural elements of cells and tissues (viz., glycoproteins and mucopolysaccharides) contain galactose.

Cataracts and Inborn Errors. Galactose levels in peripheral blood normally do not go above 1 mmol/L. If they do (galactosemia), then various tissues can remove it from the blood and convert it into galactitol (dulcitol) by the enzyme aldehyde reductase. As it is nonmetabolized, it builds up in the tissues and causes pathologic changes because of the high osmotic pressure created. In the lens of the eye, such a scenario causes cataracts (46). Cataracts can also occur in two inborn errors of galactose metabolism caused by deficiencies of the enzymes galactose-1-phosphate uridylyltransferase and galactokinase. The former enzyme deficiency creates classical galactosemia. Unless it is treated promptly in the neonate by withdrawing galactose from the diet (taken in from the lactose content of normal milk), either death or severe mental retardation can occur. Cataracts can also occur as a complication of diabetes mellitus, in which blood glucose is raised to high levels.

Fructose

Metabolism and Transport. Fructose, a monosaccharide ketohexose, is present either as the free hexose (honey, soft drinks, sweets, biscuits, apples, pears) or is produced from hydrolysis of the dietary disaccharide sucrose (yielding glucose and fructose). In humans, it is absorbed largely intact into the portal blood and is almost totally cleared in a single passage through the liver. Thus, there is essentially no appreciable fructose in the blood. After a large oral dose of 1 g free fructose/kg body weight, the blood level will increase to 0.5 mmol/L in 30 minutes and then slowly decrease during the next 90 minutes. In the liver, fructose is phosphorylated by the abundant enzyme fructokinase into fructose-1-phosphate, which is cleaved by hepatic aldolase into glyceraldehyde and dihydroxyacetone phosphate (DHA phosphate). DHA phosphate is an intermediary metabolite in both the glycolytic and gluconeogenic pathways. Glyceraldehyde, while not intermediary in either pathway, can be converted by various liver enzymes into glycolytic intermediary metabolites available to be metabolized ultimately to produce glycogen. This glycogen can then be broken down into glucose by glycogenolysis.

Absorption. Although fructose is absorbed across the enterocytes of the small intestine, it is not a substrate for the SGLT cotransporters. The evidence for this is three-fold: (a) fructose absorption is normal in those with glucose-galactose

malabsorption, who have defective SGLT-1 cotransporters; (b) fructose absorption is not reduced by phlorizin, the classic inhibitor of SGLT-1 cotransporters; and (c) fructose absorption is neither Na⁺-sensitive nor electrogenic like that of glucose or galactose. Recent studies on the expression of human GLUT 5 transporter in *Xenopus* oocytes showed that the transporter exhibited selectivity for high-affinity fructose transport that was not blocked by cytochalasin B, a potent inhibitor of facilitative glucose transport by glucose transporters (22). As GLUT 5 is also expressed in high levels in the brush border of enterocytes in the small intestine (47), the isoform is likely to be the fructose transporter of the small intestine. Indirect evidence for the likelihood of fructose transporting by GLUT 5 is the fact that it is expressed in high concentration in human spermatids and spermatozoa (47), cells known to metabolize fructose. GLUT 2, localized to the basolateral membrane of enterocytes, although having a much lower affinity for fructose transport than GLUT 5, probably mediates the exit of the absorbed fructose from the enterocytes into the blood. Recently, however, it has been reported that GLUT 5 is also localized on the basolateral membrane in the human jejunum (48), so fructose could also exit from the enterocytes by this transporter.

In humans, absorption of fructose from sucrose ingestion is more rapid than that from equimolar amounts of fructose ingestion. The numerous explanations for this phenomenon include differences in gastric emptying, enhanced fluid absorption initiated by the glucose entraining fructose, and cotransport of fructose and glucose by a disaccharidase-related transport system (49, 50).

Inborn Errors. Six genetically determined abnormalities in the metabolism of fructose have been described in humans (51). These are caused by deficiencies in fructo-kinase, aldolase A and B, fructose-1,6-diphosphatase, and glycerate kinase, and by fructose malabsorption. Limiting dietary fructose is favorable in each of these conditions except aldolase A deficiency. Fructokinase deficiency, manifest in the liver, causes fructosemia (high levels in blood) and fructosuria (excretion in urine). In contrast to the low levels of fructose observed in the blood of normal humans after ingestion of 1 g of free fructose/kg, the concentration in the fructokinase-deficient person approaches 3 mmol/L and is sustained for many hours. Despite the sustained high levels of fructose in the blood, cataracts do not develop, in sharp contrast to the cases of galactokinase deficiency and diabetes mellitus (see specific sections).

The three aldolases, A, B, and C, catalyze the reversible conversion of fructose-1-diphosphate into glyceraldehyde-3-phosphate and dihydroxyacetone phosphate. Each is coded for by a different gene: A is on chromosome 16, B on 9, and C on 17. Expression of the enzymes is regulated during development so that A is produced in embryonic tissues and adult muscle, B in adult liver, kidney, and intestine, and C in adult nervous tissue. Deficiency of A produces a syndrome of mental retardation, short stature, hemolytic anemia, and abnormal facies. The deficiency is probably detrimental because aldolase A is normally involved in fetal glycolysis. There is no treatment for the condition. Deficiency of aldolase B (hereditary fructose intolerance), the most frequent of the three deficiencies, was first observed in 1956 (52). When fructose is ingested, vomiting, failure to thrive, and liver dysfunction occur.

Deficiency of fructose-1-6-diphosphatase was described in 1970. Patients exhibit

hypoglycemia, acidosis, ketonuria, and hyperventilation. Urinalysis shows many changes in organic acids, but excretion of glycerol is diagnostic. Treatment is to avoid dietary fructose.

D-Glyceric aciduria is rare and is caused by D-glycerate kinase deficiency. The presentation of the disease is highly variable, from no clinical symptoms to severe metabolic acidosis and psychomotor retardation, which suggests that perhaps among the 10 described cases, there are other, different enzyme deficiencies.

In fructose malabsorption, ingestion of the ketohexose in quantity creates abdominal bloating, flatulence, and diarrhea. Persons with this condition appear to have a defect in fructose absorption. No assessments of intestinal GLUT 5 or its controlling gene have yet been made in any of these patients. If either glucose or galactose is ingested with fructose, fructose absorption is enhanced, and often no symptoms of malabsorption occur ([50](#), [51](#)).

GLUCOSE STORAGE

Glycogen

Glucose is stored in the liver and muscles of animals and humans as the branched polymer glycogen; the equivalent polymer in plants is starch. Glycogen is more branched than amylopectin and has 10 to 18 long chains of α -D-glucopyranose residues (in $\alpha(1 \rightarrow 4)$ glucoside links) with branching by $\alpha(1 \rightarrow 6)$ glucoside bonds ([Fig. 3.5](#)). Although it occurs in concentrations of up to 6% of liver mass but only 1% of muscle, muscle mass is so much greater that it represents 3 to 4 times as much glycogen as in the liver. Muscle glycogen is mainly used by the muscle, but liver glycogen is for storage, export, and the maintenance of blood glucose. The liver has glycogen stores for only 12 to 18 hours of fasting; it then becomes glycogen depleted.

Figure 3.5. A highly schematic diagram of a portion of a glycogen molecule. Each *solid black circle* represents a glucose moiety joined by $1 \rightarrow 4$ and $1 \rightarrow 6$ links. The branching of the structure, caused by the $1 \rightarrow 6$ links, is more random than is shown.

Formation and Breakdown of Glycogen

Glucose is first enzymically phosphorylated, then reacted with uridine triphosphate to give uridine diphosphate glucose (UDP-glucose). The enzyme glycogen synthetase fits this onto a preexisting glycogen chain (primer and/or protein backbone), splitting off the UDP. The glucose residue added by 1 \rightarrow 4 linkages is attached at the outer end of the molecule so that the branches of the glycogen tree become elongated. After 11 glucose residues, another enzyme called the “branching enzyme” (amylo(1 \rightarrow 4) \rightarrow (1 \rightarrow 6) transglucosidase) transfers part of the 1 \rightarrow 4 chain of glucose residues (>6) to a neighboring chain to form a 1 \rightarrow 6 link and create a branch point. Glycogen grows by further 1 \rightarrow 4 and 1 \rightarrow 6 additions. As the number increases the total number of reactive sites in the molecule also increases, which hastens both glycogenesis and glycogenolysis. Breakdown of glycogen is mediated by three enzymes: (a) phosphorylase acting at the 1 \rightarrow 4 linkages; (b) α (1 \rightarrow 4) \rightarrow α (1 \rightarrow 4) glucan transferase, which transfers a trisaccharide unit from one branch to another, exposing 1 \rightarrow 6 branch points; and (c) the “debranching enzyme” (amylo(1 \rightarrow 6)-glucosidase), which splits the linkage. Removal of the branch allows further action by the phosphorylase. In the liver and kidney (but not in muscle), a specific enzyme, glucose-6-phosphatase, dephosphorylates the glucose so that it can diffuse from the cells into the bloodstream. The enzymes controlling glycogen metabolism are regulated by a complex series of phosphorylations and dephosphorylations and by allosteric mechanisms under hormonal influence (see [insulin](#) and [glucagon](#)).

Glycogen Storage Diseases

Glycogen storage diseases include more than 10 genetic differences involving either enzymes or transporters. They are characterized as storing glycogen in abnormal quantity, location, or structure. Five types of glycogen storage disease have been described (53): type I (glucose-6-phosphatase deficiency), type II (acid α -glucosidase deficiency), type III (amylo-1,6-glycosidase deficiency), type IV (branching enzyme deficiency), and type V (muscle phosphorylase deficiency), which was later expanded to at least seven types (type VI, liver phosphorylase or phosphorylase B kinase deficiency; type VII, muscle fructokinase deficiency). For details, consult the review by Hers (54). In types I, III, and VI, the liver cannot convert glycogen into glucose, causing hepatomegaly (enlarged liver), hypoglycemia, hypoinsulinism, hyperglucagonemia, hyperlipidemia, and growth retardation. In types V and VII (but also in type II and a subgroup of type VI), the muscle is affected and cannot provide glycolytic fuel for contraction. Symptoms are often mild, however, and become apparent only when young adulthood is reached and strenuous exercise is taken.

In a number of the glycogen storage diseases liver transplantation is the only “curative” treatment.

Carbohydrates and Athletic Performance

Carbohydrate present in muscle (300 g), liver (90 g), and body fluids (30 g) is the major fuel for physical performance. The ATP stored in muscle cells can only give high-power output for a few seconds. It can be resynthesized anaerobically for a further few seconds (5–8) by using the phosphate from creatinine phosphate. These short, intense bursts of muscular activity are found in sprints (100 meters), track and field events, and sports such as tennis, hockey, football, gymnastics, and weightlifting. If the maximum effort lasts for 30 seconds, then breakdown of muscle glycogen can supply the energy, with buildup of muscle lactic acid. Most physical activity, however, requires an energy source that can power muscles for longer periods. The duration and intensity of exercise determines the mix of fuel used. In resting or light activity, about 60% is from free fatty acids (FFAs) and tri-glycerides in muscles. At moderate levels of activity (approximately 50% of the maximum O₂ uptake), fat and carbohydrate contribute about equal amounts as energy sources. Carbohydrate, a prime energy source, becomes more and more important as the intensity of the exercise increases. The change to using carbohydrate is not a linear response but accelerates with the intensity of the work. Endurance athletes use more fat and so conserve the carbohydrate in muscle and liver, but it is that level that ultimately limits continued performance. Fatigue arises when the store becomes depleted. The store of carbohydrate usually suffices for just 2 to 3 hours of physical exertion.

Dietary Manipulation of Glycogen Stores—Carbohydrate Loading

Dietary manipulation can be used to increase the stores of glycogen in muscle and liver. Glycogen increases when more carbohydrate is eaten. The practice is called carbohydrate loading. The athlete has 3 days of exhausting physical exercise on a low-carbohydrate diet followed by 3 days of rest on a high-carbohydrate diet. In general, athletes dislike both phases; in the first, they feel exhausted both mentally and physically, and in the second, they feel bloated because the glycogen retains extra water. However, other feeding programs exist that do not use the carbohydrate depletion phase. For athletes in general, it makes sense to eat plenty of carbohydrate to maximize glycogen storage, as the usual training periods of several hours per day deplete it. There is little doubt that a high-carbohydrate diet improves glycogen storage and athletic performance (see also [Chapter 47](#)). What to advise athletes to ingest just before an event is difficult. Solid food is not advisable before strenuous exercise. A popular solution for athletes is drinking glucose/sweetened fruit juices. Fructose ingestion is said to cause less increase in blood glucose and insulin levels and thus a slower loss of muscle glycogen (see review [55](#)).

Carbohydrate Intolerance

There is a range of clinical disorders in which sugar digestion or absorption is disturbed and gives rise to sugar intolerance, creating symptoms by the undigested or unabsorbed sugar and causing water to enter the intestine, which activates peristalsis and induces passage of frequent fluid stools. The undigested carbohydrate can also enter the colon and become fermented into diarrhetic agents. The disorders are usually classified as (a) congenital or (b) secondary to some other disease, to impaired digestion of disaccharides, or to impaired absorption of the monosaccharides. The

congenital deficiencies, although relatively rare, are life threatening; examples are sucrase-maltase deficiency (watery diarrhea after ingesting sucrose-containing foods), alactasia (absence of lactase, diarrhea from ingestion of milk), glucose-galactose malabsorption (diarrhea from ingestion of glucose, galactose, or lactose), and the very rare trehalase deficiency (intolerance to trehalose in mushrooms). Sugar intolerance secondary to underlying gastrointestinal disease is the commonest type, especially in pediatrics. Infections of the gastrointestinal tract, for example, often induce a temporary intolerance to lactose.

Lactose Intolerance. Adult mammals and most human groups after weaning keep only a fraction of the intestinal lactase activity of neonates (who need it to digest the lactose of breast milk). The persistence of lactase activity in Europeans has been regarded as the exception to the rule, since most human groups are hypolactasic and lactose malabsorbers (56). However, small amounts of dietary lactose, up to 250 mL of milk, can be tolerated by most adult lactose maldigesters. The decrease in lactase in adults is a programmed event, and feeding high-lactose diets does not prevent the decrease. The mechanisms of the decline in activity have been studied in rats. As the animal matures, more and more mRNA message for lactase is needed to maintain the decreasing lactase activity in the enterocytes, suggesting that translational events may be of great importance in lactase gene expression (57).

Diagnosis of Carbohydrate Intolerance

Sugar Tolerance Tests. Clinical quantitative assessment of the efficiency of the digestion and absorption of carbohydrates in humans rests mainly on relatively simple tests in which carbohydrate loads (at least 50 g) are ingested and blood samples are taken to estimate the sugar levels attained at various time intervals after ingestion. The levels are then compared with those obtained in normal subjects. The most commonly used test is the oral glucose tolerance test (OGGT). Typically, nonpregnant adults take 75 g of glucose over 5 minutes and the glucose is estimated in serum at 0, 30, 60, 90, and 120 minutes. A pregnant woman takes 100 g of glucose and has another estimate at 180 minutes. A child takes 1.75 g/kg up to the maximum of 75 g (58). Values above normal indicate some form of inadequate handling of the ingested glucose. This test is often used to assess for diabetes mellitus. The reproducibility of the OGTT has been claimed to be poor, even when repeated in the same individual (59). An oral tolerance test also exists for galactose. As the liver is a major site of galactose metabolism, the test has been used to assess liver function. Similar oral tolerance tests exist for fructose and the disaccharides lactose (lactase deficiency) and sucrose (sucrase deficiency).

Breath Hydrogen Tests. Carbohydrates that have not been digested or absorbed reach the colon and become fermented by the resident bacteria. Hydrogen gas is produced and is excreted in the breath. Measuring breath hydrogen thus provides an estimate of whether malabsorption of a sugar or carbohydrate occurs (see also [Chapter 57](#)). It was first used to detect lactose intolerance and has since been used in numerous studies on carbohydrate intolerance (60). It has a number of weaknesses; for example, it gives no indication of the amount of carbohydrate absorbed before the sugar reached the colon, and the hydrogen in the breath is only a fraction of that formed.

Oral Tolerance Tests and the Glycemic Index. Nutritionists use a form of oral tolerance test to assess the so-called glycemic potential of different foods. A carbohydrate load is ingested and the level of blood sugar is measured over a period of time. The increments in blood glucose are then compared with equivalent increments from different foods by normalizing these values to a baseline obtained with glucose, usually by using the area under the 2-h glucose curve after feeding a 50-g carbohydrate portion, and expressing it as a percentage of the mean obtained after 50 g of glucose. This normalized figure, designated the *glycemic index* of the food (61), enjoyed considerable popularity in the dietetic management of diabetes and hypoglycemia. However, there is a large scatter in glycemic index for each group of foodstuffs, attributed to many factors such as its form when eaten, the way it is processed, how it is chewed, how it is emptied from the stomach, and the physiologic and metabolic responses of individuals. The glycemic index has been criticized as a crude index of questionable value (62), but it still has its adherents (63). What it does illustrate is that carbohydrate foods differ widely in their effects on blood glucose and hormonal responses after a meal. Diets with a low glycemic index, designated *lente*, have been claimed to be useful in diabetes, hyperlipidemia, and even healthy subjects. They appear to prolong satiety and hence lead to a better control of food intake (63).

Caries and Sugar

Dental caries is a disease created by bacterial plaque on the enamel of teeth. Gradual and progressive demineralization of the enamel, dentine, and cementum occurs. Many studies have suggested that carbohydrates, especially sugars and in particular sucrose, are important carie-promoting components of food. However, despite a huge amount of laboratory and clinical research, the relationship between sugar and caries is still poorly characterized. A major reason for this is the complexity of the problem, for the formation of caries involves multifactorial interactions such as nutrients and food components of diet, plaque bacteria, salivary flow and composition, minerals and fluoride status, genetics, age, and even the race of the individual (see also [Chapter 66](#)). The most common organism in dental plaque associated with caries is *Streptococcus mutans*, but other bacteria contribute. Most studies have focused on the acids (lactic and acetic) generated from sugars (sucrose) by the bacteria, but the complex formation and accumulation of plaque from the insoluble dextran made from sucrose is an important feature (64, 65).

Carbohydrates and Health

The mean annual consumption of sucrose plus fructose in developed countries is about 25% of the caloric intake. Fructose is more lipogenic than glucose. This high intake of sucrose (approximately 50 kg/year/person) has been contentiously implicated in influencing the health of humans, apart from caries, because a high consumption of sucrose/fructose in experimental animals (often rats) creates, among other things, hyperlipidemia, insulin resistance, hypertension, and diabetic-like tissue lesions (66). However, while a hyperlipidemic effect of sucrose and fructose has been demonstrated in a number of human studies, firm conclusions cannot be made because of great variations in the type of subjects, duration of intake, background diet, and study

conditions (66). The general conclusion of an FDA-sponsored survey published in 1986 was that the present voluntary intake of sucrose and fructose is not harmful to humans (67). A more recent review, while accepting that the intake of sucrose was not a problem in normal individuals, suggested care when dealing with individuals with hypertriglyceridemia (68).

Glucose and Cerebral Functions

There is now good evidence that increases in plasma glucose can enhance learning in rodents and humans (69). Many drugs that impair learning and memory (e.g., opiates, g-aminobutyric agonists, cholinergic antagonists) can have their actions reduced by glucose (70). Injecting glucose into the medial septum and into the amygdala of the brain in rats attenuates the inhibitory action of morphine in a trained avoidance task (69). It is suggested that glucose metabolites, such as pyruvate, may contribute to the mechanism by which glucose regulates brain cell function. Glucose has also been shown to enhance the memory of aged rodents and humans. In healthy humans 60 to 80 years old, glucose (50 g) was more effective than saccharin (27 mg) in improving narrative memory test performance (69), but it had no effect on performance of nonmemory tasks, i.e., attention, motor speed, or overall IQ. These actions of glucose showed an inverted U-shaped dose-response curve, the optimal glucose dose producing blood levels of 8.9 mmol/L (160 mg/dL). The effects of glucose on memory outlast the increased level of glucose in the plasma, indicating a stable improvement in function. Remarkably, glucose can also enhance memory and other cognitive functions in patients with Alzheimer's disease and young adults with Down's syndrome (69). These promising findings suggest that glucose or its metabolites may be harnessed to ameliorate the normal loss of mental function with age and the cruel degeneration of mental ability with Alzheimer's disease.

HISTORICAL INTRODUCTION

In 1918, Aron first proposed that fat may be essential for normal growth and development of animals. Butter, apart from its caloric value, was deemed to have an important nutritional value because of the presence of certain lipid molecules. Evans and Burr (1927) subsequently demonstrated that a deficiency of fat severely affected both growth and reproduction of experimental animals, despite addition of the fat-soluble vitamins A, D, and E to the diet. These authors suggested that fat contained a new essential substance termed *vitamin F*. The work of Burr and Burr in 1929 first showed the nutritional importance of specific lipids in fat. Weanling rats fed a fat-free

diet showed impaired growth, scaly skin, tail necrosis, and increased mortality, conditions that were reversed by feeding linoleic acid (C18:2n-6). In further work, the same authors described impaired fertility and augmented water consumption as additional symptoms of a deficiency of either C18:2n-6 or α -linolenic acid (C18:3n-3). The term *essential fatty acids* (EFA) was coined by Burr and Burr for those fatty acids (FA) not synthesized in mammals and for which deficiencies could be reversed by dietary addition.

Arachidonic acid (C20:4n-6) was determined to be an EFA in 1938. It was found to be approximately three times as effective as C18:2n-6 in relieving essential fatty acid deficiency (EFAD) symptoms. C18:2n-6 was subsequently found to undergo biotransformation to C20:4n-6; thus, C18:2n-6 was judged to be the primary unsaturated FA required in the diet by animals. Although various researchers were able to generate EFAD in different species by feeding EFA-deficient diets, EFAD was first described in the human in 1958. Infants fed a milk-based formula diet lacking EFA showed severe skin symptoms that were alleviated by addition of C18:2n-6.

In human adults, EFAD was subsequently described as a consequence of parenteral nutrition in which fat-free solutions containing only glucose, amino acids, electrolytes, and micronutrients were continuously infused. The resulting rashes and low plasma concentrations of polyunsaturated fatty acids (PUFA) were reversed by infusion of intravenous emulsions containing C18:2n-6. Holman et al. (1982) reported the first example of deficiency symptoms attributed to C18:3n-3 deficiency in a 6-year-old girl maintained parenterally for 5 months on a safflower-oil-based emulsion rich in C18:2n-6. Deficiency symptoms, including neuropathy and low serum concentrations of C18:3n-3, were corrected by changing the parenteral nutrition recipe to include soybean oil emulsion rich in n-3 FA (1). Neuringer et al. (2) in 1984 demonstrated C18:3n-3 deficiency in the offspring of rhesus monkeys showing a loss in visual activity. C18:3n-3 deficiency was also described in nine patients who had received 0.02 to 0.09% of calories as n-3 FA via gastric tube feeding over a period of 2.5 to 12 years (3). The scaly dermatitis and depressed concentrations of n-3 FA in plasma and erythrocytes of the patients were reversed by supplementation with C18:3n-3.

CHEMISTRY AND STRUCTURE

Fats and lipids are defined as a class of compounds soluble in organic solvents, including acetone, ether, and chloroform. These compounds vary considerably in size and polarity, ranging from hydrophobic triglycerides (TGs) and sterol esters to more water-soluble phospholipids (PL) and cardiolipins. Dietary lipids also include cholesterol (CH) and phytosterols. Unlike other macronutrients, the non-water miscibility of lipids necessitates that these compounds receive specialized processing during digestion, absorption, transport, storage, and utilization. This specialization in metabolic handling distinguishes dietary lipids and their metabolites from other macronutrients.

Triglycerides and Fatty Acids

Triglycerides (TG), or triacylglycerols, make up by far the largest proportion of dietary lipids consumed by humans. A TG is composed of three FAs esterified to a glycerol

molecule in one of three stereochemically distinct bonding positions: sn-1, sn-2, and sn-3. Variation in the type of FA and their bonding pattern to glycerol further increases the heterogeneity of TG composition. For most dietary oils, approximately 90% of the TG mass consists of FA. These FA are generally unbranched hydrocarbon chains with an even number of carbons, ranging from 4 to 26 carbon atoms. Smaller quantities of longer-chain FA have also been identified in mammalian tissues and thus may exist in human diets (4). Very long-chain fatty acids (VLCFA) predominate in the brain and specialized tissues, such as retina and spermatozoa (5). Adipose tissue contains FA of varying lengths.

In addition to differences in chain length, FA vary in the number and arrangement of double bonds along the hydrocarbon chain. Major FA are given in [Figure 4.1](#). Systems for identifying the position of double bonds along the hydrocarbon chain entail carbon-counting from either end of the molecule. The less common “delta” system of identification of double bonds counts from the carboxyl end of the fatty acyl chain. More commonly used is identification of the position of the first carbon of a double bond relative to the methyl terminus of the FA. Double bonds identified relative to the methyl end use the terms “n” or “w” to indicate distance of the first bond along the carbon chain. For example, any FA described as n-6, or w-6, has the initial double bond situated between the 6th and 7th carbon atoms from the methyl end. To contain a single double bond, a FA must be at least 12 carbon atoms in length. These monounsaturated fatty acids (MUFA) typically possess a double bond at the n-9 or n-7 position. Addition of further double bonds produces a PUFA. Each subsequent double bond invariably occurs three carbon atoms further along the carbon chain from the bond preceding it. Therefore, the number of double bonds within a FA is restricted by its chain length. FA with 18 carbon atoms or more that possess more than a single double bond will contain the first bond of their series only at the n-9, n-6, or n-3 position. For a 16-carbon atom FA, the first double bond may be located at the n-7 position. A maximum of 6 double bonds occurs in dietary FA.

COMMON NAME	SYSTEMATIC NAME	CHAIN LENGTH	STRUCTURAL FORMULA
acetic acid	ethanoic acid	2:0	<chem>CC(=O)O</chem>
propionic acid	propanoic acid	3:0	<chem>CCC(=O)O</chem>
butyric acid	butanoic acid	4:0	<chem>CCCC(=O)O</chem>

Figure 4.1. Names, codes, and formulas of fatty acids mentioned in this chapter.

The essentiality of a FA depends on the distance of the first double bond from the methyl terminus. During de novo FA formation, human biosynthetic enzymes can insert double bonds at the n-9 position or higher; however, these enzymes cannot insert double bonds at any position closer to the methyl end. For this reason, FA with double bonds at the n-6 and n-3 positions are, as individual classes, considered essential. These EFA must therefore be obtained from plants or other organisms that possess the enzymatic pathways for their construction. Mammalian tissues contain four families of PUFA (n-3, n-6, n-7, n-9) designated according to the number of carbon atoms from the terminal methyl group to the first carbon of the first double bond. Among all FA, only those of n-6 and n-3 classes are essential to the diet. All other FA can be synthesized by humans from an excess of dietary energy.

Double bonds in foods we consume most commonly occur in the *cis* configuration. *Trans* bonds, also present, are a result of hydrogenation, the process used to increase the viscosity of oils, and the microbial metabolism in ruminants. *Trans* bonds reduce internal rotational mobility of the fatty acyl chain and are less reactive to electrophilic additions such as halogenation, hydration, and hydrogenation (6, 7). Most dietary *trans* FA are monoenes, 18 carbons in length. The major *trans* FA, elaidic acid (C18:1n-9 *trans*) has a melting point of 44°C, versus 13°C for oleic acid (C18:1n-9).

Phospholipids

A limited amount of dietary lipid occurs as PL. PL are distinct from TG in that they contain polar head groups that confer amphipathic properties to the molecule. PL are insoluble amphiphiles with a hydrophilic, often zwitterionic, head group, and hydrophobic tails composed of two longer-chain FA. These head groups are attached to the primary glycerol moiety via phosphate linkages. Polar head groups can vary in size and charge and include inositol, choline, serine, ethanolamine, and glycerol.

Sterols

CH, an amphipathic molecule, has a steroid nucleus and branched-hydrocarbon tail. CH is found in the diet both in the free form and esterified to FA, particularly C18:2n-6. CH is found only in foods of animal origin; plant oils are cholesterol free. Although free of CH, plant materials do contain phytosterols, compounds chemically related to CH. Common dietary phytosterols are listed in [Figure 4.2](#). Phytosterols differ in their chemical side-chain configuration and steroid-ring–bonding pattern. The most common dietary phytosterols are β -sitosterol, campesterol, and stigmasterol. 5- α -Hydrogenation of phytosterols forms saturated phytosterols, including campestanol and sitostanol. Increasing evidence suggests that saturated phytosterols, such as sitostanol, inhibit CH absorption better than more hydrophilic plant sterols, such as β -sitosterol. These saturated phytosterols are found in very small amounts in normal diets but can be commercially produced.

Figure 4.2. Molecular structure of the more important sterols in food (side chains only are shown for the bottom four structures).

DIETARY CONSIDERATIONS

Fat intake of the average North American diet represents 38% of total calories consumed (8, 9). Over 95% of the total fat intake is composed of TG; the remainder is in the form of PL, free FA, CH, and plant sterols. Total dietary TG in the North American diet is about 100 to 150 g per day. In addition to dietary intake, lipids enter the gastrointestinal tract by release from mucosal cells, biliary expulsion into the lumen, and bacterial action.

In almost no other instance can food choice influence nutrient composition as much as in the case of fats. As dietary TG vary widely in their FA composition, so does FA consumption (Table 4.1, see also more detailed tables of marine and nonmarine sources [Appendix Table IV-A-19-A and Table IV-A-19-B]). Large differences exist in the FA composition of oils from both plant and animal sources. Short-chain fatty acids (SCFA) (4 carbons) and medium-chain fatty acids (MCFA) (6 to 12 carbons) are found in vegetable oils and dairy fat, whereas fish oils and certain plants contain FA of the n-3 family. Long-chain n-3 FA can be found in a few terrestrial plants and range-fed nonruminant game animals. MUFA are found in plant oils, although meat fats also contain moderate amounts. As a rule, n-6 PUFA are found in vegetable fats and not in meat products, except in the case of C20:4n-6. Plant-derived oils vary widely in composition, largely because of genetic and environmental factors. In the case of animal fats, the composition of the feed also affects the final FA composition.

Food	Average Fat% ¹	Average Fatty Acid Composition						
		Saturated					Mono and Polyunsaturated	
		Total	16:0	18:0	18:1	18:2	18:3	20:0

⁴These values are based on the following: 100% saturated (100% SFA), 100% monounsaturated (100% MUFA), and 100% polyunsaturated (100% PUFA).
⁵These values are based on the following: 100% saturated (100% SFA), 100% monounsaturated (100% MUFA), and 100% polyunsaturated (100% PUFA).

Table 4.1 Average Triglyceride Fatty Acid Composition of Important Edible Fats^a

Intake of *trans* FA in the North American diet has not been firmly established, but it appears to range from 2 to 7% of the total energy intake (7, 10). Amounts of *trans* FA in the diet have remained relatively constant over past decades, partly because the rise in vegetable fat consumption has been counterbalanced by a decline in the *trans* FA content of many foods made with vegetable fat (6). Methodological limitations in measuring the various isomeric forms of dietary *trans* FA contribute to the imprecision in our knowledge of consumption levels.

The dietary contribution of CH varies significantly across foods. Typically, 250 to 700 mg of CH is consumed each day in the North American diet, with the larger proportion esterified to FA. Reduction of dietary CH levels can be readily achieved by excluding animal fats from the diet.

North American diets typically contain about 250 mg/day of plant sterols, with vegetarian diets containing much larger amounts (11). Most plant sterols are found as β -sitosterol, campesterol, and stigmasterol.

DIGESTION AND ABSORPTION

Digestion in Mouth and Esophagus

Digestion of dietary lipids and their metabolites evokes a series of specific processes that enable absorption through the water-soluble environment of the gut (Table 4.2). Digestion begins in the oral cavity with salivation and mastication. Lingual lipase, released from the serous glands of the tongue with saliva, starts the hydrolysis of free FA from TG. Mechanical dispersion by chewing enlarges the surface area upon which lingual lipase can act. Lingual lipase cleaves at the sn-3 position, preferentially hydrolyzing shorter-chain FA found in foods, such as milk. Hydrolysis continues in the stomach, where gastric lipase promotes further lipid digestion, preferring TG containing SCFA. Fat entering the upper duodenum is 70% TG, with the remainder being a mixture

of partially digested hydrolysis products.

Source	Factor	Location of Action	Function
Food (breast milk)	Bile salt-stimulated lipase	Duodenum	Converts monoglycerides and free fatty acids to glycerol and free fatty acids
Oil only	Lingual lipase	Mouth, esophagus, stomach	Clave triglycerides at sn-1 position
Stomach	Gastric lipase	Stomach, duodenum	Clave triglycerides at sn-3 position
Pancreas	Pancreatic lipase	Duodenum	Splitting of sn-1 and sn-3 positions
Liver	Bile salts	Duodenum	Emulsification of fats and reabsorption in small intestine and colon

Table 4.2 Factors Involved in the Digestion of Fats

Intestinal Digestion

Intestinal digestion requires bile salts (BS) and pancreatic lipase. BS, PL, and sterols are the three principal lipid components of bile, the emulsifying fluid produced by the liver. BS consist of a steroid nucleus and an aliphatic side chain conjugated in an amide bond with taurine or glycine. The number and orientation of hydroxyl groups on the nucleus vary. The hydroxyl and ionized sulfonate or carboxylate groups of the conjugate make BS water soluble. Primary BS, defined as those synthesized directly from hepatic CH, include the tri- and dihydroxy bile salts, cholate and chenodeoxycholate, respectively. Secondary BS, including deoxycholate and lithocholate, are produced from primary BS via bacterial action on cholate and chenodeoxycholate in the gut, respectively. Further modification of secondary BS by hepatocytes or bacteria produces sulfate esters of lithocholate and ursodeoxycholate. Biliary phosphatidylcholine (PC), the main PL in bile, typically contains palmitic acid (C16:0) in the sn-1 position and an unsaturated 18- or 20-carbon FA in the sn-2 position.

Pancreatic lipase, the principal enzyme of TG digestion, hydrolyzes ester bonds at the sn-1 and sn-3 positions of the glycerol moiety (Fig. 4.3). BS inhibit lipase activity through displacement of the enzyme from its substrate at the surface of the lipid droplet. Colipase, also a pancreatic protein, reverses BS inhibition of pancreatic lipase by binding lipase, ensuring its adhesion to the droplet. Then, through its affinity to BS, PL, and CH, colipase facilitates shuttling of hydrolysis product monoglycerides (MG) and free FA from the lipid droplet into the BS-containing micelle. FA linked at the sn-2 position of MG, PL, and cholesterol esters (CE) are resistant to hydrolysis by lipase. Lipolysis by pancreatic lipase is extremely rapid, so MG and free FA production is faster than their subsequent incorporation into micelles (12). Synthesis of both lipase and colipase is stimulated by the hormone secretin and the presence of dietary TG in the small intestine. Release of BS and pancreatic lipase is also regulated humorally. The

presence of amino acids and fat digestion products in the digesta evokes release of cholecystikinin (CCK) and secretin into the circulation. CCK then stimulates the production of exocrine pancreatic enzymes, while secretin enhances output of pancreatic electrolytes. CCK also induces synthesis of hepatic bile and its release through contraction of the gall bladder.

Figure 4.3. Transport hypothesis of fatty acids and 2-monoglycerides through lipase-mediated hydrolysis, micellar transfer, and cellular uptake stages.

In breast-fed infants, TG are digested by the concerted action of gastric lipase, colipase-dependent pancreatic lipase, and a bile salt-stimulated lipase (BSSL) present in breast milk. Gastric lipase initiates digestion of the milk fat globule, and BSSL nonselectively converts the resulting MG and free FA to glycerol and free FA. This process increases absorptive efficiency.

Micellar solubilization of fat hydrolysis products occurs through the amphipathic actions of BS and PL, which are secreted at a ratio of approximately 1:3. CH is present in bile only in the unesterified form, which is the major sterol form (13). The polar termini of BS orient toward the aqueous milieu of the chyme, while the nonpolar termini containing hydrocarbon groups face the center of the micelle. BS and PL naturally aggregate so that nonpolar termini form a hydrophobic core. For micelles to form, a threshold concentration of BS must be reached, termed *the critical micellar concentration* (CMC). The typical biliary CMC of BS is 2 mM. BS concentrations within the proximal duodenum generally remain well in excess of this threshold.

Incorporation of MG hydrolyzed from TG into micelles increases the ability of the particle to solubilize free FA and CH. BS micelles generally possess the highest affinity for MG and unsaturated long-chain free fatty acids (LCFA) (14). Both diglycerides (DG) and TG have limited incorporation into micelles. Upon formation, mixed micelles containing FA, MG, CH, PL, and BS migrate to the unstirred water layer adjacent to the brush border surface.

Fat digestion has been the focus of clinical attention in light of the increasing global prevalence of obesity. Creation of fat substitutes that have properties similar to those of a naturally occurring fat, but which are resistant to the action of pancreatic lipase, has been actively pursued. Olestra, formed by chemical combination of sucrose with FA, possesses “mouthfeel” and texture similar to those of TG. However, Olestra passes through the intestine undigested and unabsorbed (15). The product is heat stable and has been approved for use in certain foods. The efficacy of Olestra in long-term weight control remains to be confirmed (16). Consumption of Olestra is not without risk of side effects, including anal leakage and reduced absorption of fat-soluble vitamins.

Absorption

Lipid absorption appears to occur in large part through passive diffusion. Micelles containing fat digestion products exist in dynamic equilibrium with each other; the peristaltic, churning action of the intestine maintains high intermicellar contact. This contact results in partitioning of constituents from more- to less-populated micelles, which equalizes the overall micellar concentration of digestion products. Thus, during digestion of a bolus of fat, micelles pick up evenly and rapidly the 2-MG and free FA that are released by the action of pancreatic lipase until the micelles are saturated with them.

Penetration of micelles across the unstirred water layer bordering the intestinal mucosal cells represents the first stage of absorption. Micelles, but not lipid droplets, approach and enter this water layer for two reasons. First, micelles are much smaller (30 to 100 Å) than emulsified droplets of fat ($25,000 \pm 20,000$ Å). Second, the hydrophobic nature of the larger lipid droplet results in reduced solubilization at the site of the unstirred water layer.

Transport of micellar products across the unstirred water layer into the enterocyte is described in Figure 4.3. Micelles closest to the plasma membrane of the brush border partition their digestion products across the water envelope in a concentration-dependent fashion. Digestion products continue to be shuttled between micelles across the unstirred water layer, creating a chain-reaction effect. This action hinges on the lower cellular concentration of digestion products at the enterocyte. Intestinal fatty acid-binding proteins (FABP) assist in transmucosal shunting of digestion product FA and possibly MG and BS. Elevated FABP activity in the distal bowel is associated with higher FA absorption (17).

The overall efficiency of fat absorption in human adults is about 95%, more or less independent of the amount of fat consumed. However, the qualitative nature of the dietary fat influences overall efficiency. In general, efficiency increases with the degree of FA unsaturation (18). There is also evidence that as FA chain length increases, absorption efficiency decreases. Likewise, the positional distribution of FA on dietary TG is an important determinant of the eventual efficiency of absorption. Studies with structured lipids have shown that when octanoate, palmitate, or linoleate was substituted at different sn positions on a TG molecule, the positional distribution altered digestion, absorption, and lymphatic transport of these two FA (19, 20). The natural

tendency of C16:0 to locate at the sn-2 position in breast milk may therefore explain the high digestibility of this milk fat. FA with chain lengths less than 12 carbon atoms are also absorbed passively by the gastric mucosa and taken up by the portal vein (21).

Micellar BS are not absorbed with fat digestion products but are reabsorbed further along the gastrointestinal tract. Passive intestinal absorption of unconjugated BS occurs throughout the small intestine and colon. Active transport components predominate in the ileum and include the brush border membrane receptor, cytosolic bile acid-binding proteins and basolateral anion-exchange proteins. The enterohepatic recirculation of BS is approximately 97 to 98% efficient (22). Although bile acid production and secretion is normally not rate limiting in lipid absorption, it has been proposed that bile acid synthesis may be subnormal in infants. Dietary taurine supplementation results in higher bile acid excretion and FA absorption in preterm and small-for-gestational-age infants (23).

Digestion and Absorption of Phospholipids

Dietary PL constitute only a small portion of ingested lipid; however, PL are secreted in large quantities in bile. PL assist in emulsification of TG droplets as well as micellar solubilization of CH and other lipid-soluble components of the diet. PL, in particular PC, are also essential for stabilization of the micelle within the unstirred water layer. PL of both dietary and biliary origin are digested through cleavage by phospholipase A₂, a pancreatic enzyme secreted in bile. In contrast to pancreatic lipase, phospholipase A₂ cleaves FA at the sn-2 position of PL, yielding lysophosphoglycerides and free FA. These products undergo absorption through a process similar to that described above.

Digestion and Absorption of Sterols

CH within the intestine originates from both diet and bile. The amount of CH in the diet varies markedly depending on the degree of inclusion of foods from nonplant sources; biliary CH secretion is more consistent. Dietary and biliary CH differ in several ways. Dietary CH is up to 65% esterified, while biliary CH exists in free form, which probably explains the different absorption efficiencies of dietary (34%) and biliary (46%) CH (24). Biliary CH is also absorbed at a site more proximal within the small intestine.

CH, being hydrophobic, requires a specialized system so that digestion and absorption can occur within a water-soluble environment. The absorption efficiency for CH is much lower than that of TG. The major rate-limiting factor associated with the lower absorption of CH is its poor micellar solubility. Using various techniques, it has been demonstrated that 40 to 65% of CH is absorbed over the physiologic range of CH intakes in humans (23).

Digestion of dietary CE involves release of the esterified FA by a BS-dependent CE hydrolase secreted by the pancreas. Removal of esterified FA does not appear to be rate limiting; mixtures of free and esterified CH were absorbed with equal efficiency in rats (25). Free sterol then is solubilized within mixed micelles in the upper small intestine. Water-soluble lipid-exchange proteins of low molecular weight, located on the

luminal side of the brush border membrane, may be involved in the transmembrane movement of CH and PL (26). The concentration of sphingomyelin within the apical membrane of the intestinal cell may also regulate the rate of CH uptake from micelles.

The amount of CH in the circulatory lipoproteins appears to be marginally responsive to the amount of dietary CH, within the normal physiologic range. Likely, compensatory changes in CH absorption (27) and biosynthesis (28) serve to maintain circulatory CH levels in the face of changes in dietary intake.

In contrast to CH, plant sterol absorption is very limited and differs across dietary phytosterols. For the major plant sterol, β -sitosterol, the typical absorption efficiency is 4 to 5%, about 1/10th that of CH (29). Absorption efficiency is higher for campesterol, about 10% (29), and almost nonexistent for sitostanol (30). This structure-specific discrimination depends on both the number of carbon atoms at the C24 position of the sterol side chain and the degree of hydrogenation of the sterol nucleus double bond. Differences in absorption across phytosterols are reflected in their circulating concentrations. Plasma campesterol levels are usually higher than those of sitosterol, while circulating levels of highly saturated sitostanol are almost nonquantifiable (11).

Phytosterol absorption is markedly reduced for two reasons. First, solubilization of phytosterols within micelles may be considerably lower than that of CH. Second, inadequate esterification of phytosterols may occur within the enterocyte membranes. Acylcoenzyme A:cholesterol acyltransferase (ACAT)-dependent esterification of CH is at least 60 times that of β -sitosterol (31).

Dietary phytosterols appear to compete with each other and with CH for absorption. Sitosterol consumption reduces absorption of CH, which in turn lowers circulating CH levels. Moreover, addition of sitostanol to diets lowers circulating levels of CH more than addition of nonsaturated plant sterols does (11), apparently through more effective reduction in absorption of CH and unsaturated FA (30). Saturated plant sterol esters, such as sitostanol esters, may be useful in lowering total and low-density-lipoprotein (LDL) CH levels in serum (32).

TRANSPORT AND METABOLISM

Solubility of Lipids

Transport of largely hydrophobic lipids through the circulation is achieved in large part by use of aggregates of lipids and protein, called *lipoproteins*. Principal lipid components of lipoproteins are TG, CH, CE, and PL. Protein constituents, termed *apolipoproteins* or *apoproteins*, increase both particle solubility and recognition by enzymes and receptors located at the outer surface of lipoproteins. The major lipoprotein classes are listed in [Table 4.3 \(32a\)](#). Lipoproteins differ in composition; however, all types feature hydrophilic apoproteins, PL polar head groups, and CH hydroxyl groups facing outward at the water interface, with PL acyl tails and CH steroid nuclei oriented toward the interior of the aggregate. CE and TG molecules form the core of the lipoprotein particle. In this manner, hydrophobic lipids can be internally solubilized and transported within a water

medium. Lipoproteins represent a continuous spectrum of particles varying in size, density, composition, and function. Internal transport of lipids can be divided into exogenous and endogenous systems, reflecting lipids of dietary and internal origin, respectively.

Lipoprotein	Density (g/dl)	Molecular Mass (dalton)	Diameter (nm)	Lipid (%)		
				Triglyceride	Cholesterol	Phospholipid
Chylomicrons	0.85	1400 × 10 ³	75-1200	80-85	2-7	3-4
VLDL	0.85-1.026	10-80 × 10 ³	30-80	55-80	5-15	10-20
IDL	1.005-1.019	5-10 × 10 ³	25-35	25-50	25-40	15-25
LDL	1.019-1.063	23 × 10 ³	18-25	5-15	40-50	20-25
HDL	1.063-1.21	1.7-28 × 10 ³	5-12	5-10	15-25	20-30

^aPercentage composition of lipid components may vary. VLDL, very low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

Table 4.3 Physical-Chemical Characteristics of the Major Lipoprotein Classes

Exogenous Transport System

The exogenous transport system transfers lipids of intestinal origin to peripheral and hepatic tissues (Fig. 4.4). Such lipids may originate from diet or secretions in the intestine. The exogenous system starts with reorganization in the enterocyte of absorbed FA, 2-MG, lysophospholipids, PL, smaller amounts of glycerol, CH, and phytosterols into molecules more readily packaged within the primary secretory unit, the chylomicron. Chylomicrons are assembled in the enterocyte endoplasmic reticulum membrane in conjunction with the Golgi apparatus. Chylomicron TG are reassembled predominantly via the monoacyl-glycerol pathway. Absorbed FA are activated by microsomal FA-CoA synthase to yield acyl-CoA, then combined sequentially with 2-MG through the action of mono- and diglyceride-acyltransferases. In addition, about 20% of TG resynthesis occurs by the α -glycerophosphate pathway. α -Glycerophosphate, synthesized de novo within the enterocyte from absorbed free glycerol or triose phosphates, combines with two fatty acyl-CoA units to form phosphatidic acid. After dephosphorylation, the 1,2-diglyceride is converted to TG by addition of a further fatty acyl-CoA. Phosphatidic acid is also converted to PL with addition of FA, as is most lysophospholipid entering the enterocyte. The extent to which the phosphatidic acid pathway contributes to TG synthesis is influenced by the PL requirement of the enterocyte for chylomicron structure and assembly. Absorbed free CH is in large part reesterified using fatty acyl-CoA by acyl-CoA cholesterol acyltransferase (ACAT) located in microsomes (33).

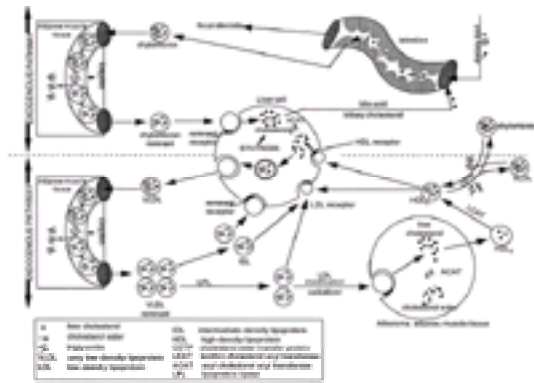

Figure 4.4. Exogenous and endogenous pathways of lipid transport.

Synthesis of new lipid appears to be a driving force in assembly and secretion of lipoproteins. Uptake of dietary long-chain fatty acids (LCFA), incorporation into TG by the glycerol-3-phosphate pathway, and assembly of lipoproteins all require fatty acid-binding protein (FABP) (34).

Not all FA require chylomicron incorporation and transport. FA less than 14 carbons in length and those containing several double bonds undergo, to a variable degree, direct internal transport via the portal circulation. Fats undergo direct portal transfer either as lipoprotein-bound TG or albumin-bound free (unesterified) FA. Portal transfer delivers FA to the liver faster than chylomicron transit. The FA structure-dependent specificity in these studies has raised questions about whether all FA can be considered equivalent in the context of energy and lipid metabolism. An accumulating body of evidence suggests that consumption of fats containing SCFA associated with portal transit results in higher rates of fat oxidation.

Chylomicrons released from mucosal cells circulate through the lymphatic system and reach the superior vena cava via the thoracic duct. Release into the circulation is followed by TG hydrolysis at the capillary surface of tissues by lipoprotein lipase. Hydrolysis of TG within the core of the chylomicron results in movement of FA into tissues and the subsequent production of TG-depleted chylomicron remnant particles. Chylomicron remnants then pick up CE from high-density lipoproteins (HDL) and are rapidly taken up by the liver.

Endogenous Transport System

The endogenous shuttle for lipids and their metabolites consists of three interrelated components. The first, involving very low-density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), and LDL, coordinates movement of lipids from liver to peripheral tissues. The second, involving HDL, encompasses a series of events that returns lipids from peripheral tissues to liver. The third component of the system, not involving lipoproteins, effects the free FA-mediated transfer of lipids from storage

reservoirs to metabolizing organs.

Components of the endogenous lipoprotein system are illustrated in [Figure 4.4](#). The system begins with assembly of VLDL particles, mostly in the liver. Assembly of nascent VLDL starts in the endoplasmic reticulum and depends on the presence of adequate core lipids, CE, and TG. It has been estimated using stable isotope tracers that most TG FA within VLDL is preformed ([35](#), [36](#)). Some VLDL particles may also originate from intestinal tissue. Addition of surface lipids, mainly PL and free CH, occurs in the Golgi apparatus before the particle is secreted.

Following secretion of the VLDL particle into the circulation, a number of interchanges with tissues and lipoproteins occur. A major event is deposition of lipids into peripheral tissues. Hydrolysis of VLDL TG occurs through the action of lipoprotein lipase, an enzyme located on the endothelial side of vessel tissue, which mediates hydrolysis of chylomicron TG. Lipase-generated free FA can be used as energy sources or structural components for lipids, including PL, leukotrienes (LT), and thromboxanes (TXA), or converted back to TG and stored. TG and PL from both chylomicron remnants and LDL are also hydrolyzed by hepatic lipase. When hepatic lipase is absent, large LDL particles and TG-rich lipoproteins accumulate. Through TG depletion, the VLDL particle is converted to a denser, smaller, and cholesterol-rich, triglyceride-rich lipoprotein (TRL) remnant. High circulatory levels of TRL remnants are associated with progression of coronary artery disease. TRL remnants themselves can be cleared from plasma through hepatic lipoprotein receptors or be converted to smaller LDL. LDL is the major cholesterol-carrying lipoprotein. Although LDL levels are associated with heart disease risk in general, recent evidence suggests that a predominance of smaller, denser LDL particles in the circulation confers an elevated risk of coronary heart disease ([37](#)). An LDL receptor allows the liver to catabolize LDL. Modified or oxidized LDL can also be taken up by a scavenger receptor on macrophages in various tissues, including the arterial wall.

The second component of the endogenous transport system, perhaps nebulously termed *reverse CH transport*, involves movement of CH from peripheral tissues to the liver. Since 1975, when Miller and Miller ([38](#)) described the protective effect of HDL on atherosclerosis, much work has been undertaken to better understand the structure and function of HDL. HDL particles are highly heterogeneous, with subcomponents originating from both the intestinal tract and liver. It has been proposed that HDL particles participate in reverse CH transport by acquiring CH from tissues and other lipoproteins and transporting it to the liver for excretion. Circumstantial evidence suggests that elevated HDL levels are associated with reduced coronary risk in humans; the link between subnormal HDL levels and higher risk has been established ([39](#)).

The third component of the endogenous lipid transport system involves non-lipoprotein-associated movement of free FA through the circulation. These FA, largely products of cellular TG hydrolysis, are secreted by adipose tissue into plasma, where they bind with albumin. Recent evidence suggests that saturated fatty acids (SAFA) and C18:1n-9 are more slowly mobilized than PUFA, at a rate that is independent of their relative proportion in adipose tissue ([40](#), [41](#)). Albumin-bound FA are removed in a concentration gradient-dependent manner by metabolically active

tissues and used largely as energy sources.

Apoproteins, Lipid Transfer Proteins, and Lipoprotein Metabolism

Interorgan movement of exogenous and endogenous lipids within lipoproteins is not incidental, but coordinated by a series of apoproteins. Apoproteins confer greater water solubility, coordinate the movement and activities of lipoproteins by modulating enzyme activity, and mediate particle removal from the circulation by specific receptors. Indeed, rates of synthesis and catabolism of the major lipoproteins are regulated to a large extent by apoproteins residing on a particular surface that is recognized by specific cellular receptors. Much has been learned about the role of apoproteins through the study of genetic defects and their effects on modification of apoprotein structure and thus lipoprotein function (42).

Lipoproteins vary in apoprotein content. Apolipoprotein B (Apo-B) is the major protein contained in chylomicrons, VLDL, IDL, and LDL particles. A larger Apo-B-100 is associated with VLDL and LDL of hepatic origin, while a lower-molecular-weight Apo-B-48 species is found in chylomicrons and intestinally derived VLDL. Apo-B-48 is thought to be generated from the same messenger RNA as Apo-B-100. During apoprotein assembly, hydrophobic Apo-B associates with PL in the endoplasmic reticulum immediately after translation and then requires the presence of adequate core lipid CE and TG. This process of assembly of Apo-B-containing lipoproteins may be influenced by FA composition.

Apoprotein E is synthesized in the liver and is present on all forms of lipoproteins. Apo-E binds both heparin-like molecules (which are present on all cells) and the LDL receptor. Apo-E displays genetic polymorphism; at least three alleles of the Apo-E gene produce six or more possible genotypes, which differ in their ability to bind the LDL receptor. Interactions between Apo-E genotype and CH absorption and synthesis have been suggested.

Most HDL particles contain apoproteins A-I, A-II, A-IV, and C. Apo-A-I and Apo-A-IV are believed to be activators of lecithin:cholesterol acyltransferase (LCAT), an enzyme that esterifies CH in plasma. Apo-A-I also appears to be the crucial structural protein for HDL. Three C apoproteins exist: Apo-C-I, Apo-C-II, and Apo-C-III; each possesses distinct functions and all are synthesized in the liver. Apo-C-II, present in chylomicrons, VLDL, IDL, and HDL, is important in activation of the enzyme lipoprotein lipase, along with Apo-E. Apo-C-III, present on chylomicrons, IDL, and HDL, may inhibit PL action.

Apoproteins play a role in interorgan lipid movement and distribution at several levels. For instance, VLDL are modified by lipoprotein lipase in peripheral tissues to form LDL particles. Apo-C-II, activating lipoprotein lipase, hydrolyzes VLDL and chylomicron TG. It is believed that HDL exchanges Apo-E and Apo-C for Apo-A-I and Apo-A-IV on chylomicrons in the circulation. Apo-E is important in the hepatic clearance of TG-depleted chylomicron remnants.

Apoproteins are critical in the removal of particles from the circulation. LDL is taken up into tissues by two processes, mostly in liver cells but also in adipocytes, smooth

muscle cells, and fibroblasts. The first process is receptor dependent and involves the interaction of Apo-B-100 and LDL with specific LDL receptors on cell surfaces. Quantitatively, most LDL receptors exist in the liver ([Fig. 4.4](#)). Postcontact events involve clustering of these receptors in coated pits and LDL internalization. The second process is receptor independent. In contrast to receptor-dependent LDL uptake, receptor-independent transport is nonsaturable and does not appear to be regulated. The rate of receptor-independent transfer is low but increases as a direct function of plasma LDL levels; thus uptake by this pathway can be substantial at high plasma LDL levels.

The LDL receptor is sensitive to both the total amount and unesterified fraction of CH within the cell. Receptor integrity, particularly for LDL, is implicated in the progression of atherosclerosis. Individuals with genetically inherited abnormalities in their LDL receptors have greatly elevated LDL levels because of faulty receptor-apoprotein interactions ([42](#)). Likewise, genetic problems with apoprotein structure can result in similar elevations of LDL. CH in LDL particles can undergo chemical modification by oxidation and can then be taken up by macrophage LDL scavenger receptors in an unregulated fashion, potentially resulting in foam cell production and atherogenesis. Higher concentrations of CH also favor formation of b-VLDL, particles that float at a density of less than 1.006 but have b-electrophoretic mobility. b-VLDL can arise from chylomicron remnants or be formed by hepatocytes. These particles interact with LDL receptors on macrophages, depositing large amounts of CE into the macrophage. Substantial increases in CE content convert macrophages to foam cells. LDL receptors on macrophages do not appear to be suppressed as CE concentration increases, unlike those on fibroblasts or smooth muscle.

Formation of HDL also critically depends on apoproteins. Coalescence of PL-apoprotein complexes results in aggregation of Apo-A-I, Apo-A-II, Apo-A-IV, and possibly Apo-E to form nascent HDL particles. These CH-poor, smaller Apo-A-I-containing forms of HDL are heterogeneous in size and can be classified overall as pre-b or discoidal HDL. Subsequently, discoidal HDL changes in size and composition in plasma and extracellular spaces as a result of acquiring free CH from cell membranes of peripheral tissues. HDL-binding proteins have been identified on plasma membranes of cells, including macrophages, fibroblasts, hepatocytes, and adipocytes. Free CH taken up by HDL is esterified by LCAT and moves to the core of the HDL particle. LCAT transfers an sn2-acyl group of PC or phosphatidylethanolamine (PE) to the free hydroxyl residue of CH. Esterification prevents reentry of CH into peripheral cells. Phospholipid transfer protein (PLTP), which provides PC to HDL, also contributes to the compositional shifts in HDL. As HDL becomes enriched with CE, proteins Apo-C-II, and C-III are picked up from other lipoproteins to form three spherical categories of HDL. In order of increasing size and lipid content, these include HDL₃, HDL_{2a}, and HDL_{2b}. Spherical HDL likely go through repeated cycles of size increase and decrease over their circulatory life span of 2 to 3 days.

Spherical HDL can be removed from the circulation and metabolized via two routes. First, HDL₂ can transfer CE to either Apo-B-containing lipoproteins or directly to cells. CH moves from HDL₂ via cholesterol ester transfer protein (CETP), which mediates the transfer of CE from HDL₂ to VLDL and chylomicrons in exchange for TG.

Apo-B-containing particles in turn transport CE to liver. CETP is produced in liver and associates with HDL. As a result of CETP, HDL₂ reconverts to the HDL₃ form. Other apoproteins on HDL that play a role in reverse CH transport and can activate LCAT include Apo-A-IV, Apo-C-I, and Apo-E. Secondly, entire particles of HDL₂ can be taken up by LDL receptors and possibly by a separate Apo-E receptor present on hepatocytes.

Actions of HDL other than reverse CH transport may include protection of lipoproteins from oxidative modification, direct removal of CH from atherosclerotic lesions, and a role in the metabolism of eicosanoids (39). HDL can inhibit oxidative modification of LDL in vitro and may contribute to HDL antiatherogenic potential in vivo (43).

Plasma albumin may also be important in reverse CH transport. Through passive diffusion, albumin picks up CH from peripheral cells and passes it to lipoproteins, including HDL and LDL. A large proportion of CH efflux persists in the absence of Apo-A-I, suggesting mainly albumin-dependent shuttling (44).

Dietary Factors That Influence Plasma Lipoproteins

Dietary factors profoundly influence lipoprotein levels and metabolism, which in turn alter an individual's susceptibility to atherosclerosis. Dietary fat, CH, fiber, protein, alcohol consumption, and energy balance all have major impact. Classic studies originally revealed that consumption of saturated fats elevated circulating total and LDL CH levels in humans (45). Plasma cholesterol-raising effects of SAFA, particularly myristic (C14:0) and C16:0 acids, are well established. Newer technologies that reduce saturated fat content in dairy products result in lower plasma CH levels when these products are consumed by humans (46). The CH-raising effect is believed to occur because the regulatory pool of liver CH is shifted from CE to free CH when hepatocytes become enriched with C14:0 and C16:0 acids. Higher levels of free CH in the liver suppress LDL receptor activity, driving up circulatory levels. Postmeal accumulation of VLDL is more prolonged in individuals consuming diets rich in SAFA than in those consuming diets containing n-6 PUFA (47).

Conversely, metabolic studies show that consumption of n-6 PUFA lowers circulatory CH values; however, epidemiologic data fail to demonstrate any direct protective effect of dietary PUFA on coronary heart disease risk. Consumption of n-3 PUFA is more strongly inversely correlated with the incidence of heart disease. Whether this action is due to lipid lowering or changing eicosanoid-related thrombosis susceptibility has not been firmly established. n-3 PUFA that lower circulating TG levels have only a minor impact on lipoprotein CH levels in humans (48).

Consumption of monounsaturated fats also results in lower CH levels, but to no greater extent than n-6 PUFA consumption. Consumption of *trans* FA raises LDL and lowers HDL levels in a dose-dependent fashion. It has been suggested recently that dietary *trans* fat consumption may increase CETP activity, explaining the higher circulatory LDL levels associated with *trans* fat consumption (49). The role of dietary CH in hyperlipidemia has engendered considerable debate. Within the range of normal CH

intakes, changing dietary CH content seems to produce little alteration in circulating CH levels or subsequent metabolism (50). Certain individuals demonstrate a hypersensitivity to dietary CH, which may result in a misleading perception of the response to dietary CH within a population overall.

Dietary fiber also influences CH levels. In general, insoluble fibers, such as cellulose, hemicellulose, and lignin from grain and vegetables (see [Chapter 3](#)), have limited effects on CH levels, whereas more soluble forms, such as gums and pectins found in legumes and fruit, possess greater CH-lowering properties. Fiber exhibits CH-lowering action by at least three mechanisms other than simple replacement of hypercholesterolemic dietary ingredients. First, fiber may act as a bile acid-sequestering agent. Second, fiber likely reduces the rate of insulin rise by slowing carbohydrate absorption, thus slowing CH synthesis. Third, fiber may produce SCFA, which are absorbed by the portal circulation and inhibit CH synthesis.

Qualitative protein intake may also influence circulating CH levels, since consumption of animal protein leads to higher circulating CH levels than consumption of plant protein. Alcohol intake is somewhat arguably associated with heart disease risk. The relationship between alcohol consumption and CH levels is “J” shaped. At lower levels of intake, wine and spirits (but not beer) produce a more favorable lipid profile: lowering LDL and raising HDL CH values. Further, consumption of excess calories resulting in obesity is associated with higher circulating CH levels. Both CH and TG levels fall during weight loss (51). The distribution of excess weight appears to have a stronger association with circulating lipid level than the amount of weight (52). In summary, these dietary factors suggest that replacing energy-dense and saturated fat-rich, animal-based foods with those obtained from plant sources is warranted to maintain a desirable profile of circulating lipids.

OXIDATION AND CONVERSION OF LIPIDS TO OTHER METABOLITES

Fatty Acid Oxidation

In an individual of stable weight, the amount of fat consumed equals the quantity partitioned to meet energy needs. FA are a more efficient energy source than other macronutrients because of their high content in bonds between carbon and hydrogen. Such bonds are stronger and therefore contain more oxidizable energy than bonds between carbon and other atoms, as found in carbohydrates, protein, and alcohol. FA used for energy proceed through stages, including transport to oxidative tissues, transcellular uptake, mitochondrial transfer, and subsequent β -oxidation.

FA partitioned for oxidation are activated to fatty acyl-CoA, which are then transported into mitochondria to be oxidized. However, LCFA and their CoA derivatives cannot cross the mitochondrial membrane without carnitine, synthesized in humans from lysine and methionine. Transferase enzymes bind activated FA covalently to carnitine. After intramitochondrial transmission, FA are reactivated with CoA while carnitine recycles to the cytoplasmic surface.

Mitochondrial β -oxidation of FA entails the consecutive release of two-carbon acetyl-CoA units from the carboxyl terminus of the acyl chain. Prior to release of each unit, the β -carbon atoms of the acyl chain undergo cyclical degradation in four stages: dehydrogenation (removal of hydrogen), hydration (addition of water), dehydrogenation, and cleavage. Completion of these four reactions represents one cycle of β -oxidation. For unsaturated bonds within FA, the initial dehydrogenation reaction is omitted. The entire cycle is repeated until the fatty acyl chain is completely degraded. Absence of chain-shortened n-6 or n-3 FA in cellular or subcellular compartments indicates that once an FA begins cyclic degradation by β -oxidation, the process continues until the acyl chain is completely broken down.

Peroxisomal FA β -oxidation is similar to mitochondrial oxidation; yet there are several differences between these two organelles. First, very long acyl-CoA synthetase, the enzyme responsible for the activation of VLCFA, is present in peroxisomes and endoplasmic reticulum but not mitochondria, likely explaining why VLCFA are oxidized predominantly in peroxisomes. Second, the initial reaction in peroxisomal β -oxidation (desaturation of acyl-CoA) is catalyzed by an FAD-containing fatty acyl-CoA oxidase that is presumed to be the rate-limiting enzyme, whereas an acyl-CoA dehydrogenase is the first enzyme in the mitochondrial pathway. Third, peroxisomal β -oxidation is not directly coupled to the electron transfer chain that conserves energy via oxidative phosphorylation. In peroxisomes, electrons generated in the first oxidation step are transferred directly to molecular oxygen, yielding hydrogen peroxide that is disposed of by catalase, while energy produced in the second oxidation step (NAD^+ reduction) is conserved in the form of high-energy electrons of nicotinamide adenine dinucleotide (NADH). Fourth, the second (hydration) and third (NAD^+ -dependent dehydrogenation) steps are catalyzed by a multifunctional protein that also displays d^3, d^2 -enoyl-CoA isomerase activity required for oxidation of unsaturated FA.

Dietary Modulation of Fatty Acid Oxidation

Recently, considerable interest has surrounded structure-dependent induction of FA oxidation. Thus, food selection may influence the partitioning of dietary fat for oxidation or retention for storage and structural use in humans. This issue is of health interest for at least two reasons. First, consumption of fats associated with greater retention may result in an increased tendency toward obesity. Second, the greater accumulation of less preferentially oxidized FA in cells may confer structural/functional changes because of shifts in membrane PL FA patterns or in prostaglandin (PG):thromboxane (TXA) ratios. The influence of tissue FA composition on functional ability, such as insulin sensitivity, is well recognized (53).

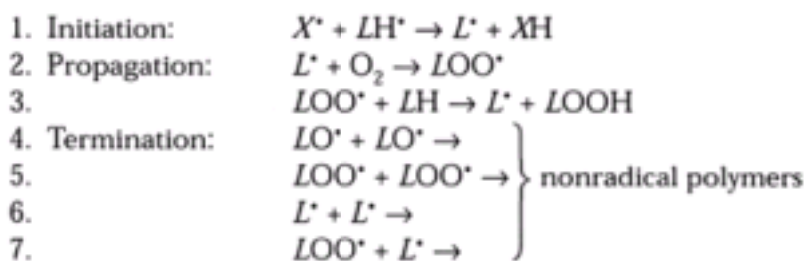

Discriminative oxidation of certain FA is well defined; for others it has been suggested. Short- and medium-chain triglyceride (MCT) consumption is associated with increased energy production in humans, perhaps because of direct portal transfer of SCFA and MCFA from gut to liver. The lack of requirement for carnitine in mitochondrial membrane transit by SCFA may also be responsible for their more rapid oxidation. For LCFA, increasing evidence suggests that n-6 and n-3 PUFA are more rapidly oxidized for energy than are SAFA. In animals, labeled PUFA are more readily converted to carbon

dioxide than are SAFA (54), while PUFA consumption exhibits greater thermogenic effect (55), oxygen consumption (56), and sympathetic nervous system stimulation (57). Whole-body FA balance data also support the concept that C18:2n-6 is more readily used for energy than are SAFA (58). Although these findings have yet to be confirmed in humans, consumption of fats containing PUFA appears to enhance the contribution of dietary fat to total energy production in healthy individuals (59) and influences the use of other FA for energy (60); however, mechanisms remain to be defined. Portal venous transfer rates, release rates of FA from adipose tissue, hepatic FA oxidation enzyme activities, and mitochondrial entry rates of FA generally increase with the degree of acyl chain unsaturation.

Peroxidative Modification of Lipids

Lipids are oxidized by reactive oxygen species produced as byproducts of normal metabolism. Reactive oxygen species include superoxide (O_2^-), hydroxyl radical ($\cdot OH$), hydrogen peroxide, singlet oxygen (1O_2), and hypochlorous acid ($HOCl$). In healthy individuals, generation of reactive oxygen species should be in balance with antioxidant defenses. Circumstances that enhance oxidant exposure, such as increased formation of reactive oxygen species caused by chemicals and drugs, or that compromise antioxidant capability, such as decreased antioxidant vitamin levels because of malnutrition, are referred to as *oxidative stress*. Possible free radical effects on cells include oxidative damage to proteins, carbohydrates, and DNA. Oxidative stress has also long been known to be capable of inducing lipid oxidation and, in the presence of oxygen, lipid peroxidation of cell membranes.

It is generally accepted that lipid oxidation proceeds via a free radical mechanism called autoxidation, which includes initiation, propagation, and termination stages and predominantly occurs with PUFA. Polyunsaturated acyl chains of membrane PL are particularly sensitive to lipid peroxidation. Lipid oxidation, both nonenzymatic and enzymatic, is self-propagating in cellular membranes. Peroxidation of PUFA is classically depicted as a series of three or four basic reactions; however, the process becomes more complex as both the degree of unsaturation and severity of peroxidative conditions increases. The following initiation, propagation, and termination reactions characterize the general scheme of autoxidation:

A peroxidation sequence in a membrane or PUFA is initiated by the attack of any free radical with sufficient reactivity to abstract a hydrogen atom from an allelic methylene group of an unsaturated FA; this includes the HO^\cdot and HO_2^\cdot radicals. The initiating free radical (X^\cdot) abstracts a hydrogen atom from the carbon chain, generating a lipid

carbon-centered radical ($L\cdot$, reaction 1). This carbon-centered lipid radical tends to be stabilized by a molecular rearrangement that produces a conjugated diene, which then readily reacts with molecular oxygen to yield a hydroperoxyl radical ($LOO\cdot$, reaction 2). The peroxy radical can propagate the oxidizing chain reaction by abstracting electrons from other susceptible PUFA, forming another lipid free radical and a molecule of lipid hydroperoxide ($LOOH$) (reaction 3). The overall chain reaction has a pyramidal effect through which a relatively few initiating radicals break down PUFA. These reactions continue until the chain is terminated, either by the combination of two radicals to form a nonradical product (reactions 4–7) or by termination of the propagation reaction in the presence of a hydrogen or an electron donor. Termination may also result from hydrogen abstraction from vitamin E (α-tocopherol) or another lipid antioxidant to form hydroperoxides. Vitamin E is termed a *chain-breaking antioxidant* because it donates a hydrogen atom to lipid radicals, thereby terminating the propagative process and lipid peroxidation. Lipid peroxidation can also be inhibited by reduction of lipid hydroperoxides by selenoperoxidases, such as glutathione (GSH)-peroxidase, to their corresponding alcohols.

Lipid peroxides are rapidly decomposed in vivo by metal ions and their complexes. The alkoxy or peroxy radical byproducts of lipid hydroperoxide breakdown can propagate the chain reaction of lipid peroxidation (61). Although lipid peroxides are highly toxic, they are poorly absorbed in vivo. The toxicity of peroxides has in part been attributed to their ability to oxidize the thiol groups of proteins, glutathione, and other sulfhydryl compounds and form insoluble deposits called *lipofuscin* in the artery wall or neural tissue (61).

The end products of lipid peroxidation include aldehydes and hydrocarbon gases. Short-chain aldehydes can attack amino groups on protein molecules to form cross-links between different protein molecules. The most commonly measured product is malondialdehyde (MDA), known to react with proteins and amino acids (Fig. 4.5). Several studies have shown a positive relationship between in vivo lipid peroxidation and urinary excretion of MDA. MDA adduct formation with proteins, PL, and nucleic acids may be a cause of pathology as MDA adducts with serine, lysine, ethanolamine, and guanidine have been detected in urine (62).

Figure 4.5. Three oxidation products associated with toxicity.

Lipid peroxidation has been implicated in the pathogenesis of diseases, including cancer and atherosclerosis. Although products of lipid peroxidation are readily measurable in blood, the significance and occurrence of lipid peroxidation is controversial. A major criticism has been that lipid peroxidation may not be initially involved in causing the underlying disease pathology, as excess production of lipid peroxidation byproducts could result from the primary disease process. Also, many analytic methods produce some disruption of cell structure. Such disruption could produce misleading findings, as lipid peroxidation may accompany tissue damage, although some recent studies have dissociated lipid peroxidation from in vitro cell death (63).

The PL components of cellular membranes are highly vulnerable to oxidative damage because of the susceptibility of their PUFA side chains to peroxidation. Membrane lipid peroxidation results in loss of PUFA, decreased membrane fluidity, and increased permeability of the membrane to substances such as Ca^{2+} ions. Lipid peroxidation can lead to loss of enzyme and receptor activity and have deleterious effects on membrane secretory functions. Continued lipid peroxidation can lead to complete loss of membrane integrity, as can be observed from the hemolysis associated with lipid peroxidation of erythrocyte membranes.

A wide range of dietary components has been reported to influence membrane susceptibility to oxidative damage. Cellular lipid peroxidation depends strongly on PUFA intake as well as intake of vitamin E and other lipid antioxidants. In isolated erythrocytes from human subjects, the production of lipid peroxidation products following hydrogen peroxide-induced oxidative stress has been measured as thiobarbituric acid-reactive substances (TBARS). Multivariate analysis showed that the unsaturation index was the best predictor of erythrocyte TBARS variability (64). A relatively stable C18:2n-6:vitamin E ratio in vegetable oils provides protection from risk of excessive lipid peroxidation and vitamin E deficiency at high PUFA intakes. Fish oils are an exception to the observation of a natural association between PUFA and vitamin E in edible fats and oils and the stability of PUFA to oxidation in the diet and body. The highly unsaturated n-3 pentanoic and hexanoic FA, found in abundance in fish and marine oils with relatively low vitamin E content, markedly increase the in vivo susceptibility of these oils to peroxidation (65). TBARS increased with higher concentrations of total n-3 PUFA in isolated human erythrocytes, whereas TBARS decreased with higher concentrations of total MUFA (64).

The effects of oxygen free radicals on membrane CH may be as important as the effects observed on membrane PL, since oxidized CH derivatives, the oxysterols or CH oxides, have been suggested to play a key role in development of atherosclerosis (66). This concept has been fostered by increasing evidence of the role of oxidatively modified lipoproteins in atherogenesis. CH readily undergoes oxidation (67), and the metabolites derived display a wide variety of actions on cellular metabolism, including angiotoxic, mutagenic, and carcinogenic effects (66). Common CH oxidation products include

cholesterol-5a,6a-epoxide, cholesterol-5b,6b-epoxide, and cholestane-3b,5a,6b triol (Fig. 4.5). CH oxides disturb endothelial integrity by perturbing vascular permeability, whereas purified CH has no effect. CH oxidation products have been detected in human serum lipoproteins and human atheromatous plaques (68). Substantial amounts of oxidized CH are detected in a variety of foods of animal origin exposed to oxidizing conditions (67). These highly atherogenic oxysterols may also be ingested and absorbed from processed foods or generated by free radical oxidation of lipoproteins. To date, however, it is unclear whether CH oxides merely serve as markers for oxidatively modified lipoproteins or if they contribute to the toxicity of oxidized lipoproteins. In addition, analysis of oxysterols is beset by such difficulties as artifact generation and decomposition of oxysterols during sample manipulation (67).

LDL oxidation has been implicated as a causal factor in development of human atherosclerosis (69). Unsaturated lipids in LDL are subject to peroxidative degradation, and the susceptibility of LDL to oxidation has been correlated with the degree of coronary atherosclerosis (70). Autoantibodies exist in human serum, and oxidized LDL is present in atherosclerotic plaque, indicating that oxidized LDL exists in vivo (71). Possible sources of oxidation include endothelial cells, smooth muscle cells, monocytes, macrophages, and other inflammatory cells. In the presence of the promoter copper, peroxidation of LDL results in formation of hydroxyalkenals and MDA, which modify Apo-B by reacting with its lysine amino groups. This modification of Apo-B could, in turn, impair its uptake by the LDL receptor. Oxidatively modified LDL may exert atherogenic effects via their cytotoxic and chemotactic properties and the promotion of LDL uptake by the scavenger receptors on macrophages leading to the formation of lipid-enriched foam cells.

Nutritional and biochemical studies suggest that diet can modulate the susceptibility of plasma LDL to oxidative degradation by altering the concentration of PUFA and antioxidants in the lipoprotein particle. The first targets of peroxidation in the oxidation of LDL are PUFA of PL on the LDL surface. In studies of LDL isolated from healthy humans and animals, a diet rich in C18:2n-6 increased the susceptibility of plasma LDL to copper-induced oxidation and to in vitro macrophage uptake, compared with a diet high in C18:1n-9 (72). C18:1n-9 and other MUFA do not contain the easily oxidized conjugated double bonds found in PUFA. Also, C18:1n-9 has a high affinity for transition metals, making them unavailable for LDL peroxidation. Depending on the dose used, subjects treated with n-3 PUFA showed either an increase or no change in LDL oxidation (73). Other studies have shown that increasing the amount of vitamin E in the LDL particle via oral supplementation decreased LDL susceptibility to in vitro oxidative damage (74). A difficulty with in vitro assays of plasma lipoprotein oxidation is that these assays are subject to influences by a variety of plasma substrates and conditions, making their relevance to physiologic situations uncertain. However, recent clinical evidence of protection against cardiovascular disease by vitamin E supplementation and the inhibition of atherosclerotic lesions in animals by antioxidants supports the oxidative hypothesis of atherosclerosis and the likely effectiveness of dietary antioxidants (75, 76). The lower incidence of cardiovascular disease in populations consuming more olive oil may be partly due to an inhibition of LDL oxidation by the antioxidant action of olive oil as well as by those antioxidants found in fruits and vegetables associated with the Mediterranean diet.

INTRACELLULAR MOVEMENT AND BIOSYNTHESIS OF LIPIDS

Fatty Acids

SAFA are biosynthesized in the extramitochondrial compartment by a group of enzymes known as FA synthetases. Compared with many animal species, human FA synthesis occurs predominantly in the liver and is much less active in adipose tissue. The FA biosynthetic pathway is almost identical in all organisms examined to date. The starting point is acetyl-CoA. Acetyl-CoA and oxaloacetate are cleaved from citrate, which is transported from the mitochondria. The first reaction in the FA biosynthetic pathway proper is the conversion of acetyl-CoA to malonyl-CoA by acetyl-CoA carboxylase, which is rate limiting for FA synthesis. Acetyl-CoA then combines sequentially with a series of malonyl-CoA molecules as follows:

In mammals, complete de novo synthesis results in C16:0. Other FA can be formed from C16:0 by chain elongation via microsomal malonyl-CoA-dependent elongase. Mammals possess a series of desaturases and elongases to generate long-chain PUFA from the metabolism of C16:0, C18:0, C18:2n-6, and C18:3n-3 (Fig. 4.6). These reactions occur predominantly in the endoplasmic reticulum membranes. Desaturase reactions are catalyzed by membrane-bound desaturases with broad chain-length specificity, including D⁹, D⁶, D⁵, and D⁴ fatty acyl-CoA desaturases. These are involved in the desaturation of the C16:1n-7, C18:1n-9, C18:2n-6, and C18:3n-3 families. The D⁴ desaturation required for formation of C22:6n-3 from C22:5n-3, and C22:5n-6 from C22:4n-6, respectively, involves three steps. These steps require an elongation reaction followed by membrane (microsomal) desaturation and shortening in peroxisomes. The desaturase enzymes are highly specific for the position of the double bond. The FA desaturase system involves three integral components: the desaturase, NADH-cytochrome b₅ reductase, and cytochrome b₅, which are constituents of microsomal membranes. Desaturases require electrons supplied mostly by NADH-cytochrome b₅ reductase in addition to the activated substrate in the form of acyl-CoA.

Precursors for the n-7 and n-9 families of PUFA are MUFA that are synthesized via microsomal D⁹ oxidative desaturation of C16:0 and C18:0 to form C16:1n-7 and C18:1n-9, respectively (Fig. 4.6). Additional double bonds can be introduced into existing MUFA C16:1n-7 and C18:1n-9 and also into C18:2n-6 via D⁶ desaturase (Fig. 4.6). Until recently, humans and other mammals were thought incapable of synthesizing long-chain n-3 (C18:3n-3) and n-6 (C18:2n-6) EFA. Recent studies, however, suggest that C18:2n-6 and C18:3n-3 can be synthesized in humans and other mammals via elongation of the dietary precursors C16:2n-6 and C16:3n-3, respectively (78). Edible green plants can contain up to 14% C16:2n-6 and C16:3n-3 (78). In a practical sense, a dietary supply of EFA is still important, since humans likely do not obtain enough

16-carbon precursors.

Figure 4.6. Effects of desaturase and elongase on essential fatty acids.

In mammals, FA from the n-3 and n-6 FA cannot be interconverted because of a lack of D¹² or D¹⁵ desaturase enzymes, although such interconversions can take place in plants. D⁶ Desaturase is the regulatory enzyme in these reactions and requires an n-9 *cis* double bond. Hence, *trans* FA, such as C18:1n-9 *trans*, formed either by rumen bacteria or by chemical hydrogenation of FA with *cis* double bonds, cannot be desaturated by this enzyme. The n-3, n-6, and n-9 FA families compete with each other, especially at the rate-limiting D⁶ desaturase step. In general, desaturase enzymes display highest affinity for the most highly unsaturated substrate. The order of preference is a-linolenic family (n-3) > linoleic family (n-6) > oleic acid family (n-9) > palmitoleic acid family (n-7) > elaidic acid family (n-9, *trans*). Competition also exists among the families of PUFA for the elongase enzymes and for the acyl transferases involved in formation of PL.

Because of the competitive nature of FA desaturation and elongation, each class of EFA can interfere with the metabolism of the other. This competition has nutritional implications. An excess of n-6 EFA will reduce the metabolism of C18:3n-3, possibly leading to a deficit of its metabolites, including eicosapentanoic acid (C20:5n-3). This is a matter of concern in relation to infant formulas, which may contain an excess of C18:2n-6 with no balancing of n-3 EFA. Conversely, as long-chain n-3 EFA markedly decrease D⁶ desaturation of C18:2n-6, excessive intake of fish oils could lead to impairment of C18:2n-6 metabolism and a deficit of n-6 EFA derivatives. High doses of fish oil in humans can cause a large reduction in the levels of C20:3n-6 in plasma PL, with a smaller effect on C20:4n-6 content (79). Although C18:1n-9 can inhibit D⁶ desaturase activity, high dietary intakes are necessary. In the presence of C18:2n-6 or C18:3n-3, little desaturation of C18:1n-9 occurs. During EFAD, C20:3n-9 is synthesized from C18:1n-9 because of the nearly complete absence of competitive effects of n-3 and n-6 EFA. The presence of C20:3n-9 in tissues instead of C20:4n-6, C20:5n-3, and C22:6n-3 indicates EFAD, which reverses on EFA feeding (80). In the catalytic

hydrogenation of vegetable oils and fish oils for the production of some margarines and shortenings, a variety of geometric and positional isomers of unsaturated FA are formed in varying amounts. After absorption, these isomers may compete with the EFA and endogenously synthesized FA for desaturation and chain elongation.

In a phenomenon called *retroversion*, very long-chain C22 PUFA present in marine oils may be shortened by two carbons with concomitant saturation of a double bond. For example, C22:6n-3 is converted to C22:5n-3 and to C20:5n-3 (81). This peroxisomal pathway is also active in converting C22:5n-6 into C20:4n-6 (82). As a result of competition among various PUFA families for desaturases, elongases, and acyl transferases, and because of retroversion, a characteristic pattern of end products accumulates in tissue lipids for each family. Hence, the major PUFA product for the palmitoleate n-7 family is C20:3n-7; for the oleate n-9, C20:3n-9; and for linoleate, C20:4n-6 and some C20:3n-6. The most common products for the n-3 fatty acid family are C20:5n-3 and C22:6n-3.

The efficiency of the multistage synthesis of PUFA is unclear in the human. It has been suggested that activities of the various required desaturase and elongase enzymes differ with developmental stage or pathologic state. Regulation of desaturase activity could be of biologic importance, since the higher homologues of EFA are physiologically important regulatory metabolites.

Dietary factors and hormonal status can influence desaturase activities. Fat-free diets result in increased D⁵ and D⁶ desaturation, which may reflect a homeostatic response to maintain membrane fluidity (83). Protein and EFAD increase D⁶ desaturase activity; conversely, low-protein diets and alcohol consumption decrease D⁶ activity. Although glucose refeeding after a fast induces D⁶ desaturase activity, a glucose-rich diet actually decreases enzymatic activity. Insulin stimulates D⁶ desaturase activity; activity is depressed by glucagon, epinephrine, glucocorticoids, and thyroxines. Diabetes also depresses D⁶, D⁵, and D⁴ desaturase activities, which are restored by insulin injection (84). Zinc may also play a role in the regulation of D⁶ desaturase activity, as the dermal and growth effects of EFA and zinc deficiency are similar (85). This concept is supported by observations that administration of C18:3n-6, which bypasses the D⁶ desaturase step, corrects most of the symptoms of zinc deficiency, whereas administration of C18:2n-6 has no effect. As the typical Western diet contains sufficient C20:4n-6, obtained from meat and dairy products, those with decreased desaturase activity could suffer from a deficiency of C20:3n-6, the precursor of the PG "1" series. Some authors have suggested that certain individuals may have increased need for EFA derivatives because of a disease condition, aging, or a metabolic block in desaturase activity. Evening primrose, borage, and black current seed oils contain C18:3n-6 that bypasses the step requiring D⁶ desaturase and have been used therapeutically for a variety of clinical conditions, including psoriasis (86).

Cholesterol

Current evidence indicates that three distinct pathways modulate the intracellular transmission of CH. Separate translocational systems exist for endogenously

synthesized and LDL-derived exogenous CH. A third transport system also exists for CH destined for steroid synthesis.

CH biosynthesis represents a major vector in the total body CH supply in humans, with up to about 75% being synthesized during consumption of the typical North American diet. Animal studies demonstrate that even though all organs incorporate acetate into sterol, the liver is the primary biosynthetic organ (87). Conversely, in humans, it has been estimated that the net contribution of liver biosynthesis does not exceed 10% of total CH biosynthesis. The role of extrahepatic organs in human cholesterologenesis remains undefined.

Acetate can be converted into mevalonic acid by a sequence of reactions starting with acetate + CoA + ATP @ 1A acetyl-CoA + PP + AMP. However, most of the acetyl-CoA used for sterol synthesis is not derived from this reaction but rather is generated within the mitochondria by b-oxidation of FA or oxidative decarboxylation of pyruvate. Pyruvate is converted into citrate, which diffuses into the cytosol and is hydrolyzed to acetyl-CoA and oxaloacetate by citrate-ATP lyase:

Citrate participating in this reaction acts as a carrier to transport acetyl carbon across the mitochondrial membranes, which are impermeable to acetyl-CoA. Subsequently, in the cytosol, acetyl-CoA is converted into mevalonate:

Mevalonic acid is phosphorylated, isomerized, and converted to geranyl- and farnesyl-pyrophosphate, which in turn form squalene. Squalene is then oxidized and cyclized to a steroid ring, lanosterol. In the last steps, lanosterol is converted into CH by the loss of three methyl groups, saturation of the side chain, and a shift of the double bond from D⁸ to D⁵. During the later stages of CH biosynthesis, intermediates are bound to a sterol carrier protein.

CH biosynthesis in humans is sensitive to a number of dietary factors. Adding CH to the diet at physiologic levels results in modest increases in circulating CH levels, with a mild reciprocal inhibition of synthesis (28, 50). Dietary fat selection exhibits a more pronounced influence on human cholesterologenesis, as consumption of polyunsaturated fats is associated with higher biosynthesis than other plant or animal fats. Differences in FA composition and levels of plant sterol levels may both be contributing factors (35). Higher meal frequency reduces biosynthesis rates in humans, which may explain the lower circulating CH synthesis rates seen in individuals consuming more numerous smaller meals (88). Insulin, which is associated with hepatic CH synthesis in animals, may be released in greater amounts when less frequent but larger meals are consumed. Circadian periodicity, with a maximum at night, is tied to the timing of meal consumption.

Of dietary factors capable of modifying CH synthesis, energy restriction exhibits the greatest effect. Humans fasted for 24 hours exhibit complete cessation of CH biosynthesis (18). How synthesis responds to more minor energy imbalance has not been examined.

There is an emerging view that CH synthesis acts both passively and actively in relation to circulatory CH levels, depending on dietary perturbation. Passively, the liver responds to high CH levels through LDL receptor-mediated suppression of synthesis (42). The modest suppression in the face of increasing dietary and circulating levels reflects the limited hepatic contribution to total body production of CH (28). Substitution of PUFA for other fats results in a decreased ratio of hepatic intracellular free CH to esterified CH, which in turn upregulates both LDL receptor number and cholesterologenesis. In both of these ways, CH synthesis responds passively to external stimuli. In contrast, nonhepatic synthesis is less sensitive to dietary CH level and fat type, while together with hepatic synthesis, nonhepatic synthesis is more responsive to synthesis pathway substrate availability (89). In this manner, several dietary factors actively modify CH synthesis and levels. Such differential sensitivity may explain the more pronounced decrement in CH synthesis and levels occurring after energy deficit in humans.

CH serves as a required precursor for other important steroid compounds, including sex hormones, adrenocorticoid hormones, and vitamin D. Steroidal sex hormones, including estrogen, androgen, and progesterone, involve removal of the CH side chain at C-17 and rearrangement of the double bonds in the steroid nucleus. Corticosteroid hormone production involves similar rearrangements of the CH molecule. 7-Dehydrocholesterol is the precursor of cholecalciferol (vitamin D) formed at the skin surface through the action of ultraviolet irradiation. Steroid hormone metabolites are excreted principally through the urine. It is estimated that humans convert about 50 mg/day of CH to steroid hormones.

Vertebrates cannot convert plant sterols to CH. However, insects and prawns can transform phytosterols into steroid hormones or bile acids through a CH intermediate.

FUNCTIONS OF ESSENTIAL FATTY ACIDS

After ingestion, EFA (C18:2n-6 and C18:3n-3) are distributed between adipose TG, other tissue stores, and tissue structural lipids. A proportion of C18:2n-6 and C18:3n-3 provides energy, and these PUFA are oxidized more rapidly than are SAFA or MUFA. In contrast, long-chain PUFA derived from EFA (i.e., C20:3n-6, C20:4n-6, C20:5n-3, and C22:6n-3) are less readily oxidized. These acids, when present preformed in the diet, are incorporated into structural lipids about 20 times more efficiently than after synthesis from dietary C18:2n-6 and C18:3n-3. The liver is the site of most of the PUFA metabolism that transforms dietary 18-carbon EFA into long-chain PUFA with 20 or 22 carbons. Long-chain PUFA are transported to extrahepatic tissues for incorporation into cell lipids, even though there is differential uptake and acylation of PUFA among different tissues. The final tissue composition of long-chain PUFA is the result of the above complex processes along with the influence of dietary factors. The major elements in the diet that determine the final distribution of long-chain PUFA in cell PL include the relative proportions of n-3, n-6, and n-9 FA families, and the preformed

long-chain PUFA versus their shorter-chain precursors (90).

Membrane structural PL contain high concentrations of PUFA and the 20- and 22-carbon PUFA that predominate from the two families of EFA. C20:4n-6 is the most important and abundant long-chain PUFA found in membrane PL and is the primary precursor of eicosanoids. The concentration of free C20:4n-6 is strictly regulated via phospholipases and acyltransferases. Most nonacylated C20:4n-6 is bound to cytosolic protein. In terms of EFA from the n-3 PUFA series, C20:5n-3 and C22:6n-3 are most prevalent in membrane PL. The long-chain PUFA derived from EFA are incorporated primarily in the 2-acyl position in bilayer PL of mammalian plasma, mitochondrial, and nuclear membranes. The 20-carbon FA, when released from their PL, can be transformed into intracellular metabolites (inositol triphosphate [IP₃] and diacylglycerol [DAG]) and extracellular metabolites (platelet-activating factor [PAF] and eicosanoids), which participate in many important cell-signaling responses. The relative proportions in tissue PL of C20:4n-6 and other long-chain PUFA (C18:3n-6, C20:4n-6, and C20:5n-3) are important, as these PUFA can compete for or inhibit enzymes involved in generation of intracellular and extracellular biologically active products. Also, dietary C18:1n-9, C18:2n-6, C18:2n-6 *trans*, C18:3n-6, C18:3n-3, and long-chain n-3 PUFA C20:5n-3 and C22:6n-3 can compete with C20:4n-6 for the acyltransferases for esterification into PL pools and thereby inhibit C20:4n-6-mediated membrane functions.

Membrane Functions and Integrity

As fragile membranes in erythrocytes and mitochondria are typical of EFAD, an early function attributed to EFA was their role as integral components of PL required for plasma and intracellular membrane integrity. EFAD results in a progressive decrease in C20:4n-6 in membrane PL, with a concomitant increase in C18:1n-9 and its product, C20:3n-9. The fluidity and other physical properties of membrane PL are largely determined by the chain length and degree of unsaturation of their component FA. These physical properties, in turn, affect the ability of PL to perform structural functions, such as the maintenance of normal activities of membrane-bound enzymes. Dietary SAFA, MUFA, and PUFA, major determinants of the composition of stored and structural lipids, alter the activity and affinity of receptors, membrane permeability, and transport properties (91).

The heterogeneity and selectivity of PUFA with respect to their tissue membrane distribution among different organs may be related to their structural and functional roles (91). For example, long-chain derivatives of n-3 PUFA are concentrated in biologic structures involved in fast movement, such as that required in transport mechanisms in the brain and its synaptic junction and in the retina (92). Approximately 50% of the PL in the disk membrane of the retinal rod outer segment in which rhodopsin resides contains C22:6n-3 (93). The C22:6n-3 is concentrated in the major PL classes, i.e., PC, PE, and phosphatidylserine (PS) in the disk membrane, whereas C20:4n-6 is found in the minor PL components, such as phosphatidylinositol (PI). This observation has led to speculation that C22:6n-3 plays a structural role in these membranes while C20:4n-6 may play a more functional role (94).

In addition to their structural role and their movement across membranes, structural

lipids can also modulate cell function by acting as either intracellular mediators of signal transduction or modulators of cell-cell interactions. These actions are initiated by phospholipases. Phospholipase A₂ cleaves FA, usually PUFA, present at the 2 position of PL. PUFA released under action of phospholipase A₂ produce metabolites released extracellularly to act on other cells. These metabolites include PAF (a choline-containing PL with an acetate residue in the 2-position) and eicosanoids. Phospholipase C acts on phosphoinositides to break the bond between glycerol and phosphoric acid, releasing intracellularly diacylglycerols (DAG) and inositol phosphates (IP), which are involved in signal transduction. After receptor stimulation, DAG and IP act intracellularly as second messengers to activate protein kinase C and release intracellular stores of calcium, respectively (5). Activated protein kinase C mediates transduction of a wide variety of extracellular stimuli, such as hormones and growth factors, leading to regulation of such cellular processes as cell proliferation and differentiation. PL can act as a cofactor for some isoforms of protein kinase C by enhancing binding to DAG (95). In addition, unesterified PUFA can activate protein kinase C with differing potencies (96). As dietary PUFA can greatly modulate PUFA composition of structural lipids, generation of intra- and extracellular products can be greatly affected by dietary lipids. For example, thrombin-stimulated platelets from rabbits fed fish oil form less IP than platelets from those fed either corn or olive oil (97).

BIOSYNTHESIS AND FUNCTION OF EICOSANOIDS

Some of the most potent effects of PUFA are related to their enzymatic conversion into a series of oxygenated metabolites called *eicosanoids*, so-named because their precursors are PUFA with chain lengths of 20 carbon units. Eicosanoids include PG, thromboxane (TXA), leukotrienes (LT), hydroxy fatty acids, and lipoxins. PG and TXA are generated via cyclooxygenase (CO) enzymes, whereas LT, hydroxy acids, and lipoxins are produced from lipoxygenase (LO) metabolism. Under stimulation, rapid and transient synthesis of active eicosanoids activates specific receptors locally in the tissues in which they are formed. Eicosanoids modulate cardiovascular, pulmonary, immune, reproductive, and secretory functions in many cells. They are rapidly converted to their inactive forms by selective catabolic enzymes.

Humans depend on the dietary presence of the n-3 and n-6 structural families of PUFA for adequate biosynthesis of eicosanoids. There are three direct precursor FA from which eicosanoids are formed by the action of membrane-bound CO or specific LO enzyme systems: C20:3n-6, C20:4n-6, and C20:5n-3. A series of prostanoids and LT with different biologic properties are generated from each of these FA (Fig. 4.7). The first irreversible, committed step in the synthesis of PG and LT is a hydroperoxide-activated FA oxygenase action exerted by either prostaglandin H synthase (PGHS) or LO enzymes on the nonesterified precursor PUFA (Fig. 4.8).

Figure 4.7. Formation of PG, TXA, and LT from DHGA (C20:3n-6), arachidonic acid (C20:4n-6), and EPA (C20:5n-3) via cyclooxygenase and lipoxygenase pathways. LT, leukotriene; PG, prostaglandin; TXA, thromboxane.

Figure 4.8. Major pathways of synthesis of eicosanoids from arachidonic acid. PG, prostaglandin; HPETE, hydroperoxyeicosatrienoic acid; HETE, hydroxy fatty acid; diHETE, dihydroxyeicosatetraenoic acid. (From Innis SM. Essential dietary lipids. In: Ziegler EE, Filer LJ, eds. Present knowledge in nutrition. 7th ed. Washington, DC: ILSI Press, 1996;58–66, with permission.)

Stimulation of normal cells via specific physiologic or pathologic stimuli, such as thrombin, adenosine diphosphate (ADP), or collagen, initiates a calcium-mediated cascade. This cascade involves phospholipase A₂ activation, which releases PUFA on position 2 of cell membrane. The greatest proportion of PUFA available to phospholipase A₂ action contains C20:4n-6. Hydrolytic release from PL esters appears to occur indiscriminantly with n-3 and n-6 types of PUFA and to involve all major classes of PL, such as PC, phosphatidyl ethanolamine (PE), and phosphatidyl inositol (PI). These FA serve as direct precursors for generation of eicosanoid products via CO and

LO enzymatic action (Fig. 4.8). Enzymatic biotransformation of the PUFA precursors to PG is catalyzed via two PG synthase isozymes designated PGH synthase-1 (PGHS-1) and PGH synthase-2 (PGHS-2) (98). PGHS-1 is located in the ER and PGHS-2 is located in the nuclear envelope. Both forms are bifunctional enzymes that catalyze the oxygenation of C20:4n-6 to PGG₂ via CO reaction and the reduction of PGG₂ to form a transient hydroxyendoperoxide (PGH₂) via the peroxidase reaction (Fig. 4.8). The PGH₂ intermediate is rapidly converted to PGI₂ by vascular endothelial cells, to TXA₂ by an isomerase in platelets, or to other prostanoids, depending on the tissues involved. The PGHS-2 generates prostanoids associated with mitogenesis and inflammation and is inhibited by glucocorticoids. On the other hand, PGHS-1 is expressed only after cell activation and is inhibited by nonsteroidal antiinflammatory drugs such as aspirin but not by glucocorticoids.

C20:4n-6 can be oxygenated via the 5-, 12-, and 15-LO pathways (Fig. 4.7). From C20:4n-6, the 5-LO pathway generates mainly LTB₄, LTC₄, and LTD₄, which are implicated as important mediators in a variety of proliferative and synthetic immune responses. LTB₄ in particular has been indicated a key proinflammatory mediator in inflammatory and proliferative disorders (98). From C20:4n-6, the 12-LO pathway generates 12-L-hydroxyeicosatetraenoic acid (12-HETE) and 12-hydroperoxyeicosatetraenoic acid (12-HPETE). A proinflammatory response can be generated by 12-HETE in a variety of cell types. Products generated from C20:4n-6 metabolism by the 15-LO reaction include 15-hydroxyeicosatetraenoic acid (15-HETE), which has antiinflammatory action and may inhibit 5- and 12-LO activities (99).

Since the major eicosanoids are synthesized from C20:4n-6, the availability of C20:4n-6 in PL pools of tissue may be a primary factor in regulating the quantities of eicosanoids synthesized by tissues in vivo. Also, the intensity of the n-6 eicosanoid signal from the released PUFA will be greater as C20:4n-6 becomes a greater proportion of the PUFA. The levels of C20:4n-6 in tissue PL pools are affected by the elongation and desaturation of dietary C18:2n-6 and by intake of C20:4n-6 (170–220 mg/day in the Western diet) (100). Although dietary concentrations of C18:2n-6 up to 2 to 3% of calories increase tissue C20:4n-6 concentrations, intake of C18:2n-6 above 3% of calories is poorly correlated with tissue C20:4n-6 content (101). Since C18:2n-6 constitutes approximately 6 to 8% of the North American diet, moderate dietary changes in C18:2n-6 would not be expected to modulate tissue C20:4n-6 levels. Intakes of C18:2n-6 above 12%, however, may actually decrease tissue C20:4n-6 because of inhibition of D₆ desaturase. In contrast, dietary C20:4n-6 is much more effective in enriching C20:4n-6 in tissue PL (101) and, compared with C18:2n-6, relatively low dietary levels of C20:4n-6 may be physiologically significant in enhancing eicosanoid metabolism (100).

Feeding diets high in n-3 FA results in substitution of C20:4n-6 by n-3 PUFA in membrane PL. This can suppress the response of C20:4n-6-derived eicosanoids by decreasing availability of the C20:4n-6 precursor and by competitive inhibition of C20:5n-3 for eicosanoid biosynthesis (102). Although less pronounced than the effect observed with C20:5n-3 and C22:6n-3 dietary supplementation, C18:3n-3-enriched diets suppress PGE₂ production by peripheral blood mononuclear cells in monkeys (102).

C18:3n-3 could competitively inhibit desaturation and elongation of C18:2n-6 for conversion into C20:4n-6. The eicosanoids derived from n-3 are homologues of those derived from C20:4n-6 with which they compete (Fig. 4.9), and they are associated with less active responses than n-6 eicosanoids when bound to the specific receptors.

Figure 4.9. Prostaglandin formation.

Diets rich in competing and moderating FA (n-3 PUFA, C18:3n-6) may produce changes in the production of eicosanoids which are more favorable with respect to inflammatory reactions. For instance, the PGE₃ formed from C20:5n-3 has less inflammatory effect than PGE₂ derived from C20:4n-6. The LTB₅ derived from C20:5n-3 is substantially less active in proinflammatory functions than the LTB₄ formed from C20:4n-6, including the aggregation and chemotaxis of neutrophils. Two 15-LO products, 15-HEPE and 17-hydroxydocosahexanoic acid (17-HoDHE), are derived from C20:5n-3 and C22:6n-3, respectively (99). Both metabolites are potent inhibitors of LTB₄ formation.

Overproduction of C20:4n-6-derived eicosanoids has been implicated in many inflammatory and autoimmune disorders such as thrombosis, immune-inflammatory disease (e.g., arthritis, lupus nephritis), cancer, and psoriatic skin lesions, among others. Because the typical American appears to maintain n-6 PUFA in PL near the maximal capacity, some have suggested that the n-6-rich diet in the United States may contribute to the incidence and severity of eicosanoid-mediated diseases such as thrombosis and arthritis (103). Because platelet aggregation and activation are indicated to play a critical role in progression toward vascular occlusion and myocardial infarction, the counterbalancing roles of TXA₂ and PGI₂ in cardiovascular functions have been emphasized. C20:4n-6 is required for platelet function as a precursor of the proaggregatory TXA₂. Biosynthesis of TXA₂ is the rate-limiting step in the aggregation of platelets, a key event in thrombosis. The effects of TXA₂ are counteracted by PGI₂, a potent antiaggregatory agent that prevents adherence of platelets to blood vessel walls. Due to displacement of C20:4n-6 from membrane PL by C18:2n-6, C18:3n-6, and C20:3n-6, stepwise increases in dietary C18:2n-6 from 3 to 40% of calories actually

decreased platelet aggregation, indicating inhibition of eicosanoid synthesis by these n-6 PUFA. However, the antithrombotic influence of C18:2n-6 is substantially less than that observed after high intake of n-3 PUFA-rich fish oils (104). This has been related to the observations that PGI₃ generated from C20:5n-3 has antiaggregatory potency. Conversely, TXA₃ derived from C20:5n-3 has a very weak proaggregatory effect while TXA₂ synthesis is reduced (105). Chronic ingestion of aspirin (106) and n-3 PUFA reduces the intensity of TXA₂ biosynthesis, which could decrease rates of cardiovascular mortality. However, epidemiologic studies on the effects of dietary n-3 FA on cardiovascular disease have been inconsistent. A recent prospective study demonstrated no protective effect of fish consumption on cardiovascular disease mortality and morbidity (107), whereas another showed protective effects in elderly persons who ate only small amounts of fish (108). Results of several studies suggest that C18:3n-6 and n-3 EFA are involved in the regulation of cell-mediated immunity and that administration of these FA may be beneficial in suppressing pathologic immune responses. For example, subjects with rheumatoid arthritis fed fish oils high in n-3 PUFA have consistently obtained symptomatic benefit in doubly blinded, randomized, controlled trials (109). Although it appears that inhibition of the proinflammatory eicosanoids LTB₄ and PGE₂ can account for many of the protective effects of n-3 PUFA, decreased production of the cytokines interleukin-1b and tumor necrosis factor are also likely involved (110).

ESSENTIAL FATTY ACID REQUIREMENTS

n-6 Fatty Acid Requirements

In studies on EFA, C18:2n-6 and C20:4n-6 have been emphasized because mammals have an absolute requirement for the n-6 family of FA. EFA are required for stimulation of growth, maintenance of skin and hair growth, regulation of CH metabolism, lipotropic activity, and maintenance of reproductive performance, among other physiologic effects. On a molecular level, EFA are components of specific lipids and maintain the integrity and optimal levels of unsaturation of tissue membranes. Because EFA are necessary for normal function of all tissues, the list of symptoms of EFAD is long (111). Detailed studies on the symptoms of EFAD have been done in young rats, in which EFAD was found to be avoided by providing 1 to 2% of calories as C18:2n-6 (112). In these rat studies, classic signs of EFAD included reduced growth rates, scaly dermatitis with increased loss of water by a change of skin permeability, male and female infertility, and depressed inflammatory responses. Also observed during EFAD are kidney abnormalities, abnormal liver mitochondria, decreased capillary resistance, increased fragility of erythrocytes, and reduced contraction of myocardial tissue (113).

C18:2n-6 is specifically required in the skin to maintain the integrity of the epidermal water barrier. In this regard, C18:2n-6 seems to be required as an integral component of acylglucoceramides. Animals with EFAD lose considerable amounts of water through the skin, which limits growth rates. Repletion of C18:2n-6 at 1% of calories corrects excessive transepidermal water loss, and growth is restored (114). Although transdermal water loss during EFAD symptoms may reflect the role of C18:2n-6 as a key component of skin acylglucoceramides, the major metabolic effects of C18:2n-6

derive from its further metabolism to C20:4n-6 and thence to eicosanoids. In EFAD, platelet adherence and aggregation are impaired because of limited thromboxane synthesis secondary to limiting supplies of C20:4n-6 and possible inhibition by accumulated eicosatrienoic acid C20:3n-9. The action of eicosanoids in modulating the release of hypothalamic and pituitary hormones has been indicated to be a major factor in the role of the n-3 and n-6 EFA in supporting growth and development (103). The skin is subject to rapid infection, and surgical wounds heal very slowly in humans who have EFAD. This probably reflects the lack of C20:4n-6, which is required for eicosanoid-mediated protective inflammatory and immune cell functions and for tissue proliferation (103). Monocyte and macrophage function is defective in EFAD because eicosanoid production is impaired. The scalliness of the skin of an EFA-deficient patient has been ascribed to insufficient synthesis of PG, and the efficacy of various EFA of the n-6 type against the scaly dermatitis has been demonstrated at low dose levels.

Columbinic acid (C18:3n-6, 9, 13 *cis, cis, trans*), found in the seed oil of the columbine, *Aquilegia vulgaris*, and dihomocolumbinic acid (C20:3n-6, 9, 13 *cis, cis, trans*) have been used to differentiate the roles of EFA as structural components in biomembranes versus their roles as eicosanoid precursors (115). Neither columbinic acid nor dihomocolumbinic acid can be converted to PG; however, columbinic acid can be incorporated into membrane PL in contrast to dihomocolumbinic acid. As EFAD results in decreased tissue concentrations of C20:4n-6, EFAD symptoms are worsened further by dietary addition of dihomocolumbinic acid. Columbinic acid given to EFA-deficient rats, either orally or by topical skin application, efficiently restores their growth rate and normal skin function (114). When EFA-deficient rats treated with columbinic acid became pregnant, however, they died of inadequate labor during parturition, since uterine labor depends on normal PG biosynthesis (116).

One of the most often used and sensitive diagnostic indicators of EFAD in all species tested, including humans, is the triene (n-9):tetraene (n-6) ratio (111); C20:3n-9 (triene) is the major product derived from nonessential FAs. C20:4n-6 with four double bonds (tetraene) is the major metabolite of C18:2n-6. The triene:tetraene ratio in plasma remains below 0.4 when dietary EFA are adequate and increases to above 0.4 with EFAD. Dietary intake of adequate amounts of EFA decreases formation of triene as a consequence of competitive inhibition among families of PUFA for desaturases and acyl transferases. If EFA are not available, the biosynthesis of PUFA with three double bonds derived from C18:1n-9 and C16:n-7 continues, leading to the accumulation of n-9 FA, specifically C20:3n-9, resulting in turn in an increased plasma triene:tetraene ratio. Feeding diets with 0.1 to 0.5% of C18:2n-6 normalizes an abnormally high triene/tetraene ratio in a few days (117). The optimum dietary C18:2n-6 intake required for a ratio less than 0.4 and prevention of EFAD symptoms is 1 to 2% of total calories. The triene:tetraene ratio, however, does not resolve if the EFAD is caused by a lack of either n-3 or n-6 EFA, since adequate intake of either C18:2n-6 or C18:3n-3 prevents synthesis of C20:3n-9 (118).

The exact requirement for EFA in humans is not clearly defined but is apparently very low. The first study of EFAD, in human adults maintained for 6 months on a diet extremely low in fat, did not produce dramatic symptoms (119). It has been suggested that because adults contain approximately a kilogram of C18:2n-6 in body stores, depletion of EFA stores to produce deficiency symptoms would require maintaining an

EFAD diet for more than 6 months. Most diets contain enough EFA or their metabolic products to meet daily EFA requirements; thus EFAD is relatively rare in humans. When it does occur in humans, some of the symptoms characteristic in animals, such as abnormal skin conditions, increased susceptibility to infection, and an increase in triene:tetraene ratio, are observed.

An important role for C20:4n-6 in optimal fetal development has been suggested because C20:4n-6 exerts growth-promoting effects (120). Crawford et al. (121) demonstrated that mothers of low-birth-weight infants had lower intakes of C18:2n-6 than mothers of normal-birth-weight infants. However, lower C20:4n-6 concentrations in plasma and in plasma PC have been associated with depressed intrauterine and extrauterine growth, despite adequate dietary C18:2n-6 levels (122). In a doubly blinded, randomized, controlled trial, depressed plasma PC C20:4n-6 concentrations induced by supplementation of formulas with C20:5n-3-rich marine oils were associated with slower growth rates in preterm infants (123). Supplementation of formula with a low C20:5n-3-concentration marine oil caused relatively minor decreases in plasma PC C20:4n-6 concentration and in weight-to-length ratio in preterm infants (124).

Long-chain EFA of 20- and 22-carbon chain length are incorporated about 10 times more efficiently into the developing brain than are the parent EFA. However, whether term or preterm infants have sufficient enzymatic activity to synthesize their own long-chain PUFA from EFA to meet their requirement for brain growth and development is controversial. Despite knowledge that the developing and mature brain can desaturate and elongate C18:2n-6 and C18:3n-3 to their respective long-chain PUFA products and that brain and retina can incorporate C20:4n-6 and C22:6n-3 from plasma, the quantitative importance of these two pathways is uncertain. Lower levels of C20:4n-6 in the red blood cell PL of formula-fed infants than in PL from breast milk-fed infants has led to debate about whether C20:4n-6 is essential for optimal central nervous system development in infants (125). The lower erythrocyte C20:4n-6 levels of formula-fed babies (vs. breast-fed babies) can be normalized by inclusion of C20:4n-6 in formula. Stable isotope studies have indicated in vivo C20:4n-6 synthesis in term infants, but the rate of this synthesis is low and only about 6% of total plasma C20:4n-6 is renewed in this manner (126). However, postmortem studies of brain FA composition showed that brain C20:4n-6 is maintained in formula-fed infants (127).

The concept has emerged that an optimal ratio of n-3 and n-6 FA is required in the diet because n-3 and n-6 families compete for eicosanoid production. Various authorities have recommended that at least 3% of daily calories be provided as linoleate, to prevent EFAD; however, equal amounts of C18:2n-6 and various SAFA have been recommended to reduce serum CH for the prevention of atherosclerosis (117). Advocacy for increased intake of vegetable oils rich in C18:2n-6 has resulted in C18:2n-6 consumption of approximately 6 to 7% of calories in the United States, leading to a ratio of n-6:n-3 PUFA consumption above 10 (117). Although this amount of C18:2n-6 may be beneficial for reduction of elevated plasma CH in those on a high-fat diet, it has been argued that an n-6:n-3 PUFA ratio exceeding 10 is imbalanced compared with n-6:n-3 ratios of 2 to 4 found in food lipids of hunter/gatherer societies (103, 117). There is concern that a high intake of C18:2n-6 relative to n-3 PUFA may lead to excessive or imbalanced eicosanoid production conducive to various pathophysiologicals. The optimal n-6:n-3 ratio in the diet is not yet clear and may vary

with developmental stage, the presence of long-chain EFA, and other factors. Some authorities have suggested that the n-6:n-3 EFA ratio should be in the range of 4:1 to 10:1 ([128](#)); others believe optimal n-6:n-3 ratios to be 4:1 or lower ([129](#), [130](#)).

n-3 Fatty Acid Requirements

Requirements for n-3 FA have been less definitive because it has been difficult to demonstrate their essentiality in animal studies; n-3 FA levels in mammalian tissues are generally much lower than n-6 FA levels. Biochemical studies have indicated differences in the metabolism and tissue distribution of the two series of EFA. C20:4n-6 and C20:3n-6 tend to predominate in liver and platelets, while the main biologic activity of long-chain n-3 EFA appears to reside in retina, testes, and the central nervous system. C18:3n-3 is similar to C18:2n-6 with regard to growth rate, capillary resistance, erythrocyte fragility, and mitochondrial function. Dietary C18:3n-3 and C20:5n-3 are inferior to C18:2n-6 and the other n-6 PUFA in resolving skin lesions and preventing transepidermal water loss. Because of the inability of C18:3n-3 to normalize all physiologic functions during EFAD and because EFA activities attributed to C18:3n-3 were also expressed equally or more potently by C18:2n-6, n-3 FA were until recently designated nonessential or partially essential.

In the past 15 years, studies have suggested that n-3 FA may be essential in development of neural tissue and visual function, beyond the requirement for n-6 FA, for which they can partially substitute. Across mammalian species, levels of C22:6 n-3 in brain and retinal PL are extremely stable despite wide variations in diet ([131](#)). The strong affinity of brain lipids for C22:6n-3 suggest a requirement for n-3 EFA, but this requirement is difficult to study because n-3 EFAD develops only under extreme dietary conditions ([125](#), [131](#)). In particular, C22:6n-3 is selectively retained by the brain, and depletion of C22:6n-3 is difficult after weaning. Multigenerational studies in rats have been needed to produce drastic reductions in brain C22:6n-3 levels. For example, feeding rats fat-free diets from weaning reduced retinal C22:6n-3 concentrations in adults by only 10 to 20%. In the first generation, feeding diets containing 2.5% C18:2n-6 and free of n-3 PUFA decreased C22:6n-3 concentrations by 60% and in the second generation by more than 87% ([132](#)).

An essential role for C22:6n-3 in brain and retinal PL was described by Neuringer and Connor, who demonstrated C18:3n-3 deficiency in rhesus monkeys fed during gestation diets with safflower oil (n-6:n-3 ratio of 255:1) as the sole source of fat ([133](#)). Their offspring reared on the same diet developed abnormal electroretinograms compared with those of the control group of offspring fed soybean oil (n-6:n-3 ratio of 7). Decreased concentrations of C18:3n-3 and long-chain n-3 PUFA in plasma PL were observed in offspring who showed loss of visual activity. Learning capacity, as tested in a spatial-reversal learning task, was not affected, possibly because of the observed compensatory increase of n-6 PUFA, particularly C22:5n-6, in PL. Retinal n-3 PUFA deficiency was reversed at the ages of 10 and 24 months by feeding a fish oil diet rich in C20:5n-3 and C22:6n-3 ([133](#)). Although such extremely high n-6:n-3 ratios rarely occur in human nutrition because of the wide availability of n-3 PUFA in foods, these ratios have been induced by total parenteral nutrition. A 6-year-old child developed peripheral neuropathy and periods of blurred vision after receiving total parenteral nutrition whose

sole source of lipid was a safflower oil emulsion (1). After 5 months, she experienced episodes of numbness, weakness, inability to walk, leg pain, and blurred vision. Very low serum concentrations of C18:3n-3 and other n-3 PUFA were detected. Replacement of the lipid source by a soybean oil emulsion containing C18:3n-3 caused all symptoms of deficiency to disappear, and serum concentrations of n-3 PUFA returned to normal (1). Recent reports on neurologic symptoms in an infant, associated with a parentally fed C18:3n-3-poor formula, and deficiency symptoms in adults that were corrected by C18:3n-3 support the essentiality of this FA in the diet (1, 134). In the above cases, however, the C18:3n-3 deficiency symptoms could arguably be attributed to low levels of vitamin E or total EFAD (127).

As human brain gray matter and retinal membranes contain significant amounts of C22:6n-3, the requirement for n-3 EFA may be more critical during the last trimester of gestation and first months of life, when rapid accretion of these FA occurs in the central nervous system (125, 131). Brain PL acquires only long-chain derivatives of EFA, not their 18-carbon precursors, and C22:6n-3 is the predominant PUFA in PL in synaptosomal membranes and photoreceptors (131). C22:6n-3 also accounts for approximately 50 to 60% of FA in the PL of the photoreceptor disks that contain rhodopsin and the G-protein. Much of the C22:6n-3 acquired by the brain is accrued during the suckling period, when the brain undergoes rapid development. A number of animal studies have demonstrated an impairment in the visual process, altered learning behavior, and low brain C22:6n-3 content because of a deficiency in C18:3n-3 and its metabolites C20:5n-3 and C22:6n-3 (125, 131). Permanent learning defects and alterations in synaptic function in the brain, observed in EFAD during pregnancy, can be prevented by feeding n-3 EFA (133, 135). In addition, a correlation has been noted between diet-induced changes in C22:6n-3 in the retina and a modification of electrical potentials induced in rod outer segments by light stimulation (136).

Although adequate dietary intake of n-3 EFA appears to be critical for central nervous system development, the optimum requirements for n-3 EFA for infants are not known. Human milk provides both C18:3n-3 and C22:6n-3 that are often absent from most infant formulas on the market. Formula-fed infants thus depend on endogenous synthesis of long-chain PUFA. Infant formulas provide nutrition that results in growth rates equal or superior to those of breast milk-fed infants. There is a suggestion, however, that long-chain n-3 PUFA may not be synthesized from their parent EFA at optimal rates for brain development during the first few weeks after birth, particularly in preterm infants. Clandinin et al. (137) have indicated that the infant's requirement for neural accumulation of long-chain PUFA can be met by intake of long-chain PUFA alone, without endogenous synthesis. Using the FA composition of red blood cell PL as an index of cerebral membrane composition, infants fed human milk had a significantly better C22:6n-3 status than formula-fed infants (138). The extent to which diet-induced changes in red blood cell membranes reflect changes in brain PL is not clear. However, recent postmortem studies indicate a lower C22:6n-3 brain content in formula-fed infants than in infants receiving breast milk (139). In a randomized trial of n-3 PUFA supplementation of formulas fed to term infants, C22:6n-3-treated infants had better visual acuities than infants fed standard formula (140). Other work, however, has shown no effect of long-chain PUFA formula supplementation on visual, psychomotor, or mental development (141).

Preterm infants may be especially susceptible to n-3 EFAD because of their relatively immature desaturase and elongase enzyme systems and their low fat stores. In two randomized clinical trials, intake of formula containing marine oil by preterm infants normalized blood levels of C22:6n-3 and improved certain aspects of visual function relative to breast-fed infants ([142](#)). In one of the randomized studies, however, marine oil supplementation was associated with decreases in linear growth, some measures of cognitive development, and blood C20:4n-6 content. These results are of concern in view of the important role of C20:4n-6 in growth and development ([123](#)). However, a more physiologic formulation containing pure C22:6n-3 resulted in better cognitive and visual performance and a less detrimental effect on growth than the mixture of C20:5n-3 and C22:6n-3 given over a shorter interval ([124](#), [143](#)).

Pregnancy

Rapidly developing fetal organs, such as the liver and brain, incorporate large amounts of long-chain n-3 and n-6 EFA into membrane PL ([144](#)). The accumulation of EFA during human pregnancy has been approximated to be 620 g, which includes the demand for fetal, placental, mammary gland, and uterine growth and the increased maternal blood volume. On the basis of this estimate of expected EFA acquisition by maternal tissues and the conceptus, it is advised that maternal EFA consumption during pregnancy be increased from 3 to 4.5% of calories ([145](#)). In circumstances of relatively low dietary intake of n-6 EFA (i.e., 2 to 4% of calories), EFAD may be more likely to develop during periods of rapid cell division and growth.

Lactation

In well-nourished mothers, approximately 4 to 5% of total calories in human milk is present as C18:2n-6 and C18:3n-3, and a further 1% as long-chain PUFA derived from these FA, amounting to about 6% of total energy as EFA and its metabolites. The efficiency of conversion of dietary EFA into milk FA is not clear; however, an additional 1 to 2% of calories in the form of EFA is recommended during the first 3 months of lactation. Another 2 to 4% of calories above the basic requirement is recommended thereafter ([145](#)).

Infancy and Childhood

The optimum requirements for EFA of the n-6 and n-3 families for infants are still not known, although normal growth of infants depends on an adequate supply of EFA. Growing individuals apparently require a minimum of 1 to 4.5% of total calories as C18:2n-6 to ensure an adequate supply of EFA for tissue proliferation, membrane integrity, and eicosanoid formation ([128](#), [146](#)). The need for n-3 EFA has been indicated to be higher during growth and development. Estimates based upon FA compositional data from autopsy tissue and breast milk n-3 EFA concentrations have ranged from 0.5 to 1.2% of calories ([146](#)). The Canadian Nutrition Recommendations suggest infant dietary intakes of C18:3n-3 of 1% of energy in the absence of intake of long-chain n-3 PUFA, compared with C18:3n-3 of 0.5% of energy when a supply of long-chain n-3 EFA is available in the diet ([128](#)). However, the bioequivalency of C18:3n-3 and its

long-chain products, C20:5n-3 and C22:6n-3, has not yet been determined, although long-chain PUFA clearly contribute to the C20:5n-3 and C22:6n-3 content of plasma and erythrocyte PL (131). Another question that needs to be addressed is whether long-chain PUFA, especially C22:6n-3, are conditionally essential for optimal visual and neural development of preterm and term infants.

Adults

For adults, appropriate minimum amounts of n-6 EFA are in the range of 1 to 4% of energy to prevent signs of EFAD (131). The C18:3n-3 requirements for adults are suggested to range from 0.2 to 0.3% of energy to 1% of energy, although more studies are needed to define the minimal requirements in humans (3, 147).

Nutrient Interrelationships

Several dietary components are known to affect EFA requirements because of their interactions with EFA use or metabolism. Dietary SAFA slightly increase EFA requirements, as evaluated by growth and dermal symptoms of deficiency and the triene:tetraene ratio in plasma (148). This effect has been related to the action of SAFA in raising plasma levels of CH that forms esters with PUFA, thereby depleting the availability of the EFA pool for PL. In addition, in several animal species, induction of serum CH via a high-CH diet can aggravate EFAD. *cis*-MUFA (mainly C18:1n-9 and its product C20:3n-9) can replace EFA in the lipids of EFAD animals and humans. High dietary levels of C18:1n-9 suppressed desaturation of EFA such that if dietary concentrations of C18:1n-9 were 10 times higher than that of C18:2n-6, triene:tetraene ratios indicating EFAD were observed (149). Partial hydrogenation of vegetable oils in the production of margarines and shortenings forms SAFA and a variety of *trans* and positional isomers. The estimated average daily *trans* FA intake is 8 to 10 g, or 6 to 8% of the total dietary FA. *Trans*-MUFA increase the EFA requirement in animals when fed at moderate levels and can influence the desaturase reactions critical to the metabolism of PUFA (150). *Trans*-FA can also raise plasma levels of LDL and total CH, which could further increase EFA use.

High-Risk Clinical Situations

Although development of human EFAD has traditionally been regarded as rare, use of the sensitive triene:tetraene ratio as a diagnostic index has recently indicated the existence of EFAD in a number of high-risk clinical conditions. EFAD appears to be exacerbated by increased metabolic demands associated with either growth or the hypermetabolism seen following stress, injury, or sepsis (151).

The supply of C18:2n-6 is of concern in premature infants because of their borderline stores of EFA and high caloric expenditure (151). Unless C18:2n-6 is supplied to premature infants in parenteral or enteral diets, early onset of EFAD may occur. Biochemical changes in the plasma and clinical signs indicating EFAD can develop rapidly within 5 to 10 days of life in premature infants (151, 152).

In patients receiving long-term parenteral nutrition without lipid, continuous glucose infusion results in high circulating levels of insulin that inhibit lipolysis and depress release of EFA from adipose fat stores (131). Development of EFAD in infants, children, and adults maintained on continuous fat-free or minimal-fat parenteral nutrition has been reversed by oral or intravenous administration of C18:2n-6 (151). Parenteral nutrition containing only amino acids and completely free of glucose does not produce evidence of EFAD (153). Clinical signs of EFAD include alopecia, scaly dermatitis, increased capillary fragility, poor wound healing, increased platelet aggregation, increased susceptibility to infection, fatty liver, and growth retardation in infants and children (153).

EFAD development has been described in several human diseases, including cystic fibrosis (154), acrodermatitis enteropathica (149), peripheral vascular disease (PVD) (155), and multiple sclerosis (156). Enteral supplementation of vegetable oils high in C18:2n-6 has been demonstrated to improve EFAD in patients with cystic fibrosis (154). Children with cystic fibrosis may require 7 to 10% of energy as C18:2n-6 to prevent reduced weight gain and growth, and infants with cystic fibrosis may require formula with a C18:2n-6 content above 12% of total calories (154, 157). Subjects with anorexia nervosa may have EFAD exhibited by plasma PL profiles showing lowered n-6 and n-3 PUFA concentrations (158). Low total plasma PUFA concentrations, particularly those of 20- and 22-carbon n-3 PUFA, have been noted in patients with acquired immune deficiency syndrome (AIDS) (159). Development of EFAD as measured by the triene:tetraene ratio has been demonstrated in elderly patients with PVD (160), in subjects with fat malabsorption after major intestinal resection, during low-fat, high-protein dietary supplementation for treatment of kwashiorkor (161), and after serious accidents and burns. Oral or intravenous feeding of C18:2n-6-containing TG corrects the biochemical and clinical abnormalities in these conditions.

ACKNOWLEDGMENTS

The authors extend special thanks to Catherine Vanstone for her invaluable contribution to research-ing and writing this chapter. The graphic art work of Helen Rimmer is also gratefully acknowledged. Finally, appreciation is extended to Fady Ntanios and Andrea Papamandjaris, who offered suggestions on improving the quality and composition of the chapter.

Abbreviations: **BS**—bile salt; **CH**—cholesterol; **CE**—cholesterol ester; **DG**—diglyceride; **EFA**—essential fatty acid; **EFAD**—essential fatty acid deficiency; **FA**—fatty acid; **HDL**—high-density lipoprotein; **IDL**—intermediate density lipoprotein; **LCFA**—long-chain fatty acid; **LDL**—low-density lipoprotein; **MCFA**—medium-chain fatty acid; **MCT**—medium-chain triglyceride; **MG**—monoglyceride; **MUFA**—monounsaturated fatty acid; **PAF**—platelet-activating factor; **PL**—phospholipids; **PUFA**—polyunsaturated fatty acid; **PG**—prostaglandin; **PGHS**—prostaglandin synthase; **SAFA**—saturated fatty acid; **SCFA**—short-chain fatty acid; **TG**—triglyceride; **VLCFA**—very long-chain fatty acid; **VLDL**—very low-density lipoprotein.

HISTORICAL PERSPECTIVE

The understanding and assessment of energy requirements in humans have been enhanced by the advent of indirect calorimetry. In indirect calorimetry, the type and rate of substrate oxidation and energy are measured in vivo from gas exchange measurements. This method in combination with other measurement techniques permits investigation of numerous aspects of metabolism, heat production, energy requirements of physical activity, and altered energy metabolism in injury and disease. The development and interpretation of indirect calorimetry have represented a fundamental milestone for chemistry, biology, and medicine.

The high level of interest in indirect calorimetry over the past decades as a method of determining energy needs has resulted from several factors. Media and “lay” attention to food, exercise, and the prevention of obesity as important ways to improve lifestyle has been associated with greater awareness of indirect calorimetry. Moreover, commercial availability of improved and convenient equipment for measuring gaseous exchange in healthy humans and hospitalized patients has made indirect calorimetry readily available to both clinicians and scientists. At the same time, measurements of energy expenditure have assumed new importance in investigating and managing obesity.

Historical developments from 1650 to 1950 were primarily directed toward measuring

basal metabolic rates. Discussions of gas exchange often start with the references to Lavoisier and his contemporaries, who were the first to demonstrate animal respiration (1). Lavoisier was studying the combustion and oxidation of metals. He gave the name *oxygene* to the material absorbed by the metal when heated in air. Moreover, he introduced the term *calorique* to describe heat. In collaboration with the physicist, Laplace, he conducted studies of the heat released in combustion, which laid the foundation for thermal chemistry. Later, Lavoisier carried out elegant experiments to relate the uptake of oxygen by an animal to the output of CO₂ and heat. Heat production was measured by an ice calorimeter and helped to establish the science of calorimetry.

During the first half of the 1800s, techniques for chemical measurement of foods and other biologic materials were being developed and the scientific concepts of Lavoisier were still considered quite controversial. The second half of the 1800s saw a growth in organic and biochemistry. The gas exchange of nutrients upon oxidation was related to heat production in a bomb calorimeter. Such studies were extended to animals and then to men by the use of direct and indirect calorimetry. Voit established a center for investigators in Germany, and studies there led the way in establishing the relationship between gas exchange and calorimetry of the whole body (2). Such studies had widespread influence on calorimetry in Europe as well as in the United States, where Atwater (3), Benedict (4), Lusk (5), and DuBois (6) were particularly influential in advancing the field.

The measurement of gas concentration before World War II was largely gravimetric for chamber or room calorimeters and volumetric when measuring basal metabolic rates of individuals. The classic portable basal metabolic rate apparatus of Benedict (4) depended on a closed system, in which a container of oxygen would decrease in volume in proportion to the uptake of oxygen by the subject, while the CO₂ was absorbed but not measured. Oxygen consumption was then translated into calories per hour by assuming an amount of expired CO₂, which would yield a nonprotein respiratory quotient (RQ) of 0.82 and hence a caloric equivalent for oxygen of 4.825 kcal (20.19 kJ) liter⁻¹. The wartime events of the early 1940s provided a stimulus to develop more rapid and accurate methods of gas analysis, particularly for the new demands of combat aviation at higher altitudes. Following World War II, physical methods of gas analysis began to dominate the field of gas exchange. Mass spectrometry was introduced for measuring both O₂ and CO₂, as well as paramagnetic analyzers for O₂ and infrared analyzers for CO₂.

A significant advancement in the 1980s was the use of doubly labeled water to measure energy expenditure in free-living individuals, the first noninvasive technique to do so accurately in free-living humans. The technique was first introduced by Lifson et al. in the 1950s (7) as an isotopic technique for measuring the CO₂ production rate in small animals. Unfortunately, it was not possible to apply the technique to humans because the dose required was cost prohibitive given the relatively poor sensitivity of isotope-ratio mass spectrometry at that time. Not for another 20 years did Lifson et al. describe the feasibility of applying the technique to measuring free-living energy expenditure in humans (8), an application later recognized by Schoeller et al. (9), who administered both ¹⁸O- and ²H-labeled water and followed the decay rates of each

isotope in body water over 1 to 2 weeks. The difference in the decay rates then allowed calculation of the CO₂ production over that time period. For the first time, an accurate calculation of daily energy expenditure in free-living individuals was possible.

KEY ASPECTS OF ENERGY EXPENDITURE

Changes in body energy content occur through changes in the balance between daily intake and energy expenditure. Energy intake is episodic, derived primarily from the carbohydrates, proteins, and fats in foods consumed. Total daily energy expenditure for theoretical and analytic purposes can be divided into several components ([Fig. 5.1](#)).

Figure 5.1. The components of daily energy expenditure.

Resting Metabolic Rate

The *resting metabolic rate* (RMR) represents the largest portion of daily energy expenditure (60 to 75%) and is a measurement of the energy expended for maintenance of normal body functions and homeostasis. These processes include resting cardiovascular and pulmonary functions, the energy consumed by the central nervous system, cellular homeostasis, and other biochemical reactions involved in the maintenance of resting metabolism.

Another term to describe basal levels of energy expenditure is *basal metabolic rate* (BMR). While at the Mayo Clinic, Dr Boothby defined and popularized use of the BMR for the diagnosis of thyroid disorders. He defined this function as the energy expended by an individual bodily and mentally at rest in a thermoneutral environment 12 to 18 hours after a meal. Much to the inconvenience of the patient, measurements were done during the early morning hours when, in addition, the circadian rhythm of oxygen consumption was known to be low. Because of the increase in metabolism caused by the muscular and mental unrest introduced by this procedure, it is unlikely that the true basal metabolism was often measured. Therefore, for practical and conceptual reasons,

the BMR is now rarely measured. In its place, we now measure what is referred to as the resting metabolic rate (or resting energy expenditure), which may be (but is not always) higher than the BMR.

The RMR is primarily related to the fat-free mass of the body and is also influenced by age, gender, body composition, and genetic factors. For example, the RMR decreases with advancing age (2 to 3%/decade), which is primarily attributed to the loss of fat-free mass. Males tend to have a higher RMR than females because of their greater body size. The dependency of the RMR on body composition must be considered when individuals of different age, sex, and physical activity status are compared. Other processes, such as sympathetic nervous system activity, thyroid hormone activity, and sodium-potassium pump activity, contribute to the variation in the RMR among individuals. (See WHO equations for predicting basal metabolic rates from body weights and heights for different age groups and both sexes and their derived data in Appendix [Table III-10-b](#), [Table III-10-c](#), [Table III-10-d](#) and [Table III-10-e](#)).

Thermic Effect of Feeding

The thermic effect of feeding (TEF) is the increase in energy expenditure associated with food ingestion. The TEF represents approximately 10% of the daily energy expenditure and includes the energy costs of food absorption, metabolism, and storage. The magnitude of the TEF depends on several factors, including the caloric content and composition of the meal as well as the antecedent diet of the individual. Following meal ingestion, energy expenditure increases for 4 to 8 hours, its magnitude and duration depending on the quantity and type of macronutrient (i.e., protein, fat, or carbohydrate).

The TEF has been divided into subcomponents: obligatory and facultative thermogenesis. The obligatory component of the TEF is the energy cost associated with absorption and transport of nutrients and the synthesis and storage of protein, fat, and carbohydrate. The “excess” energy expended above the obligatory thermogenesis is the facultative thermogenesis and is thought to be partially mediated by sympathetic nervous system activity.

The TEF also decreases with advancing age and may be associated with development of insulin resistance ([10](#)). It is presently unclear how exercise training influences the TEF, although there is clearly some interaction between physical exercise and TEF. There is presently no evidence that gender influences postprandial thermogenesis.

Thermic Effect of Physical Activity

The most variable component of the daily energy expenditure is the thermic effect of physical activity ([11](#)). The component includes the energy expended above the RMR and the TEF and includes the energy expended through voluntary exercise and the energy devoted to involuntary activity such as shivering, fidgeting, and postural control. In sedentary individuals, the thermic effect of activity may be as low as 100 kcal/day; in highly active individuals it may approach 3000 kcal/day (see [Chapter 47](#)). Thus, physical activity represents a significant factor in the daily energy expenditure in humans because it is extremely variable and subject to voluntary control. Physical

activity tends to decrease with advancing age; this decrease in physical activity may be associated with a loss of fat-free mass and an increase in adiposity. Males in general tend to have a greater caloric expenditure associated with physical activity than females, partially because of the greater energy cost of moving a larger body mass. Average values of the energy cost of different grades of physical activity for men and women are given in Appendix [Table III-A-11-D](#) and [Table III-A-11-E](#).

The RMR, TEF, and physical activity often overlap during the course of a normal day. Although daily variations in energy balance put individuals in a slight energy deficit or surplus, maintenance of a stable body weight depends on tight coupling of energy intake and energy expenditure over long periods of time. It is presently unclear which psychologic and/or physiologic factors influence the coupling of energy intake with energy expenditure to maintain energy balance.

METHODS OF MEASUREMENT

Many methods of measuring energy expenditure have become available over the years, and they vary in complexity, cost, and accuracy ([12](#)). It is important to gain an appreciation of the differences in the methods and of their applications in laboratory and other settings. The techniques used to measure total daily energy expenditure and its components are briefly described below. A more detailed explanation of the laboratory methods of measuring energy expenditure has been published ([13](#)).

The most widely used methods for measuring the energy expenditure involve indirect calorimetry. Direct calorimetry (measurement of heat loss from a subject) has been used to measure energy expenditure, but the high cost and complicated engineering of this method have discouraged investigators from using this approach.

Indirect Calorimetry

The term *indirect* refers to the estimation of energy production by measuring O₂ consumption and CO₂ production rather than by directly measuring heat transfer. This method requires a steady state of CO₂ production and respiratory exchange and subjects with a normal acid-base balance. To determine the RMR, measurements are usually taken with the subject in a supine or semireclined position after a 10- to 12-hour fast. Depending on the equipment, the subject typically breathes through a mouthpiece, face mask, or ventilated hood or is placed in a room calorimeter in which expired gases are collected. Typical RMR values range from 0.7 to 1.6 kcal/min, depending on the subject's body size, body composition, level of physical training, and gender. The room in which the measurements are made is usually darkened and quiet, and the volunteer remains undisturbed during the measurement process. Measurement of RMR typically lasts 30 minutes to 1 hour, whereas postprandial measurements frequently take 3 to 8 hours. These measurements are generally easily reproducible (with a coefficient of variation below 5%).

Several methods have been used to measure O₂ consumption and CO₂ production at rest. Generally, an "open circuit" method is used in which both ends of the system are

open to atmospheric pressure and the subject's inspired and expired air are kept separate by means of a three-way respiratory valve or nonrebreathing mask. The expired gases are usually collected in a Douglas bag or Tissot respirometer for measurement of O₂ and CO₂ content. Hyperventilation may occur in subjects who are not well adapted to a mouthpiece and may result in inappropriately high levels of O₂ consumption and CO₂ production. When a mask is used, it is frequently difficult to obtain an airtight seal around the subject's nose and mouth.

To circumvent some of these problems, ventilated hoods have been developed in which the subject is fitted with a transparent hood equipped with a snugly fitting collar. Fresh air is drawn into the hood via an intake port, and expired air is drawn out of the hood by a motorized fan. The flow rate is measured by a pneumotachograph, and aliquots of the outflowing air are analyzed for O₂ consumption and CO₂ production after temperature and water vapor content have been adjusted. O₂ consumption and CO₂ production are calculated from the differences in their concentrations in the inflowing and outflowing air and the flow rate. Ventilated hoods are excellent for both short- and long-term measurements but are less useful in measuring the energy expenditure of physical activity; in the latter case the subject may find the hood uncomfortable, and there is a problem with dissipation of perspiration and water vapor.

Measurement of the energy expenditure of physical activity has traditionally presented several methodological challenges. Indirect calorimetry using a mouthpiece or face mask has been used to assess O₂ consumption and CO₂ production. This method generally yields reliable and accurate measurements of the energy cost of physical activity in a laboratory setting but provides no information about the energy cost of physical activity under free-living conditions because of the stationary nature of the equipment. Portable respirometers use a face mask with valves that direct expired air through collection tubes to a respirometer carried on the subject's back. The respirometer contains a flowmeter and a sampling device that collects an aliquot of expired gases for analysis at a later time. There are drawbacks to this method: first, there is an inherent delay in obtaining results, and second, the rate of energy expended during work performance is integrated over the entire period of gas collection.

In an attempt to avoid some of the problems associated with measurement of free-living physical activity, several less complicated (and less accurate) methods have been devised. These methods use physiologic measurements, observation, and records of physical activity, as well as activity diaries or recall. Heart-rate recording, used to measure energy expenditure, is based on the correlation between heart rate and oxygen consumption during moderate to heavy exercise ([13](#), [14](#)). The correlation, however, is much poorer at lower levels of physical activity, and a subject's heart rate may be altered by such events as anxiety or change in posture without significant changes in oxygen consumption.

It is possible to estimate energy expenditure over relatively long periods of time by measuring energy intake and changes in body composition. However, there are errors inherent in attempting an accurate determination of energy intake over several days, weeks, or months, as well as in the methods available for determination of body

composition.

Time-motion studies have also been used to estimate the energy expenditure of physical activity in real-life situations. In time-motion studies, detailed records of physical activity are kept by an observer, and energy expenditure is estimated from the duration and intensity of the work performed. The major problem with this method is the marked individual variations in the energy costs of doing a particular task.

Physical activity diaries and physical activity recall instruments have been used to quantify the energy costs of different activities over a representative period of time. Record keeping is often inaccurate and may interfere with the subject's normal activities. Furthermore, the subject's recall of physical activity depends on his or her memory, which may not always be reliable. Measuring motion by devices such as a pedometer or an accelerometer may provide an index of physical activity (i.e., counts) but does not quantitate energy expenditure. In summary, measurement of free-living physical activity continues to be the most significant challenge in the field of energy metabolism.

In recent years, large respiration chambers have been built in laboratories. Such a chamber operates on the same principle as the ventilated hood system: it is essentially a large, airtight room in which temperature and humidity are controlled. Fresh air is drawn into the chamber and allowed to mix. Simultaneously, air is drawn from the chamber, and the flow rate is measured and analyzed continuously for O₂ and CO₂ content. The size of the room affords the subject sufficient mobility to sleep, eat, exercise, and perform normal daily routines, making detailed measurements of energy expenditure possible over a period of several hours or days. Room calorimeters are probably the best method currently available for conducting short-term studies (several days) of energy expenditure in humans when the object is to measure RMR, TEF, and the energy expenditure of physical activity. Physical activity level is quantified by a radar system that is activated by the subject's movement within the chamber. As with other movement devices, the radar system does not quantitate the intensity of activity. It is also likely, however, that free-living physical activity is blunted in the room calorimeter because of its confining nature. Thus room calorimeters do not offer the best model for examining adaptations in free-living physical activity. Although room calorimeters are moderately expensive to construct, they provide reliable information on daily energy expenditure and substrate oxidation.

Substrate Oxidation

The assessment of nutrient use is frequently used in combination with the assessment of energy expenditure. This area has been previously reviewed (14) and is briefly summarized in this chapter. When the measurement of $\dot{V}O_2$ is available (in liters of O₂ STPD [standard temperature (0°C), pressure (760 mm Hg), and dry] per minute), metabolic rate (\dot{M}), which corresponds to energy expenditure, can be calculated (in kJ/min) as follows:

$$\dot{M} = 20.3 \times \dot{V}O_2 \quad (5.1)$$

where 20.3 is the mean value (in kJ/L) of the energy equivalent for the consumption of 1 L (STPD) of O₂. To take into account the heat generated by the oxidation of the three macronutrients (carbohydrates, fats, and proteins), three measurements must be performed: oxygen consumption ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$), and urinary excretion (N). Simple equations for computing metabolic rate (or energy expenditure) from these three determinations are written in the following form:

$$\dot{M} = a\dot{V}O_2 + b\dot{V}CO_2 - cN \quad (5.2)$$

The factors *a*, *b*, and *c* depend on the respective constants for the amount of O₂ used and the amount of CO₂ produced during oxidation of the three classes of nutrients (Table 5.1). An example of such a formula is given below:

Substrates	O ₂ Consumed ^a	CO ₂ Produced ^b	RQ ^c	Energy Equivalent (per gram)					
				Heat Released per Gram		H ₂		H ₂ O	
				kJ	kcal	kJ	kcal	kJ	kcal
Starch	0.829	0.829	1.00	17.6	4.20	21.2	5.06	21.2	5.06
Sucrose	0.796	0.796	1.00	16.6	3.96	21.1	5.04	21.1	5.04
Glucose	0.746	0.746	1.00	15.6	3.74	21.0	5.01	21.0	5.01
Lipid	2.019	1.421	0.71	39.6	9.46	19.6	4.69	27.7	6.63
Protein	1.010	0.844	0.83	19.7	4.70	19.0	4.56	20.3	5.91
Lactic acid	0.746	0.746	1.00	15.1	3.62	20.3	4.85	20.3	4.85

^aliters per gram of substrate oxidized

^bliters respiratory quotient

Table 5.1 Energy Equivalent from Oxidation of Substrates

$$\dot{M} = 16.18 \dot{V}O_2 + 5.02 \dot{V}CO_2 - 5.99 N \quad (5.3)$$

where *M* is in kilojoules per unit of time, *VO*₂ and *VCO*₂ are in liters STPD per unit of time and *N* is in grams per unit of time. For example, if $\dot{M}O_2 = 600$ L/day, $\dot{M}CO_2 = 500$ L/day (respiratory quotient, or RQ = 0.83) and *N* = 25 g/day, then *M* = 12,068 kJ/day. The simpler equation (5.1) gives a value of 12,180 kJ per day.

Indirect calorimetry also allows computation of the nutrient oxidation rates in the whole body. An index of protein oxidation is obtained from the total amount of nitrogen excreted in the urine during the test period. One approach to calculating the nutrient oxidation rate is based on the O₂ consumption and CO₂ production due to the oxidation

rates of the three nutrients, carbohydrate, fat, and protein, respectively. In a subject oxidizing c g/min of carbohydrate (as glucose) and i g/min of fat, and excreting n g/min of urinary nitrogen, the following equations, based on [Table 5.1](#)), can be used:

$$\dot{V}O_2 = 0.746c + 2.02f + 6.31n \quad (5.4)$$

and

$$\dot{V}CO_2 = 0.746c + 1.43f + 5.27n \quad (5.5)$$

We can solve [equation 5.4](#) and [equation 5.5](#) for the unknown c and i this way:

$$c = 4.59 \dot{V}CO_2 - 3.25 \dot{V}O_2 - 3.68n \quad (5.6)$$

$$f = 1.69 \dot{V}O_2 - 1.69 \dot{V}CO_2 - 1.72n \quad (5.7)$$

Because 1 g of urinary nitrogen arises from approximately 6.25 g protein, the protein oxidation rate p (in g/min) is given by the equation

$$p = 6.25n \quad (5.8)$$

Thus, indirect calorimetry allows calculation of net rates of nutrient oxidation. It is important to appreciate that indirect calorimetry measures the net appearance by oxidation of a substrate. Moreover, it is important to understand that there is a slight difference in the heat produced per liter of O_2 consumed when one compares carbohydrate, lipid, and protein oxidation. An examination of substrate oxidation has broadened our knowledge of the effects of environment (i.e., diet, exercise), disease, and nutrient requirements in humans.

Doubly Labeled Water

The doubly labeled water technique offers promise as a method of determining energy requirements in free-living populations and in subjects in whom traditional measures of energy expenditure, using indirect calorimetry, have proven impractical and difficult (e.g., infants and critically ill patients). The basis of this technique is that after a bolus dose of two stable isotopes of water (2H_2O and $H_2^{18}O$), 2H_2O is lost from the body in water alone, whereas $H_2^{18}O$ is lost not only in water but also as $C^{18}O_2$ via the carbonic anhydrase system (9). The difference in the two turnover rates is therefore related to the CO_2 production rate, and with a knowledge of the fuel mixture oxidized (from the composition of the diet), energy expenditure can be calculated.

The main advantages of the doubly labeled water technique are (a) it measures total

daily energy expenditure, which includes an integrated measure of RMR, TEF, and the energy expenditure of physical activity; (b) it permits an unbiased measurement of free-living energy expenditure; and (c) measurements are conducted over extended periods of time (1 to 3 weeks). Thus, energy values derived from the doubly labeled water method are representative of the typical daily energy expenditure and therefore the daily energy needs of free-living adults. Furthermore, this technique provides an accurate estimate of free-living physical activity. Daily free-living physical activity is calculated from the difference between the total daily energy expenditure and the combined energy expenditures of the RMR and TEF. Thus the doubly labeled water technique provides the most realistic estimate in free-living subjects of the average daily energy expenditure associated with physical activity.

Disadvantages of the doubly labeled water method are its expense and limited availability ([Table 5.2](#)). Consequently, the technique does not lend itself to epidemiologic studies or studies of large groups of subjects. However, this technique is now being used to examine energy requirements of persons in a variety of healthy and diseased states. With use of the doubly labeled water method, measurement of daily energy expenditure becomes a proxy measure of daily energy requirements.

Advantages	Disadvantages
Noninvasive and unobtrusive Measurements are performed under free-living conditions.	Availability and expense of oxygen-18 Reliance on isotope ratio mass spectrometry for analysis of samples
Measurements are performed over extended time periods (7-14 days)	A direct measurement of CO ₂ production and O ₂ consumption; the method does not measure substrate oxidation
Measurements can be used to estimate physical activity energy expenditure when combined with measurement of resting metabolic rate	The method is not suitable for epidemiological studies

Table 5.2 Advantages and Disadvantages of the Doubly Labeled Water Technique

Labeled Bicarbonate

The labeled bicarbonate (¹³C or ¹⁴C) method has recently won favor as a technique for measuring energy expenditure over shorter periods of time (several days) than those covered by the doubly labeled water method ([15](#)). When labeled bicarbonate is infused at a constant rate, it reaches a rapid equilibrium with the body's CO₂ pool. The extent of isotopic dilution depends on the rate of CO₂ production, provided there is not isotopic exchange or fixation. Thus variations in the dilution of isotope reflect variations in CO₂ production and hence energy expenditure. Because the method assesses CO₂ production rather than O₂ consumption, it requires assumptions about the respiratory

quotient similar to those required by the doubly labeled water method.

In the final analysis, cost and the specific research questions generated should direct the selection of methods of measuring energy expenditure. Questions of substrate oxidation and its impact on the regulation of energy balance, for example, are most applicable to the techniques of indirect calorimetry using room calorimeters and ventilated hood systems. On the other hand, more reliable information on the adaptations of free-living subjects to environmental perturbations (exercise, dietary interventions, etc.) over long periods of time is provided by the use of the doubly labeled water method combined with indirect calorimetry systems.

CAN ENERGY INTAKE BE ACCURATELY MEASURED IN HUMANS?

Self-recorded food intake has been the traditional method of estimating energy requirements. However, available methods for estimating food intake are fraught with limitations and methodological problems. While there is a clear need to provide well-founded recommendations for dietary energy, there have been major technical, physiologic and conceptual problems in doing so. The establishment of individual energy requirements has been problematic because of reliance on (a) measurement of energy intake from self-recorded diaries and/or dietary interviews, (b) the use of a multiple of BMR (or RMR) to predict energy needs, and (c) the failure of current recommended daily energy requirements to take into account the diversity of the population with respect to body composition and physical activity. The shortcomings of each of these approaches are briefly discussed below.

Self-recording of energy intake depends on the cooperation of the volunteer, and the very act of recording energy intake may actually alter ingestive behavior, even in compliant volunteers who wish to “please” the investigator. Thus, recording food intake becomes an unreliable tool on which to base guidelines for determining energy needs. Several recent studies suggest consistent underreporting of actual energy intake when validated against measures of total daily energy expenditure from doubly labeled water ([16](#), [17](#) and [18](#)). Data from our laboratory suggest a significant underreporting of energy intake by as much as 30% in older individuals, compared with measurement of daily energy expenditure ([16](#)). Underreporting was more pronounced in women (30%) than in men (15%). Thus, it is apparent that using measures of energy intake to estimate energy requirements lacks scientific credibility because of the uncertainty and unreliability of subject reporting.

An alternative method of estimating energy needs uses multiples of RMR ([19](#)). In this approach, estimates of daily energy expenditure are not derived directly but by a factorial approach in which RMR and the estimated energy expenditure from various physical activities are summed ([20](#)). This method suffers from a number of methodological problems. First, it does not consider the components of daily energy expenditure that contribute to individual variation in daily energy expenditure. These “neglected” components include (a) the TEF, which contributes approximately 10 to 15% of daily energy expenditure ([21](#)), and (b) the thermic effect of physical activity. Data from our laboratory showed that under free-living conditions, physical activity is highly variable in normal persons and can range from as low as 187 kcal/day to 1235

kcal/day (11, 16). Furthermore, knowledge of RMR alone provides insufficient information for explaining variation in daily energy expenditure, as variation in RMR explains less than half of individual variation in daily energy expenditure (16).

Another “general method” of assessing energy needs is based on recommended daily allowances (22) (see Appendix Table II-A-2-a-1). The current RDAs divide the adult population into two age groups those who are 19 to 50 years old and those 51 years old and older. The frequent use of the category of “51 and older” is recognized as inappropriate, because normal and diseased aging produces increased heterogeneity in almost all physiologic measurements. The physiologic status and energy requirements of individuals who are 50 to 60 years old are very different from those of persons who are 80 to 90 years old. Furthermore, the RDAs do not take into account energy recommendations for individuals who vary in physical activity or disease state. It is evident, however, that the use of a single energy value is far too crude an approach and should be abandoned for medical, nutritional, and planning purposes. These methods were necessitated, until recently, by the lack of a direct method to measure daily energy expenditure under free-living conditions.

The World Health Organization Consultative Panel has stated that future guidelines should be based on measurements of energy expenditure “if and when these became available” (19). As noted above, the doubly labeled water technique ($^2\text{H}_2^{18}\text{O}$) provides a measure of free-living energy expenditure. In the adult individual, daily energy expenditure defines the level of energy intake to maintain energy balance (23). Measurement of total daily energy expenditure with the doubly labeled water technique therefore acts as a proxy indicator of the amount of energy intake that is required to maintain energy balance and body energy stores.

ENERGY NEEDS OF SPECIFIC POPULATIONS

Below, we examine recent applications of doubly labeled water methodology in healthy and diseased older individuals to understand better daily energy requirements and the regulation of energy balance. We consider several diseases that are associated with negative energy balance and generalized wasting.

Heart Failure

Heart failure is an increasingly important and frequent clinical problem, with the highest prevalence observed in the elderly (24). The incidence of heart failure increases 50-fold between the ages of 40 and 60 years. The unexplained loss of body weight and muscle mass are hallmark clinical features of end-stage congestive heart failure (25). It is unclear whether reduction in caloric intake or elevated caloric expenditure accounts for the negative energy balance and subsequent weight loss in advanced heart failure. Furthermore, daily energy requirements in heart failure are unknown.

Several studies have examined energy expenditure in heart failure. RMR, body composition, and dietary intake were examined in 20 heart failure patients with documented systolic dysfunction and compared with an age-matched cohort of 40

healthy elderly volunteers (26). RMR was measured by indirect calorimetric techniques and fat mass and fat-free mass were measured by dual-energy x-ray absorptiometry. Fat-free mass (lean body mass minus skeleton) was approximately 4 kg lower in heart failure patients, despite similar amounts of fat mass. Although lower fat-free mass was noted, the RMR was 18% higher in heart failure patients than in healthy controls (Fig. 5.2). These results suggest that heart failure patients have a higher RMR (for their metabolic size), which may contribute to their propensity for unexplained weight loss and musculoskeletal wasting.

Figure 5.2. The relationship between resting metabolic rate and fat-free mass in healthy individuals and patients with heart failure. This figure shows that resting metabolic rate (per kg of fat-free mass) is higher in heart failure patients. (Adapted from Poehlman ET, Scheffers J, Gottlieb SS, et al. *Ann Intern Med* 1994;121:860–2).

Measurement of the RMR, however, only provides partial information on whether energy needs are indeed higher in congestive heart failure patients. Ultimately, the balance between daily energy expenditure and food intake regulates body composition in humans. Although recent work (26, 27 and 28) provided evidence that resting energy requirements are higher in heart failure and that the magnitude of the increase in resting energy needs increases with symptom severity (27), it was unclear whether daily energy needs are higher in heart failure patients in their free-living environment. Accordingly, daily energy expenditure and physical activity were measured in free-living cachectic (12) and noncachectic (13) patients with heart failure and 50 healthy control volunteers, by doubly labeled water and indirect calorimetry methodology (29) (Table 5.3). As expected, fat mass and fat-free mass were lower in cachectic patients than in noncachectic patients and controls. Daily energy expenditure was lower ($P < .05$) in cachectic patients (1870 ± 347 kcal/day) than in noncachectic patients (2349 ± 545 kcal/day) and healthy controls (2543 ± 449 kcal/day) (Table 5.3). Differences in daily energy expenditure were due to lower ($P < .05$) free-living physical activity energy expenditure in cachectic (269 ± 307 kcal/day) and noncachectic patients (416 ± 361 kcal/day) compared with healthy controls (728 ± 374 kcal/day). Thus, the hypothesis that daily energy requirements are higher in heart failure patients is not supported by these initial studies using doubly labeled water methodology. Moreover, these findings

underscore the need to measure daily energy expenditure in free-living patients accurately before drawing conclusions about the presence or absence of elevated daily energy expenditure and its relationship to weight loss. Because no evidence for an elevated daily energy expenditure in cachectic heart failure patients was found, the suggestion is that inadequate energy intake is a likely determinant of weight loss. Several factors including abdominal pain and distention, gastrointestinal hypomotility, and delayed gastric emptying have been suggested to contribute to anorexia in heart failure patients (25). The fact that daily energy expenditure was not elevated in noncachectic patients, however, argues against an elevated daily energy expenditure preceding weight loss.

Variable	Cachectic Patients	Noncachectic Patients	Healthy Controls
Daily energy expenditure (kcal/day)	1870 ± 347*	2349 ± 545	2543 ± 449
Resting metabolic rate (kcal/day)	1414 ± 210*	1698 ± 252	1561 ± 223
Physical activity energy expenditure	269 ± 307	416 ± 361	728 ± 223**

Adapted from Toth MJ, Gottlieb SS, Goran MI, et al. *Am J Physiol* 1997;272:E469-75.

*Values are mean ± SD.

* P < .05 less than noncachectic and healthy controls.

** P < .05 greater than noncachectic and cachectic.

Table 5.3 Daily Energy Expenditure,^a Its Components and Energy Intake in Cachectic and Noncachectic Heart Failure Patients and Healthy Controls

Alzheimer's Disease

Alzheimer-type dementia, a growing health problem, is one of the leading causes of death among elderly people (30). The overall estimate is that more than 10% of persons over 65 suffer from senile dementia of the Alzheimer's type (31). Annual medical costs for Alzheimer's disease are estimated to be more than 40 billion dollars (32).

Unexplained weight loss is a frequent clinical finding in patients with Alzheimer's disease. The National Institute of Neurological and Communicative Disorders and Strokes Task Force on Alzheimer's Disease has included weight loss as a "clinical feature consistent with the diagnosis of Alzheimer's disease" (33). Moreover, it has been postulated that Alzheimer's disease may be characterized by dysfunction in body weight regulation (34).

Weight loss is due to a mismatch of energy intake with energy expenditure, which leads to low body weight, atrophy of muscle mass, and accelerated loss of functional independence in persons with Alzheimer's disease. Weight loss also increases the risks of decubitus ulcers, systemic infection, mortality, and greater consumption of health

care resources (35, 36). Although it may not yet be possible to prevent, treat, or permanently alter the course of the underlying disease, identification and amelioration of nutritional problems may prove an ideal strategy for lessening the burden of the disease.

Is the energy imbalance associated with Alzheimer's disease caused by reduced energy intake, an elevated rate of energy expenditure, or a combination of both? Studies examining the caloric adequacy of diets of Alzheimer's patients as a potential contributor to weight loss (37, 38 and 39) have yielded inconclusive results. This is not surprising, since the recording of food intake is an unreliable method that provides little useful information on an individual's actual habitual energy intake. Therefore, investigators have focused on the possibility that elevated energy expenditure contributes to unexplained weight loss in Alzheimer's patients. Several investigators found an elevated RMR in Alzheimer's patients, which might itself result in weight loss, (40, 41 and 42), although these results remain controversial (43, 44, 45 and 46). A more important question, however, is whether free-living Alzheimer's patients have a higher daily energy expenditure than normal elderly persons.

Doubly labeled water methodology was used to examine the hypothesis that Alzheimer's patients are characterized by high levels of daily energy expenditure (47). Thirty Alzheimer's patients (73 ± 8 years of age; Mini-Mental score: 16 ± 8) and 103 healthy elderly persons (69 ± 7 years of age) were studied. Daily energy expenditure and its components (RMR and free-living physical activity) from doubly labeled water and indirect calorimetry were measured over a 10-day period. Fat-free mass tended to be lower in Alzheimer's patients (45 ± 9 kg) than in the healthy controls (49 ± 10 kg; $P = .07$), whereas no differences were noted in fat mass between groups. Daily energy expenditure was 14% lower in Alzheimer's patients (1901 ± 517 kcal/day) than in the controls (2213 ± 513 kcal/day; $P \leq .001$) because of a lower RMR (1287 ± 227 vs. 1418 ± 246 kcal/day; $P < .01$) and physical activity–related energy expenditure (425 ± 317 vs. 574 ± 342 kcal/day; $P < .05$) (Table 5.4). There were no differences between groups when energy expenditure was normalized for differences in fat-free mass. Thus, the lower energy expenditure in Alzheimer's patients is primarily due to their lower fat-free mass.

Variable	Alzheimer's Volunteers (N = 30)	Healthy Elderly (N = 103)
Daily energy expenditure (kcal/day)	1901 ± 517	2213 ± 513**
Resting metabolic rate (kcal/day)	1287 ± 227	1418 ± 246*
Physical activity energy expenditure (kcal/day)	425 ± 317	574 ± 342*

Table 5.4 Daily Energy Expenditure^a and Its Components in Alzheimer's Patients and

Healthy Elderly Persons

Daily energy expenditure was also examined in a subgroup ($N = 11$) of Alzheimer's patients who had lost significant body weight (5.6 ± 2.3 kg) within the previous year. A lower daily energy expenditure was found in cachectic Alzheimer's patients (1799 ± 474 kcal/day) than in noncachectic Alzheimer's patients (1960 ± 544 kcal/day) and healthy elderly controls (2213 ± 513 kcal/day; $P < .01$). Thus, daily energy expenditure is not higher, but lower in Alzheimer's patients, because of lower levels of resting and physical-activity-related energy expenditure and fat-free mass.

Collectively, the hypothesis that an increased daily energy expenditure contributes to weight loss in heart failure or Alzheimer's diseases is not supported by these findings. These findings, again, underscore the importance of assessing daily energy expenditure in free-living individuals before drawing conclusions regarding the presence or absence of a "hypermetabolic state."

Parkinson's Disease

Approximately 50% of patients afflicted with Parkinson's disease experience significant weight loss during the course of the disease. The suggestion has been made that inappropriately high levels of energy expenditure contribute to their unexplained weight loss. Several studies have compared differences in RMR between Parkinson's disease patients and an age-matched control population in an attempt to address this question. Several investigators ([48](#), [49](#) and [50](#)) found an elevated RMR in Parkinson's disease patients, compared with healthy controls. The elevated RMR was at least partially attributed to tremor, rigidity, and a general dyskinesia in these patients.

More recently, total daily energy expenditure was assessed in Parkinson's patients to examine the hypothesis that free-living daily energy expenditure and its components (RMR and physical activity energy expenditure) are elevated ([51](#)). In contrast to the proposed hypothesis, daily energy expenditure was 15% lower in Parkinson's disease patients (2214 ± 460 kcal/day) than in healthy elderly controls (2590 ± 497 kcal/day). This was primarily due to lower physical activity energy expenditure (339 ± 366) in Parkinson's disease patients compared with that of the controls (769 ± 412 kcal/day). Thus, although excessive muscular activity in the form of rigidity and tremor may contribute to an elevated RMR ([48](#), [49](#) and [50](#)), the overall effect of Parkinson's disease is to lower daily energy expenditure by reducing the energy expenditure associated with purposeful physical activity. Impairment of gain and movement associated with the signs and symptoms of Parkinson's disease probably promotes a reduction in physical activity.

The absence of an elevated daily energy expenditure suggests that an abnormally elevated daily energy expenditure is not a likely predisposing factor to weight loss. Thus, it is likely that a lower caloric intake is implicated in the weight loss of these patients. Swallowing disorders, impaired hand-to-mouth coordination, nausea,

excessive saliva production, and delayed gastric emptying time may contribute to reduced energy intake in Parkinson's disease patients (52).

REGULATION OF INTRA- AND EXTRACELLULAR VOLUME AND OSMOLALITY

The body fluid, an aqueous solution containing many electrolytes, consists of intracellular and extracellular compartments. The intracellular fluid is not a single large compartment; each cell has its own separate environment, communicating with other cells only via interstitial fluid and plasma. Consequently, cells in various tissues differ considerably in their solute content and concentrations.

Regardless of the nature of the solute and its electrical charge, however, osmotic equilibrium is maintained so that each particle of solute throughout the body is surrounded by the same number of water molecules. Since cell membranes are very permeable to water, osmolality is the same throughout the body fluids. Operation of normal metabolic functions of the body requires maintaining an optimal ionic strength in

its environment, primarily the intracellular fluid, where most metabolic activities occur. The homeostatic mechanisms of the body are therefore constantly at work to provide such an environment.

Because the extracellular fluid (ECF) is not the site of major metabolic activity, substantial alteration in its ionic strength may occur without adverse effects on the body function. The main function of the ECF is to serve as a conduit between cells and between organs. The plasma is a route of rapid transit, and the interstitial fluid serves as a slow supply zone, which by flowing around the cell permits the entire cell surface to be used as an area of exchange. The ability of the ECF to function efficiently as a conduit requires maintenance of optimal extracellular volume, particularly of plasma volume, the vehicle of rapid transportation through the circulation.

An additional important function of the ECF is regulation of the intracellular volume and its ionic strength. Because of the requirement for osmotic equilibrium between the cells and the ECF, any alteration in extracellular osmolality is followed by an identical change in intracellular osmolality, which is usually accompanied by a reciprocal change in cell volume.

Although cells and organs can be supplied with substrate and relieved of metabolic products with a much slower circulation, normal circulation is required to supply sufficient oxygen for the body's metabolic needs. Normal plasma volume is a prerequisite for maintenance of normal circulation. Because plasma is in equilibrium with the interstitial fluid, the maintenance of normal plasma volume requires normal extracellular volume. A low extracellular volume can result in impaired organ perfusion, and an excessive extracellular volume may lead to vascular congestion and pulmonary edema.

Volumes of Body Fluid

Total body water can be determined by dilution of various substances including deuterium, tritium, and antipyrine. Total body water measured with antipyrine in hospitalized adults without fluid and electrolyte disorders is about 54% of the body weight. The fractional water content is higher in infants and children and decreases progressively with aging. The water content also depends on the body content of fat; women and obese persons, because of their higher fat content, tend to have less water for a given weight.

A useful short cut for calculation of total body water, using the fact that 54% of body weight in kg is body water, and 1 kg is 2.2 lb, is:

$$\text{Total body water (L)} = \text{Body weight (lb)}/4$$

For an obese subject, subtract 10% from the calculated body water, and for a lean person add 10%. For a very obese person, subtract 20%. Women have about 10% less body water than men for the same body weight.

Extracellular volume is measured directly, and the intracellular volume is estimated as the difference between total body water and extracellular volume. Measurement of total body water by dilution techniques is reproducible and reliable, but measurement of extracellular volume is not, because different markers have different volumes of distribution. Markers such as sodium, chloride, and bromide penetrate the cells to some extent, whereas markers such as mannitol, inulin, and sucrose do not penetrate certain parts of the ECF. Thus, depending on the type of marker used, ECF volume could vary from 27 to 53% of total body water ([Table 6.1](#)).

Intracellular volume	24 L (60%)
Extracellular volume	16.0 L (40%)
Interstitial volume	11.2 L (28%)
Plasma volume	3.2 L (8%)
Transcellular volume	1.6 L (4%)

^aA normal man weighing 73 kg (160 lb) with 40 L of total body water is used as a model.

Table 6.1 Volumes of Body Fluid Compartments^a

Extracellular volume measured with chloride and expressed as percentage of total body water varies from 42 to 53%, greater in older subjects and women. Extracellular volumes measured with inulin and sulfate are smaller, about 30 to 33% of total body water. For clinical application, a value of 40% of total body water will be considered to represent extracellular volume. Extracellular volume is further divided into three fractions: interstitial volume (28% of total body water), plasma volume (8%), and transcellular water volume (4%). Transcellular water includes luminal fluid of the gastrointestinal tract, the fluids of the central nervous system, fluid in the eye as well as the lubricating fluids at serous surfaces ([Table 6.1](#)).

Composition of Body Fluid

Extracellular Composition

The concentrations of electrolytes in plasma are easily measured and their values are well known. These concentrations increase by about 7% when expressed in plasma water, because about 7% of plasma is solids. Thus, plasma sodium is 140 meq/L but the concentration in plasma water is 151 meq/L. The concentrations of electrolytes in interstitial fluid differ from those in plasma because of differences in protein

concentrations between plasma and interstitial fluid. The actual differences in electrolyte concentrations can be predicted by the Donnan equilibrium. With normal plasma protein concentrations, the concentrations of diffusible cations are higher in plasma water than in interstitial water by about 4%, while the concentrations of diffusible anions are lower in the plasma than in the interstitium by the same percentage. The concentrations of calcium and magnesium in the interstitial fluid are lower than the values predicted by the Donnan equilibrium, because these ions are substantially protein bound.

Interstitial fluid consists of two phases, the free phase and the gel phase. The latter is invested with a fibrous meshwork that is largely made up of collagen fibers that hold the cells together. A ground substance consists of glycosaminoglycans, which also limit the mobility of water, holding some of the bound water in an icelike lattice. That part of the interstitial fluid in the free form is what we usually regard as the free “interstitial fluid,” which is a route for water and solutes from capillaries to lymphatics.

Intracellular Composition

While sodium, chloride, and bicarbonate are the main solutes in the ECF, potassium, magnesium, phosphate, and proteins are the dominant solutes in the cell. The intracellular concentrations of sodium and chloride cannot be measured accurately because of technical difficulties and are estimated by subtracting the extracellular amount from the total tissue value. Since concentrations of electrolytes in the ECF are high, a small error in extracellular water volume measurement causes a large error in the measurement of intracellular concentration of these ions. The concentration of bicarbonate is calculated from cell pH, and the bicarbonate concentration shown in [Table 6.2](#) is based on the assumption that average cell pH is 7.0.

	Plasma		Interstitial Fluid		Plasma Water		Cell Water in Muscle	
	(meq/L)	(mmol/L)	(meq/L)	(mmol/L)	(meq/L)	(mmol/L)	(meq/L)	(mmol/L)
Na ⁺	140	140	140.1	140.1	140.0	140.0	13	13
K ⁺	4.5	4.5	4.7	4.7	4.8	4.8	140	140
Ca ²⁺	5.0	2.5	2.8	2.8	5.2	5.2	1×10^{-1}	0.5×10^{-1}
Mg ²⁺	1.7	0.85	1.0	0.5	1.8	0.9	3.0	3.5
Cl ⁻	104	104	104.7	104.7	101.4	101.4	3	3
HCO ₃ ⁻	24	24	26.5	26.5	25.7	25.7	10	10
SO ₄ ²⁻	1	0.5	1.2	0.6	1.1	0.6	—	—
Phosphate	2	1.2 ^a	2.3	1.3 ^a	2.2	1.2 ^a	10 ^b	5 ^b
Protein	15	1	8	0.5	16	1	40	2.5 ^c
Organic anions	5	9 ^d	5.6	10 ^d	5.2	10 ^d	—	—

^aThe calculation is based on the assumption that the pH of the interstitial fluid is 7.4 and the pH of the cell is 7.0.
^bThe intracellular concentration of phosphate is calculated with the assumption that the pH of the cell is 7.0 and the interstitial pH is 7.4.
^cThe calculation is based on the assumption that each millimole of intracellular protein has an average 15 meq/L, for the reason that proteins in red blood cells are 150 meq/L.
^dThe assumption is that all the organic anions are of anions.

Table 6.2 Electrolyte Concentrations in Extracellular and Intracellular Fluids

The electrolyte composition of intracellular fluid is not identical throughout the tissues. For example, the concentration of chloride in muscle is very low, about 3 meq/L, but it is 75 to 80 meq/L in erythrocytes. The concentration of potassium in the muscle cell is

about 140 meq/L, but in the platelets only about 118 meq/L. The concentration of sodium in muscle and red blood cells is about 13 meq/L, but in leukocytes, about 34 meq/L. Because muscle represents the bulk of the body cell mass, it is customary to use the electrolyte concentration of the muscle cells as representative of the intracellular electrolyte concentration.

Because a substantial part of the anions inside the cell consists of polyvalent ions such as phosphate and protein, a total ionic concentration in the cell in meq/L is higher than that of the ECF, but osmolal concentrations of the extracellular and intracellular fluid are the same.

Osmolar Relations and Regulation

Measurement of Plasma Osmolality

The plasma osmolality can be measured with an osmometer or estimated as the sum of the concentration of all the solutes in the plasma. Because an osmometer does not distinguish between effective osmols and ineffective osmols, effective osmolality can only be estimated. Urea is the only ineffective osmol that has substantial concentration in the plasma. Still, its normal concentration is only 5 mosm/L. In the normal plasma, therefore, total osmolality is nearly equal to effective osmolality. Plasma osmolality is estimated as follows:

$$\text{Plasma osmolality} = \text{Plasma Na (meq/L)} \times 2 + \text{glucose (mg/dL)}/18 + \text{urea (mg/dL)}/2.8.$$

Many of the solutes that may accumulate abnormally in the body are anions of an acid (e.g., salicylate, glycolate, formate, lactate, b-hydroxybutyrate). These substances should not be added in estimating plasma osmolality, since they are largely balanced by sodium and therefore already included in the value when plasma sodium is multiplied by 2.

Nonelectrolyte solutes that accumulate abnormally in the serum, e.g., ethanol, isopropyl alcohol, ethylene glycol, methanol, and mannitol, will cause the measured osmolality to exceed the calculated osmolality, producing an osmolal gap. This osmolal gap is frequently a useful clinical clue to the presence of the toxic substances listed above. Accumulation of neutral and cationic amino acids can also cause a serum osmolal gap.

Control of Intracellular Volume: Concept of Effective Osmolality

When the osmolal concentration of the ECF increases by accumulation of solutes that are restricted to the ECF (e.g., glucose, mannitol, and sodium), osmotic equilibrium is reestablished as water shifts from the cell to the ECF, increasing intracellular osmolality to the same level as the extracellular osmolality. When the extracellular osmolality increases by accumulation of solutes that can enter the cell freely (e.g., urea and alcohol), the osmotic equilibrium is achieved by entry of those solutes into the cell. Such solutes are ineffective osmols. Since most of the solutes normally present in the ECF

are effective osmols, loss of extracellular water will increase effective osmolality and hence cause water to shift from the cells. Reduction in extracellular osmolality either by loss of normal extracellular solutes or by retention of water reduces effective osmolality for the same reasons and hence causes water to shift into the cells.

Effect of Hyperglycemia on Serum Sodium. The permeability of a membrane for a given solute varies with the cell type. For example, glucose does not accumulate in the muscle. It does not enter the muscle cell freely, and when it enters the cell with the help of insulin, it is quickly metabolized. Thus, glucose is an effective osmol for the muscle cell (i.e., hyperglycemia will cause water to shift from the muscle cell). On the other hand, glucose is an ineffective osmol for red blood cells and liver and kidney cells, because it enters these cells freely. Glucose is generally categorized as an effective osmol because the muscle cells represent the largest body cell mass. Glucose enters some of the brain cells.

Accumulation of glucose or mannitol in the ECF is a well-known cause of hyponatremia. The relationship between change in serum sodium level and change in glucose concentration in a normal adult is about 1.5 meq/L of Na for 100 mg/dL of glucose. This figure is valid, however, only when the volume of distribution of glucose is somewhere between 40 and 50% of total body water. As the volume of distribution of glucose increases, the effect of glucose on serum sodium decreases progressively. Decreased volume of distribution of glucose has an opposite effect. The change in serum Na caused by hyperglycemia can be estimated with the following formula:

$$DNa \text{ (meq/L)} = (5.6 - 5.6a)/2,$$

where DNa is a reduction in serum Na in meq/L for each 100-mg increase in glucose, and *a* is the fraction of the volume of glucose distribution over total body water.

With marked expansion of extracellular volume (e.g., congestive heart failure and other edema-forming states), the volume of distribution of glucose represents a much greater fraction of total body water, and hence a fall in serum sodium caused by hyperglycemia would be much less than usual. For example, when the volume of distribution of glucose is 80% of total body water (0.8), the decrease in serum Na for 100 mg/dL rise in glucose would be only about 0.55 meq/L; $(5.6 - 5.6 \times 0.8)/2 = 0.55$. When the glucose volume is 20% of total body water, DNa would be 2.2 meq/L for 100 mg/dL increase in glucose.

Concept of Tonicity

In the strict sense, the tonicity of a solution is expressed only in reference to a physiologic system: a hypertonic solution is one that shrinks the cells, while a hypotonic solution causes them to swell. Tonicity may also be used to compare a given physiologic state with the normal state. The body fluid is called hypertonic if effective osmolality is increased, causing dehydration of the cells. When the term *tonicity* is applied to a fluid in vitro, it is used almost interchangeably with total osmolality. Thus, a solution that contains a high concentration of urea is called hypertonic. Similarly, urine is

said to be hypertonic if its osmolality is high, regardless of the nature of its solute.

Osmolality and Specific Gravity

Whereas osmolality of fluid depends on osmolal concentration of its solute, specific gravity is determined by the weight of the solute relative to the volume it occupies in solution. Plasma protein contributes little to osmolality because of its low molal concentration, but it is the major factor determining specific gravity of plasma. Urinary specific gravity and osmolality usually change in parallel, but discrepancy between the two occurs with heavy proteinuria and severe glycosuria.

Signs and Symptoms of Abnormal Cell Volume and Electrolyte Concentrations

A variety of signs and symptoms appear with an increase or decrease in effective osmolality, which is accompanied by a reciprocal change in intracellular volume. Whether these manifestations are caused by abnormal cell volume or abnormal tonicity is not clearly known. Some clinical manifestations are probably caused by cell swelling and shrinkage.

In contrast, some cerebral manifestations of hyper- and hypoosmolality may persist even after the brain cell volume has been restored to normal. Since restoration of normal brain cell volume may not normalize electrolyte concentration, the persisting signs and symptoms may be attributed to abnormal electrolyte concentration in the brain cells rather than to the abnormal brain cell volume. The fact that some of the most serious cerebral manifestations of altered osmolality are related to brain cell volume and that brain cells have the capacity to regulate their volume with time may help explain why the rapidity as well as the extent of alteration in osmolality are important determinants of severity of symptoms.

Signs and Symptoms of Hypoosmolality. For obvious reasons, hypoosmolality without hyponatremia is physiologically impossible. There is no evidence that a reduced concentration of sodium ion in the extracellular fluid, without low effective osmolality, causes any adverse effect, except in the presence of severe hyperkalemia. Thus, when hyponatremia is caused by hyperglycemia or mannitol administration, the signs and symptoms are those of hyperosmolality and cell dehydration. When moderate hyponatremia is caused by salt depletion, some of the symptoms such as easy fatigability and muscle cramps and spasms attributed to hyponatremia, may be due at least in part to reduced effective vascular volume.

Most of the signs and symptoms of hyponatremia, which include nausea, vomiting, headache, papilledema, and mental confusion, originate in the central nervous system and are clearly due to brain swelling and increased intracranial pressure. Lethargy, weakness, hyper- and hyporeflexia, delirium, coma, psychosis, focal weakness, ataxia, aphasia, generalized rigidity, and seizure are probably caused by increased cell volume and reduced electrolyte concentration of the brain cells.

Gastrointestinal manifestations include abdominal cramps, temporary loss of sense of

taste and flavor, decreased appetite, nausea, vomiting, salivation, and paralytic ileus. Cardiovascular effects of hypoosmolality are usually manifested as hypotension and other signs of low effective vascular volume. Hyponatremia can also be accompanied by muscle cramps, twitching, and rigidity, but these muscular manifestations may still result from hypoosmolality.

Signs and Symptoms of Hyperosmolality. Increased effective osmolality need not be accompanied by hypernatremia. Accumulation of effective solutes other than sodium salts in the extracellular fluid can cause hyperosmolality and cell dehydration but may be accompanied by normal or low serum sodium concentration. However, hypernatremia is always accompanied by hyperosmolality and cell dehydration. Since alteration of the concentration of sodium ion does not produce profound physiologic effects, any clinical signs and symptoms of hypernatremia are likely to be those of hyperosmolality and cell dehydration. Hence, if hyperosmolality is caused by glucose, mannitol, or glycerol, clinical manifestations will mimic those of hypernatremia despite the low serum sodium concentration.

As in the hypoosmolal states, the symptoms and signs of hyperosmolality depend on the rapidity of its development as well as the severity of hyperosmolality. A patient may be comatose when the serum sodium reaches 160 meq/L rapidly, whereas the patient may remain conscious with a serum sodium concentration of 190 meq/L if hypernatremia occurs gradually.

Most of the symptoms and signs of hyperosmolality are those that originate in the central nervous system. Acute hyperosmolality due to hypernatremia both in human subjects and in animals can lead to subdural, cortical, and subarachnoid hemorrhages because of sudden shrinkage of the brain cells. Depression of mental state ranges from lethargy to coma. Generalized seizure is also observed, although somewhat less commonly than in hypoosmolality. Muscular symptoms of hyperosmolality include muscular rigidity, tremor, myoclonus, hyperreflexia, spasticity, and rhabdomyolysis. In children, spasticity, chronic seizure disorder, and retardation of mental development may occur with chronic hyperosmolality.

Regulation of Intracellular Volume

When cells swell in response to extracellular hypoosmolality, the regulatory mechanism that works to reduce cellular solute content and thereby reduce their volume is referred to as volume regulatory decrease (VRD). In shrunken cells, the volume regulatory mechanisms work to increase the solute content of the cells and thereby increase their volume; this process is termed volume regulatory increase (VRI). Most cells are capable of volume regulation with both VRD and VRI. In contrast, the muscle cells do not have volume regulatory mechanisms.

Red blood cells of all species studied so far have shown a capacity to regulate the cell volume, but different species seem to use different mechanisms for volume regulation. In general, VRD in blood cells is achieved by loss of electrolytes, namely NaCl and KCl. The initial defense against brain swelling in hyponatremia also seems to include osmotic inactivation as well as osmotic disequilibrium; the brain osmolality is significantly higher

than that of serum in animals made acutely hyponatremic in 2 hours.

As in the case of VRD, different species use different mechanisms to achieve VRI. VRI is accounted for by increases in Na, K, and Cl but also by other osmols, which have been collectively termed *idiogenic osmols*. However, since the nature of most of these osmols is now well known, such terminology is inappropriate.

The total contribution of electrolytes to the changes in tissue osmolality in the presence of hyperosmolality is estimated to be about 50 to 60%, and the remainder is accounted for by organic solutes. There are three major classes of organic substances that participate in VRI: polyols (sorbitol and myoinositol), methylamines (betaine and glycerophosphotidylcholine), and amino acids (taurine, glutamine, glutamic acid, aspartic acid). Among the organic solutes, amino acids are most important for VRI.

Unlike the muscle cells whose volumes remain chronically altered as long as effective osmolality is abnormal, brain cells can restore the volume to normal when effective osmolality remains chronically altered ([Fig. 6.1](#) and [Fig. 6.2](#)). In acute hyponatremia, the brain cell volume is initially increased. If the hypoosmolal state persists, the brain cell volume is normalized over a few days, as the cellular solute content decreases. Sudden normalization of osmolality from a chronic hypoosmolal state then causes extracellular shift of water and hence shrinkage of the brain to a subnormal level. Similarly, in a chronic hyperosmolal state, brain volume is normalized by increasing total solute content of the brain, and a sudden reduction in osmolality from a chronic hyperosmolal state can therefore cause brain swelling.

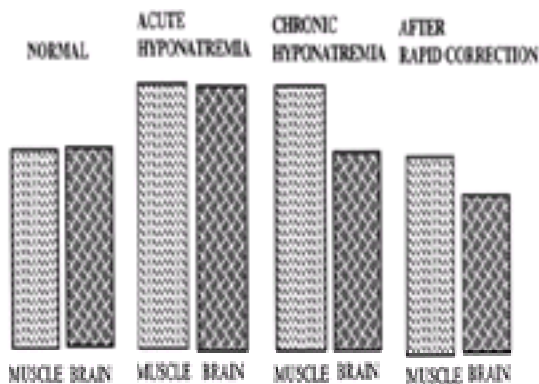

Figure 6.1. Cell volume regulation in hyponatremia. Note that both brain and muscle cell volume are increased in acute hyponatremia; in chronic hyponatremia, brain cell volume returns to normal, while muscle cell volume remains increased. With rapid correction of hyponatremia, muscle cell volume returns to normal, and brain becomes dehydrated.

Figure 6.2. Cell volume regulation in hypernatremia. In acute hypernatremia, both muscle and brain cell volumes are reduced; in chronic hypernatremia, brain volume returns to normal. Rapid correction of hypernatremia normalizes muscle cell volume but causes brain edema.

Regulation of Extracellular Volume

Because the extracellular sodium concentration is maintained within a fairly narrow range through regulation of antidiuretic hormone (ADH) release, the extracellular volume depends primarily on its sodium content. In most clinical situations, the extracellular volume correlates well with vascular volume, which in turn correlates positively with the effective vascular volume, an imaginary volume that correlates with the cardiac output in relation to the tissue's demand for oxygen.

Hence, the main efferent mechanisms for regulation of extracellular volume are designed to sense the changes in effective vascular volume rather than the extracellular volume or vascular volume. This situation sometimes leads to a pathologic retention of salt. For example, salt is retained in congestive heart failure despite markedly expanded extracellular volume and vascular volume, because *effective* vascular volume is reduced.

Theoretically, there are two ways to alter the salt content of the body: to alter the intake of salt and to alter renal salt output. There is no well-developed mechanism to change the behavior of salt intake in response to changes in effective vascular volume. Thus, the salt content of the body is altered primarily through changes in renal salt output, which can be achieved through physical and humoral factors. The physical factors for renal salt regulation work through changes in glomerular filtration rate (GFR) or changes in peritubular capillary oncotic and hydrostatic pressures. Humoral factors work primarily through their effects on renal tubular salt reabsorption, either by increasing or decreasing it, but they can also work via effects on physical factors. [Figure 6.3](#) shows the nomenclature of the nephron sites, and [Figure 6.4](#) summarizes various salt reabsorption mechanisms at different nephron sites.

Figure 6.3. Anatomy of nephron. 1, proximal convoluted tubule; 2, proximal straight tubule; 3, thin descending limb of Henle; 4, thin ascending limb of Henle; 5, medullary thick ascending limb of Henle; 6, cortical thick ascending limb of Henle; 7, distal convoluted tubule; 8, cortical collecting duct; 9, outer medullary collecting duct; 10, inner medullary collecting duct.

Figure 6.4. Salt transport in various nephron sites. *Solid*, active salt transport; *diagonal lines*, little salt transport; *horizontal lines*, passive salt transport; *clear areas*, no salt transport.

A number of humoral factors are proven or suggested to participate in regulating renal salt output. Among these, those that have well-proven physiologic effects are aldosterone, catecholamines, angiotensin II, and perhaps ADH and prostaglandins. The proof for the physio-logic relevance of some other hormones such as atrial natriuretic peptide, urodilatin, guanylin, uroguanylin, kallekreins and kinins, insulin, and glucagon is not very convincing at the moment. [Figure 6.5](#) summarizes the regulation of effective

vascular volume by various humoral and physical factors that affect renal output of salt.

Figure 6.5. Regulation of effective vascular volume. Volume depletion leads to net renal salt retention, which in turn leads to restoration of volume. Net renal salt retention is achieved by increased renal salt transport and reduction of GFR. Increased renal salt transport is achieved by activation of humoral agents and physical factors. Among the humoral agents with well-proven physiologic effects are *aldosterone*, *angiotensin II*, *catecholamines*, and *ADH*. Physiologic impact of reduced production or *urodilatin* and *uroguanylin* is unclear. Physical factors that contribute to renal salt retention include decreased *peritubular hydrostatic pressure* and increased *plasma oncotic pressure*. Reduced renal plasma flow results in reduced GFR.

Nonrenal Control of Water and Electrolyte Balance

Water is lost from the skin primarily as a means of eliminating heat. Water loss from the skin without sweat is called insensible perspiration. Sweat contains about 50 meq/L of sodium and 5 meq/L of potassium. Because the main purpose of water loss from the skin is elimination of heat, water loss from the skin depends mainly on the amount of heat generated:

Water loss from the skin = 30 mL per 100 calories.

The water content of inspired air is less than that of expired air; hence, water is lost with respiration. Because the ventilatory volume is determined by the amount of CO_2 production, which is in turn determined by the caloric expenditure, the ventilatory water loss in normal environmental conditions also depends on caloric expenditure:

Respiratory water loss = 13 mL per 100 calories at normal pCO_2 .

By coincidence, the quantity of water lost during normal respiration is about equal to the metabolic water production. Hence, in calculating water balance, respiratory water loss

may be ignored in the measurement of insensible water loss, provided that metabolic water gain is also ignored. Respiratory water loss increases with hyperventilation or fever, disproportionately to metabolic water production.

The net activity of the gastrointestinal (GI) tract to the level of the jejunum is secretion of water and electrolytes. The net activity from jejunum to colon is reabsorption. Most of the fluid entering the small intestine is absorbed there, and the remainder by the colon, leaving only about 100 mL of water to be excreted daily in the feces. The contents of the GI tract are isotonic with plasma, and any fluid that enters the GI tract becomes isotonic via secretion and reabsorption. Thus, if water is ingested and vomited, solute is lost from the body.

Routes of Fluid and Electrolyte Loss

Fluid and electrolytes may be lost from the GI tract for a variety of reasons such as diarrhea, vomiting or gastric drainage, and drainage or fistula from the bile ducts, pancreas, and intestine. Although diarrheal fluid is usually isotonic in terms of cations (Na and K), diarrhea caused by nonabsorbable solutes (e.g., lactulose, mannitol, sorbitol, or disaccharides, as in a patient with disaccharide malabsorption) causes greater water loss than electrolyte loss. Diarrheal fluid usually contains substantial amounts of bicarbonate and potassium; hence diarrhea tends to cause metabolic acidosis and hypokalemia. Because vomitus contains HCl, vomiting tends to produce metabolic alkalosis. The amount of HCl depends on the rate of acid secretion; when acid secretion is maximally stimulated, the concentration of HCl is about 100 meq/L. Because gastric fluid contains little Na in relation to water, vomiting without fluid intake tends to cause hypernatremia.

Obstruction of the bowel may cause transfer of fluid from the extracellular space into the intestinal lumen. Since the composition of the sequestered fluid is similar to that of the extracellular fluid, effective arterial volume will be reduced without much alteration in composition. The patient may give evidence of extracellular volume depletion without weight loss.

The loss through skin increases with fever, increased metabolism, sweating, and burns. The fluid lost through the skin is markedly hypotonic.

Water is lost through the lung with ventilation, and the amount depends on the ventilatory volume. Fever and hyperventilation increase water loss through the lung.

The kidney may lose sodium excessively in a number of situations, including diuretic therapy, aldosterone deficiency or unresponsiveness, and relief of urinary tract obstruction.

Miscellaneous losses include drainage from the pleural and peritoneal cavity, seepage from burns and transected lymphatics, and fluid loss during hemo- and peritoneal dialysis.

Types of Dehydration

Depending on the quantity of salt loss in relation to water loss, several types of dehydration are encountered. The net alteration in body composition is determined by the sum of the losses and gains. The net change in dehydration may be (a) isotonic dehydration, in which net salt and water loss are equal; (b) hypertonic dehydration, with loss of water alone or water in excess of salt; or (c) hypotonic dehydration, in which salt loss exceeds water loss ([Fig. 6.6](#)).

Figure 6.6. Changes in extracellular volume (*ECV*) and intracellular volume (*ICV*) in different types of dehydration. Note that for the same amount of total body water loss, *ECV* is lowest in hypotonic dehydration.

Isotonic Dehydration. Salt may be lost isotonicly through the GI tract or directly from the ECF by aspiration of pleural effusion, ascites, etc. With GI fluid loss, salt is lost with an equal or larger water loss, and the osmolality of the body fluids is subsequently adjusted to isotonicity by oral intake of salt or urinary excretion of water. Isotonic fluid loss is borne completely by the extracellular fluid space. Treatment calls for isotonic salt solution.

Hypertonic Dehydration. The primary aberration in hypertonic dehydration is water deficit. Two major mechanisms account for abnormal water deficit: inadequacy of water intake and excessive water loss. Dehydration due to excessive water loss usually develops more rapidly than that due to reduced water intake. Inadequacy of water intake is always caused by either (a) defective thirst due to a defective thirst center or impaired consciousness or (b) lack of water or an inability to drink water.

Water loss may occur through the kidney (e.g., osmotic diuresis and diabetes insipidus) or through the nonrenal routes (e.g., sweating, osmotic diarrhea, vomiting of HCl). Loss of HCl with water is almost equivalent to the loss of pure water for the Na balance, since

it leaves sodium bicarbonate behind replacing sodium chloride in the ECF.

Even when excessive water loss is the cause of hypertonic dehydration, one of the conditions that limit water intake must be present to maintain hypertonicity. Otherwise, stimulation of thirst by increased osmolality will lead to increased water drinking and correction of the hypernatremia.

Salt content of the body in hypertonic dehydration may be normal, increased, or decreased, and the extent of extracellular volume depletion depends on the degree of salt retention. On the other hand, intracellular volume depletion depends solely on the magnitude of hypertonicity. Salt administered or ingested in a state of water deficit is retained, resulting in increased salt content in the body.

The water required to lower the serum sodium concentration to a desired level can be determined with the following formula:

$$\text{Water requirement} = (\text{actual Na/goal Na} - 1) \times \text{TBW} = \text{DNa/goal Na} \times \text{TBW}$$

where DNa is the difference between the actual and goal sodium concentration.

Water requirement calculated using this formula is based on the assumption that water is lost without gain or loss of salt. If salt retention is part of the reason for the hypernatremia, administering the total amount calculated by the above formula will overexpand volume. However, if the kidney is functioning normally, the excess salt and water will be excreted.

Rapid correction of hypernatremia to normal levels offers no advantage and is potentially harmful, as it may cause brain edema. It is advisable to reduce serum sodium at a rate no greater than 0.7 meq/L/h, or 10% of actual serum Na per day; in acute hypernatremia, the speed of correction can be faster.

Hypotonic Dehydration. Fluids lost from the body, especially GI tract loss, are almost always either hypotonic or isotonic in relation to serum sodium concentration, and loss of such fluid cannot cause hypotonicity of body fluid. Hypotonic dehydration usually occurs because the patient loses a salt solution and replaces it with water or with a solution containing less sodium and potassium than the fluid that has been lost.

In the presence of normal renal function, net loss of salt alone is difficult to achieve because the resultant hyponatremia would suppress ADH, resulting in water loss. Decreased effective vascular volume then causes the release of ADH to prevent further depletion of the extracellular volume, and hyponatremia develops.

Hypoosmolality of the ECF causes a shift of water into the cells to achieve osmotic equilibrium. Hence cell volume is increased despite extracellular volume contraction. Patients with hypotonic dehydration may thus show more evidence of compromised circulation for a given degree of body water loss than do patients with isotonic or hypertonic dehydration ([Fig. 6.6](#)). In addition, acute hyponatremia per se may also

diminish vascular tone and cardiac output.

Hypotonic dehydration may be treated by estimating the amount of salt needed to restore the osmolality of the body fluids to normal, administering this amount of salt in the form of hypertonic saline, and adding normal saline to restore the extracellular volume. The sodium requirement to increase serum sodium concentration is calculated with the following equation:

$$\text{Na requirement} = \text{DNa} \times \text{TBW (in L)},$$

where DNa is desired serum Na – actual serum Na.

Even though the administered sodium would be distributed mainly in the ECF, total body water is used for this calculation because an increase in serum Na is accompanied by an exactly proportionate increase in serum osmolality ($\text{Na} \times 2 = \text{osmolality}$). Estimation of the amount of solutes required to increase serum osmolality must always be based on total body water, because extracellular osmolality cannot be increased without increasing intracellular osmolality to the same extent.

As an alternative therapeutic approach, one can raise serum Na levels with isotonic or hypotonic saline; as ECF volume increases, ADH is suppressed; as free water is excreted, serum sodium levels return to normal. This approach is recommended in patients who suffer more from hypovolemia than from hypotonicity. In patients with chronic hyponatremia, rapid correction of hyponatremia may be particularly dangerous because of the possible occurrence of central pontine myelinolysis, a demyelinating disease primarily of the central pons, which causes severe motor nerve dysfunction, e.g., quadriplegia. This complication is more likely to occur with rapid treatment of chronic hyponatremia than with acute hyponatremia. The complication may be avoided by increasing serum sodium more slowly (no faster than 8 meq/24 h; about 0.35 meq/h). Although hypertonic saline is the main culprit, administration of isotonic saline may also cause rapid correction of hyponatremia and central pontine myelinolysis.

Principles of Fluid Therapy

Goals of Salt and Water Replacement. The goal of therapy is to restore the patient to a state of normal hemodynamics and normal body fluid osmolality. There are several components in the program of water and electrolyte therapy: (a) existing deficits must be identified and made up; (b) daily basal requirements for sodium, potassium, and water must be supplied; and (c) ongoing losses must be quantified and provided for. Short-term parenteral therapy does not require inclusion of calcium, phosphate, and magnesium.

Basal Requirements. The basal requirement for water depends on sensible (urinary) and insensible losses of water. Fever increases respiratory water loss by increasing the vapor pressure of the expired air and increases loss of water from the skin by increasing the vapor pressure on the skin surface and the basal metabolic rate. Urinary loss of water depends on the total amount of solute excreted and urine osmolality. Solute

excretion depends mainly on salt ingestion and protein intake, but sometimes the water requirement may be increased by severe glycosuria.

Daily Water Requirements. In the absence of fever and sweating, water loss through the skin is relatively fixed, but urinary water excretion varies greatly and depends on the total amount of solute to be excreted and urine osmolality. For example, if the total solute excretion is 600 mosm/day, the urine volume will be 500 mL if urine is concentrated to 1200 mosm/L and 15 L if urine osmolality is 40 mosm/L. For such a person, the minimum water requirement would be 1100 mL (500 mL for urinary water loss plus 600 mL for skin water loss at 2000 cal/day). On the other hand, the maximal allowable water intake would be 15.6 L. If the concentration mechanism is impaired and the kidney can increase urine osmolality to only 600 mosm/L, the minimum water requirement would be 1.6 L. Similarly, impaired urine dilution reduces the maximum allowable water intake. If urine can be diluted to only 300 mosm/L, the maximal allowable water intake decreases to 2.6 L ($600/300 + 0.6$).

Clearly, in the absence of abnormal urine concentration and dilution, a large range of water intake causes neither dehydration nor overhydration. However, for a variety of reasons, underestimating water requirement is safer than overestimating. First, the excessive amount of water gained with impaired urine dilution tends to be greater than the water deficit resulting from impaired urine concentration. Second, clinically, impaired urine dilution (e.g., syndrome of inappropriate ADH secretion [SIADH]) is more common than impaired urine concentration. Finally, if the patient is conscious, hypernatremia has thirst as an effective defense mechanism, whereas patients with severe hyponatremia often lapse into coma without warning.

Clinical problems and answers for this section are presented before the selected readings.

DISORDERS OF POTASSIUM METABOLISM

Total body K^+ in hospitalized adults is about 43 meq/kg body weight, and only about 2% of this is found in the ECF. The gradient of K concentration across the cell membrane determines the membrane potential (E_m) according to the Nernst equation:

$$E_m = -60 \log \text{intracellular } K^+ / \text{extracellular } K^+$$

Intracellular K^+ /extracellular K^+ is normally about 30, and therefore the normal E_m is -90 mv.

The membrane potential tends to increase with hypokalemia and to decrease with hyperkalemia. In hypokalemia, both intra- and extracellular K^+ tend to decrease, but the extracellular concentration tends to decrease proportionately more than the intracellular concentration. Hence, intracellular K^+ /extracellular K^+ tends to increase. In hyperkalemia, this ratio tends to decrease for the same reason.

Potassium Flux and Excretion

Control of Transcellular Flux of Potassium

Transmembrane electrical gradients cause diffusion of cellular K^+ out of cells and Na^+ into cells. Since the Na^+-K^+ ATPase pump, which reverses this process, is stimulated by insulin and β -catechols (through β_2 -adrenergic receptors), alterations in levels of these hormones can affect K^+ transport and its serum levels. Efflux of K^+ can also be stimulated by acidosis and a rise in effective osmolality (Fig. 6.7). The effect of acidosis and alkalosis on transcellular K^+ flux depends not only on the pH but also on the type of anion that accumulates. In general, metabolic acidosis causes greater K^+ efflux than respiratory acidosis. Metabolic acidosis due to inorganic acids (e.g., sulfuric acid and hydrochloric acid) causes greater K^+ efflux than that due to organic acids (e.g., lactic acid and keto acids). Acidosis causes efflux of K^+ from the cell because of a shift of H^+ into the cell in exchange for K^+ . A modifying factor appears to be the anion accumulation in the cells. In organic acidosis, much H^+ entering the cell is balanced by organic anions, lactate and ketone anions, and therefore efflux of K^+ is prevented. In respiratory acidosis, bicarbonate accumulates in the cell to balance the incoming H^+ . Alkalosis tends to lower serum K^+ levels. As with acidosis, K^+ influx varies with the type of alkalosis. In respiratory alkalosis, probably because of a drop in cellular bicarbonate concentration, K^+ influx is lower than in metabolic alkalosis. When pH is kept normal with increased concentration of bicarbonate and pCO_2 , K^+ tends to move into the cells; accumulation of bicarbonate in the cell must be accompanied by Na^+ and K^+ . Similarly, when pH is kept normal with low bicarbonate and low pCO_2 , K^+ tends to move out of the cells.

Figure 6.7. Transcellular shift of potassium.

Control of Renal Excretion of Potassium

About 90% of the daily K^+ intake (60–100 meq) is excreted in the urine, and 10% in the stools. Potassium filtered at the glomerulus is largely (70–80%) reabsorbed by active and passive mechanisms in the proximal tubule. In the ascending limb of Henle's loop, K^+ is further reabsorbed together with Na^+ and Cl^- , so that a very small amount is delivered into the distal nephron. The K^+ appearing in the urine is largely what has been secreted into the cortical collecting duct by mechanisms shown in [Figure 6.8](#).

Figure 6.8. Factors that regulate K^+ secretion in the collecting duct include high concentrations of plasma aldosterone, increased delivery of Na^+ to the nephron site, increased urine flow, hyperkalemia, and increased concentrations of poorly reabsorbable anions such as sulfate and bicarbonate. Alkaline luminal pH also stimulates K^+ secretion.

Na^+-K^+ ATPase located on the basolateral side of the cortical collecting duct pumps K^+ into the cell while it pumps Na^+ out of the cell. Luminal Na^+ enters the cell through Na^+ channels, providing a continuous supply of Na^+ . Because Na^+ that has entered the cell and is then pumped out to the peritubular space is not followed one to one by Cl^- , an excess negative charge develops in the lumen, and K^+ is passively secreted through specialized K^+ channels to balance this charge. Aldosterone increases K^+ secretion by increasing passive entry of Na^+ from the lumen to the cell, thereby stimulating Na^+-K^+ ATPase activity. Aldosterone also stimulates Na^+-K^+ ATPase activity directly and increases passive K^+ secretion by enhancing the activity of the K^+ channel. The peritubular K^+ concentration and pH also influence K^+ secretion through their effects on Na^+-K^+ ATPase activity. High serum K^+ concentration and alkaline pH stimulate the enzyme activity, and low serum K^+ and acidic pH inhibit the activity.

Anions that accompany Na^+ and that penetrate the tubular membrane less readily than Cl^- allow greater luminal negativity and hence greater K^+ secretion. Examples of such

anions include sulfate, bicarbonate, and anionic antibiotics such as penicillin and carbenicillin. Bicarbonate in the tubular fluid has an additional effect of enhancing potassium secretion apart from being a poorly reabsorbable anion. The luminal bicarbonate concentration is the main determinant of the luminal pH in the cortical collecting duct, and a high luminal bicarbonate concentration, through its effect on pH, increases K^+ secretion by the enhanced luminal K^+ channel activity. A marked increase in renal K^+ excretion in patients who vomit may be explained by this mechanism. ADH also appears to increase luminal K^+ channel activity. If tubular K^+ is washed away by rapid urine flow, more K^+ is secreted to satisfy the electrical gradient. Renal K^+ wasting during osmotic diuresis could be explained by this mechanism. The more Na^+ is presented to the distal nephron, the more can be absorbed and more K^+ secreted "in exchange." Increased Na^+ delivery to the collecting duct also increases renal K^+ excretion by its effect on urine flow. [Figure 6.8](#) summarizes factors that influence K^+ secretion in the collecting duct.

Plasma Renin Activity (PRA), Plasma Aldosterone Concentration (PA), and Abnormalities in K^+ Metabolism

Because abnormalities in PRA and PA are frequently either responsible for, or caused by, abnormalities in K^+ metabolism, it is important to understand their relationships. In general

1. Expansion of effective arterial volume caused by primary increase in aldosterone (primary aldosteronism) or by other mineralocorticoids suppresses PRA; when mineralocorticoids other than aldosterone are present in excess, they retain salt and water, and the resulting volume expansion suppresses both PRA and PA
2. Increased PRA always increases PA (secondary aldosteronism), unless the rise in PRA is caused by a primary defect in aldosterone secretion; PRA may be high because of
 - a. volume depletion secondary to renal or extrarenal salt loss
 - b. abnormality in renin secretion (e.g., reninoma [hemangiopericytoma of afferent arteriole], malignant hypertension, renal artery stenosis)
 - c. increased renin substrate production (e.g., oral contraceptives)
3. When renin is deficient primarily, aldosterone is always low (e.g., hyporeninemic hypoaldosteronism)
4. Elevated serum K^+ levels can directly stimulate the adrenal cortex to release aldosterone

Hypokalemia

Causes and Pathogenesis

Because the intracellular K^+ concentration greatly exceeds the extracellular concentration, K^+ shift into the cell can cause severe hypokalemia with little change in its intracellular concentration ([Table 6.3](#)). Alkalosis, insulin, and b_2 -agonists can cause hypokalemia by stimulating Na^+-K^+ ATPase activity. The mechanism of cellular K^+

accumulation in periodic paralysis is not clearly understood. In barium poisoning, K^+ accumulates in the cell, and hypokalemia develops because inhibition of the K^+ channel by barium prevents K^+ efflux from the cell in the face of continuous cellular uptake of K^+ through the action of Na^+-K^+ ATPase. K^+ accumulates in the cell along with anions as the cell mass increases during nutritional recovery, because K^+ is the main intracellular cation. Poor intake of K^+ by itself rarely causes hypokalemia, because poor intake of K^+ is usually accompanied by poor caloric intake, which causes catabolism and release of K^+ from the tissues.

Intracellular shift (e.g., alkalosis, periodic paralysis, β_2 -agonists, barium poisoning, insulin, nutritional recovery state)
Poor intake
Gastrointestinal loss (e.g., vomiting, diarrhea, drainage, laxative abuse)
Excessive renal loss
1° Aldosteronism (adrenal adenoma or hyperplasia); PRA is suppressed
2° Aldosteronism (the rise in aldosterone is secondary to rise in renin)
Malignant hypertension, renal artery stenosis, reninoma
Diuretics
Bartter's syndrome, Gitelman's syndrome
Excess mineralocorticoids other than aldosterone (e.g., Cushing's syndrome, ACTH-producing tumor, licorice)
Chronic metabolic acidosis (e.g., type I and type II RTA)
Delivery of poorly reabsorbed anions to the distal tubule (e.g., bicarbonate, ketone anions, carbenicillin)
Miscellaneous causes: magnesium deficiency, acute leukemia, Liddle's syndrome

Table 6.3 Causes of Hypokalemia

Vomiting and diarrhea are common causes of hypokalemia. Diarrhea causes direct K^+ loss in the stool, but in vomiting, hypokalemia results mainly from K^+ loss in the urine rather than in the vomitus. Vomiting causes metabolic alkalosis, and the subsequent renal excretion of bicarbonate leads to renal K^+ wasting.

Renal loss of K^+ is the most common cause of hypokalemia. Renal K^+ wasting occurs when increased aldosterone concentration is accompanied by adequate distal delivery of Na^+ . In primary aldosteronism, distal delivery of Na^+ increases because increased $NaCl$ reabsorption in the cortical collecting duct by the action of aldosterone inhibits salt reabsorption in the proximal tubule and Henle's loop. In secondary aldosteronism, hypokalemia occurs only in conditions that are accompanied by increased distal Na^+ delivery. Examples include renal artery stenosis, diuretic therapy, and malignant hypertension. Heart failure does not lead to hypokalemia despite secondary aldosteronism unless distal delivery of Na^+ is increased by diuretic therapy.

Bartter's syndrome is caused by defective $NaCl$ reabsorption in the thick ascending limb of Henle, whereas in Gitelman's syndrome, the defect in $NaCl$ reabsorption is in the distal convoluted tubule. Defective Na reabsorption proximal to the aldosterone-effective site results in increased delivery of Na to the cortical collecting duct and hence in hypokalemia. In chronic metabolic acidosis, hypokalemia probably develops because

reduced proximal reabsorption of NaCl allows increased delivery of NaCl to the distal nephron. In licorice, renal K⁺ wasting results from the sustained mineralocorticoid activity of cortisol as licorice inhibits the enzyme 11- β -hydroxy steroid dehydrogenase, which normally rapidly metabolizes cortisol in the kidney. Liddle's syndrome is caused by increased Na⁺ channel activity in the collecting duct; accumulation of Na⁺ in the cell leads to stimulation of Na⁺-K⁺ ATPase activity, resulting in increased K⁺ secretion. [Figure 6.9](#) shows a schematic approach to the differential diagnosis of hypokalemia ([Table 6.3](#)).

Figure 6.9. Differential diagnosis of hypokalemia. The first step is measuring 24-h urine K excretion. If the amount is more than 40 meq/day, it signifies renal wasting of K; less than 20 meq/L suggests an extrarenal cause. Once renal K wasting is suspected, measurement of PRA and plasma aldosterone will help differentiate among different causes of renal K wasting.

Clinical Manifestations

Low serum K⁺ levels lead to characteristic electrocardiographic changes, alterations in cardiac rate, rhythm, and conduction, and to muscle weakness. Depletion of cellular K⁺ leads to a number of structural and functional alterations in a variety of organs. These include skeletal muscle cell necrosis and acute rhabdomyolysis, nephrogenic diabetes insipidus (possibly due to inhibition of ADH by excess prostaglandin), and cardiac cell necrosis. K⁺ depletion is often associated with metabolic alkalosis, in part because K⁺ deficiency leads to increased renal production and retention of bicarbonate. Reduced insulin secretion and reduced intestinal motility are other common disorders of hypokalemia.

Hypokalemia produces abnormalities of rhythm and of rate of electrical conduction in the heart through alteration in several physiologic states. Alteration in ventricular repolarization leads to depression of the S-T segment, flattening and inversion of T waves, and appearance of U waves, the most common ECG abnormalities of hypokalemia. Combinations of altered states of polarization and conduction can produce

arrhythmias, most commonly supraventricular and ventricular ectopic beats and tachycardia, A-V conduction disturbances, and ventricular fibrillation. Rapidly developing hypokalemia is more likely to produce abnormal cardiac function than more slowly developing hypokalemia. Potassium depletion intensifies digitalis toxicity through an unknown mechanism.

Treatment

Hypokalemia is usually treated either by potassium administration or by prevention of renal loss of potassium. Renal loss of potassium is prevented either by treating its cause (e.g., removal of aldosterone-producing adenoma or discontinuation of diuretics) or by administering potassium-sparing diuretics. The potassium-sparing diuretics in current use are aldosterone antagonists (e.g., spironolactone), triamterene, and amiloride. Aldosterone antagonists are effective in preventing renal potassium loss only if an increased mineralocorticoid concentration is responsible for hypokalemia. In Liddle's syndrome, spironolactone is ineffective because plasma aldosterone is reduced; triamterene and amiloride are effective regardless of the plasma aldosterone concentration. The daily dose of spironolactone ranges from 25 to 400 mg. The usual doses of triamterene range from 50 to 150 mg twice daily. Amiloride is administered at 5 mg/day and can be slowly increased up to 20 mg/day; it should be administered with food to avoid gastric irritation. Because reduced delivery of sodium to the distal nephron reduces potassium secretion, a low-salt diet helps reduce renal potassium loss from any cause, independent of the plasma aldosterone concentration.

In a nonemergency setting, potassium should be given orally as potassium chloride, potassium phosphate, or the salt of an organic acid. In the critical care setting, potassium is usually given intravenously and primarily as potassium chloride. The first goal in treating severe hypokalemia is elimination of cardiac arrhythmias. A decline in serum $[K^+]$ of 1 meq/L generally indicates a loss of 150 to 200 meq of potassium and a decline of 2 meq/L, a loss in excess of 500 meq, but the relationship is not rigidly fixed. For example, in acidotic states, serum potassium may be high in the face of potassium depletion.

To initiate rapid intravenous administration of potassium, it may be useful to estimate the number of liters of ECF as body weight in kg \times 0.2. This figure times the desired increment in serum potassium per liter represents the amount of potassium that can be safely given in 20 to 30 minutes without danger of hyperkalemia.

Although it is usually unnecessary to give potassium at a rate greater than 10 to 20 meq/h, a rate in excess of 100 meq/h may be needed in certain life-threatening situations (e.g., a patient with ketoacidosis, severe hypokalemia, and an ECG showing a dangerous arrhythmia). Glucose-containing solution should not be used as a vehicle for KCl when serum K^+ is to be increased rapidly; glucose stimulates insulin release, which, in turn, drives K^+ into cells.

Potassium at concentrations above 40 meq/L may produce pain at the infusion site and may lead to sclerosis of smaller vessels. When a concentration above 100 meq/L is used, a femoral line is preferable. It is advisable to avoid central venous infusion of

potassium at high concentrations; depolarization of the conduction tissues may lead to cardiac arrest.

Hyperkalemia

Causes and Pathogenesis

Hyperkalemia may be caused by one of three mechanisms: (a) shift of potassium from the cells to the ECF, (b) increased potassium intake, and (c) reduced renal potassium excretion ([Table 6.4](#)). Hyperkalemic familial periodic paralysis, administration of succinylcholine in paralyzed patients, administration of cationic amino acids such as e-aminocaproic acid, arginine, or lysine; rhabdomyolysis or hemolysis; and acute acidosis all cause hyperkalemia by extracellular potassium shift. Rhabdomyolysis and hemolysis cause hyperkalemia only when they are accompanied by renal failure.

Pseudohyperkalemia
Thrombocytosis, massive leukocytosis, use of tourniquet with fist exercise, in vitro hemolysis
True hyperkalemia
Due to extracellular shift: acute acidosis (especially inorganic acidosis), catabolic states, periodic paralysis, succinylcholine, cationic amino acids, exercise while using a β -blocker, digitalis intoxication
Due to excessive ingestion: rare if renal excretion of K is normal
Decreased renal excretion
Hypoaldosteronism: Addison's disease; selective hypoaldosteronism (hyporeninemic hypoaldosteronism, heparin, congenital adrenal enzyme deficiencies, angiotensin-converting enzyme inhibitors)
Tubular unresponsiveness to aldosterone (pseudohypoaldosteronism type I and II): congenital, salt-losing nephropathy
Potassium-sparing diuretics
Severe dehydration

Table 6.4 Causes of Hyperkalemia

Although hyperkalemia is not as predictable with organic acidosis as with inorganic acidosis in experimental situations, hyperkalemia is common in diabetic ketoacidosis and phenformin-induced lactic acidosis. The more frequent occurrence of hyperkalemia in clinical organic acidosis may be explained by the longer duration of acidosis and the presence of other factors such as dehydration and renal failure and insulin deficiency in diabetic ketoacidosis. Hyperkalemia can also occur in severe digitalis intoxication by extracellular shift of potassium, as digitalis inhibits the $\text{Na}^+\text{-K}^+$ ATPase pump.

The kidney's ability to excrete potassium is so great that hyperkalemia rarely occurs solely on the basis of increased intake of potassium. Thus, hyperkalemia is almost always due to impaired renal excretion. There are three major mechanisms of diminished renal potassium excretion: reduced aldosterone or aldosterone responsiveness, renal failure, and reduced distal delivery of sodium.

Aldosterone deficiency may be part of a generalized deficiency of adrenal hormones (e.g., Addison's disease) or it may represent a selective process (e.g., hyporeninemic hypoaldosteronism). Hyporeninemic hypoaldosteronism is the most common cause of all aldosterone deficiency states and by far the commonest cause of chronic hyperkalemia among nondialysis patients. Selective hypoaldosteronism can also occur with heparin therapy, which inhibits steroid production in the zona glomerulosa. In patients with reduced aldosterone secretion, any agent that limits the supply of renin or angiotensin II may provoke hyperkalemia; for example, ACE inhibitors, nonsteroidal antiinflammatory agents, and b-blockers. The latter may compound the tendency to hyperkalemia by interfering with potassium transport into cells. Renal tubular unresponsiveness to aldosterone (pseudohypoaldosteronism) may be congenital, but it is more often an acquired defect. This defect may involve only potassium secretion (pseudohypoaldosteronism type II) or sodium reabsorption as well as potassium secretion (pseudohypoaldosteronism type I). Most cases of so-called salt-losing nephritis appear to represent the latter defect. Severe volume depletion may cause hyperkalemia despite secondary hyperaldosteronism, because volume depletion causes a marked reduction in delivery of sodium to the cortical collecting duct.

Pseudohyperkalemia, defined as increased potassium concentration only in the local blood vessel or in vitro, has no physiologic consequences. Prolonged use of a tourniquet with fist exercises can increase the serum potassium level by as much as 1 meq/L. Thrombocytosis and severe leukocytosis cause pseudohyperkalemia through potassium release from the platelets and white blood cells, respectively, during blood clotting.

Clinical Manifestations

In severe hyperkalemia, paralysis of the skeletal muscle occurs. Rapidly ascending neuromuscular weakness or paralysis has been observed in very severe hyperkalemia. Hyperkalemia can also cause mental confusion and paresthesia. The main dangers of hyperkalemia are abnormalities of cardiac rhythm and of its rate of conduction.

Increased velocity of repolarization results in tall, peaked T waves with shortened QT intervals. This is the earliest sign of hyperkalemia, and it begins to appear when potassium concentration in serum rises above 5.5 meq/L. However, as was the case with hypokalemia, the rate of development of hyperkalemia is important in the development of cardiac rhythm abnormalities. Reduction in the resting potential of the cardiac conduction system and muscle by high extracellular potassium concentration is associated with slowing of conduction. As hyperkalemia worsens, P-waves flatten and QRS-complexes widen progressively, then the P-waves disappear entirely and the QRS merge with the T waves simulating a sine wave. Other ECG findings include fascicular block and complete heart block (especially in digitalized subjects), ventricular tachycardia, flutter and fibrillation, and cardiac arrest.

Treatment

Hyperkalemia may be treated by removing potassium from the body, by shifting

extracellular potassium into the cells, and by antagonizing potassium action on the membrane of the cardiac conduction system (Table 6.5). Potassium may be removed by several routes: through the GI tract with a potassium exchange resin given orally or by enema; through the kidney by diuretics, mineralocorticoids, and increased salt intake; and by hemodialysis or peritoneal dialysis. A potassium exchange resin, sodium polystyrene sulfonate (Kayexalate), is more effective when it is given with agents such as sorbitol or mannitol that cause osmotic diarrhea. One tablespoon of Kayexalate mixed with 100 mL of 10% sorbitol or mannitol can be given by mouth two to four times a day. When it is given as an enema, a larger quantity is given more frequently.

Reduction in body potassium content
Reduction in intake
Increased fecal excretion: potassium-exchange resin and sorbitol
Increased renal excretion: mineralocorticoids, increased salt intake, diuretics
Peritoneal or hemodialysis
Intracellular shift of potassium
Glucose and insulin
Administration of alkali
β -Agonists: Salbutamol, albuterol
Antagonizing the membrane effect of hyperkalemia
Calcium salts
Hypertonic sodium salts

Table 6.5 Treatment of Hyperkalemia

Hemodialysis can rapidly remove potassium from the body, but it takes time to set up the dialysis machine. Potassium can be shifted into cells with glucose and insulin or by increasing the blood pH with sodium bicarbonate. Bicarbonate was not very effective against hyperkalemia in patients with renal failure, but when given with insulin, bicarbonate appears to have a synergistic effect. Specific β_2 -agonists such as salbutamol and albuterol drive K^+ into cells by stimulating the Na^+K^+ ATPase. Antagonizing the action of potassium on the heart with intravenous calcium salts or hypertonic sodium solution has the fastest effect against hyperkalemia and is used in life-threatening hyperkalemia.

Prolonged administration of diuretics and a high-salt diet is an effective treatment for hyporeninemic hypoaldosteronism. This regimen ensures delivery of an adequate amount of sodium to the cortical collecting duct without causing further volume expansion. Mineralocorticoid may be required as an adjunct therapy for hyporeninemic hypoaldosteronism, and the agent most commonly used is a synthetic mineralocorticoid, fludrocortisone (Florinef). However, since renal salt retention may be important in the pathogenesis of hyporeninemic hypoaldosteronism, mineralocorticoid replacement may lead to salt retention and worsening of hypertension. Reduced potassium intake may be added to any of the methods recommended above in the long-term management of

hyperkalemia.

Clinical problems and answers for this section are presented before the selected readings.

PATHOPHYSIOLOGY OF WATER AND ANTIDIURETIC HORMONE METABOLISM

Regulation of Thirst and Antidiuretic Hormone Release

A rise in effective osmolality shrinks the hypothalamic osmoreceptor cells, which then signal the cerebral cortex (thirst center) and the ADH-releasing mechanism in the supraoptic and paraventricular nuclei. ADH is released from the posterior pituitary and carried by the circulation to the kidney, where it increases the permeability of the collecting ducts to water and enhances salt reabsorption in the outer medullary thick ascending limb of Henle's loop.

Decline in plasma osmolality of only 2 to 3% produces maximum suppression of ADH, so even mild clinical hyponatremia should produce maximally dilute urine (<100 mosm/L). ADH has two classes of receptors: V1 receptors cause increased vasomotor tone and certain metabolic effects, and V2 receptors are associated with antidiuresis. Vasopressinase, which normally breaks down ADH rapidly, may rise in pregnancy and occasionally causes polyuria. DDAVP, a synthetic analogue of arginine vasopressin, which resists vasopressinase and therefore has a prolonged effect, is useful in polyuria of pregnancy.

Because solute excretion is normal in water diuresis, osmolality of urine is very low. About 180 L of water is filtered daily; 160 L is reabsorbed in the proximal tubule and in the descending limb, and 20 L of dilute urine is delivered to the distal nephron. In the proximal tubule, water reabsorption passively follows salt reabsorption, whereas in the descending thin limb, water reabsorption is unaccompanied by salt reabsorption and in response to salt reabsorption in the ascending limbs. Both thin and thick ascending limbs of Henle and distal convoluted tubules are water impermeable, in the presence or absence of ADH. Reabsorption of water in the collecting duct is regulated by ADH ([Fig. 6.10](#)). With deficiency of ADH or tubular unresponsiveness to ADH, little water is reabsorbed in the collecting duct, and a large volume of dilute urine is excreted. In the presence of maximal ADH, urine can be concentrated up to 1200 mosm/L as water is reabsorbed in the cortical and medullary collecting duct. Osmotic concentration of the urine with the countercurrent mechanism results in medullary hypertonicity, sufficient ADH, and tubular membrane responsive to ADH.

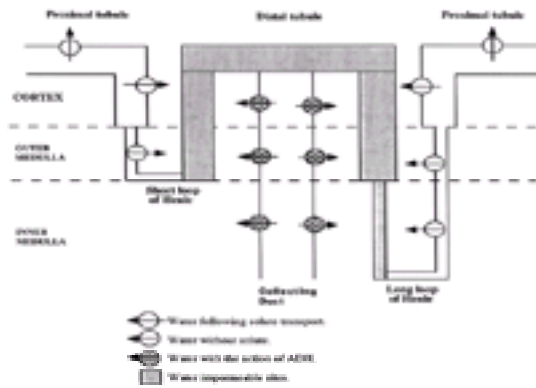

Figure 6.10. Transport of water at various nephron sites.

ADH release is also regulated by nonosmotic factors. Low effective arterial volume provokes thirst and ADH output, and high volume has the reverse effects. The effects are mediated through atrial stretch receptors and baroreceptors. α -Catechols suppress, and β -catechols enhance, ADH output. Prostaglandins inhibit the effect of ADH on the kidney. Angiotensin II stimulates thirst and ADH. Lack of glucocorticoid enhances ADH action on the kidney and may increase plasma ADH.

Physical and emotional stress (e.g., major surgery) enhance ADH output, possibly in part through emetic stimuli. Many drugs affect ADH release or action; for example, ethanol inhibits output of ADH. Lithium and demeclocycline inhibit the effect of ADH on the kidney. Chlorpropamide increases the action of ADH on the kidney. Some drugs may operate through emetic stimulus, one of the most potent physiologic stimuli to ADH release.

The urine may become osmotically concentrated in the absence of ADH if effective vascular volume is very low. The combination of reduced GFR and enhanced proximal reabsorption of filtrate reduces the volume of dilute urine formed in Henle's loop. This small volume moves so slowly down the collecting duct that even the limited permeability of the membrane permits withdrawal of a significant fraction of the water from the filtrate. Water retention by this mechanism may contribute to hyponatremia.

Polyuria

Polyuria is arbitrarily defined as urine volume in excess of 2.5 L/day ([Table 6.6](#)). There are two types of polyuria: osmotic diuresis and water diuresis.

Lack of ADH

Central diabetes insipidus

Suppression by excessive water intake: psychogenic, organic brain disease, iatrogenic

Excess vasopressinase: pregnancy

Failure of the kidney to respond to ADH

Congenital nephrogenic diabetes insipidus

Chronic renal failure

Acquired nephrogenic diabetes insipidus: certain drugs, structural and functional renal disorders

Table 6.6 Causes of Polyuria

Osmotic Diuresis. Osmotic diuresis is characterized by an excessive rate of solute excretion, in excess of 60 mosm/h, or 1440 mosm/day, in the adult. Urine osmolality is characteristically greater than that of plasma, but it need not be when it coexists with water diuresis. Only the excessive solute excretion is the hallmark of osmotic diuresis. Solutes commonly responsible for osmotic diuresis include glucose, urea, mannitol, radiopaque media, and NaCl.

Water Diuresis. Water diuresis is characterized by excretion of a large volume of dilute urine. The cause of polyuria in water diuresis is reduced reabsorption of water in the collecting duct. Water is not reabsorbed in the collecting duct either because of the lack of ADH or unresponsiveness to ADH (nephrogenic diabetes insipidus). The lack of ADH is due to either primary deficiency (central diabetes insipidus) or physiologic suppression by low serum osmolality (primary polydipsia).

The deficiency of ADH is usually partial and, therefore, can be mild, moderate, or severe. In a rare instance, ADH can be made but cannot be released in response to a rise in osmolality of the ECF because of a defect involving the osmoreceptor cells (e.g., hypothalamic lesions). In such instances, ADH may be released in response to hypovolemia or to drugs.

Lack of ADH may have many causes, including idiopathic cell degeneration, tumors and granulomas, surgery involving the pituitary or nearby structures, trauma, infarction, and infection. When the diagnosis of central diabetes insipidus is made, the patient is usually treated with replacement of ADH as DDAVP via the nasal mucosa. Less commonly, low levels of ADH may have their effects boosted by drugs such as chlorpropamide. Since ADH deficiency is not an all-or-none phenomenon, urine osmolality may be very low with severe deficiency or fairly close to normal with mild deficiency.

Congenital nephrogenic diabetes insipidus is a rare disorder with severe polyuria, expressed only in males, and invariably evident in the neonate. It is treated with salt

restriction and thiazide diuretics to produce a state of volume depletion; with reduced effective arterial volume, reabsorption of filtrate in the proximal tubule is increased, and less fluid is presented to the ascending limb where dilute urine is made. Acquired nephrogenic diabetes insipidus, which can be treated in the same manner, is caused by a number of disorders including amyloidosis, light-chain nephropathy, and hypercalcemia. Patients with chronic renal failure may also have varying degrees of unresponsiveness to ADH.

Primary polydipsia is defined as increased water drinking that is not caused by physiologically stimulated thirst (i.e., in the absence of hyperosmolality or volume depletion). In contrast, polydipsia in patients with diabetes insipidus or diabetic patients with marked glycosuria could be termed *secondary polydipsia*, since in these conditions polydipsia is secondary to thirst stimulation due to hyperosmolality. In primary polydipsia, ADH secretion is suppressed physiologically, and urine output is therefore increased markedly. When polydipsia is modest, serum Na remains within normal limits, but at the low range of normal, in contrast to high normal serum Na levels seen in patients with diabetes insipidus. Primary polydipsia is usually of psychogenic origin, hence the term *psychogenic polydipsia*.

Differential Diagnosis of Polyuria. The first step in the differential diagnosis should be measurement of urine osmolality. Osmotic diuresis is ruled out or diagnosed solely on the basis of the rate of osmolal excretion. Osmotic diuresis is defined as the excretion of osmols at a rate greater than 60 mosm/h, or 1440 mosm/day. For example, a urine output of 5 L/day at an osmolality of 400 mosm/L equals the osmolal excretion rate of 2000 mosm/day and therefore is an osmotic diuresis. On the other hand, excretion of 10 L of urine at 100 mosm/L gives only 1000 mosm/day and therefore is water diuresis.

For the differential diagnosis of water diuresis, the first step is determining the serum Na concentration. In diabetes insipidus, serum Na tends to be high normal, and in primary polydipsia, it tends to be low normal. However because of much overlap, a water-deprivation test is needed to confirm the diagnosis. Water is restricted overnight or until loss of 5% of the body weight. In primary polydipsia, maximum urine osmolality (>700 mosm/L) can usually be achieved by water restriction. A submaximal response that improves significantly upon administration of ADH indicates central diabetes insipidus; a submaximal response that fails to respond to ADH points to nephrogenic diabetes insipidus (Fig. 6.11).

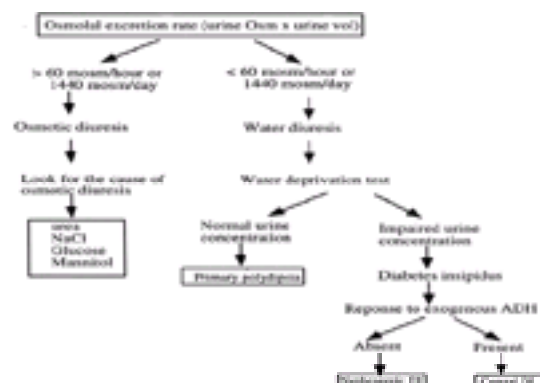

Figure 6.11. Differential diagnosis of polyuria.

Treatment. If the cause of polyuria is osmotic diuresis, the cause of the increased solute excretion must be removed. If the patient has glycosuria, diabetes should be controlled. If the patient is ingesting a high-protein diet, curtailing protein intake would reduce urea excretion.

If the cause is diabetes insipidus, the distinction should be made between nephrogenic and central (pituitary) diabetes insipidus. Administering ADH or stimulating ADH secretion is helpful only for pituitary diabetes insipidus. Exogenous ADH is available in three forms. Pitressin tannate in oil is administered intramuscularly. Desmopressin (dDAVP), a synthetic analogue of ADH, is administered intranasally, subcutaneously, or intravenously. A synthetic lysine vasopressin (lypressin, Diapid) is administered as a nasal spray. The usual dose of intranasal dDAVP is 0.1 or 0.2 mL twice daily by tube or by nasal spray, and the usual dose for Diapid is one to two sprays in each nostril four times a day.

Some patients may prefer oral agents, and the two that have been used extensively are chlorpropamide and thiazide diuretics. Chlorpropamide (100–250 mg/day) stimulates secretion of endogenous ADH and may also enhance the effect of ADH. Its use has been markedly curtailed since the advent of dDAVP. Thiazide diuretics produce vascular volume depletion and enhance reabsorption of fluid in the proximal tubule. Thus, they increase urine concentration by reducing delivery of fluid to the distal diluting segment of the nephron. Addition of a thiazide diuretic to chlorpropamide may prevent the hypoglycemia that may occur if the latter is used alone. Two other drugs used for the treatment of central diabetes insipidus are clofibrate and carbamazepine. Since both drugs are less effective than chlorpropamide and have more serious side effects, they should be the last resources. Nephrogenic diabetes insipidus cannot be treated with ADH preparations or an agent that stimulates ADH release, but measures to reduce the distal delivery of salt and water (i.e., low-salt diet and thiazide diuretics) are effective.

Hyponatremia

Hyponatremia, the most common electrolyte disorder, is defined as a reduced plasma sodium concentration (<135 meq/L). Generally, clinical concern arises when the concentration is less than 130 meq/L.

The term *pseudohyponatremia* is applied to a spurious reduction in serum sodium concentration caused by a systematic error in the measurement. The common causes include hyperlipidemia, hyperproteinemia, or increased viscosity of the plasma. The error in measurement in pseudohyponatremia results from dilution of the sample. Measurements of serum sodium with a flame photometer can result in this type of error because the sample is always diluted in such measurements. The same error also

occurs even with an ion-specific electrode method, if the sample is diluted (indirect method). In pseudohyponatremia, plasma osmolality, which is customarily measured without dilution, is normal.

However, a low plasma sodium concentration with a normal plasma osmolality need not indicate the presence of pseudohyponatremia; true hyponatremia may be accompanied by a normal plasma osmolality because of hyperglycemia, azotemia, or the presence of mannitol or alcohol. In hypergammaglobulinemic states such as multiple myeloma, serum sodium is falsely low because of displacement of serum water by g-globulins, but, on the other hand, the sodium concentration is also truly low because cationic charges on g-globulins displace sodium to maintain electrical neutrality.

A mechanism of pseudohyponatremia not widely appreciated is *in vitro* hemolysis, a well-known cause of pseudohyperkalemia. Since cell lysis does not change osmolality of the plasma, any rise in serum potassium must be met by a reciprocal decrease in serum sodium. However, the reduction in serum Na from hemolysis is somewhat greater than the increase in serum K, by a factor of 1.3, because hemoglobin released from the red cells causes additional reduction in serum Na as in hyperproteinemia. In pseudohyponatremia, effective osmolality is normal. Although in true hyponatremia, serum osmolality is usually low, it may also be normal; by coincidence, true reduction in serum sodium could be accompanied by accumulation of some solutes to give a normal serum osmolality ([Table 6.7](#)).

-
1. Normal effective osmolality: pseudohyponatremia (e.g., hyperlipidemia, hyperproteinemia, and *in vitro* hemolysis), accumulation of abnormal cations (e.g., lithium, γ -globulins)
 2. Increased effective osmolality: hyperglycemia, mannitol infusion
 3. Low effective osmolality: usual hyponatremia
-

Table 6.7 Types of Hyponatremia According to Effective Osmolality

Causes and Pathogenesis

The immediate mechanisms responsible for a reduction in extracellular sodium concentration are (a) shift of water from the cell caused by accumulation of extracellular solutes other than sodium salts; (b) retention of excess water in the body; (c) loss of sodium; and (d) shift of sodium into the cells ([Fig. 6.12](#)). The appropriate physiologic response to hypotonicity is suppression of ADH release, which leads to rapid excretion

of excess water and correction of hyponatremia. Persistence of hyponatremia indicates failure of this compensatory mechanism. In most instances, hyponatremia is maintained because the kidney fails to produce water diuresis, but sometimes ingestion of water in excess of the limits of normal renal compensation is responsible.

Figure 6.12. Pathogenetic mechanisms of hyponatremia. Hyponatremia is caused by one of four mechanisms: loss of Na from the body fluid, shift of Na into cells, gain of water from the outside, and shift of water from cells.

The reasons for the inability of the kidney to excrete water include (a) renal failure, (b) reduced delivery of glomerular filtrate to the distal nephron, and (c) the presence of ADH. The mechanism for impaired water excretion in renal failure is obvious and needs no further explanation. Reduced distal delivery of filtrate results from a low glomerular filtration rate and enhanced proximal tubular reabsorption of salt and water, and these states are most commonly caused by volume depletion.

Abnormal retention of water is the main reason for development of hyponatremia in most instances, and water retention is usually caused by ingestion or administration of hypotonic fluid. However, in certain clinical settings, water retention can occur despite administration of isotonic fluid. The latter phenomenon occurs when urine is excreted containing sodium and potassium at concentrations that exceed the sum of serum concentrations of the two ions. Excretion of hypertonic urine requires an increased amount of ADH in the presence of marked sodium diuresis. Clinical examples include a patient who receives a large amount of isotonic fluid in the immediate postoperative period, a patient with SIADH who is treated with isotonic fluid, and a patient who receives a thiazide diuretic.

Normal dilution of urine requires delivery of adequate amounts of fluid to the diluting segment and reabsorption of solute without water at that segment. Increased body fluid tonicity causes release of ADH, which allows reabsorption of water in the collecting duct, helping to restore the body fluid tonicity. Thus, the response is considered appropriate when ADH is released in response to hypertonicity of the body fluid.

However, release of ADH in the presence of hyponatremia is also not inappropriate if the effective arterial volume is reduced. ADH secretion is considered inappropriate when it occurs despite hyponatremia and despite a normal or increased effective arterial volume. The causes of SIADH include tumors, pulmonary diseases such as tuberculosis and pneumonia, central nervous system diseases, and drugs.

Hyponatremia in clinical states associated with reduced effective arterial volume such as congestive heart failure and cirrhosis of the liver is caused by a combination of reduced delivery of fluid to the distal nephron and increased secretion of ADH. Salt restriction and diuretics increase the severity of hyponatremia. ADH secretion may be present despite hyponatremia in myxedema and glucocorticoid deficiency states. It is not clear, however, whether ADH secretion in these conditions is truly inappropriate or appropriate.

Finally, mild hyponatremia may be caused by “resetting of the osmostat” at an osmolality lower than the usual level. In such cases, urine dilution occurs normally when the plasma osmolality is brought down below the reset level. Resetting of the osmostat is a form of SIADH, since ADH secretion occurs inappropriately at hyponatremic levels without evidence of reduced effective arterial volume. Patients with chronic debilitating diseases such as pulmonary tuberculosis often manifest this phenomenon ([Table 6.8](#)).

Increased water intake, e.g., primary polydipsia
Reduced renal water excretion
Reduced delivery of fluid to the distal nephron because of low effective arterial volume (ADH release is usually stimulated as well)
Edema-forming states: heart failure, nephrotic syndrome, cirrhosis of the liver
Nonrenal sodium loss: gastrointestinal sodium loss, sweating
Renal sodium loss: thiazide diuretics, aldosterone deficiency
Advanced renal failure
Inappropriate secretion of ADH (SIADH)
Tumors
Pulmonary diseases
Central nervous system disorders
Drugs, e.g., chlorpropamide, barbiturate, morphine, indomethacin
Physical and emotional stress
Idiopathic
Reset osmostat
Unknown mechanisms
Glucocorticoid deficiency
Myxedema

Table 6.8 Causes of Hyponatremia According to Mechanisms of Maintenance

Diagnosis

The presence of a low plasma sodium level and normal osmolality suggests pseudohyponatremia but does not confirm it. By coincidence, true hyponatremia may be accompanied by a high concentration of urea or alcohol, resulting in normal osmolality. A more direct proof is demonstration of a normal sodium concentration using a sodium-specific electrode or demonstration of reduced water content of plasma. Pseudohyponatremia due to hyperlipidemia is caused by accumulation of chylomicrons, which consist mostly of triglyceride, and is obvious from the milky appearance of serum

or plasma. Substantial hyponatremia due to hyperlipidemia requires accumulation of more than 5 to 6 g/dL of lipids, and this degree of hyperlipidemia does not occur with hypercholesterolemia alone. Each gram per deciliter of lipid falsely reduces serum sodium by 1.7 meq/L and each gram per deciliter of protein by 1.0 meq/L. Pseudohyponatremia due to hyperproteinemia can be confirmed by measurement of plasma proteins. Hyponatremia caused by mannitol or glucose is suspected from the history or by simultaneous measurements of plasma sodium, osmolality, and glucose.

In evaluating hyponatremia associated with hypoosmolality, the main concern is distinguishing between SIADH and hyponatremia from other causes, mainly volume-depletion states and edematous states. The major distinction between SIADH and other causes of hyponatremia lies in the status of effective arterial volume (EAV). EAV is normal or increased in the former and reduced in the latter. However, no single diagnostic test measures EAV with certainty. Physical examination is notoriously inaccurate in determining mild-to-moderate volume depletion. A more reliable method for estimating EAV uses measurements of urinary Na, serum urea nitrogen (SUN), serum creatinine, and serum uric acid. Urinary Na excretion above 20 meq/L, SUN below 10 mg/dL, serum creatinine below 1 mg/dL, and serum urate below 4.0 mg/dL all suggest normal or increased EAV. In contrast, measurement of urine osmolality has virtually no diagnostic value and often misleads physicians. Contrary to the common belief, urine osmolality in SIADH need not be greater than plasma osmolality. Furthermore, a high urine osmolality does not necessarily support the diagnosis of SIADH, because most other causes of hyponatremia are also accompanied by urine osmolality higher than plasma osmolality.

The only situation in which urine osmolality may be appropriately low in the presence of hyponatremia is the hyponatremia caused by primary polydipsia, and this is usually apparent when a careful history reveals polyuria and polydipsia (Fig. 6.13). In all other causes of hyponatremia, urine osmolality is inappropriately increased (i.e., greater than 100 mosm/L).

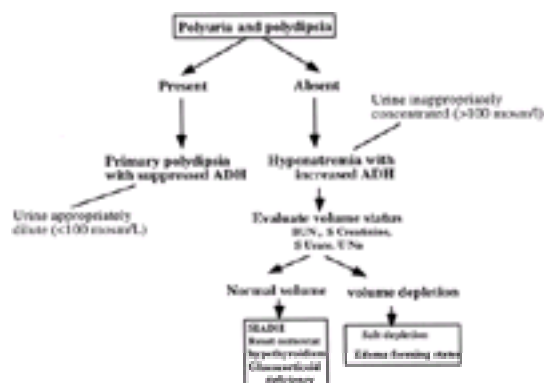

Figure 6.13. Differential diagnosis of hyponatremia.

Treatment

Hyponatremia is treated either by addition of sodium or by removal of water. Salt is given to patients with hyponatremia due to salt depletion. Water is removed in hyponatremic states with normal or increased body sodium content. *The speed of correction of hyponatremia should depend on the speed of development and on the patient's symptoms.* Clearly, severe symptomatic hyponatremia is a life-threatening condition, but there are dangers associated with treatment of hyponatremia. In the past, volume overload was thought to be the main danger associated with administration of a large quantity of salt-containing solution. Now, central pontine myelinolysis is considered a major danger associated with rapid correction of hyponatremia. This demyelinating disease of the central pons and the other areas of the brain is characterized by motor nerve dysfunction including quadriplegia. This complication tends to occur more often with chronic hyponatremia than with acute hyponatremia and is more frequently observed in malnourished and debilitated patients. To minimize this complication, hyponatremia should be corrected at a rate less than 0.35 meq/L/h or less than 8 meq/24 h. Since the danger of central pontine myelinolysis is limited mainly to those with asymptomatic chronic hyponatremia, rapid correction (at a rate of 1–2 meq/L/h) should be restricted to those with acute symptomatic hyponatremia. Even then, there is no advantage in rapidly increasing serum sodium to a level above 125 meq/L.

For patients admitted with hypotonic dehydration and chronic asymptomatic hyponatremia, the traditional recommendation has been administration of isotonic saline. As the volume expansion suppresses ADH release induced by the low EAV, a rise in serum sodium concentration follows rapid water excretion, provided that renal function is adequate. Sometimes, rapid excretion of water following isotonic saline administration in these patients may lead to development of central pontine myelinolysis. Alternating 0.45% and 0.9% sodium chloride solutions may therefore be safer. If potassium depletion coexists, appropriate treatment is with 0.45% NaCl containing 40 meq/L potassium.

Acute Treatment. For hyponatremia with sodium depletion and symptomatic hyposmolality, intravenous administration of sodium as hypertonic saline will correct hyposmolality effectively. The amount of sodium necessary to increase the sodium to a desired level is calculated as follows:

$$\text{Sodium requirement (meq)} = \text{TBW} \times \text{DNa}$$

where DNa is the desired serum sodium level minus the actual serum sodium.

Sodium may be administered as a 3 or 5% NaCl solution. When accumulation of excess water is primarily responsible for hyponatremia, as in SIADH, water may be rapidly removed by intravenous administration of osmotic diuretics such as mannitol or urea. More readily available is a loop diuretic (e.g., furosemide) to be given simultaneously with hypertonic saline. Furosemide causes loss of water and sodium, but hypertonic saline replaces the lost sodium; the net result is removal of water. The response to

furosemide cannot be predicted with precision, and frequent follow-up measurements of serum sodium levels must be made. There is no theoretical advantage to replacing exactly the amount of sodium lost in urine with hypertonic saline. Administration of hypertonic saline alone usually causes a salt and water diuresis, but addition of a loop diuretic makes correction of hyponatremia easier by preventing excretion of concentrated urine. Another advantage of a diuretic is prevention of fluid overload.

Chronic Treatment. Chronic hyponatremia may be treated by a reduction in water intake or by an increase in renal water excretion. Reduction of water intake is preferable but not always feasible. If water restriction is difficult or unsuccessful, the latter approach may be used. Increased renal water excretion can be achieved by the use of pharmacologic agents that interfere with urine concentration. Lithium and demeclocycline increase urine output by reducing production of cyclic adenosine monophosphate (AMP) and also interfering with its action. Demeclocycline is more effective and has fewer side effects, but it may cause nephrotoxicity in patients with liver disease.

Administration of a loop diuretic such as furosemide in conjunction with increased salt and potassium intake is safer for treating chronic hyponatremia than the above methods. The diuretic prevents high medullary interstitial osmolality by limiting reabsorption of salt in Henle's loop and hence prevents urine concentration. Increased salt and potassium intake increases water output by increasing delivery of solutes. There is evidence that ethacrynic acid may impair ADH-stimulated water movement across the collecting duct, and furosemide may have the same effect. Finally, vasopressin antagonists, not yet commercially available, may become an important addition to both chronic and acute treatment of hyponatremia in the future. Daily ingestion of urea has been used successfully, but again, it is not as practical as a loop diuretic.

Hypernatremia

Hypernatremia is defined as an increased sodium concentration in plasma water. Whereas hyponatremia may not be accompanied by hypoosmolality, hypernatremia is always associated with an increased effective plasma osmolality and hence with reduced cell volume. However, the extracellular volume in hypernatremia may be normal, decreased, or increased.

Causes and Pathogenesis

Hypernatremia is caused by loss of water, gain of sodium, or both ([Table 6.9](#)). Loss of water could be due to increased loss or reduced intake, and gain of sodium is due either to increased intake or to reduced renal excretion. Increased loss of water can occur through the kidney (e.g., in diabetes insipidus or osmotic diuresis), the GI tract (e.g., gastric suction or osmotic diarrhea), or the skin. Reduced water intake occurs most commonly in comatose patients or in those with a defective thirst mechanism. Less frequent causes of reduced water intake include continuous vomiting, lack of access to water, and mechanical obstruction such as esophageal tumor. The excess gain of sodium leading to hypernatremia is usually iatrogenic, e.g., from hypertonic saline

infusion, accidental entry into maternal circulation during abortion with hypertonic saline, or administration of hypertonic sodium bicarbonate during cardiopulmonary resuscitation or treatment of lactic acidosis. Reduced renal sodium excretion leading to sodium gain and hypernatremia is usually in response to dehydration caused by primary water deficit.

Reduced water content of the body
Reduced water intake
Defective thirst due to altered mental state or thirst center defect
Inability to drink water
Lack of access to water
Increased water loss
Gastrointestinal loss: vomiting, osmotic diarrhea
Cutaneous loss: sweating and fever
Respiratory loss: hyperventilation and fever
Renal loss: diabetes insipidus, osmotic diuresis
Increased sodium content of the body
Increased intake
Hypertonic saline or sodium bicarbonate infusion
Ingestion of sea water
Renal salt retention: usually in response to primary water deficit

Table 6.9 Causes of Hypernatremia

Water depletion due to diabetes insipidus, osmotic diuresis, or insufficient water intake leads to secondary sodium retention in those who continue to ingest or are given sodium. Consequently, in chronic hypernatremia, sodium retention is more important than water loss. Whether hypernatremia is due to sodium retention or water loss can be determined by examination of the patient's volume status. For example, if a patient with a serum sodium level of 170 meq/L does not have obvious evidence of dehydration, hypernatremia is not caused entirely by water loss. To increase the serum sodium to 170 meq/L by water deficit alone, one would have to lose more than 20% of total body water.

Whereas the physiologic defense against hyponatremia is increased renal water excretion, the physiologic defense against hypernatremia is increased water drinking in response to thirst. Because thirst is such an effective and sensitive defense mechanism against hypernatremia, it is virtually impossible to increase serum sodium by more than a few milliequivalents per liter if the water drinking mechanism is intact. Therefore, in a patient with hypernatremia, there will always be a reason for reduced water intake ([Table 6.9](#)).

Treatment

Acute Treatment. Hypernatremia is treated by either addition of water or removal of sodium. The choice depends on the body sodium and water content. If water depletion is the cause of hypernatremia, water is added. If sodium excess is the cause, sodium must be removed. When the water deficit is severe, isotonic (0.9%) NaCl or 0.45% NaCl

may be given initially to stabilize circulatory dynamics, followed by administration of hypotonic solutions to normalize the tonicity. Administration of 5% dextrose solution would also correct the extracellular volume depletion, but a larger volume is needed to expand the extracellular volume, and the ensuing rapid reduction of the plasma osmolality might result in cerebral edema. In acute symptomatic hypernatremia, serum sodium may be reduced by 6 to 8 meq/L in the first 3 to 4 h, but thereafter, the rate of decline should not exceed 1 meq/L/h. As with hyponatremia, chronic hypernatremia usually does not cause central nervous system symptoms and thus does not require rapid correction. A safe rate of correction is 0.7 meq/L/h, or about 10% of the serum sodium concentration over 24 h. The amount of water needed to correct hypernatremia can be estimated with the following equation:

$$\begin{aligned}\text{Water deficit (in liters)} &= \text{TBW} \left(\frac{\text{Na}_2}{\text{Na}_1} - 1 \right) \\ &= \text{TBW} \times \text{D Na} / \text{Na}_1\end{aligned}$$

where Na_1 is the desired serum sodium level, Na_2 the observed serum sodium, TBW total body water, and DNa the difference between the desired and observed serum sodium levels.

In hypernatremia with excess sodium, reducing serum sodium with fluids usually initiates natriuresis, but if natriuresis does not occur promptly, sodium may be removed with diuretics. Furosemide plus 5% dextrose solution might be an appropriate regimen to treat hypernatremia associated with excess sodium. If a hypernatremic patient with sodium excess has renal failure, salt should be removed by dialysis.

Chronic Treatment. Hypernatremic disorders that require chronic preventive therapy include diabetes insipidus and primary hypodipsia. Although diabetes insipidus is often listed as a cause of hypernatremia, it does not cause hypernatremia in the absence of thirst defect. Treatment is therefore directed toward curtailment of polydipsia and polyuria. Subjects with primary hypodipsia should be educated to drink on schedule. In some instances, stimulation of the thirst center with chlorpropamide has been effective.

Clinical problems and answers for this section are presented before the selected readings.

ACID-BASE DISORDERS

Bicarbonate and CO_2 Buffer System

All body buffers are in equilibrium with protons (H^+) and therefore with pH as shown in the following equation:

$$\text{pH} = \text{pK} + \log \frac{\text{A}^-}{\text{HA}}$$

where A^- is a conjugate base of an acid HA.

Because HCO_3^- and CO_2 are the major buffers of the body, pH is typically expressed as a function of their ratio, as in the Henderson-Hasselbalch equation:

$$\text{pH} = 6.1 + \log \frac{HCO_3^-}{pCO_2} \times 0.03,$$

where 6.1 is the pK of the HCO_3^- and CO_2 buffer system, and 0.03 is the solubility coefficient of CO_2 . The equation can be further simplified by combining the two constants, pK and solubility coefficient of CO_2 :

$$\begin{aligned}\text{pH} &= 6.1 + \log \frac{HCO_3^-}{pCO_2} \times 0.03 \\ &= 6.1 + \log 1/0.03 + \log \frac{HCO_3^-}{pCO_2} \\ &= 7.62 + \log \frac{HCO_3^-}{pCO_2} \\ &= 7.62 - \log pCO_2/HCO_3^- \\ &= 7.62 + \log HCO_3^- - \log CO_2.\end{aligned}$$

When H^+ is expressed in nanomoles instead of pH (a negative log value), pCO_2 can be related to HCO_3^- in an equation:

$$H \text{ (nM)} = 24 \times pCO_2 \text{ (mm Hg)} / HCO_3^- \text{ (mM)}$$

The Henderson-Hasselbalch equation indicates that pH depends on HCO_3^-/pCO_2 . pH increases when this ratio increases (alkalosis), and pH decreases when it decreases (acidosis). The ratio may be increased by increasing HCO_3^- (metabolic alkalosis) or by decreasing pCO_2 (respiratory alkalosis). The ratio may be decreased by decreasing HCO_3^- (metabolic acidosis) or increasing pCO_2 (respiratory acidosis).

Whole-Body Acid-Base Balance

Net Acid Production

On a typical American diet, the daily production of nonvolatile acid is about 90 meq/day. The main acids are sulfuric acid (about 40 meq/day), which originates from metabolism of sulfur-containing amino acids such as methionine and cystine, and incompletely metabolized organic acids (about 50 meq/day). The total amount of organic acid produced normally is much more than 50 meq/day, but the bulk of organic acid produced in the body is metabolized, and only a small amount is lost in the urine as organic anions, by escaping metabolism (e.g., citrate) or as a metabolic end product (e.g., urate). On typical American diets, the amount of alkali absorbed from the GI tract

is about 30 meq/day. Thus, the net amount of acid produced daily can be estimated as the sum of sulfate and organic anions in the urine minus the net alkali absorbed from the GI tract.

Determination of the net alkali (or acid) content of diet is based on the metabolic fates of dietary chemicals after absorption into the body rather than their in vitro states. For example, dietary citric acid is considered neutral because it is metabolized to CO₂ and water in the body, whereas K⁺ citrate is an alkali because it would be converted to K⁺ bicarbonate after metabolism. Similarly, arginine Cl⁻ is an acid, because metabolism of arginine in the body results in formation of HCl. Thus, the net alkali value of diet is best determined by the total number of noncombustible cations (Na⁺, K⁺, Ca²⁺, and Mg²⁺) relative to the total number of noncombustible anions (Cl and P):

$$\text{Net alkali content} = (\text{Na}^+ + \text{K}^+ + \text{Ca}^{2+} + \text{Mg}^{2+}) - (\text{Cl}^- + 1.8 \text{ P}).$$

All units are expressed as meq/day except P, which is expressed as mmol/day. Only the above six ions are considered in the equation because other noncombustible ions are present in negligible amounts in normal food. Sulfate is not included here because the ion is formed in the body only after metabolism of sulfur-containing amino acids.

The amount of alkali absorbed from food does not equal the amount present in food, because absorption of divalent noncombustible ions, Ca²⁺, Mg²⁺, and P, is incomplete. Hence, traditionally, measurement of net GI alkali absorption required analysis of both food and stool, which necessitated prolonged collection of stool. Thus, net GI alkali absorption is expressed as net alkali of food minus net alkali of stool.

Analysis of food for measurement of net alkali content is cumbersome, and analysis of stool is even more cumbersome. Such analyses typically require admitting patients to a special metabolic unit. Recently, a new method was developed to measure net GI alkali absorption. In this new method, urine electrolytes, instead of diet and stool electrolytes, are measured. The method is based on the assumption that noncombustible ions absorbed from the GI tract are eventually excreted in the urine, and thus, individual amounts of these electrolytes excreted in the urine would equal those absorbed from the GI tract. Hence

$$\text{Net GI alkali absorption} = \text{urine} (\text{Na}^+ + \text{K}^+ + \text{Ca}^{2+} + \text{Mg}^{2+}) - \text{urine} (\text{Cl}^- + 1.8 \text{ P})$$

and 24-h urine can be collected in outpatient settings, while the subjects are eating their usual diets. The amount of net alkali absorbed on typical American diet stated earlier, 30 meq/day, was measured by analysis of urine electrolytes using the above formula.

Net Acid Excretion

The most important function of the kidney in acid-base homeostasis is excretion of acid, which is tantamount to generation of alkali. Acid is excreted in the form of NH₄⁺ and titratable acid. Another important function of the kidney is excretion of HCO₃⁻. Although

the main function of renal excretion of HCO_3^- is prevention of metabolic alkalosis, a small amount of bicarbonate is normally excreted in the urine (about 10 meq/day). Thus, net acid excretion, which is tantamount to net renal production of alkali, can be determined by subtracting HCO_3^- excretion from acid excretion.

$$\text{Net acid excretion} = \text{acid excretion} - \text{HCO}_3^- \text{ excretion} = \text{NH}_4^+ + \text{titratable acid} - \text{HCO}_3^-$$

Normally about two-thirds of acid excretion occurs in the form of NH_4^+ , but in acidosis, NH_4^+ excretion may increase as much as 10-fold. Excretion of titratable acid is usually modest because of the limited amount of buffer that produces titratable acid (i.e., phosphate, creatinine, and urate) but may be increased markedly in disease states (e.g., b-hydroxybutyrate in diabetic ketoacidosis). Maintenance of acid-base balance requires that net acid production equals net acid excretion (Fig. 6.14). Metabolic acidosis develops when net acid production exceeds net acid excretion, and metabolic alkalosis develops when net acid excretion exceeds net acid production.

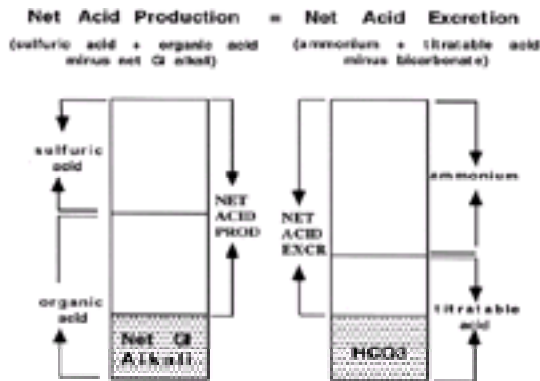

Figure 6.14. Balance between net acid excretion and net acid production. Net acid production is measured as the sum of sulfuric acid and organic acid minus net GI alkali. Net GI alkali represents a net amount of alkali absorbed from the GI tract from the food. Net acid excretion is measured as the sum of urine ammonium and titratable acid minus urine bicarbonate. In acid-base equilibrium, net acid production equals net acid excretion.

Terminology

The terms *acidosis* and *alkalosis* refer to a pathologic process leading to acidic or alkaline pH, whereas *acidemia* and *alkalemia* refer to acidic and alkaline pH. Patients could have acidosis but actually have alkaline pH. For example, we may say that a

patient has combined respiratory acidosis and metabolic alkalosis. Obviously, the patient cannot have acidic and alkaline pH at the same time, and therefore those terms must refer to pathologic processes. However, clinicians often use the terms interchangeably. For example, if someone says, “the patient has an acidotic pH,” she means a low pH, not a pathologic process leading to a low pH.

Metabolic Acidosis

Classification by Net Acid Excretion

All metabolic acidoses result from reduction in bicarbonate content of the body with two minor and clinically unimportant exceptions: acidosis resulting from dilution of the body fluid by administration of a large amount of saline solution (dilution acidosis) and acidosis that results from shift of H^+ from the cell. Reduction in bicarbonate content may be due to a primary increase in acid production (extrarenal acidosis) or due to a primary reduction in net acid excretion (renal acidosis) ([Table 6.10](#)). In extrarenal acidosis, net acid excretion is markedly increased as the kidney compensates to overcome acidosis. On the other hand, net acid excretion may be restored to normal in chronic renal acidosis as acidosis stimulates renal H^+ excretion. Normal net acid excretion in the presence of acidemic pH suggests a defect in renal acid excretion, and therefore renal acidosis. If the renal acid excretion capacity is normal, net acid excretion should be supernormal in the presence of acidemic pH ([Fig. 6.15](#)).

Renal acidosis: absolute or relative reduction in net acid excretion
Uremic acidosis
Renal tubular acidosis
Distal renal tubular acidosis (type I)
Proximal renal tubular acidosis (type II)
Aldosterone deficiency or unresponsiveness (type IV)
Extrarenal acidosis: increase in net acid excretion
Gastrointestinal loss of bicarbonate
Ingestion of acids or acid precursors: ammonium chloride, sulfur, toluene
Acid precursors or toxins: salicylate, ethylene glycol, methanol, paraldehyde
Organic acidosis
L-Lactic acidosis
D-Lactic acidosis
Ketoacidosis

Table 6.10 Causes of Metabolic Acidosis According to Net Acid Excretion

Figure 6.15. Relationship between net acid excretion and net acid production in renal and extrarenal acidosis.

Renal Acidosis. Renal acidosis is further classified into two types: uremic acidosis and renal tubular acidosis (RTA). In uremic acidosis, reduced net acid excretion results from reduced nephron mass (i.e., renal failure); in renal tubular acidosis, reduction in net acid excretion results from a specific tubular dysfunction. Because development of renal acidosis depends on the rate of net acid excretion as well as the rate of net acid production, which varies greatly according to the diet, the level of renal failure at which uremic acidosis develops varies greatly. On a usual diet, uremic acidosis can develop when the GFR falls below 20% of normal.

There are three types of RTA. Type I RTA, also called classical RTA or distal RTA, is characterized by an inability to reduce urine pH below 5.5. Since acidification of urine to a very low urine pH occurs at the collecting duct, the likely site of defect in type I RTA is the collecting duct, which is a part of the distal nephron, hence the term *distal RTA*. Because H^+ secretion in the collecting duct is somewhat impaired also in type IV RTA, some authors consider both type I and type IV RTA a form of distal RTA. Still, most authorities use type I RTA and distal RTA synonymously. In type I RTA, net acid excretion usually remains persistently below daily net acid production, and thus patients develop progressively more severe metabolic acidosis. Type I RTA can develop as a primary disorder or secondary to drug toxicity, tubulointerstitial renal diseases, or other renal diseases.

Type II RTA, also called proximal RTA, has defective proximal bicarbonate reabsorption characterized by a reduced renal bicarbonate threshold. Urine can be made free of bicarbonate and acidified normally when serum bicarbonate decreases to a low level. Most patients with proximal RTA have evidence of generalized proximal tubular dysfunction (i.e., Fanconi's syndrome), which is manifested by bicarbonaturia, aminoaciduria, glycosuria, phosphaturia, and uricosuria. Of these, renal glycosuria (glycosuria in the presence of normal blood glucose levels) is most useful in diagnosing Fanconi's syndrome. Type II RTA may be a primary disorder or secondary to genetic or acquired renal dysfunction. Hypokalemia is a characteristic finding of both type I and

type II RTA but tends to be more severe in type I than in type II. A hybrid of types I and II RTA is called type III RTA.

Type IV RTA is caused by aldosterone deficiency or tubular unresponsiveness to aldosterone, resulting in impaired renal tubular potassium secretion and hence hyperkalemia. Although reduced H^+ secretion in the collecting duct plays a role, the major mechanism of acidosis in type IV RTA is hyperkalemia-induced impairment in ammonia production in the proximal tubule. Type IV RTA is far more common than either type I or type II RTA, and the most common cause of type IV RTA is hyporeninemic hypoaldosteronism ([Table 6.10](#)).

Organic Acidosis. Extrarenal acidosis may result from administration or ingestion of acid, overproduction of endogenous acid, or loss of bicarbonate. Among these, overproduction of endogenous acid, especially of lactic acid and keto acids, is the most important mechanism. Only marked overproduction leads to acidosis, because of the enormous capacity to metabolize organic acids. For example, about 1300 meq of lactic acid are produced daily in a normal person without resulting in acidosis.

Organic acids are titrated immediately by the body's alkaline buffers. When they react with bicarbonate, organic anions and CO_2 are formed. When the anions are retained in body fluid, the result is metabolic acidosis with increased anion gap. When the anions are excreted in the urine, the anion gap returns to normal, and acidosis becomes hyperchloremic. *Retention of these anions per se is not responsible for acidosis.* Their presence merely provides a clue to the mechanism of reduced bicarbonate concentration. Their removal from the body fluid, by dialysis or renal excretion, would not improve the pH. The retained organic anions are potential bicarbonate; when they are metabolized, bicarbonate is regenerated. Thus, loss of organic anions in the urine is tantamount to loss of bicarbonate. If an organic anion is entirely retained, subsequent metabolism results in the complete recovery of the lost alkali. Characteristically, organic acidosis is rapid in onset and in recovery.

Lactic Acidosis Lactic acid is produced from pyruvic acid by the action of the enzyme lactic acid dehydrogenase (LDH) and the cofactor NADH. Metabolism of lactic acid requires its conversion back to pyruvic acid, using the same enzyme and NAD as a cofactor. For this reason, production and metabolism of lactic acid are reciprocally influenced by the same factors; increased concentration of pyruvic acid and an increased NADH:NAD ratio increase lactic acid production while reducing its metabolism. Consequently, in most cases of lactic acidosis, lactic acid production is increased, and at the same time, its metabolism is reduced.

By far the most common cause of lactic acidosis is tissue hypoxia, which results from circulatory shock, severe anemia, severe heart failure, acute pulmonary edema, cardiac arrest, carbon monoxide poisoning, seizures, vigorous muscular exercise, etc. Normally, lactic acid is produced by extrahepatic tissues and metabolized by the liver, but every organ in the body, except red blood cells, can produce and use lactic acid; red cells can only produce lactic acid. Lactic acidosis in acute alcoholism and severe liver disease is caused by impaired lactic acid metabolism ([Table 6.11](#)).

Tissue hypoxia, e.g., circulatory shock, hypoxemia, heart failure, anemia
Acute alcoholism
Drugs and toxins, e.g., phenformin, isoniazid
Diabetes mellitus
Leukemia
Idiopathic
Short bowel syndrome (D-lactic acidosis)

Table 6.11 Causes of Lactic Acidosis

Lactic acidosis, unless specified, refers to the acidosis caused by L-lactic acid, the isomer normally produced in the human body. The enzyme, LDH, responsible for production of lactic acid in the human body is an L-isomer, and therefore only L-lactic acid is formed from human metabolism. D-Lactic acidosis, which is due to the accumulation of D-lactic acid, has been reported in humans. D-Lactic acidosis is characterized by severe acidosis and neurologic manifestations. The affected patients behave as if they are alcohol intoxicated despite normal blood ethanol levels. The mechanism of D-lactic acidosis is the colonic overproduction of D-lactic acid by bacteria. Necessary requirements for overproduction of D-lactic acid in the colon are delivery of a large amount of substrate to the colon (i.e., malabsorption syndrome) and proliferation of D-LDH-forming bacteria in the colon. Treatment of D-lactic acidosis is oral administration of antibiotics.

Ketoacidosis Keto acids, acetoacetic acid and β -hydroxybutyric acid, are produced in the liver from free fatty acids (FFAs) and metabolized by the extrahepatic tissues. Unlike lactic acidosis, increased production of keto acids alone, not impaired use, is the mechanism for keto acid accumulation. Increased production requires a high concentration of FFAs and their conversion to keto acids in the liver. Insulin deficiency is responsible for increased mobilization of FFAs from the adipose tissue, and glucagon excess and insulin deficiency stimulate conversion of FFAs to keto acids in the liver.

Two major keto acids in the body are acetoacetic acid and β -hydroxybutyric acid. β -hydroxybutyric acid (BB) is produced from acetoacetic acid (AA) with the enzyme BB dehydrogenase and the cofactor NAD⁺. The same enzyme and NAD⁺ are required to convert BB to AA. Consequently, the NADH:NAD ratio is the sole determinant of the BB:AA ratio. Clinical diagnosis of ketoacidosis is usually made with Acetest, which detects AA but not BB. Although BB is the predominant acid in typical ketoacidosis (the usual ratio of BB to AA is about 2.5 to 3.0), the reaction to Acetest represents a fair estimate of the total concentration of keto acids as long as the ratio remains normal. When the ratio of BB to AA is greatly increased, Acetest may be negative or only slightly

positive despite retention of a large amount of total ketones in the form of BB. This condition, called b-hydroxybutyric acidosis, is commonly seen in alcoholic ketoacidosis.

Serum Anion Gap

The serum anion gap (AG) is estimated as

$$\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-) \text{ or } (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-).$$

Since the normal serum potassium concentration is quantitatively a minor component of serum electrolytes, the fluctuation in its concentration affects the overall result little, and hence the first of the two equations is more commonly used to estimate the anion gap, with a normal value of about 12 meq/L (8–16 meq/L). Some authors subtract the normal anion gap from the observed anion gap as we have defined it; calculated this way, the normal anion gap should be zero.

The term *anion gap* implies that there is a gap between cation and anion concentration, but there is no gap; the concentration of total cations in the serum must be exactly equal to the concentration of total anions. Although the total concentration of unmeasured anions (i.e., all anions other than chloride and bicarbonate) is about 23 meq/L, the anion gap, $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$, is only 12 meq/L because there are about 11 meq/L of unmeasured cations (i.e., all cations other than sodium). Let us assume that total serum cations = $\text{Na}^+ + \text{unmeasured cations (UC)}$, and that total serum anions = $\text{Cl}^- + \text{HCO}_3^- + \text{unmeasured anions (UA)}$. Since total serum cations = total serum anions, $\text{Na}^+ + \text{UC} = (\text{Cl}^- + \text{HCO}_3^-) + \text{UA}$. Hence, $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-) = \text{UA} - \text{UC}$. Since $\text{AG} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$, the anion gap (AG) = $\text{UA} - \text{UC}$ (Fig. 6.16). The anion gap is estimated from concentrations of Na^+ , Cl^- , and HCO_3^- , but alterations in anion gap can be predicted more readily from changes in unmeasured anions or unmeasured cations than from changes in Na, Cl, or HCO_3^- . Figure 6.16 shows this relationship graphically.

$$\text{AG} = \text{Na} - (\text{Cl} + \text{HCO}_3) = \text{UA} - \text{UC}$$

UC: Unmeasured cations.
UA: Unmeasured anions.

Figure 6.16. Anatomy of anion gap (AG).

Clearly, a change in the anion gap must involve changes in UAs or UCs or a laboratory error involving the measurement of Na^+ , Cl^- , or HCO_3^- . The anion gap can be increased by increased UA or decreased UC or by a laboratory error resulting in a false increase in serum Na^+ or a false decrease in serum Cl^- or HCO_3^- . AG can be decreased by decreased UA or increased UC or by laboratory errors resulting in a false decrease in serum Na^+ or a false increase in serum Cl^- or HCO_3^- . The equation also predicts that a change in UA may not change AG if UC is changed to the same extent in the same direction. For example, hypermagnesemia due to MgSO_4 intoxication does not reduce the AG although a high serum magnesium level increases UC, because the sulfate accumulation also causes an increase in UA. Decreased AG is most commonly due to reduction in serum albumin concentration, while increased AG is most often due to accumulation of anions of acids, such as sulfate, lactate, ketone anions. Since bromide is an unmeasured anion, bromide intoxication should lead to increased AG. However, bromide intoxication is accompanied by a low serum AG, because bromide causes a false increase in serum Cl^- .

A change in serum Na^+ usually does not cause a change in AG, because serum Cl^- usually changes in the same direction. For the same reason, HCO_3^- concentrations cannot be used to predict a change in AG. For example, when the serum HCO_3^- concentration increases in metabolic alkalosis, Cl^- concentration almost invariably decreases reciprocally to maintain electrical neutrality, so AG is unchanged. When HCO_3^- concentration decreases, Cl^- concentration may remain unchanged or increase. If bicarbonate is replaced by another anion, Cl^- concentration remains unchanged, hence normochloremic acidosis with increased AG (e.g., organic acidosis and uremic acidosis). When bicarbonate concentration decreases without another anion replacing it, electrical neutrality is maintained by a higher Cl^- concentration; hence, hyperchloremic acidosis with normal AG.

Proper interpretation of serum AG requires the knowledge of existence of conditions that influence AG even though they may have no effect on metabolic acidosis. For example, if a person with hypoalbuminemia develops lactic acidosis, the AG could be normal because the low albumin and the lactate accumulation have opposite effects on it.

Diagnosis

One approach to the differential diagnosis of metabolic acidosis is to measure the serum AG. If the AG is increased, the likely conditions include organic acidosis, uremic acidosis, and acidosis due to certain toxins ([Table 6.12](#)). If the AG is normal, the likely conditions include renal tubular acidosis and acidosis due to diarrheal loss of bicarbonate. Contrary to the common misconception, most cases of uremic acidosis are accompanied by normal AG; only in advanced chronic renal failure and acute renal

failure is AG increased. Furthermore, the vast majority of patients with ketoacidosis pass through a phase of hyperchloremic acidosis (normal AG) during the recovery phase.

Metabolic acidosis with increased anion gap (normochloremic acidosis)
Ketoacidosis
Lactic acidosis, D-lactic acidosis
β-Hydroxybutyric acidosis
Uremic acidosis
Ingestion of toxins: salicylate, methanol, ethylene glycol
Metabolic acidosis with normal anion gap (hyperchloremic acidosis)
Renal tubular acidosis
Uremic acidosis (early)
Acidosis following respiratory alkalosis
Intestinal loss of bicarbonate
Administration of chloride-containing acid: HCl, NH ₄ Cl
Ketoacidosis during recovery phase

Table 6.12 Classification of Metabolic Acidosis by Anion Gap

Another approach to the differential diagnosis of metabolic acidosis is to classify it into renal and extrarenal acidosis. Two major causes of extrarenal acidosis are organic acidosis and diarrheal loss of bicarbonate. Organic acidosis is usually obvious from clinical findings (e.g., evidence of tissue hypoxia in lactic acidosis, or hyperglycemia and ketonemia in ketoacidosis). Diarrhea as the cause of metabolic acidosis is first suspected from the history, but history is often misleading, because the severity of diarrhea cannot easily be determined. The measurement of urine AG is useful in determining the severity of diarrhea. Urine AG, which is measured as urine $(\text{Na}^+ + \text{K}^+) - \text{urine Cl}^-$, is reduced or negative when diarrhea is severe. Diarrheal loss of bicarbonate leads to metabolic acidosis, which in turn causes increased urinary excretion of ammonium as a part of the renal compensatory mechanism. Vomiting causes metabolic alkalosis and hence urinary excretion of bicarbonate, leading to increased urine AG.

Once extrarenal acidosis is excluded, renal acidosis is the only alternative diagnosis. Of the two types of renal acidosis, uremic acidosis can be readily diagnosed by measuring serum creatinine and BUN. If renal acidosis is confirmed but uremic acidosis is ruled out, the diagnosis must be renal tubular acidosis (RTA). Among the three types of RTA, type IV RTA will be suspected by the presence of hyperkalemia. Hypokalemia suggests either type I or type II RTA. If spontaneous urine pH is below 5.5, type I RTA is ruled out. If urine pH is higher than 5.5, urine pH should be measured after administration of 40 mg of furosemide by mouth. If the urine pH remains above 5.5, the likely diagnosis is type I RTA.

Treatment

Restoration of normal blood pH and bicarbonate concentration is the ultimate aim of

therapy for metabolic acidosis. Rapid restoration of normal pH is usually unnecessary and may be undesirable for several reasons. When the pH is increased acutely, restoration of a normal concentration of the red blood cell 2,3-DPG (diphosphoglucerate) lags behind. In addition, a sudden increase in extracellular pH can cause a paradoxical cerebrospinal fluid (CSF) acidosis. Rapid restoration of a normal serum bicarbonate level in metabolic acidosis would also be undesirable, because persistent hyperventilation would produce a very high blood pH.

The initial aim in the treatment of severe metabolic acidosis should be to increase the blood pH to a level at which adverse cardiovascular effects of severe acidemia can be avoided. Although the risk of acidosis varies with age and cardiovascular status, it is considered prudent, at least in older patients, to keep blood pH above 7.1 to 7.2. The blood pH may be increased by administration of alkali or by allowing alkali to be produced by metabolism of retained organic anions (OA^-) in the case of organic acidosis:

Successful treatment of the cause of organic acidosis increases the serum bicarbonate concentration by this mechanism. When ketoacidosis is treated with insulin and fluid, the outcome is usually predictable: a substantial increase in the plasma bicarbonate concentration. Thus, exogenous alkali is seldom necessary in ketoacidosis. In contrast, response to treatment in lactic acidosis is usually poor. In type A lactic acidosis (due to hypoxia), the prognosis depends on the cause of hypoxia. In most cases of circulatory shock, the prognosis is extremely poor. The prognosis of lactic acidosis due to acute alcohol intoxication is fairly good. With seizure-induced lactic acidosis, recovery is usually complete within hours after the control of the seizure.

Type B lactic acidosis can be treated with administration of alkali in the hope of spontaneous recovery, but administration of bicarbonate tends to be self-defeating because it increases lactic acid production. Rising cell pH increases glycolysis and therefore increases lactic acid production. Discouraged by the poor results of bicarbonate therapy and offering theoretical arguments against alkali therapy, some authors have recommended against using bicarbonate in the treatment of all types of lactic acidosis, but judicious use of bicarbonate is beneficial in severe acidosis.

Three types of alkali can be used for the treatment of metabolic acidosis: bicarbonate, salts of organic acids, and THAM (tromethamine). Organic salts used as a bicarbonate substitute include lactate, acetate, and citrate. Each milliequivalent of the organic salts produces 1 meq of bicarbonate. However, because they require metabolism, an increase in bicarbonate concentration is delayed. Furthermore, when metabolism is impaired (e.g., in lactic acidosis) organic salts may have no effect. The amount and speed of administration of bicarbonate and organic salts vary widely depending on the severity of acidosis.

THAM increases pH by producing HCO_3^- in a reaction with H_2CO_3 :

Because bicarbonate formation by THAM occurs at the expense of carbonic acid, rapid infusion of THAM results in a marked reduction in pCO_2 ; the rate should not exceed 2 mmol/min. Administration of THAM probably has no advantage in treatment of metabolic acidosis in most situations, but it should be more advantageous than bicarbonate in treating metabolic acidosis complicated by respiratory acidosis.

For a given quantity of administered bicarbonate, the serum bicarbonate level rises less in severe, than in mild, metabolic acidosis (i.e., the apparent volume of distribution of bicarbonate is greater in severe than mild metabolic acidosis). However, the absolute increase in pH for a given dose of bicarbonate administered is greater in more severe metabolic acidosis than in mild acidosis, because the increase in serum bicarbonate is proportionately greater, though less in absolute magnitude, with severe acidosis than with mild acidosis. In practice, however, there is no need to estimate bicarbonate requirements accurately to achieve a certain specific level. Since changes in pCO_2 following acute increase in serum bicarbonate cannot be accurately predicted, it is difficult to predict the pH for a given increase in bicarbonate. The best approach is to administer two to three ampules of sodium bicarbonate (44.5 or 50 meq per ampule) by intravenous injection and then repeat a blood gas measurement 20 to 30 min after bicarbonate injection to determine the need for further therapy.

For treatment of chronic acidosis, citrate (available as Shohl's solution) is more palatable than bicarbonate. For treatment of uremic acidosis in dialysis patients, sodium bicarbonate is the most commonly used alkali in hemodialysis fluids, and sodium lactate in peritoneal dialysis fluids.

Metabolic Alkalosis

At normal serum bicarbonate concentration, bicarbonate filtered at the glomerulus is virtually completely reabsorbed. As serum bicarbonate concentration rises above the normal level, bicarbonate reabsorption is incomplete, and bicarbonaturia begins. A slight increase in serum bicarbonate above 24 meq/L causes marked bicarbonaturia. Hence, when renal tubular bicarbonate handling and GFR are normal, it is very difficult to maintain a high plasma bicarbonate unless an enormous amount of bicarbonate is given.

Maintenance of metabolic alkalosis requires two conditions: a mechanism to increase plasma bicarbonate and a mechanism to maintain the increased concentration. Bicarbonate concentration may be increased by administration of alkali, gastric loss of HCl through vomiting or nasogastric suction, or renal generation of bicarbonate. Plasma

bicarbonate concentration can be maintained at a high level if bicarbonate is not filtered at the glomerulus because of advanced renal failure or if filtered bicarbonate is absorbed avidly because of an increased renal threshold for bicarbonate. The two most common causes for increased renal bicarbonate threshold are volume depletion and K^+ depletion ([Table 6.13](#)).

Reduced effective arterial volume, e.g., diuretic therapy, vomiting, edema formation
Potassium deficiency
Chloride deficiency accompanied by volume depletion, e.g., vomiting
High pCO_2
Secondary hyperparathyroidism, e.g., milk-alkali syndrome, hypercalcemia of malignancy due to an osteolytic mechanism
Advanced renal failure

Table 6.13 Mechanisms and Causes of Maintaining High Extracellular Bicarbonate

The renal threshold for bicarbonate is increased in K^+ depletion because of enhanced tubular reabsorption of bicarbonate and a decrease in glomerular filtration rate, which could reduce the filtered load of bicarbonate. When metabolic alkalosis is caused by volume depletion of nonrenal causes, urinary excretion of Cl^- is reduced. Urinary Na^+ is an unreliable index of volume depletion in metabolic alkalosis, because excretion of bicarbonate may cause obligatory loss of Na despite volume depletion. Metabolic alkalosis accompanied by low urinary chloride can be corrected by administration of chloride-containing fluid (e.g., $NaCl$ or KCl solution), hence the term *chloride-responsive metabolic alkalosis*, e.g., vomiting-induced alkalosis. Patients with chloride-responsive metabolic alkalosis are volume depleted. However, when volume depletion is caused by primary renal sodium loss, urinary loss of Cl^- is not reduced despite volume depletion. Metabolic alkalosis accompanied by normal excretion of chloride in urine is called chloride-resistant metabolic alkalosis (e.g., hypokalemia-induced alkalosis); administration of Cl^- does not correct alkalosis. In edema-forming conditions, administration of Cl^- may not improve metabolic alkalosis even though the pattern of urinary excretion of Cl^- would suggest chloride-responsive metabolic alkalosis, because fluid administration usually does not restore the effective vascular volume to normal. Common clinical conditions that increase serum bicarbonate levels are shown in [Table 6.14](#).

Loss of HCl from the stomach, e.g., gastric suction, vomiting
Administration of bicarbonate or bicarbonate precursors, e.g., sodium lactate, sodium acetate, sodium citrate
Shift of H⁺ into the cell, e.g., K⁺ depletion
Rapid contraction of extracellular volume without loss of bicarbonate, e.g., contraction alkalosis by the use of loop diuretics
Increased renal excretion of acid, e.g., diuretic therapy, high aldosterone state, potassium depletion, high pCO₂, secondary hypoparathyroidism

Table 6.14 Mechanisms and Causes of Increasing Extracellular Bicarbonate

Treatment

When the increased renal bicarbonate threshold in metabolic alkalosis is caused by reduced EAV and hypokalemia, correction of these abnormalities leads to rapid restoration of bicarbonate concentration in most patients. Correction of low EAV is accomplished by administration of normal saline or half-normal saline. Sometimes discontinuation of an offending agent (e.g., a diuretic) and restoration of normal salt intake suffices. If volume depletion is to be corrected, chloride must be given to replace the excreted bicarbonate, either as sodium chloride or as potassium chloride. In certain clinical situations such as edema-forming states, treatment of reduced EAV with salt solution is not effective. In such situations, acetazolamide (Diamox), a carbonic anhydrase inhibitor, will treat metabolic alkalosis as well as edema. Acetazolamide administration usually reduces the renal bicarbonate threshold to a subnormal level, but bicarbonate threshold may remain supernormal despite the drug in severe volume depletion.

Correction of metabolic alkalosis by renal excretion of bicarbonate requires adequate renal function. In renal failure, metabolic alkalosis can be treated by administration of dilute HCl, by acidifying salts, or by dialysis. Acidifying salts include ammonium chloride, arginine chloride, and lysine chloride. Metabolism of these salts results in release of HCl, which then titrates bicarbonate. If continuous acid loss from the stomach is the cause of metabolic alkalosis, an inhibitor of acid secretion such as cimetidine, ranitidine, nizatidine, or famotidine is useful.

Respiratory Alkalosis

With the exception of respirator-induced alkalosis and voluntary hyperventilation, respiratory alkalosis always results from stimulation of the respiratory center. The two most common causes of respiratory alkalosis are hypoxic stimulation of the respiratory center and stimulation through the pulmonary receptors, caused by various lung lesions such as pneumonia, pulmonary congestion, and pulmonary embolism. Certain drugs,

e.g., salicylate and progesterone, stimulate the respiratory center directly. Respiratory alkalosis is common in gram-negative sepsis; the mechanism is unclear. Blood pH tends to be extremely high when respiratory alkalosis is caused by psychogenic stimulation of the respiratory center, because the condition is usually superacute, and therefore there is no time for compensation ([Table 6.15](#)).

Diseases of the lung: any intrapulmonary pathology such as pneumonia, pulmonary fibrosis, pulmonary congestion, pulmonary embolism
Hypoxemia
CNS lesions
Gram-negative sepsis
Drugs: salicylate, progesterone

Table 6.15 Causes of Respiratory Alkalosis

Treatment

In chronic respiratory alkalosis, treatment is usually not needed because the excellent compensation restores the blood pH to normal or nearly normal values. In acute respiratory alkalosis due to psychogenic hyperventilation, the patient should be sedated to depress the respiratory center. $p\text{CO}_2$ can also be increased by the use of a rebreath-ing bag.

Respiratory Acidosis

The causes of respiratory acidosis are usually quite apparent. They include diseases of the lung (most common), respiratory muscle, respiratory nerve, thoracic cage, and airways, and suppression of the respiratory center by stroke, drugs such as phenobarbital, or severe hypothyroidism ([Table 6.16](#)).

Lung diseases: chronic obstructive lung disease, advanced interstitial lung disease, acute asthma

Thoracic deformity or airway obstruction

Diseases of respiratory muscle and nerve: myasthenia gravis, hypokalemic paralysis, botulism, amyotrophic lateral sclerosis, Guillain-Barré syndrome

Depression of the respiratory center: barbiturate intoxication, stroke

Table 6.16 Causes of Respiratory Acidosis

Treatment

Treatment should be directed toward removing the cause. If the cause cannot be removed quickly and the patient is in acute respiratory distress, mechanical ventilation with endotracheal intubation is indicated. However, the decision to intubate is more often based on hypoxemia than on respiratory acidosis.

Mixed Acid-Base Disorders

The term *mixed acid-base disorder* refers to a clinical condition in which two or more primary acid-base disorders coexist. They generally present with one obvious disturbance and what appears to be an inappropriate (excessive or inadequate) compensation. The “inappropriateness” of the compensatory process is the result of a separate primary disorder. The appropriate degrees of compensation for primary acid-base disorders have been determined by analysis of data from a large number of patients and are expressed as equations in [Table 6.17](#). When the two disorders influence the blood pH in opposite directions, the blood pH is determined by the dominant disorder. If the disorders cancel out each other's effects, blood pH can be normal.

Metabolic acidosis	$\Delta p\text{CO}_2 = \Delta\text{HCO}_3 \times 1.2 \pm 2$
Metabolic alkalosis ^b	$\Delta p\text{CO}_2 = \Delta\text{HCO}_3 \times 0.7 \pm 5$
Acute respiratory acidosis	$\Delta\text{HCO}_3 = \Delta p\text{CO}_2 \times 0.07 \pm 1.5$
Chronic respiratory acidosis	$\Delta\text{HCO}_3 = \Delta p\text{CO}_2 \times 0.4 \pm 3$
Acute respiratory alkalosis	$\Delta\text{HCO}_3 = \Delta p\text{CO}_2 \times 0.2 \pm 2.5$
Chronic respiratory alkalosis	$\Delta\text{HCO}_3 = \Delta p\text{CO}_2 \times 0.5 \pm 2.5$

^a ΔHCO_3 and $\Delta p\text{CO}_2$ represent the difference between normal and actual values.

^bNo matter how high the serum HCO_3 rises, $p\text{CO}_2$ rarely rises above 60 mm Hg in metabolic alkalosis.

Table 6.17 Formulas for Predicting Normal Acid-Base Compensation^a

When there is any compensation for acid-base disorders, $p\text{CO}_2$ and HCO_3^- change in the same direction (i.e., both are high or both low). If $p\text{CO}_2$ and HCO_3^- are changed in opposite directions (e.g., $p\text{CO}_2$ is high and HCO_3^- is low, or $p\text{CO}_2$ is low and HCO_3^- is high), a mixed acid-base disorder is certain.

Appropriateness of compensation can be determined by consulting [Table 6.17](#). Compensation can be excessive, insufficient, or appropriate. One can get an idea of the appropriateness of compensation from the degree of pH deviation without consulting the formula for normal compensation. In general, compensation is most effective in respiratory alkalosis (pH is often normalized), the next best is respiratory acidosis (pH may become normal), and the third best is metabolic acidosis. Compensation is least effective in metabolic alkalosis, partly because hypoxemia, an inevitable consequence of hypoventilation, stimulates ventilation. If a patient has low $p\text{CO}_2$ and low HCO_3^- with normal pH, the likely diagnosis is compensated respiratory alkalosis rather than compensated metabolic acidosis.

CLINICAL PROBLEMS AND ANSWERS

[Regulation of Intra- and Extracellular Volume and Osmolality](#) [Disorders of Potassium Metabolism](#) [Water and ADH Metabolism](#) [Acid-Base Disorders](#)

Regulation of Intra- and Extracellular Volume and Osmolality

Problems

1. A 45-year-old chronic alcoholic was brought in coma to the emergency room. The

patient had the following laboratory values: serum Na, 115 meq/L; serum osmolality, 400 mosm/L; serum glucose, 1000 mg/dL; BUN, 42 mg/dL; and total serum osmolality, 400 mosm/L.

- a. Is the patient's intracellular volume (ICV) increased, decreased, or normal?
[Answer](#)
- b. When serum glucose is normalized by metabolism, will serum sodium increase, decrease, or remain the same? [Answer](#)
- c. When glucose is normalized by metabolism, will extracellular osmolality increase, decrease, or remain the same? [Answer](#)
2. Which of the following patients has an increased ICV? [Answer](#)
 - a. A diabetic patient with serum sodium of 110 meq/L and serum glucose of 2000 mg/dL? [Answer](#)
 - b. An alcoholic with serum sodium of 125 meq/L and serum alcohol of 500 mg/dL? [Answer](#)
 - c. A uremic patient with serum sodium of 150 meq/L and serum urea nitrogen of 140 mg/dL? [Answer](#)
 - d. A patient with serum sodium of 150 meq/L with anasarca? [Answer](#)
 - e. A patient who developed hyponatremia after receiving 200 g mannitol? [Answer](#)
3. A patient weighing 120 lb has serum sodium level of 110 meq/L. How much sodium is needed to increase serum sodium to 120 meq/L? Assume that total body water volume is kept constant. [Answer](#)
4. A patient has total body water of 40 L and serum Na concentration of 180 meq/L. What amount of water is required to reduce serum Na to 163 meq/L? [Answer](#)
5. Match lettered conditions with numbered laboratory data.
 - a. vomiting, b) diarrhea, c) diuretic therapy [Answer](#)
 - i. Low serum K, low serum bicarbonate, urine Cl more than the sum of urine Na and K [Answer](#)
 - ii. Low serum K, high serum bicarbonate, normal urine Cl [Answer](#)
 - iii. Low serum K, high serum bicarbonate, low urine Cl [Answer](#)
6. Three patients with identical size, weight, and body composition are admitted to the hospital after acute weight loss of 5 lb overnight, but with different serum Na concentrations. Patient A has serum Na⁺ of 120 meq/L; patient B, 140 meq/L; and patient C, 160 meq/L. Which patient do you think has the smallest extracellular volume? [Answer](#)

Answers

1. a. The ICV is normal because effective serum osmolality is normal, even though total serum osmolality is increased; alcohol is not an effective osmol. The effective osmolality in this patient is $(115 \times 2) + (1000/18) = 285$ mosm/L.
b. Metabolism of glucose will cause loss of osmols from the ECF, and hence a shift of water into the cells. Serum sodium therefore will increase.
c. Extracellular osmolality decreases as glucose enters the cell and is metabolized.
[Return to Regulation of Intra- and Extracellular Volume and Osmolality Problems](#)
2. b. Only this patient has reduced effective osmolality. The laboratory data do not show an actual value of sodium in Case e, but since mannitol causes hyponatremia by a shift of water from the intracellular fluid to the ECF, the intracellular volume must be decreased.

[Return to Regulation of Intra- and Extracellular Volume and Osmolality Problems](#)

3. Sodium requirement = $D \text{ serum Na}^+ \times \text{TBW} = 10 \times 30 = 300 \text{ meq}$, where $D \text{ serum Na}^+$ is actual serum Na^+ minus the goal serum Na^+ , and total body water (TBW) is calculated as body weight (lb)/4. Although the administered Na^+ is going to remain mostly in the ECF, TBW is used to calculate the sodium requirement, because an increase in serum Na^+ causes an increase in serum osmolality that is exactly twice the value of the increase in serum Na^+ . Of course, to calculate the amount of solute required to increase the serum osmolality, one must use TBW rather than ECV. An increase in extracellular osmolality is impossible without increasing intracellular osmolality to the same extent; otherwise, water will keep coming out of the cell.

[Return to Regulation of Intra- and Extracellular Volume and Osmolality Problems](#)

4. The formula to calculate the amount of water removal to reduce serum Na^+ is $(D \text{ serum Na}^+/\text{goal serum Na}^+) \times \text{TBW}$; thus $(17/163) \times 40 = 4.17 \text{ L}$.

[Return to Regulation of Intra- and Extracellular Volume and Osmolality Problems](#)

5. a-iii, b-i, c-ii. Diarrhea causes loss of bicarbonate and K^+ in the stool, and thus hypokalemia and metabolic acidosis. Because the loss of bicarbonate in diarrhea is accompanied by loss of K^+ and Na^+ , urinary excretion of Na^+ and K^+ tends to be less than that of Cl^- . The higher concentration of Cl^- in urine is accompanied by increased excretion of ammonium, which occurs in response to metabolic acidosis. Both vomiting and diuretic therapy cause hypokalemia and metabolic alkalosis, but the former is accompanied by low urine Cl^- as Cl^- is lost in the vomitus.

[Return to Regulation of Intra- and Extracellular Volume and Osmolality Problems](#)

6. Patient A has the smallest ECV. Since they all started with the same TBW and lost the same amount of water (5 lb), the current TBW must be the same for all three patients. Remember that acute weight loss is considered to be entirely water loss. Patient A has the smallest ECV, because A has the largest ICV. Patient A has the largest ICV, because ICV is inversely proportional to the effective osmolality, which is smallest in A.

Disorders of Potassium Metabolism

Problems

1. A 64-year-old man is admitted to the hospital with severe pneumonia, fever, and bacteremia. White blood cell count is 28,500 and platelet count, 700,000. As part of his general evaluation, a blood sample is sent for serum electrolyte concentrations. Serum potassium is reported to be 5.7 meq/L. Rapid evaluation of the electrocardiogram shows no abnormalities. The patient is not acidotic and renal function is nearly normal. What is the likely cause of this patient's hyperkalemia? [Answer](#)
2. A 60-year-old woman with diabetes mellitus since age 48 is admitted to the hospital because of shortness of breath. Blood pressure is 160/107. She has slight edema. Serum Na^+ , 140; Cl^- , 114; bicarbonate, 15; K^+ , 6.5 meq/L. Blood glucose concentration is 170 mg/dL. She is treated with diuretics and with Kayexalate and sorbitol. Serum K^+ the next day is 4.0 meq/L. What is the likely cause of this

- patient's hyperkalemia? [Answer](#)
3. A well-known actress in musical comedy complains of severe weakness and is afraid of falling off the stage during dance routines. The only remarkable physical findings are a transient drop in blood pressure upon standing up, sluggish tendon reflexes, and muscle weakness. ECG shows S-T depression and sagging T waves. An additional complaint is moderate polyuria. Urinary K^+ excretion is 9 meq in 24 h. Blood pH is normal. What is the likely cause of this patient's hypokalemia? [Answer](#)

Answers

1. The likely cause is pseudohyperkalemia due to thrombocytosis. Leukocytosis can also cause pseudohyperkalemia, but only when white cell counts are extremely high. However, the absence of ECG abnormality should not be taken as evidence for pseudohyperkalemia, since chronic hyperkalemia, even when quite severe, is often accompanied by a normal ECG.
[Return to Disorders of Potassium Metabolism](#)
2. The most likely cause is hyporeninemic hypoaldosteronism, mainly because it is the commonest cause of chronic hyperkalemia. Furthermore, diabetic nephropathy is the most common pathology that causes hyporeninemic hypoaldosteronism. The presence of hypertension further suggests hyporeninemic hypoaldosteronism rather than Addison's disease. Lacking both glucocorticoids and mineralocorticoids, Addison's disease is expected to cause hypotension. Hypotension might also be expected in patients with hyporeninemic hypoaldosteronism, since they are lacking in both renin and aldosterone. However, they are usually hypertensive, suggesting that the effective volume is increased in these patients. In fact, the likely pathogenetic mechanism of the hyporeninemia in this condition is the primary volume expansion resulting from renal salt retention. Low serum bicarbonate is probably the result of type IV RTA, a common complication of hyporeninemic hypoaldosteronism.
[Return to Disorders of Potassium Metabolism](#)
3. Nonrenal loss of potassium, such as laxative abuse or diarrhea, is the likely cause of her hypokalemia. The clue is the low excretion of urine K^+ . A diuretic therapy or primary hyperaldosteronism would be accompanied by a normal rate of K^+ excretion. Vomiting is also a common cause of hypokalemia, but the main route of K^+ loss in vomiting is the kidney rather than the stomach, as the increased urine bicarbonate causes renal K^+ wasting.
[Return to Disorders of Potassium Metabolism](#)

Water and ADH Metabolism

Problems

1. A 63-year-old man with alcoholic cirrhosis of the liver, weighing 120 lbs, was admitted to the hospital complaining of progressive weakness and vomiting for several days, but without neurologic abnormality. On examination, he had poor skin turgor and no subcutaneous fat. Serum Na^+ was 108 meq/L; Cl^- , 78 meq/L;

K^+ , 2.3 meq/L; HCO_3^- , 29 meq/L. Urine osmolality was 650 mosm/L; BUN, 15 mg/dL; serum creatinine, 1.1 mg/dL; uric acid, 5.5 mg/dL; urine Na, 45 meq/L; and urine pH, 7.5. The patient was treated with 1 L normal saline (154 meq/L of Na^+), with addition of 40 meq/L of K^+ every 6 h for the first 24 h. In 16 hours the serum Na^+ had risen to 121 meq/L, and in 24 hours to 128 meq/L. Three days later, the patient was unable to speak or swallow. CT scan and MRI of the brain showed a hypodense area in the central pons.

- a. Why was hyponatremia corrected so fast with normal saline? Did K^+ administration play a role? [Answer](#)
 - b. How do you explain the neurologic abnormality? [Answer](#)
 - c. Does urine osmolality on admission suggest SIADH? If the value had been 200 mosm/L, would you have ruled out SIADH? [Answer](#)
 - d. Does urine Na^+ on admission suggest SIADH or a volume depletion state? [Answer](#)
2. A 65-year-old woman, weighing 150 lbs, was admitted to the hospital because her family felt she was weak and “not quite herself.” She had no specific complaints and was able to answer questions. Physical examination suggested moderate dehydration, and the resident estimated her fluid loss at about 4 L. She had a 10-cm curved scar over the area of the frontal lobe of the brain, BUN was 45 mg/dL; creatinine, 1.3. Serum Na^+ was 182 meq/L; urine osmolality, 550 mosm/L; urinary Na^+ , 75 meq/L. After pitressin was administered, the urine osmolality rose to 750 mosm/L.

True or False?

- a. The patient's hypernatremia is entirely due to water loss. [Answer](#)
 - b. CT scan of the head would show marked brain shrinkage consistent with severe hyperosmolality. [Answer](#)
 - c. The patient has central diabetes insipidus. [Answer](#)
 - d. The patient has a thirst defect as well as a defect in water conservation. [Answer](#)
 - e. The patient should immediately receive an infusion of pitressin and water sufficient to lower her serum Na to 140 meq/L within the next 12-16 hours. [Answer](#)
 - f. From the information given, can you prove that the patient does not have osmotic diuresis? [Answer](#)
3. A 72-year-old healthy man ingests a diet that allows him to excrete a total of 800 mosm/day solute and 2 L water.
- a. What will be his average urine osmolality on the diet indicated? [Answer](#)
 - b. What would be his average urine osmolality if he increased salt intake and excreted 1000 mosm of solute and drank less water to decrease urine output to 1 L/day? [Answer](#)
 - c. What would be his average urine osmolality if he reduced his food intake and excreted only 320 mosm of solute and drank enough water to increase urine output to 4 L/day? [Answer](#)
 - d. What would his fluid balance be if he developed lung cancer and had a high blood level of ADH that prevented urine osmolality from falling below 400 mosm/L while ingesting the original diet and drinking the 4 L/day of water?

[Answer](#)

Answers

1.
 - a. As volume depletion was corrected, water diuresis occurred. Administration of K^+ has almost the same effect as that of sodium for the following reasons. Potassium is retained mostly in the cell, and therefore it requires a shift of K^+ into the cells in exchange for extracellular shift of Na . Potassium in this case thus has the same effect on extracellular sodium concentration as sodium. Alternatively, if the administered K^+ is excreted in the urine, it will be accompanied by water. The loss of water causes a rise in serum Na^+ .
 - b. A rapid increase in serum Na^+ in a patient with chronic hyponatremia can cause central pontine myelinolysis (CPM), and the patient has characteristic clinical findings of CPM.
 - c. Urine osmolality is rarely useful in differential diagnosis of hyponatremia, because virtually every patient with hyponatremia has inappropriately concentrated urine, i.e., urine osmolality in excess of 100 mosm/L in the presence of hyponatremia. The only exception is hyponatremia due to primary polydipsia, in which urine osmolality is expected to be less than 100 mosm/L. However, the polyuria and polydipsia of primary polydipsia make the diagnosis obvious. Urine osmolalities of 650 mosm/L and 200 mosm/L are both consistent with SIADH, but they are also consistent with most other causes of hyponatremia.
 - d. Urine Na^+ concentration on admission argues against dehydration. On the other hand, a high urine pH (7.5) indicates increased excretion of bicarbonate, which can cause Na^+ diuresis despite dehydration. When urine pH is high, urine Cl^- concentration is a more reliable indicator of the volume status.
[Return to Water and ADH Metabolism](#)
2.
 - a. False. If water deficit were the sole cause of hypernatremia, serum Na^+ concentration of 182 meq/L would require a loss of 9.2 L water for a person with total body water of 40 L. The amount of water deficit needed to raise serum Na^+ to 182 meq/L is calculated as $(DNa \times TBW)/\text{goal } Na^+ = (42 \times 40)/182 = 9.2 \text{ L}$. The patient was judged to be only moderately dehydrated by the resident, who estimated the loss of water at 4 L. Obviously, a big part of hypernatremia was caused by the retention of Na^+ .
 - b. False. Because the hypernatremia was chronic as shown by the lack of severe neurologic abnormalities, the brain volume would be nearly normal.
 - c. True. Urine osmolality of 550 mosm/L is inappropriately low for the patient's severe hypernatremia, and therefore the patient has diabetes insipidus (DI). The subsequent response to exogenous ADH indicates that it was central DI.
 - d. True. The patient has deficiency of ADH and a thirst defect. In fact, if ADH deficiency were the only defect the patient had, the patient would have been polydipsic and polyuric but not hypernatremic.
 - e. False. Since the patient has chronic hypernatremia with a near normal brain volume, rapid correction of hyponatremia can cause brain edema and therefore should be avoided.
 - f. To rule out osmotic diuresis one must know the rate of solute excretion, which requires urine osmolality and urine volume. Since only urine osmolality is known, osmotic diuresis cannot be ruled out in this case.

[Return to Water and ADH Metabolism](#)

3. a. $800 \text{ mosm}/2 \text{ L} = 400 \text{ mosm}/\text{L}$
- b. $1000 \text{ mosm}/1 \text{ L} = 1000 \text{ mosm}/\text{L}$
- c. $320 \text{ mosm}/4 \text{ L} = 80 \text{ mosm}/\text{L}$
- d. The patient will retain water and develop hyponatremia.

[Return to Water and ADH Metabolism](#)

Acid-Base Disorders

Problems

1. A 46-year-old alcoholic man with type I diabetes mellitus is brought to the hospital after he was discovered unconscious. In the ambulance, his vital signs were BP, 80/40 mm Hg; pulse, 120/min; respiration rate, 40/min. The chest and abdomen were normal, except for a surgical scar in the middle line of the upper abdomen. The ER physician subsequently learned that a day before the patient became ill, he drank whiskey and skipped his usual insulin dose. He gave no history of malabsorption syndrome. The laboratory tests on admission to the ER showed the following. Urinalysis: 4+ glucose, 4+ ketones, 1+ protein, no RBC. Serum Na^+ , 144 meq/L; Cl^- , 109 meq/L; K^+ , 5.5 meq/L; CO_2 , 14 mmol/L; glucose, 920 mg/dL; creatinine, 2.1 mg/dL; BUN, 90 mg/dL; serum ketone, 2+; serum lactate, 2.5 meq/L; measured serum osmolality, 360 mosm/L. Arterial blood gases: pH 7.32, pCO_2 28 mm Hg, pO_2 105 mm Hg on room air.
 - a. Does the patient have ketoacidosis? [Answer](#)
 - b. Is the respiratory compensation appropriate? [Answer](#)
 - c. If net acid excretion had been 70 meq/day (usual normal value 40-100) in this patient at the time of admission, would this have ruled out renal acidosis? [Answer](#)
2. The serum anion gap can be best predicted from the formula $\text{AG} = \text{unmeasured anion} - \text{unmeasured cation}$, where unmeasured anions are defined as any anions other than Cl and bicarbonate, and unmeasured cations any cations other than Na.
 - a. Bromide is an unmeasured anion according to the above definition. However, bromide intoxication lowers anion gap. Why? [Answer](#)
 - b. Why is serum anion gap usually normal in hypermagnesemia due to MgSO_4 ? [Answer](#)
 - c. What is the effect of high serum Na^+ or Cl^- on serum anion gap? [Answer](#)
3. $\text{HCO}_3^-/\text{pCO}_2$ determines pH. Normal blood pH is 7.4 with normal HCO_3^- of 24 mmol/L and normal pCO_2 of 40 mm Hg; the normal ratio is 24/40. If pCO_2 is 20 mm Hg and HCO_3^- 14 mM, will pH be higher or lower than 7.4? [Answer](#)
4. Data: Serum Na^+ , 138; K^+ , 4.2 meq/L; Cl^- , 114, bicarbonate, 12 meq/L. Within seconds you know the diagnosis, hyperchloremic metabolic acidosis, and suspect two conditions: diarrhea and renal tubular acidosis (RTA).
 - a. What serum electrolyte value argues against RTA in this patient? [Answer](#)
 - b. What is the commonest cause of type IV RTA? [Answer](#)
 - c. What test would you need to diagnose diarrhea as the cause? [Answer](#)
 - d. Do you think your diagnosis, hyperchloremic acidosis, is premature? What test

- is essential before such a conclusion? [Answer](#)
- e. If blood pH were 7.4, what would $p\text{CO}_2$ be? What would your diagnosis be? If a drug was responsible for this type of acid-base disorder, what would it be? [Answer](#)
5. Why are there two phases of compensation (acute and chronic) for respiratory acidosis and respiratory alkalosis, but only one phase of compensation for metabolic acidosis and metabolic alkalosis? [Answer](#)
6. Indicate whether the serum anion gap is increased (I), decreased (D), or unchanged (U) with the following.
- Low serum Na^+ [Answer](#)
 - Low serum Cl^- [Answer](#)
 - Lithium intoxication [Answer](#)
 - Hypoalbuminemia [Answer](#)
 - Lactic acidosis [Answer](#)
 - Bromide intoxication [Answer](#)
 - Diarrhea-induced metabolic acidosis [Answer](#)
 - Hypermagnesemia due to MgSO_4 overdose [Answer](#)

Answers

- The increased serum anion gap suggests organic acidosis or advanced uremic acidosis. The serum creatinine of 2.1 mg/dL rules out advanced uremic acidosis. Among the organic acidoses, lactic acidosis is ruled out by the serum lactate level of only 2.5 meq/L (the value must be at least 6 meq/L). Usual ketoacidosis requires a stronger Acetest reaction. However, b-hydroxybutyric acidosis (a type of ketoacidosis) can occur with a modest elevation in acetoacetate, which Acetest primarily reacts with. D-Lactic acidosis does not occur in the absence of malabsorption syndrome.
 - Yes. Using the formula for normal compensation in [Table 6.17](#) shows that a $p\text{CO}_2$ of 28 mm Hg is an appropriate compensation for 14 meq/L bicarbonate.
 - If net acid excretion were only 70 meq/day, you would have to suspect renal acidosis. In extrarenal acidosis, net acid excretion is not normal but markedly increased.
[Return to Acid-Base Disorders](#)
- Bromide is measured as chloride in most hospital laboratories at higher than its actual concentration. This results in pseudohyperchloremia and hence a low serum anion gap.
 - Because both unmeasured anion (sulfate) and unmeasured cation (Mg) are increased.
 - The effects of high serum Na^+ or Cl^- on serum anion gap cannot be predicted without knowing how other ions are altered.
[Return to Acid-Base Disorders](#)
- The pH would be higher than 7.4, because $p\text{CO}_2$ is exactly a half of the normal value, but bicarbonate is slightly higher than the normal value. Thus, bicarbonate/ $p\text{CO}_2$ is slightly increased.
[Return to Acid-Base Disorders](#)

 - In types I and II RTA, serum K^+ is low, and in type IV RTA, serum K^+ is high.

Therefore, a normal serum potassium concentration in this patient argues against RTA.

b. Hyporeninemic hypoaldosteronism.

c. Urine anion gap, which is expected to be reduced or negative. The low urine anion gap in diarrhea is due to increased renal excretion of ammonium.

d. Chronic respiratory alkalosis can also be accompanied by low serum bicarbonate and high serum chloride concentrations. The blood pH will allow one to decide between chronic respiratory alkalosis and hyperchloremic metabolic acidosis. In the former, the blood pH would be slightly high or high normal, and in the latter, the blood pH would be low.

e. The normal blood pH suggests chronic respiratory alkalosis more than chronic metabolic acidosis; the former is better compensated than the latter. Salicylate and progesterone are two drugs that can produce chronic respiratory alkalosis.

[Return to Acid-Base Disorders](#)

5. In respiratory acid-base disorders there are two distinct stages of compensation. The first stage, which is completed within seconds, is due to tissue buffering. The second stage is due to renal compensation, which requires several days. Thus, no matter how acute respiratory acid-base disorder may be, the acute phase of compensation is always completed. In contrast, in metabolic acid-base disorders, there is only one stage of compensation, the ventilatory adjustment, which requires 12 to 24 hours to complete.

BIOLOGIC ROLES OF CALCIUM

In higher mammals, the most obvious role of calcium is structural or mechanical and is expressed in the mass, hardness, and strength of the bones and teeth. But calcium has another fundamental function: shaping key biologic proteins to activate their catalytic and mechanical properties. A significant portion of the regulatory apparatus calcium metabolism of the body is concerned with protection of this second function (e.g., all activities and roles of parathyroid hormone (PTH), calcitonin, and vitamin D). The structural role is discussed in greater detail in [Chapter 83](#), while the cell metabolic, regulatory, and nutritional aspects of this critical element are discussed in this chapter.

Calcium and the Cell

The calcium ion (Ca^{2+}) has an ionic radius of 0.99 Å and is able to form coordination bonds with up to 12 oxygen atoms (1). The combination of these two features makes calcium nearly unique among all cations in its ability to fit neatly into the folds of the peptide chain. By binding with the oxygen atoms of glutamic and aspartic acid residues projecting from the peptide backbone, calcium stiffens the protein molecule and fixes its tertiary structure. Magnesium and strontium, which are chemically similar to calcium in the test tube, have different ionic radii and do not bond so well with protein. Lead and cadmium ions, by contrast, substitute quite well for calcium, and in fact, lead binds to various calcium-binding proteins with greater avidity than does calcium itself. (Fortunately, neither element is present in significant quantity in the milieu in which living organisms thrive. Nevertheless, the ability of lead to bind to the calcium-binding proteins is a part of the basis for lead toxicity.)

Binding of calcium to a large number of cell proteins (see [Table 7.1](#) for some examples) results in the activation of their unique functions (2). These proteins range from those involved with cell movement and muscle contraction to nerve transmission, glandular secretion, and even cell division. In most of these situations, calcium acts as both a signal transmitter from the outside of the cell to the inside and an activator of the functional proteins involved. In fact, ionized calcium is the most common signal transmitter in all of biology. It operates from bacterial cells all the way up to cells of highly specialized tissues in higher mammals.

Protein	Function
Calmodulin	Modulator/regulator of several protein kinases
Troponin C	Modulator of muscle contraction
Calretinin, retinin	Activator of guanyl cyclase
Calneurin B	Phosphatase
Protein kinase C	Widely distributed protein kinase
Phospholipase A_2	Synthesis of arachidonic acid
Caldesmon	Regulator of muscle contraction
Parvalbumin	Calcium storage
Calbindin	Calcium storage
Calsequestrin	Calcium storage

Table 7.1 Examples of Cell Proteins Binding or Activated by Calcium

When a cell is activated (e.g., a muscle fiber receives a nerve stimulus to contract), the first thing that happens is that calcium channels in the plasma membrane open to admit a few calcium ions into the cytosol. These bind immediately to a wide array of intracellular activator proteins, which in turn release a flood of calcium from the intracellular storage vesicles (the sarcoplasmic reticulum, in the case of muscle). This

second step quickly raises cytosol calcium concentration and leads to activation of the contraction complex. Two of the many calcium-binding proteins are of particular interest here: (a) troponin c, after it has bound calcium, initiates a series of steps that lead to the actual muscle contraction; and (b) calmodulin, a second and widely distributed calcium-binding protein, activates the enzymes that break down glycogen to release energy for contraction. In this way, calcium ions both trigger the contraction and fuel the process. When the cell has completed its assigned task, the various pumps quickly lower the cytosol calcium concentration, and the cell returns to a resting state. These processes are described in more detail below.

If all of the functional proteins of a cell were fully activated by calcium at the same time, the cell would rapidly self-destruct. For that reason, cells must keep free calcium ion concentrations in the cytosol at extremely low levels, typically on the order of 0.1 μmol . This is 10,000-fold lower than the concentration of calcium ion ($[\text{Ca}^{2+}]$) in the extracellular water outside the cell. Cells maintain this concentration gradient by a combination of mechanisms: (a) a cell membrane with limited calcium permeability; (b) ion pumps that move calcium rapidly out of the cytosol, either to the outside of the cell or into storage vesicles within the cell; and (c) a series of specialized proteins in the storage vesicles that have no catalytic function in their own right, but which serve only to bind (and hence sequester) large quantities of calcium. Low cytosolic $[\text{Ca}^{2+}]$ ensures that the various functional proteins remain dormant until the cell activates certain of them, which it does simply by letting $[\text{Ca}^{2+}]$ rise in critical cytosolic compartments.

OCCURRENCE AND DISTRIBUTION IN NATURE

Calcium is the fifth most abundant element in the biosphere (after iron, aluminum, silicon, and oxygen). It is the stuff of limestone and marble, coral and pearls, sea shells and egg shells, antlers and bones. Because calcium salts exhibit intermediate solubility, calcium is found both in solid form (rocks) and in solution. It was probably present in abundance in the watery environment in which life first appeared. Today, seawater contains approximately 10 mmol calcium per liter (approximately eight times higher than the calcium concentration in the extracellular water of higher vertebrates), and even fresh waters, if they support an abundant biota, typically contain calcium at concentrations of 1 to 2 mmol. In most soils, calcium exists as an exchangeable cation in the soil colloids. It is taken up by plants, whose parts typically contain from 0.1 to as much as 8% calcium. Generally, calcium concentrations are highest in the leaves, lower in the stems and roots, and lowest in the seeds.

In land-living mammals, calcium accounts for 2 to 4% of gross body weight. A 60-kg adult human female typically contains about 1000 to 1200 g (25–30 mol) of calcium in her body. More than 99% of that total is in the bones and teeth. About 1 g is in the plasma and extracellular fluid (ECF) bathing the cells, and 6 to 8 g in the tissues themselves (mostly sequestered in calcium storage vesicles inside cells, see above).

In the circulating blood, calcium concentration is typically 2.25 to 2.5 mmol. About 40 to 45% of this quantity is bound to plasma proteins, about 8 to 10% is complexed with ions such as citrate, and 45 to 50% is dissociated as free ions. In the ECF outside of the blood vessels, total calcium concentration is on the order of 1.25 mmol, which differs

from the concentration in plasma because of the absence of most plasma proteins from the ECF. It is the calcium concentration in the ECF which the cells see, and which is tightly regulated by the parathyroid, calcitonin, and vitamin D hormonal control systems.

With advancing age, humans commonly accumulate calcium deposits in various damaged tissues, such as atherosclerotic plaques in arteries, healed granulomas, and other scars left by disease or injury, and often in the rib cartilages as well. These deposits are called dystrophic calcification and rarely amount to more than a few grams of calcium. These deposits are not caused by dietary calcium but by local injury, coupled with the widespread tendency of proteins to bind calcium. Calcification in tissues other than bones and teeth is generally a sign of tissue damage and cell death.

METABOLISM

Homeostatic Regulation

Plasma calcium, which is in exchange with ECF calcium, is tightly regulated at approximately 2.5 mM (9–10 mg/dL). If serum calcium concentration lies more than 10% away from the population mean, there is reason to suspect disease. The homeostatic regulation of serum calcium requires a system of controlling factors and feedback mechanisms ([Fig. 7.1](#)).

Figure 7.1. Homeostatic regulation of serum calcium depicting the positive and negative controls in effect when plasma calcium falls below 2.5 mM.

When plasma calcium concentration falls, the parathyroid gland is stimulated to release PTH. PTH promptly increases renal phosphate clearance, increases renal tubular reabsorption of calcium, activates bone resorption loci and augments osteoclast work at existing resorption loci, and activates vitamin D to enhance intestinal calcium absorption. Activation of vitamin D occurs in two steps. An initial hydroxylation by vitamin D 25-hydroxylase in a microsomal cytochrome enzyme system similar to the

P450 system that occurs in the liver. The second hydroxylation by 25-OH-D-1 α -hydroxylase in the proximal convoluted tubule cells of the kidney converts the vitamin to its active potent form, 1,25-dihydroxyvitamin D (1,25(OH)₂D), or calcitriol (see [Chapter 18](#) for additional details.) This step is stimulated by PTH through a fall in serum phosphate. PTH and 1,25(OH)₂D act synergistically to enhance renal tubular reabsorption of calcium and to mobilize calcium stores from bone. PTH acts in a classical negative feedback loop to raise the ECF [Ca²⁺], thereby closing the loop and reducing PTH release. Although this sophisticated regulatory mechanism allows a rapid response to correct transient hypocalcemia, in situations of a chronically deficient calcium diet it does so only with serious consequences to the skeleton.

When plasma calcium concentration rises in response to increased calcium absorption, increased tubular reabsorption, and bone resorption, the renal excretory threshold changes, and extra calcium is excreted in the urine.

In infants and children, a principal defense against hypercalcemia is release of calcitonin by the C cells of the thyroid gland. Calcitonin is a peptide hormone with binding sites in the kidney, bone, and central nervous system. Absorption of calcium from an 8-oz feeding in a 6-month-old infant dumps 150 to 220 mg calcium into the ECF. This is enough, given the small size of the ECF compartment at that age (1.5–2 L), to produce fatal hypercalcemia if other adjustments are not made. What happens is that calcitonin (CT) is released, in part in response to the rise in serum calcium concentration, but even before that, in response to gut hormones signaling coming absorption. This burst of CT slows or halts osteoclastic resorption, thus stopping bony release of calcium. Later, when absorption stops, CT levels fall also, and osteoclastic resorption resumes. By contrast, CT has little significance in adults because absorption is lower to begin with, and the ECF is vastly larger. As a result, absorptive calcemia from a high-calcium diet raises the ECF [Ca²⁺] by only a few percentage points.

Absorption

Calcium usually is freed from complexes in the diet during digestion and is released in a soluble and probably ionized form for absorption. However, low-molecular-weight complexes, such as calcium oxalate and calcium carbonate, can be absorbed intact ([3](#)).

Fractional calcium absorption (absorptive efficiency) generally varies approximately inversely with intake, but the absolute quantity of calcium absorbed increases with intake ([4](#), [5](#)). However, only 20% of the variation in calcium absorption can be accounted for by the usual calcium intake that is thought to reflect calcium status ([6](#)). Rather, individuals seem to have preset absorptive efficiencies; approximately 60% of the variance in calcium absorption between individuals can be accounted for by their individual fractional calcium absorption ([7](#)).

An exception to the inverse relationship between fractional calcium absorption and load occurs in the presence of wheat bran given as extruded cereal. The enormous calcium-binding capacity of this fiber-rich food bound half of the calcium across the

spectrum of usual dietary in-takes (8).

Mechanisms of Absorption

Calcium absorption occurs by two pathways:

1. Transcellular: saturable (active) transfer that involves a calcium-binding protein, calbindin
2. Paracellular: a nonsaturable (diffusional) transfer that is a linear function of the calcium content of the chyme

The relationship between calcium intake and absorbed calcium is shown in [Figure 7.2](#). At lower calcium intakes, the active component contributes to absorbed calcium. As calcium intakes increase and the active component becomes saturated, an increasing proportion of calcium is absorbed by passive diffusion. The figure illustrates that the adaptive component (i.e., the change in active transport produced by intakes that differ from the group mean) is rather small. This demonstrates our inefficiency in compensating for a fall in calcium intake.

Figure 7.2. Relationship between calcium intake and absorbed calcium in women tested on their usual calcium intakes (adaptive) and in women tested with no prior exposure to the test load (load-related, a physiochemical effect).

Active absorption is more efficient in the duodenum and proximal jejunum where the pH is more acid (pH \gg 6.0) and where calbindin is present. However, absorption is greater in the ileum where the residence time is greatest. Absorption from the colon accounts for about 5% of the total absorption in normal individuals but may be important in patients with small bowel resections and where colonic bacteria break down dietary complexes.

Transcellular Calcium Transport. Calcium (and phosphorus) movement into the

epithelial cells probably occurs through calcium channels or a transporter (9) down a steep gradient and does not require energy. The main regulator of transport across the epithelial cell against the energy gradient is 1,25(OH)₂D. As illustrated in Figure 7.3, 1,25(OH)₂D, which is responsive to serum calcium levels, regulates the synthesis of calbindin by DNA transcription upon binding of the vitamin with receptors in the nucleus. This affects the stability (i.e., translation) of the calbindin mRNA. Intestinal calbindin, a 9-kDa protein in mammals and a 28-kDa protein in birds, is capable of binding two Ca²⁺ per molecule. Calbindin operates by binding Ca²⁺ on the surface of the cell, then internalizing the ions via endocytic vesicles that probably fuse with lysosomes. After release of the bound calcium in the acidic lysosomal interior, the calbindin returns to the cell surface, and the Ca²⁺ ions exit the cell via the basolateral membrane (10). Calbindin serves both as a Ca²⁺ translocator and a cytosolic Ca²⁺ buffer (11). Using ion microscopic imaging of injected ⁴⁴Ca²⁺, calcium entry into the villus was observed in vitamin D-deficient chicks, but the rapid transfer of Ca²⁺ through the cytoplasm to the basolateral pole did not occur in the absence of the ability to synthesize calbindin (12).

Figure 7.3. Calcium absorption showing active, transcellular absorption and passive, paracellular absorption. Paracellular absorption is bidirectional; transcellular absorption is unidirectional. Calcium enters the cytosol down a concentration gradient. Calcium is transported across the enterocyte against an uphill gradient with the aid of vitamin D-induced calbindin, probably at least partially via endosomes and lysosomes. Finally, it is extruded at the basolateral membrane, primarily via the ATP-dependent Ca²⁺ pump and secondarily via the Na⁺/Ca⁺ exchanger or by exocytosis.

Vitamin D-induced calcium transport also seems to involve activation of calcium-dependent ATP pumps to effect extrusion of calcium against an electrochemical gradient into the plasma. Relative Ca²⁺ binding capacities across the enterocyte are brush border = 1, calbindin = 4, and the ATP-dependent Ca²⁺ pump = 10, which ensures unidirectional transfer of Ca²⁺ (13).

Paracellular Calcium Transport. In the paracellular pathway, calcium transfer occurs

between cells. Theoretically, this can be in both directions, but normally the predominant direction is from lumen into blood. Rate of transfer depends on calcium load and tightness of the junctions. Water probably carries calcium through the junctions by solvent drag (14). Citrate appears to enhance paracellular calcium transport (15).

Physiologic Factors Affecting Absorption

Various host factors affect fractional calcium absorption (Table 7.2). Vitamin D status, intestinal transit time, and mucosal mass are the best established (16). Phosphorus deficiency, as may occur through prolonged use of aluminum-containing antacids, can cause hypophosphatemia, increased circulating levels of 1,25(OH)₂D and elevated calcium absorption, hypercalciuria, bone pain, and increased bone resorption.

Increased Absorption	Decreased Absorption
Vitamin D adequacy	Vitamin D deficiency
Increased mucosal mass	Decreased mucosal mass
Calcium deficiency	Menopause
Phosphorus deficiency	Old age
Pregnancy	Decreased stomach acid (without a meal)
Lactation	Rapid intestinal transit time
Mucosal permeability	

Table 7.2 Physiologic Factors Affecting Calcium Absorption

Stage of life cycle also influences calcium absorption. In infancy, absorption is dominated by diffusion. Therefore, the vitamin D status of the mother does not affect fractional calcium absorption of breast-fed infants. Both active and passive calcium transport are increased during pregnancy and lactation. Calbindin and plasma 1,25(OH)₂D and PTH levels increase during pregnancy. From midlife on, absorption efficiency declines by about 0.2 absorption percentage points per year, with an additional 2% decrease at menopause (17).

Decreased stomach acid, as occurs in achlorhydria, reduces the solubility of insoluble calcium salts (e.g., carbonate, phosphate), thereby reducing absorption of calcium unless fed with a meal (18). Absorption of calcium supplements improves when they are taken with food, perhaps by slowing gastric emptying and thereby extending the time in which the calcium-containing chyme is in contact with the absorptive surface.

Excretion

Calcium is lost from the body in urine, feces, and sweat. Differences in losses between adult women and adolescent girls on equal and adequate calcium intakes are given in [Figure 7.4](#). This figure demonstrates conservation of calcium at the kidney, for building bone during the rapid skeletal growth during puberty.

Figure 7.4. Calcium metabolism. Daily mass transfer in adult women (*lower values*) and adolescent girls (*upper values*). Data were taken from reference [20](#), except skin loss in adults, taken from [19](#). Circles represent compartments determined from kinetic modeling and do not necessarily represent discrete physiologic entities.

Turnover of the miscible calcium pool in healthy adults is about 16%/day and that of the rapidly exchanging component (of which the ECF is a part) about 40%/day. The filterable load of the kidney is determined by the glomerular filtration rate and the plasma concentration of ultrafilterable calcium (ionized plus that bound to low-molecular-weight anions). In adults, this is about 175 to 250 mmol per day (7–10 g per day). More than 98% of this calcium is reabsorbed by the renal tubule as the filtrate passes through the nephron, but 2.5 to 5 mmol (100–200 mg) is excreted in urine daily. Endogenous fecal excretory loss is similar to the amount excreted in urine. Loss in sweat is typically 0.4 to 0.6 mmol (16–24 mg) per day ([19](#)), and additional diurnal losses from shed skin, hair, and nails bring the total to as much as 1.5 mmol (60 mg) per day.

Endogenous Fecal Calcium

Fecal calcium includes calcium that is unabsorbed from the diet plus calcium that enters the gut from endogenous sources, including shed mucosal cells, saliva, gastric juices, pancreatic juice, and bile. Endogenous fecal calcium losses are approximately 2.5 to 3.0 mmol (100–120 mg) per day. These losses are inversely proportional to absorption efficiency and directly related to gut mass (and hence to food intake). Urinary calcium increases during childhood up to adolescence. Endogenous fecal calcium values of adolescent girls and adult women (shown in [Fig. 7.4](#)) are not significantly different.

Urinary Excretion

Calcium losses in the urine are load dependent except during adolescence. During this period of rapid growth, absorbed calcium is diverted to bone growth at calcium intakes typically ingested, except for obligatory losses in urine, skin, and endogenous secretions (21).

Machinery for calcium transport described above for the intestinal epithelial cells is also present in the nephrons of the kidney, but it is not known if it is functional. Both processes are calcium-load dependent, stimulated by PTH and $1,25(\text{OH})_2\text{D}$, and have a microvillar myosin I–calmodulin complex that could serve as a calcium transporter (22). Active transport occurs in the distal convoluted tubule against a concentration gradient. In the mammalian kidney, vitamin D regulation works through calbindin- $\text{D}_{28\text{k}}$, which binds four Ca^{2+} per molecule and shares no sequence homology with calbindin- $\text{D}_{9\text{k}}$ of the intestine. This calcium-binding protein has been cloned and is regulated by both transcriptional and posttranscriptional mechanisms. Administration of $1,25(\text{OH})_2\text{D}$ to rats induces calbindin- $\text{D}_{28\text{k}}$ mRNA and vitamin D–receptor mRNA in vitamin D–sufficient animals (23). However, in the absence of vitamin D, hypercalciuria is not observed as would be predicted if mechanisms were similar to those in the gut. A fall in filtered load is associated with slight reductions in urine calcium. Even so, renal calcium clearance is reduced in vitamin D deficiency and increased in PTH deficiency, indicating that the major effect on conservation of calcium is exerted by PTH.

Paracellular transport dominates in the proximal tubule as reabsorption occurs across a concentration gradient, and it also occurs in the thick ascending limb of the loop of Henle, the distal nephron, and the collecting ducts. Tubular reabsorption decreases in postmenopausal women. Calcium resorption is determined by Na^+ . For every 100 mmol of sodium excreted, approximately 0.5 to 1.5 mmol of calcium is pulled out with it in the urine.

DIETARY CONSIDERATIONS

Dietary sources and calcium intakes have altered considerably during human evolution. Early man derived calcium from roots, tubers, nuts, and beans in quantities believed to exceed 37.5 mmol (1500 g) per day (24) and perhaps up to twice this when consuming food to meet the caloric demands of a hunter-gatherer of contemporary body size. After domestication of grains, calcium intakes decreased substantially because the staple foods became grains (fruits), the plant parts that accumulate the least calcium. Consequently, the modern human consumes on average insufficient calcium to optimize bone density. The food group that supplies the bulk of the calcium in the Western diet is now the dairy food group.

Food Sources and Bioavailability

For adults, dairy products supply 72% of the calcium in the U.S. diet, grain products

about 11%, and vegetables and fruits about 6% (25). Although corn tortillas processed with lime and dried beans provide the bulk of dietary calcium for some ethnic groups, it is difficult for most individuals to ingest enough calcium from foods available in a cereal-based economy without liberal consumption of dairy products. Thus, food manufacturers have developed calcium-fortified products, which have had limited market success. Many individuals have turned to dietary supplements to meet their calcium needs. However, it is prudent to remember that calcium is not the only nutrient important to health supplied by dairy products (Table 7.3). Users of milk in the U.S., compared to nonusers, get 35% more vitamin A, 38% more folate, 56% more riboflavin, 22% more magnesium, and 24% more potassium, in addition to 80% more calcium (26).

Nutrient	%
Calcium	16.8
Phosphorus	35.7
Riboflavin	34.7
Potassium	21.1
Protein	20.6
Magnesium	19.8
Vitamin B ₁₂	17.8
Fat	11.8
Vitamin B ₆	16.7
Energy	9.9
Vitamin A	9.6

From the 1967-68 Nationwide Food Consumption Survey.

Table 7.3 Contribution of Foods Represented by the Milk Group to Nutrients Available in the U.S. Food Supply

Aside from gross calcium content, potential calcium sources should be evaluated for bioavailability. Although calcium absorption efficiency varies inversely with load, fractional calcium absorption from various dairy products is similar, at approximately 30% (27). The calcium from most supplements is absorbed as well as that from milk, since solubility of the salts at neutral pH has little impact on calcium absorption (28). Absorption of one very soluble salt, calcium-citrate-malate (CCM), is better than that of other salts (29). Several plant constituents form indigestible salts with calcium, thereby decreasing absorption of calcium.

The most potent inhibitor of calcium absorption is oxalic acid, found in high concentration in spinach and rhubarb and to a lesser extent in sweet potatoes and dried beans (30). Calcium absorption from spinach is only 5%, compared with 27% from milk ingested at a similar load (31). When these two foods of dissimilar bioavailability are coingested during the same meal, calcium fractional absorption from milk is depressed 30% of the difference between milk and spinach (fed alone) by the presence of spinach, and calcium fractional absorption from spinach is enhanced 37% of the difference between milk and spinach by the presence of milk (32). The absence of complete exchange and the failure to find equal absorption from the two foods intermediate

between the values for the foods fed singly suggest that calcium does not completely form a common dietary pool as has been reported for iron and zinc.

Phytic acid, the storage form of phosphorus in seeds, is a modest inhibitor of calcium absorption. The phytic acid content of seeds, which depends on the phosphorus content of the soil in which the plants are grown, influences calcium absorption (33). Fermentation, as occurs during bread making, reduces phytic acid because of the phytase present in yeast, resulting in increased calcium absorption (34). Since the early balance studies of McCance and Widdowson, who reported negative calcium balance while consuming whole wheat products (35), it has been assumed that fiber negatively affects calcium balance through either physical entrapment or cationic binding with uronic acid residues (36). However, it is more likely that the phytic acid associated with fiber-rich foods is the component that affected balance, since purified fibers do not negatively affect calcium absorption (37). Only concentrated sources of phytate such as wheat bran ingested as extruded cereal (34) or dried beans (38) substantially reduce calcium absorption. For other plants rich in calcium (primarily the *Brassica* genus, which includes broccoli, kale, bok choy, cabbage, and mustard and turnip greens), calcium bioavailability is as good as that from milk (39). The *Brassica* are an anomaly in the plant kingdom in that they do not accumulate oxalate to detoxify excess calcium to protect against cell death.

Several foods and the number of servings required to equal the amount of calcium in one glass of milk are listed in Table 7.4.

Food	Serving Size (g)	Calcium Content (mg)	Fractional Absorption (%)	Estimated Absorbable Calcium (mg)	Servings Needed to Equal 1 Glass of Milk
Milk (or 1 glass yogurt or 1/2 oz. cheddar cheese)	240	300	32.1	96.3	1.0
Beans, dried	137	93	15.6	14.5	10.3
Broccoli	71	35	61.2	21.5	4.5
Cabbage	65	70	52.7	36.9	2.3
Kale	65	47	58.0	27.4	3.3
Spinach	90	122	5.1	6.2	15.5
Tofu, calcium-set	126	258	31.8	82.0	1.2

Adapted from references 38-41.

¹Adjusted for food for milk, this is fractional absorption (Fabs) = 1000 - 10000 ÷ food. In food for low-oxalate vegetables, after adjusting for the rate of fractional absorption, the need for kale relative to milk is the same food, the equation becomes (Fabs) = 1000 - 10000 ÷ food.

²Calcium content (mg) × (% abs).

Table 7.4 Food Sources of Bioavailable Calcium

True enhancers of calcium absorption have not been well characterized. Lactose appears to enhance calcium absorption in infants. However, in adults, calcium absorption from various dairy products is equivalent, regardless of the lactose content, chemical form of calcium, or presence of flavorings (29, 41).

Nutrient-Nutrient Interactions

Several nutrients and food constituents affect aspects of calcium homeostasis other than through a simple effect on digestibility and absorbability as described above. Several dietary components influence urinary calcium excretion. A major determinant of urinary calcium is urinary sodium, which reflects dietary sodium ([42](#), [43](#)). Sodium and calcium share some of the same transport systems in the proximal tubule, so that each 100-mmol (2.3 g) increment of sodium excreted by the kidney pulls out approximately 0.6 to 1.0 mmol ([24](#), [25](#), [26](#), [27](#), [28](#), [29](#), [30](#), [31](#), [32](#), [33](#), [34](#), [35](#), [36](#), [37](#), [38](#), [39](#) and [40](#)) of accompanying calcium ([44](#)). Because urinary calcium losses account for 50% of the variability in calcium retention, dietary sodium has a tremendous potential influence on bone loss. In adult women, each extra gram of sodium per day is projected to produce an additional rate of bone loss of 1% per year if the calcium loss in the urine comes from the skeleton ([45](#)). A longitudinal study of postmenopausal women showed a negative correlation between urinary sodium excretion and bone density of the hip ([42](#)). The authors concluded, from the range of values available to them, that bone loss could have been prevented either by a daily dietary calcium increase of 891 mg calcium or by halving the daily sodium excretion.

Another dietary component that influences urinary calcium excretion is protein. Each gram of protein metabolized increases urinary calcium levels by about 1.75 mg; thus, doubling the amount of purified dietary proteins or amino acids in the diet increases urinary calcium by about 50% ([46](#)). The acid load of the sulfate produced in the metabolism of sulfur-containing amino acids is mainly responsible for increasing urinary calcium. However, protein-rich foods typically also contain phosphorus, which has a hypocalciuric effect, thereby offsetting the hypercalciuric effect of the protein. Although urinary calcium loss is unchanged by inclusion of protein and phosphorus-rich foods such as meat, cereal, beans, and dairy products, the phosphorus increases the calcium content of the digestive secretions and therefore increases endogenous calcium losses in the feces. Thus, increasing consumption of protein-rich foods results in net calcium loss, which can exacerbate risks of a low calcium diet. The dietary calcium:protein ratio was more closely related to the rate of bone gain in young women than either dietary calcium or protein alone ([47](#)). At the other extreme, inadequate protein intakes compromise bone health and may contribute to osteoporosis in the elderly.

Although widely varying intakes of dietary phosphorus and calcium have produced no changes in calcium balance ([48](#)) (presumably because of the offset of increased endogenous secretion of calcium by decreased urinary calcium), some investigators have been concerned about the popular trend toward high phosphate consumption in soft drinks. Elevated PTH levels, if sustained, could lead to bone resorption, but this effect has been reported in diets that have both elevated phosphorus and low calcium levels ([49](#)). Other investigators ([50](#)) reported the same elevated PTH levels with lower calcium intakes without elevated phosphorus intakes. Thus, low calcium level alone accounts for the observed elevation in PTH.

Although caffeine in large amounts acutely increases urinary calcium ([51](#)), 24-h urinary calcium was not altered in a double-blind, placebo-controlled trial ([52](#)). Daily

consumption of caffeine equivalent to 2 to 3 cups of coffee accelerated bone loss from the spine and total body in postmenopausal women who consumed less than 744 mg calcium per day (53). The relationship between caffeine intake and bone loss in this observational study may be due to a small decrease in calcium absorption (54) or to a confounding factor such as a probable inverse association between milk intake and caffeine intake.

Fat intake has a negative impact on calcium balance only during steatorrhea. In this condition, calcium forms insoluble soaps with fatty acids in the gut.

Increased use of calcium supplements and fortified foods have raised concern about high calcium intakes producing relative deficiencies of several minerals. High calcium intakes have produced relative magnesium deficiencies in rats (55); however, calcium intake does not affect magnesium retention in humans (56). Similarly, except for a single report in postmenopausal women (57), decreased zinc retention has not been associated with high calcium intakes. The nature of this interaction is controversial and requires further study. Iron absorption from nonheme sources is decreased by half from radiolabeled test meals in the presence of calcium intakes up to 300 mg calcium a day, after which there is no further reduction. Thus, practically speaking, it is prudent to set iron requirements assuming that individuals are going to ingest the amount of calcium in at least one glass of milk with each meal (58). The inhibition of iron absorption by calcium does not appear to be a gut effect and may involve competition with the transport of iron in the intestinal mucosa (59), possibly at the level of mobilferrin (see Chapter 10). Up to 12 weeks of calcium supplementation does not change iron status (60), probably because of compensating upregulation of iron absorption. Single-meal iron-absorption studies quite possibly exaggerate inhibitory effects that disappear in the context of the whole diet.

FUNCTIONS

Intracellular Messenger

Ionized calcium is the most common signal transduction element in cells because of its ability to reversibly bind to proteins. To effect a regulatory change, an internal or external stimulus (physical, electrical, or chemical) causes a change in $[Ca^{2+}]$ at a specific site in the cell by releasing a store of Ca^{2+} from within or by causing Ca^{2+} to enter the cell from the outside (Fig. 7.4). $[Ca^{2+}]$ is maintained at about 0.1 μM in the cytosol via many binding and specialized-extrusion proteins. This is necessary because Ca^{2+} is not metabolized like other second-messenger molecules. A released Ca^{2+} ion probably migrates less than 0.1 to 0.5 μm , existing as a free ion only about 50 μsec before encountering a binding protein. The endoplasmic reticulum (sarcoplasmic reticulum in muscles) with its Ca^{2+} -ATP pumps is the major intracellular calcium sink housing Ca^{2+} -binding proteins. Accumulation of Ca^{2+} in the cytosol would lead to cell death because it would precipitate phosphate (vital in energy transfer).

The plasma membrane is important in maintaining calcium homeostasis because the resting membrane is only slightly permeable to entering Ca^{2+} , and a Ca^{2+} - Mg^{2+} -

ATPase pump pumps Ca^{2+} out of the cell cytosol back to the ECF space. The pump is activated by calmodulin, an intracellular Ca^{2+} receptor protein that lowers the K_m (Ca^{2+}) from 0.4 to 0.8 μM to 0.2 μM and increases the total capacity of the pump. Thus, a momentary increase in cytosolic $[\text{Ca}^{2+}]$ caused by an influx of Ca^{2+} is quickly returned to preexcitation levels. Other less important pathways of Ca^{2+} flux across the plasma membrane include influx pathways, potential-operated (voltage-dependent) channels, receptor-operated channels, and Na^+ channels, and the efflux pathway, a Na^+ - Ca^{2+} -exchange pathway maintained by the Na^+ pump. Calcium messenger systems include trigger proteins in excitable cells and sustained responses in nonexcitable and excitable cells (1).

Sustained Responses

When an external or internal stimulus such as a hormone or neurotransmitter binds to a receptor in the plasma membrane, a series of responses occur as depicted in [Figure 7.5](#). Receptors can be G protein-coupled receptors as shown in the figure or receptor tyrosine kinases. The phospholipase C is activated, which breaks down phosphatidylinositol-4,5-bisphosphate (PIP_2) in the cell membrane into inositol-1,4,5-triphosphate (InsP_3) and diacylglycerol (DG). Released into the cytosol, InsP_3 binds to receptors in the endoplasmic reticular (or sarcoplasmic reticular in muscles) membrane, which induces liberation of Ca^{2+} from internal stores. Ca^{2+} can also enter the cytosol via plasma membrane Ca^{2+} -selective voltage-independent channels. Cytosolic Ca^{2+} concentrations can change from 0.1 μM to 10 μM . The increased cytosolic Ca^{2+} binds to calmodulin, which in turn activates kinases to phosphorylate specific proteins. This system accounts for the secretion of aldosterone from adrenal cells in response to angiotensin II, insulin secretion from b cells, and contraction of smooth muscles.

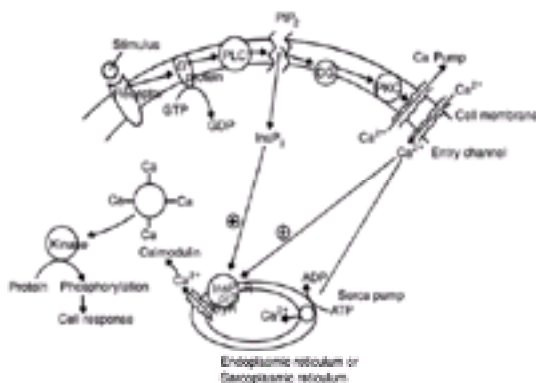

Figure 7.5. Intracellular Ca^{2+} signaling. Abbreviations: PLC, phospholipase C; InsP_3 , inositol-1,4,5-triphosphate; GTP, guanosine triphosphate; GDP, guanosine diphosphate; PIP_2 , phosphatidylinositol-4,5-bisphosphate; DG, diacylglycerol; PKC, protein kinase C; $\text{InsP}_{3\text{R}}$, InsP_3R receptor; RYR, ryanodine receptor; Ca pump, plasma membrane Ca^{2+} -ATPase pump; SERCA, smooth endoplasmic reticulum Ca^{2+} -ATPase pump.

(Adapted from Clapham DE. Cell 1995;80:259–68.)

Meanwhile the lipid portion of PIP_2 , DG, remains in the membrane and activates another membrane-attached enzyme, protein kinase C, which stimulates activity of the calcium pump. Thus, waves of Ca^{2+} are initiated by extra Ca^{2+} cycling in and out of cells (61). As Ca^{2+} concentration returns to resting levels following action of Ca^{2+} pumps, recovery occurs in about 1 second, setting the stage for another Ca^{2+} spike.

Trigger Proteins

Calcium receptor protein pathways are almost universal and are present in excitable and nonexcitable cells. They are important for fast switch processes in which Ca^{2+} acts as an on-off switch. Examples of excitable cells are skeletal muscle and neurons. Excitable cells contain voltage-dependent Ca^{2+} channels in the plasma membrane in addition to the system described above for nonexcitable cells, which allow dramatic increases in intracellular Ca^{2+} . Entering Ca^{2+} activates ryanodine receptors (RyR) to release Ca^{2+} from internal stores.

We have much to learn about how one diffusible ion can regulate such diverse cellular processes as proliferation, differentiation, neuronal adaptation, and movement.

Cofactor for Extracellular Enzymes and Proteins

Calcium is necessary to stabilize or allow maximal activity for a number of proteases and blood clotting enzymes. These functions are not significantly affected by changes in extracellular Ca^{2+} concentration. Those that do not seem to be calmodulin activated by the system described above include glyceraldehyde phosphate dehydrogenase, pyruvate dehydrogenase, and α -ketoglutarate dehydrogenase.

Bones and Teeth

The role of calcium in bones and teeth is described more fully in [Chapter 83](#). Calcium exists primarily as the insoluble hydroxyapatite with the general formula $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$. Calcium comprises 39.9% of the weight of bone mineral.

Aside from the obvious structural role, the skeleton is an important reservoir of calcium to maintain plasma calcium concentrations. Mobilization of calcium from bone may involve as yet unidentified calcium-binding sites (62).

The bone calcium pool turns over every 10 to 12 years on average, but turnover does not occur in the teeth. Remodeling of bone continues throughout life. Bone-resorbing osteoclasts begin this process by extruding packets of citric and lactic acids to dissolve

bone and proteolytic enzymes to digest organic matrix. Bone-forming osteoblasts then synthesize new bone to replace resorbed bone. Usually, these processes are coupled. Bone formation exceeds resorption during growth. Bone resorption exceeds formation during development of osteoporosis. Osteoblasts have receptors for PTH, $1,25(\text{OH})_2\text{D}$, estrogen, and prostaglandin E_2 . Osteoclasts have receptors for calcitonin. Bone resorption is enhanced by PTH and inhibited by calcitonin.

ASSESSMENT OF CALCIUM STATUS

Assessment of calcium nutrient status presents challenges unique among the nutrients. The skeleton, as noted in [Chapter 83](#), functions as a very large calcium reserve both for maintenance of ECF calcium concentrations and for the critical cellular functions of calcium. This reserve is so large that calcium deficiency at a cell or tissue level is essentially never encountered, at least for nutritional reasons. However, since the mechanical function of the skeleton is directly proportional to skeletal mass, i.e., to the size of the calcium reserve, it follows that any reduction whatsoever in the reserve will result in a decrease in bone strength. In this sense, calcium is the only nutrient for which the reserve has a distinct function in its own right. The size of that reserve can be assessed by total-body bone mineral estimation using dual-energy x-ray absorptiometry (DEXA) (see [Chapter 83](#)). A problem arises in the interpretation of the results: the reserve can be low not only for nutritional causes but for other reasons as well, such as lack of adequate physical activity, weight loss, gonadal hormone deficiency, and various medical diseases and their treatments.

In a research setting, calcium balance (intake minus excretion) can be used to determine whether losses of calcium from the body are being met by the intake of the controlled diet. If an individual is in negative balance, calcium is being lost from bone. However, the calcium status of a free-living population on self-selected calcium intakes cannot be readily assessed.

The other aspect of calcium metabolism, the concentration of $[\text{Ca}^{2+}]$ in the blood and ECF, can, however, readily be measured. Low serum $[\text{Ca}^{2+}]$ usually mean some abnormality of parathyroid function; serum $[\text{Ca}^{2+}]$ is rarely ever low because of dietary calcium deficiency. This is basically because (as noted above) the skeleton serves as a very large calcium reserve and protects the ECF $[\text{Ca}^{2+}]$ essentially without limit. As described elsewhere in this chapter, it is the function of the parathyroid glands to draw down calcium from these reserves for the maintenance of ECF $[\text{Ca}^{2+}]$.

DEFICIENCY

Overt, uncomplicated calcium metabolic deficiencies are almost nonexistent given the large skeletal reserves as discussed above. One possible exception is the report in children aged 7 to 12 years on daily calcium intakes of 3.1 mol (125 mg) ([61](#)). Abnormal biochemistry values were observed including hypocalcemia, hypercalciuria, and elevated alkaline phosphatase levels.

Chronic inadequacy of calcium in the diet is one factor in the etiology of several disorders (64). Adequate calcium intakes have been definitely established as protective against osteoporosis and have been associated with reducing the risk of hypertension, colon cancer, lead poisoning, and kidney stones in patients with the short bowel syndrome.

The primary strategies for reducing the risk of osteoporosis are to maximize development of peak bone mass during growth and to reduce bone loss later in life. Achieving optimal calcium intakes is a goal for both of these aims. Further details on the role of calcium in preventing this debilitating disease may be found in [Chapter 85](#). The role of calcium in ameliorating hypertension is less well documented than for osteoporosis but has been extensively studied in the last decade. The evidence is reviewed in an LSRO report (65). A recent metaanalysis (66) of randomized, controlled intervention trials showed that calcium supplementation has a small lowering effect on systolic blood pressure (−1.27 mm Hg) but not on diastolic blood pressure. However, a metaanalysis specifically confined to calcium supplementation trials with pregnant women showed a much more dramatic effect of calcium (67). Both systolic and diastolic blood pressures were significantly lowered (−5.40 mm Hg and −3.44 mm Hg, respectively). The odds ratio with calcium supplementation was 0.30 for pregnancy-induced hypertension, 0.38 for preeclampsia, and 0.69 for premature infants. In contrast, no effect of calcium supplementation was observed in women already consuming 24.5 mmol (980 mg) daily in the randomized, controlled trial of Calcium for Preeclampsia Prevention (CPEP) (68). Other groups that may be vulnerable to calcium deficiency–related hypertension include African Americans and the elderly.

The effect of dietary calcium in reducing the risk for colonic tumors has been suggested in a number of studies. Dietary calcium may protect against abnormal epithelial growth. One proposed mechanism is that Ca^{2+} precipitates bile acids and fatty acids that can otherwise stimulate colon cell proliferation. Intakes of 1800 mg/day for men and 1500 mg/day for women have been recommended to reduce the incidence of colon cancer (69). However, two prospective studies showed that the occurrence of colorectal adenoma was related neither to calcium intake nor to milk consumption (70). The role of calcium in colon cancer of humans requires further study.

High calcium intakes decrease the risk of kidney stones (see [toxicity](#) section below) (71). Unabsorbed calcium in the gut forms a highly insoluble oxalate salt in the colon, thereby reducing absorption of oxalate from the diet. Large calcium supplements are the accepted therapy for the kidney stone problem of intestinal hyperoxalosis.

REQUIREMENTS AND RECOMMENDED INTAKES

The calcium requirement is the amount of dietary calcium required to replace losses in the urine, feces, and sweat, plus the calcium needed for bone accretion during periods of skeletal growth. Calcium is a plateau nutrient; above a certain intake, little further increase in calcium retention can occur because the excess is excreted. Plateau intakes for achieving maximal calcium retention were used with other data to set the 1997 dietary reference intakes for calcium. Recommendations across the life span for

adequate intakes of calcium by the National Academy of Science Food and Nutrition Board are given in [Table 7.5](#). Calcium requirements throughout life are not uniform because of changes in skeletal growth and age-related changes in absorption and excretion.

Group	Adequate Intake (mg/day)
Infant	
Birth–6 months	210
6 months–1 year	270
Children	
1–5 years	500
4–8 years	800
Adolescents 9–18 years	1300
Adults	
19–50 years	1000
Over 50 years	1200
Pregnant and lactating	
14–18	1300
≥19	1000

From Food and Nutrition Board, National Academy Press. Dietary reference intakes: calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington, DC: National Academy Press, 1997.

Table 7.5 Adequate Calcium Intakes during the Life Span

Infancy

A term human infant contains approximately 0.65 to 0.75 mol (26–30 g) of calcium. During the first year of life, the rate of calcium deposition in relation to body size is higher than at any other period during life.

Childhood and Adolescence

Calcium accretion continues throughout childhood. Rate of growth slows between the ages of 2 and 8 years. Maximal accretion occurs during the pubertal growth spurt, which occurs for most girls between the ages of 12 and 14 years and for boys, 14 and 16 years. The intake required for mean maximal calcium retention in adolescent girls is 1300 mg/day ([72](#)). Between the ages of 9 and 17 years, approximately 45% of the adult skeleton is acquired. This represents a gain in bone mass of about 7 to 8%/year.

Several calcium or dairy supplementation trials have been conducted in children. They all demonstrate that calcium intake can positively influence bone accumulation ([73](#), [74](#), [75](#) and [76](#)). However, the differential gain in bone mass wanes after cessation of calcium supplementation ([77](#)).

Peak Bone Mass

After adult height is achieved, calcium accretion continues during the phase of bone consolidation. At the end of consolidation, when the maximum amount of bone has been

accumulated, the adult is said to have achieved his or her peak bone mass. In females, 90% of total body bone mineral content is achieved by age 16.9 years, 95% by 19.8 years, and 99% by age 22.1 years (78). However, the timing of peak bone mass varies with the skeletal site. The hip achieves peak bone mass first at approximately age 16.7 years for the trochanter, 17.2 years for the femoral neck, and 18.5 years for Ward's triangle, whereas the spine can add mass throughout most of the 2nd decade of life in females (79). The skull accumulates bone throughout life, as does the femur shaft (80).

Although 60 to 80% of peak bone mass is genetically predetermined, a number of environmental factors affect bone mass. The main determinant of bone density in adolescent girls is calcium intake (81). During this period, urinary calcium is relatively unaffected by calcium intake (72). Aside from calcium intake, other lifestyle choices that affect peak bone mass include physical activity, intake of other nutrients that affect calcium balance (covered elsewhere in this chapter), anorexia, and substance abuse. Beyond the timing of peak bone mass, lifestyle choices can affect rate of bone loss, but the window of opportunity to build bone has passed.

Adults

The mature female has 23 to 25 mol (920–1000 g) body calcium, and the mature male has approximately 30 mol (1200 g) body calcium. The population coefficient of variation around these means is about 15%. Total body bone mass remains relatively constant over the reproductive years, as decreases in the proximal femur and other sites after age 18 are offset by continued growth of the forearm, total spine, and head. Then age-related bone loss occurs, which varies with the individual, but occurs most rapidly during the first 3 years after menopause in women. The average adult loses bone at a rate of ~1%/year. Age-related decreases in calcium absorption and increases in urinary calcium contribute to this loss. These physiologic changes are more abrupt at the menopause in women. The explanation for bone loss during aging includes a variety of causes such as declining calcium intakes (discussed below), declining physical activity, decreased levels of gonadal hormones, decreased circulating levels of $1,25(\text{OH})_2\text{D}$, and intestinal resistance to $1,25(\text{OH})_2\text{D}$. The calcium intake required by older adults to achieve mean maximal retention or minimal loss was determined to be 1200 mg/day by the Panel on Calcium and Related Nutrients (Table 7.5) using the balance data of Spencer et al (82).

Calcium intakes required to prevent bone loss also suffice to protect against risk of hypertension. The calcium intake threshold for reducing risk of high blood pressure is likely to be 12.5 to 15 mmol/day (500–600 mg/day). Optimal calcium intakes to reduce risk of other diseases are not known.

Pregnancy

Fetal skeletal calcium accretion is not great until the third trimester. During the third trimester, approximately 5 mmol/day (200 mg/day) of calcium is required for fetal growth. The mother's calcium absorption increases beginning by the second trimester to meet fetal demands and to store calcium for the subsequent lactational drain (83). At

low calcium intakes, the mother's skeleton is compromised to meet calcium demands of the fetus, and the fetal skeleton is protected except at exceptionally low calcium intakes. In one study, calcium supplementation increased bone density of neonates of malnourished women in India (84). There is no evidence to date that multiple births are harmful to women, even on low calcium intakes.

During pregnancy, biologically active PTH falls, calcitonin increases during early pregnancy, and prolactin increases 10- to 20-fold.

Lactation

Calcium transfer to breast milk varies mainly with changes in volume; calcium concentration is relatively constant at 7 ± 0.65 mmol/L (280 ± 26 mg/L). Daily calcium transfer from maternal serum to breast milk increases from 4.2 mmol/day (168 mg/day) at 3 months following parturition to 7 mmol/day (280 mg/day) at 6 months following parturition. To meet this need, the maternal skeleton is depleted at a rate of about 1% per month; this loss is not prevented by calcium and vitamin D supplementation (85). A postlactation anabolic phase allows recovery of bone density to prelactation levels. Whether this recovery is complete in all individuals, such as older lactating women, is not known.

ADEQUACY OF CALCIUM INTAKE

The median calcium intakes by age, for males and females in the United States, collected by the USDA 1994 Continuing Survey of Food Intakes by Individuals (CSFII) and adjusted for day-to-day variation are shown in Figure 7.6, compared with the 1997 dietary reference intakes (DRIs) for calcium. It is obvious that the typical man consumes more calcium at all stages of life than do women. Calcium intakes are highest in boys during their adolescent growth spurt. In contrast, just as girls enter their period of most rapid skeletal growth, intakes decline. Calcium intakes of females were below the DRI for calcium above the age of 9 years. Low calcium intakes are also associated with low intakes of other nutrients, including vitamins B₆, B₁₂, thiamin, riboflavin, and magnesium (87).

Figure 7.6. Mean calcium intakes by age for U.S. males and females assessed by 24-h dietary recall adjusted for day-to-day variation (86) compared with 1997 dietary reference intakes for calcium adequate intakes and the 1989 RDA. 40 mg Ca = 1 mmol.

Assessment of calcium intakes of populations is important for determining nutritional status and drawing conclusions about the relationship between diet and health and disease. However, assessing the usual calcium intake of an individual is fraught with errors. Calcium intake can be assessed with food-frequency questionnaires, diet recalls, or diet records or by duplicate plate analysis. The latter eliminates many of the errors associated with other methods but is not practical for assessing large groups of individuals. Food-frequency questionnaires assess calcium better than some nutrients because dairy foods are the major source of calcium, and individuals recall dairy product consumption reasonably well. However, hidden calcium taken in as food additives (anticaking agents, etc.), water, fortified foods, and components of pharmaceuticals can be easily overlooked. Diet recall and diet records suffer from errors in estimating portion size, from variability in food composition, and from inadequacies of existing food composition tables. Multiple diet records can improve the estimate of an individual's average calcium intake. However, the generally large variability in calcium intake from day to day precludes confidence in estimates of usual calcium intake of an individual (88, 89).

TOXICITY

Nutritional toxicity of calcium means an elevation of blood calcium levels (hypercalcemia) because of overconsumption of calcium, or an elevation of urine calcium excretion to the point that either the kidneys calcify or renal stones develop. Hypercalcemia, particularly if severe, results in lax muscle tone, constipation, large urine volumes, nausea, and ultimately confusion, coma, and death. It essentially never occurs from ingestion of natural food sources. A good illustration of the safety of food calcium sources is provided by nomadic, pastoral people, such as the Masai (90). Because their diets consist mostly of the milk of their herds and flocks, they have calcium intakes above 5000 mg/day (and often higher), roughly 5 to 10 times what people of industrialized nations ingest. Such pastoral people are not known to have an unusual incidence of hypercalcemia or kidney stones.

Hypercalcemia is reported only with ingestion of large quantities of calcium in the form of supplements, usually taken with absorbable alkali (which raises the pH of the urine and predisposes to calcium deposits in the kidneys). In the past, this outcome sometimes occurred in the treatment of peptic ulcer with large quantities of milk, calcium carbonate, and sodium bicarbonate and was termed the *milk alkali syndrome*. Even so, this complication was unusual, and most individuals can consume large quantities of calcium supplements for years without difficulty.

Kidney stones are not usually caused by dietary calcium. More often, individuals with kidney stones have high urine calcium levels because they have a renal leak of calcium. Accordingly, they often have some reduction of their skeletal calcium reserves. Lowering calcium intake in such individuals rarely affects their kidney stone problem but always leads to further reduction in bone mass. While high calcium intakes may contribute to kidney stone formation in certain susceptible individuals, in most individuals, the stone problem is actually helped by *increasing* calcium intakes (70). This is because urinary oxalate excretion is a more important risk factor for stones than is urinary calcium excretion. A high calcium diet binds oxalate of dietary origin in the gut and prevents its absorption, thereby reducing urinary oxalate load.

CLINICAL DISORDERS INVOLVING CALCIUM

As noted above, low calcium intakes, coupled with high obligatory calcium losses from the body, deplete skeletal calcium reserves. In other words, low intakes cause subnormal bone mass (and strength). This is one of the contributing causes of osteoporosis (covered in [Chapter 85](#)). Medical science recognizes no clear disorder of intracellular calcium regulation. However, cell injury, damage, or serious dysfunction is always associated with a rise in cytosolic calcium concentration, probably reflecting impaired ability of the cell to maintain the normal 10,000-fold gradient. Moreover, it is likely that the rise in cytosolic calcium worsens the cell damage and hastens cell death (91).

The most common disorders of calcium metabolism (other than osteoporosis, which is multifactorial in etiology), involve regulation of ECF $[Ca^{2+}]$. Usually these are due to disorders of parathyroid gland function and are not nutritional. As noted elsewhere in this chapter, the skeletal calcium reserves are so vast, relative to the size of the ECF $[Ca^{2+}]$ compartment, that simple dietary deficiency of calcium essentially never compromises ECF $[Ca^{2+}]$ regulation. There are, however, a few rare exceptions that are worth noting because they illustrate how the system operates.

During growth, when the demands of skeletal mineralization are highest, extremely low calcium diets may lead to hypocalcemia, despite maximal secretory output of the parathyroid glands. One consequence of hypersecretion of PTH is a lowering of serum phosphate levels. The combination of low calcium and low phosphorus levels in the ECF results both in undermineralization of newly deposited bone matrix and in osteoblast dysfunction. The result is rickets. Usually rickets is produced by vitamin D deficiency, by hypophosphatemia from other causes, or by osteoblast toxicity (see [Chapter 83](#)). However, as this example shows, it can sometimes be caused by calcium deficiency alone (89).

Another example of nutritional hypocalcemia occurs as a result of magnesium deficiency, most often noted in severe alcoholism or as a result of intestinal fistulas or malabsorption that causes excessive magnesium loss from the body. Magnesium, of course, is an essential cation for many cell metabolic processes (see [Chapter 9](#)), and with severe magnesium depletion, many organs and systems function abnormally. The

system regulating ECF $[Ca^{2+}]$ is an example. Both PTH release from the parathyroid glands and bony response to PTH depend on magnesium, and both are defective in magnesium deficiency (90). Evidence that both steps are impaired is provided by the fact that PTH levels in Mg-deficient patients fail to rise adequately in response to hypocalcemia, and exogenous PTH fails to elevate their bone remodeling as it should. Magnesium repletion corrects both problems.

[Chapter References](#)

Hypophosphatemia and phosphorus deficiency are exceptionally common among seriously ill, hospitalized patients. Although both conditions have many causes, they are most commonly seen during treatment of diabetic ketoacidosis (DKA) and alcoholic withdrawal and while administering nutrients to a starved or wasted patient ([Table 8.1](#)).

Table 8.1 Causes of Hypophosphatemia

Refeeding a starved person or administering nutrients to an undernourished sick patient may result in a predictable derangement of blood composition, a variety of specific organ dysfunctions, and sudden death secondary to arrhythmias. This condition has been termed the *refeeding syndrome*. Old historical records describe epidemics of death when starving persons gained access to food, engorged themselves, then became sick and died. One report describes deaths of Jews in the first century who had been entrapped and starved by the Romans. Some escaped, stuffed themselves with food, and died. Flavius Josephus pointed out clearly that death occurred in those who overindulged themselves but not in those who were skillful enough to restrain their appetites (1). Similar descriptions of death during refeeding were related by physicians observing liberated prisoners during WWII. Although the appearance of anasarca suggested beriberi precipitated by feeding carbohydrates, incorporation of brewers' yeast did not prevent the disease. As foretold from biblical descriptions (1), it was finally realized that refeeding with small amounts of food or milk would prevent this disaster. Since laboratory measurements were not available then, it was never clearly appreciated that overly aggressive refeeding could cause serious derangements of plasma. However, more recent studies on patients with anorexia nervosa treated with parenteral nutrition or overzealously with a normal diet have shown that hypophosphatemia and phosphorus deficiency play major roles in their metabolic complications.

CHEMISTRY AND PROPERTIES OF PHOSPHORUS

At normal blood pH, phosphate ions exist as 4 parts of HPO_4^{-2} and 1 part of $\text{H}_2\text{PO}_4^{-1}$. Thus $(4 \times 2^-) + (1 \times 1^-) \times (4 + 1) = 1.8$, which is the average valence of PO_4 in arterial plasma. In most laboratories, phosphorus is reported as inorganic P, and its normal range is 3.0 to 4.5 mg/dL or since the molecular weight of P is 30, 1.0 to 1.5 mM. About 5 to 10% of phosphorus is bound to protein, so most of the element is freely filtered by the glomerulus.

Children have higher plasma phosphorus concentrations, which may result from growth hormone and insulin-like growth factor activities (2). Plasma phosphorus concentration regulates erythrocyte synthesis and stores of 2,3-diphosphoglycerate (2,3-DPG), which is bound to hemoglobin (3). This substance plays an important role in hemoglobin affinity for oxygen. When 2,3-DPG is elevated, as it is in children, hemoglobin releases its oxygen more easily, and blood hemoglobin concentration and hematocrits are set at lower values. Nevertheless, oxygen delivery to tissues is normal. This phenomenon is also seen in patients with end-stage renal disease. If phosphate-binding antacids are administered to cause hypophosphatemia, 2,3-DPG in erythrocytes falls, and blood hemoglobin levels rise to complement the reduction of oxygen delivery that would occur otherwise (2).

Metabolism of Phosphorus

Recommended Phosphorus Intake

The current recommendations for daily dietary intake (known as dietary reference intake) of phosphorus by the Food and Nutrition Board of the Institute of Medicine (3a) are as follows: (a) 0 to 6 months, 100 mg (provided by human milk); 6 to 12 months, 275 mg (provided by milk plus food); (b) 1 through 8 years, 460 to 500 mg; (c) age 9 to 18, 1250 mg; (d) age 19 to 70, 700 mg; and during pregnancy or lactation, 1250 mg.

Dietary Sources of Phosphorus

Protein-rich foods and cereal grains are rich sources of phosphorus. In the United States about one-half of dietary phosphorus comes from milk, meat, poultry, and fish. Cereals provide 12%. Processed meats and cheese contain more phosphorus than natural products.

Absorption of Phosphorus

Phosphorus from soluble products such as meat is more available than that from other sources. Milk casein contains a phosphopeptide resistant to enzymatic hydrolysis; human milk, being lower in casein, may have more phosphorus available for absorption than cow's milk. Phytic acid in cereal grains reduces bioavailability. A low phytase content of corn and oats reduces phosphorus bioavailability, and accordingly, these grains may be rachitogenic (4).

Absorption of phosphorus occurs throughout the length of the small intestine and is under the control of vitamin D and specific phosphate transporters. Absorption is reduced by a number of phosphate-binding antacids.

Total Body Content of Phosphorus

A normal 70-kg man contains about 700 g (23 mol) of phosphorus. Eighty percent is contained in bone and 9% in skeletal muscle. Most intracellular phosphorus exists as organic compounds, such as creatine phosphate and adenosine monophosphate (AMP) and triphosphate (ATP). As potassium is the most concentrated cation in the cell, phosphate is the most abundant anion. Total tissue phosphorus and nitrogen contents exist in a molar ratio of 0.03 in health.

Renal Handling of Phosphorus

In health, the kidneys retain about 80% of phosphorus filtered by the glomerulus. The major regulators of phosphate balance by the kidney are glomerular filtration and parathyroid hormone. Phosphorus is reabsorbed mainly in the proximal tubule by active transport. Parathyroid hormone reduces phosphorus reabsorption by the proximal tubular cells. The fractional clearance rises with hyperphosphatemia and falls with hypophosphatemia. Expansion of extracellular volume independently raises phosphate

clearance (2). Vitamin D plays a small role in renal phosphate balance. Nevertheless, serum phosphorus levels play a major role in renal conversion of 25-hydroxyvitamin D₃ to 1,25-dihydroxyvitamin D₃.

Functions of Phosphorus

Phosphorus is a critically important element in every cell of the body. It is a major component of bone where it exists as hydroxyapatite. Plasma membranes require phosphorus as a component of phospholipids. All energy production and storage in the body depend upon adequate sources of phosphorus, including adenosine triphosphate, creatine phosphate, and other phosphorylated compounds. Phosphorus is a critical component of virtually all enzymes, cellular messengers such as the G-proteins, and carbohydrate fuels. A number of hormones depend upon phosphorylation for their activation. Phosphorus is of vital importance for acid-base regulation, not only serving as one of the most important buffers at the bone surface but also in renal regulation of proton balance.

HYPOPHOSPHATEMIA

Hypophosphatemia without Phosphorus Deficiency

Hypophosphatemia, i.e., a plasma concentration below 2.5 mg/dL (0.83 mM), is especially common in hospitalized patients who are seriously ill. It commonly occurs in the absence of a total body phosphorus deficit. For example, hyperventilation and respiratory alkalosis can reduce plasma phosphorus to values as low as 0.3 mg/dL (0.1 mM) in normal persons. By reducing plasma pCO₂, cytosolic pCO₂ falls, intracellular pH rises, and phosphofructokinase activity increases, resulting in phosphorylation of glucose. As a result, cytosolic phosphate falls, plasma phosphate enters the cell, and hypophosphatemia follows. Hyperventilation, respiratory alkalosis, and hypophosphatemia in the absence of phosphorus deficiency can occur in hepatic coma, endotoxic sepsis and shock, severe pain, recovery from exercise, and hyperthermia due to either heat stroke or the neuroleptic malignant syndrome. Administration of glucose or amino acids stimulates release of insulin, or administration of insulin causes cellular uptake of phosphorus and hypophosphatemia (2).

Intravenous fructose is dangerous because it can cause severe liver injury and induce modest hypophosphatemia as a result of "phosphate trapping" (2, 5). In this process, fructose is converted in the liver to fructose-1-phosphate without feedback inhibition of continued fructose uptake. For example, when glucose is transported into a hepatocyte, the glucose-6-phosphate formed inhibits glucokinase, thereby downregulating the process of glucose uptake. In the case of fructose, fructose-1-phosphate does not inhibit fructokinase, and accordingly, the unregulated uptake of fructose goes on, resulting in hypophosphatemia. The cytosolic phosphate trapping causes a sharp elevation in the phosphorylation potential ($ATP \times (ADP \times P^i)$), which results in decreased mitochondrial respiration and decreased ATP production. Cytosolic hypophosphatemia activates AMP deaminase, which reduces the nucleotide pool. The resulting inosine monophosphate is irreversibly converted to uric acid. Injury resulting from intravenous (not oral) fructose is

seen only in tissues capable of metabolizing fructose, including the liver, proximal tubules of the kidney, and probably the small intestinal epithelium.

Hypophosphatemia with Phosphorus Deficiency

Hypophosphatemia in association with phosphorus deficiency is most commonly seen in chronic alcoholics during withdrawal and in patients recovering from DKA. Chronic ingestion of ethanol in large quantities causes depletion of body phosphorus stores in both humans and experimental animals (2). Indeed, phosphorus deficiency in this setting may play an important role in alcoholic myopathy and acute rhabdomyolysis (Table 8.1).

Hypophosphatemia occurs in as many as 50% of hospitalized alcoholics (2). Most chronic alcoholics who are not acutely ill show either a normal or slightly depressed serum phosphorus concentration (6). Hospitalized alcoholic patients are commonly unable to eat for a period of days before admission to the hospital, because of alcoholic ketoacidosis or, alternatively, alcohol withdrawal. Two important factors generally explain hypophosphatemia in such patients. First, administration of intravenous fluids containing nutrients without phosphorus is commonly responsible. Second, the usual hyperventilation and respiratory alkalosis that prevails in withdrawing alcoholics may result in hypophosphatemia that may be severe. On the first day of hospitalization of alcoholic patients, before the decline of serum phosphorus, urinary phosphorus excretion rates may equal 1 g or more (7). This is a high phosphorus excretion for a person who has virtually no phosphorus intake. Phosphaturia in such instances has been ascribed to the associated ketoacidosis (8), lactic acidosis, or proximal tubular injury (7). Nevertheless, consequent to administration of nutrients, correction of volume depletion, reversal of ketoacidosis, and development of respiratory alkalosis, phosphorus virtually disappears from the urine. Thus, the development of hypophosphatemia is caused by a shift of phosphorus out of extracellular fluid into the intracellular compartment. Hypokalemia and hypomagnesemia occur less commonly in these patients.

Measurement of muscle composition in severe chronic alcoholics discloses a complex derangement in which total phosphorus and magnesium are abnormally low, and sodium, chloride, and calcium contents are abnormally high (6, 9, 10). In some patients, potassium content of skeletal muscle is also low. While the average value for total phosphorus content in alcoholic patients is 20.4 mmol/dg of dried fat-free muscle, some patients demonstrate values as low as 12 mmol/dg. If one assumes that all muscle tissue is uniformly affected and that skeletal muscle occupies 40% of the body mass, the total deficiency of phosphorus in skeletal muscle alone extrapolates to 1800 mmol in patients with the lower values.

The causes of phosphorus deficiency in chronic alcoholics are multifactorial. Chronic administration of intoxicating quantities of ethanol to dogs for 2 months causes equally severe phosphorus deficiency in skeletal muscle despite a generous intake of all essential nutrients, including phosphorus (9, 10). Our observations suggest that alcohol exerts toxicity on the muscle cell and is responsible for disorganization of muscle composition, despite a nutritious diet (11). The precise mechanism of these effects is

unknown. Since ethanol interferes with sodium transport in a variety of tissues, including skeletal muscle (10, 11), and since phosphate transport in nearly all tissues examined depends upon normal sodium transport, perhaps deranged sodium transport is somehow responsible for loss of phosphate from muscle. It has been proposed that cytosolic production of the anion acetaldehyde during metabolism of ethanol may electrically dislocate phosphate from the cell (12).

Alcohol may also damage the proximal tubule epithelium of the kidney. It has been reported that urinary γ -glutamyltranspeptidase (GGT), a tubular brush border membrane enzyme and the fractional clearance of lysozyme, a marker of proximal tubular function, are elevated in 61% of chronic alcoholics (13). Reduced capacity for phosphate reabsorption is seen in 82% of hypophosphatemic alcoholics but in none who were normophosphatemic. Others have described a renal phosphorus leak causing hypophosphatemia that resolves on abstinence (7). Parathyroid hormone is inhibited by acute alcoholic intoxication and therefore is unlikely to be responsible for these abnormalities (15). Poor phosphorus intake, use of phosphate-binding antacids, impaired vitamin D metabolism, magnesium deficiency, vomiting, or diarrhea might also cause such a deficit of phosphorus.

Simple dietary deficiency as a cause of phosphorus deficiency and hypophosphatemia is very rare because phosphorus is abundant in all foods and is avidly retained by the kidney. However, if the diet is deprived of phosphorus while a person ingests a phosphate-binding drug (e.g., aluminum hydroxide gel) severe and potentially fatal phosphorus deficiency may occur. In fact, refeeding a diet containing inadequate phosphorus to a starving person may allow tissue to be resynthesized without adequate phosphorus. This refeeding or nutritional recovery syndrome is heralded by hypophosphatemia with or without hypokalemia, progressively severe weakness, and a multitude of tissue and organ dysfunctions described below in more detail.

Hyperparathyroidism causes only mild hypophosphatemia in most instances. Malabsorption of fat causes modest hypophosphatemia, mainly from urinary loss. Thus, steatorrhea causes reduced absorption of vitamin D, vitamin D deficiency, malabsorption of calcium, hypocalcemia, increased production of parathyroid hormone, phosphaturia, and hypophosphatemia.

Primary impairment of phosphorus absorption by the renal tubule is seen in several conditions, including X-linked hypophosphatemia and Fanconi syndrome. Dietary vitamin D deficiency and interference with vitamin D production in oncogenic osteomalacia are acquired causes. Extracellular volume-expanded states, including the syndrome of inappropriate secretion of antidiuretic hormone, and primary aldosteronism also reduce phosphorus absorption (2). Acute infusion of sodium chloride solutions causes phosphaturia and hypophosphatemia by two mechanisms. First, the resulting volume expansion per se appears to reduce tubular reabsorption of phosphorus, and in addition, acute reduction of serum calcium causes release of parathyroid hormone and phosphaturia.

Two important conditions causing excessive loss of phosphorus into the urine are chronic respiratory acidosis and DKA. A reduction in intracellular pH causes degradation

of organic phosphates, which allows phosphorus to enter plasma. Both conditions, untreated, are usually associated with a normal or even elevated serum phosphorus concentration. Because of this, phosphorus is lost into the urine and depletion occurs. The associated osmotic diuresis in DKA abets phosphorus losses. Effective treatment of either condition unveils the phosphorus deficiency. Thus, relief from hypercarbia allows cell pH to rise, glucose phosphorylation increases, and phosphorus in serum falls to potentially very low levels. Treatment of DKA with insulin, fluids, and electrolytes results in rapid hypophosphatemia as phosphorus is taken up by cells.

Effect of Phosphorus Deficiency and Hypophosphatemia

Phosphorus deficiency impairs growth. This is seen especially in the various forms of vitamin D deficiency in humans, such as celiac sprue, and in diseases causing renal tubular loss of phosphorus. Numerous experimental studies have documented the role of phosphorus in growth. Early phosphorus deficiency is often associated with losses of potassium, magnesium, and nitrogen. Reductions in major cell components are almost invariably associated with abnormalities of cellular ion transport, eventually resulting in accumulation of sodium, chloride, calcium, and water.

Osteomalacia, defined as a defect in bone mineralization, often occurs in longstanding phosphorus deficiency. Experimental phosphorus deprivation in conjunction with phosphate-binding antacid ingestion in human volunteers (16) resulted in profound muscle weakness and bone pain. In clinical settings, vitamin D deficiency resulting from steatorrhea or in patients with tumors that produce a substance interfering with renal production of $1,25(\text{OH})_2\text{D}_3$ eventually causes osteomalacia (17).

Distinct from osteomalacia, dietary phosphorus deprivation acutely results in skeletal demineralization, even before serum phosphorus levels fall (2). Although the substance responsible for this phenomenon is unknown, it appears to be either a hormone or a cytokine, but not parathyroid hormone. In normal adults, phosphorus deprivation causes release of calcium from the skeleton and hypercalcuria; however, hypercalcemia does not occur. In contrast, in growing children or in adults with various diseases affecting bone, such as Paget's disease, hyperparathyroidism, or metastatic malignancy involving bone, the skeletal response to phosphorus deprivation is more brisk, and hypercalcemia may occur. In experimental animals, dissolution of hydroxyapatite from the skeleton with phosphorus deprivation is prevented by colchicine (18).

Myopathy and Rhabdomyolysis

Chronic phosphorus deficiency in man causes a proximal myopathy (19). Proximal muscle atrophy and weakness may be striking. Osteomalacia usually accompanies this disorder. Laboratory findings characteristically show normal creatine phosphokinase (CPK) and aldolase activities; phosphorus levels in serum are modestly depressed, calcium levels may be low or normal, and alkaline phosphatase activity is usually sharply elevated.

Selective phosphorus deficiency causes reversible injury to muscle cells of the dog (20).

These changes include depressed resting muscle transmembrane electrical potential, increased cellular content of Na, Cl, and water, and decreased phosphorus content. Serum CPK activity is normal. Chronic phosphorus deficiency apparently does not cause acute rhabdomyolysis. However, acute hypophosphatemia may precipitate rhabdomyolysis if superimposed upon chronic phosphorus depletion (21, 22). Most cases have occurred either during acute alcohol withdrawal or in severe chronic alcoholism treated with nutrients devoid of phosphorus. In alcoholics, rhabdomyolysis usually appears within the first few days in the hospital and is marked by a sudden elevation of CPK activity. The clinical manifestations include severe muscle pain, profound weakness, muscle tenderness, stiffness, swelling, and rarely muscular paralysis and diaphragm failure. Some patients are relatively asymptomatic and show very few abnormal muscle findings despite severely elevated serum creatine kinase or aldolase activities. In either situation, muscle creatine kinase activity in serum is consistently elevated, sometimes exceeding 100,000 IU/L. Other classical laboratory findings may be seen, i.e., myoglobinuria, hyperkalemia, hypocalcemia, hyperuricemia, and hypo-albuminemia (23). Hypophosphatemia and phosphorus deficiency may be obscured by release of residual phosphate from necrotic skeletal muscle and correction of the hypophosphatemia (22).

Rhabdomyolysis during total parenteral nutrition (TPN) is very rare and has not been observed if important intracellular element deficiencies are prevented. Apparently, rhabdomyolysis does not occur with acute hypophosphatemia in the absence of preexisting damage to muscle cells (24). If chronically phosphorus-depleted dogs with hypophosphatemic myopathy are hyperalimented without phosphorus, their serum phosphorus levels rapidly decline to values below 1.0 mg/dL and they become very ill, displaying marked weakness, inability to swallow their secretions, muscle fasciculations, and, in some, convulsions. They also show a pronounced elevation of CPK activity in serum. Histologic examination of skeletal muscle shows frank rhabdomyolysis. However, if phosphorus-deficient dogs are hyperalimented with phosphorus, serum phosphorus does not fall, CPK activity does not increase, and muscle histology remains normal (21).

The apparent prerequisite that muscle injury must exist before hypophosphatemia can cause acute florid rhabdomyolysis expresses itself both positively and negatively in several clinical settings. Patients with chronic alcoholic myopathy develop frank rhabdomyolysis if they become acutely hypophosphatemic, and patients with the neuroleptic malignant syndrome (25) develop florid rhabdomyolysis that appears to correlate inversely with the degree of hypophosphatemia. Negative expressions of this relationship are exemplified by the rarity of rhabdomyolysis in the patient who becomes hypophosphatemic during treatment of DKA or in the patient with simple starvation who becomes hypophosphatemic during TPN therapy (26). Usually neither of the latter instances show evidence of preexisting skeletal muscle damage.

Normal dogs deprived of calories but otherwise fed a diet replete with all other nutrients develop acute hypophosphatemia when hyperalimented. They show no evidence of rhabdomyolysis (24). Organs were sampled to determine their total phosphorus, sodium, potassium, chloride, magnesium, and calcium content. Although hypophosphatemia appeared quickly and usually attained levels below 1 mg/dL by the 2nd or 3rd day of hyperalimentation, CPK levels did not become abnormally high. Total

phosphorus content fell substantially in skeletal muscle, liver, and bone. In contrast, total phosphorus content of cerebral cortex, left ventricle, adrenal gland, pancreas, renal cortex, renal medulla, thyroid, and spleen remained within normal limits. Despite sharp reduction in total muscle phosphorus and inorganic phosphorus concentrations in serum, ATP, ADP, and inorganic content of muscle tissue remained normal in dogs with acute hypophosphatemia that were not already phosphorus deficient. Thus, the phosphorylation potential (855 mmol/L in control animals) remained essentially unchanged (863 mmol/L in the hypophosphatemic animals) (24).

In contrast to the acute hypophosphatemic model, chronic phosphorus deficiency caused a pronounced change in muscle content of high energy components. ATP, ADP, and inorganic phosphate each fell by approximately 50%, thus seriously reducing the total adenine nucleotide pool. In addition, the increased value for the phosphorylation potential indicates a reduced rate of mitochondrial respiration, hence a reduced rate of ATP synthesis (24).

Our studies also suggest that not only bone but also skeletal muscle is apparently an endogenous reservoir for phosphorus. Thus, in the event of acute phosphorus depletion causing hypophosphatemia, muscle phosphorus is rapidly mobilized to provide phosphorus for vital organs. A low value for ATP, such as that observed in dogs with chronic phosphorus deficiency, implies that such a cell is in jeopardy. Thus, in the event of a superimposed insult, such as more pronounced hypophosphatemia or perhaps anorexia from a variety of influences in the phosphorus-deficient state, ATP levels must necessarily fall further. Much evidence suggests that when ATP levels decline to critically low values, cellular death may supervene. Additional evidence indicates that if sodium transport is so impaired that sodium ions accumulate in muscle cytoplasm, sodium-calcium exchange is decreased (27), so that sufficient calcium may accumulate in the cell to activate lysosomal enzymes and lead to destruction of the cell.

An important species difference appears to exist between rats, dogs, and humans in terms of the effect of phosphorus depletion and hypophosphatemia on skeletal muscle (28). Humans and dogs respond to phosphorus depletion in a virtually identical manner. In contrast, rats fed a phosphorus-deficient diet without added phosphate-binding antacids showed no changes in sodium, adenine nucleotides, resting transmembrane potential difference, potassium, or water contents of skeletal muscle although serum phosphorus levels declined from 8.3 to 2.8 mg/dL (29). Similarly, there was only a very slight change in phosphate content of muscle and no change in calcium content or transport. It appears that in experimental phosphate depletion, dogs are the ideal model if one wishes to replicate human disease.

Hypophosphatemic Cardiomyopathy and Arrhythmias

Calculated cardiac stroke work increases after phosphorus administration in seriously ill patients with hypophosphatemia. These improvements occur independently of Starling effects and probably represent an improvement in myocardial contractility (2, 30, 31).

In phosphorus-deficient dogs (32), left ventricular end-diastolic pressure increased and stroke work decreased. Myocardial stroke work fell independently of the Frank-Starling

effect. Left ventricular ejection velocity and ventricular contractility are both reduced by phosphorus deficiency (33). Isoproterenol, which usually increases stroke work of the left ventricle, fails to do so in the presence of phosphorus deficiency. The phosphorylation potential of left ventricular muscle became substantially elevated in dogs with chronic phosphorus deficiency. This occurred because of 30% reduction of cytosolic inorganic phosphate concentration. The resulting alteration of the phosphorylation potential implies that the capacity for mitochondrial energy production is reduced. All abnormalities return to normal with phosphorus repletion.

Phosphorus-depleted rats show reductions in myocardial inorganic phosphorus, glycogen, glucose-6-phosphate, cytidine triphosphate, phosphatidylcholine, phosphatidylethanolamine, and total phospholipid phosphorus (34) and impaired fatty acid oxidation. Such abnormalities of lipid metabolism suggest defective phospholipid biosynthesis and might explain cellular membrane injury. Others have shown that feeding growing pigs aluminum hydroxide gel to induce phosphorus deficiency causes low levels of ATP and glucose-6-phosphate in the myocardium (35).

Approximately 20% of hypophosphatemic patients show cardiac arrhythmias, even without underlying heart disease, hypokalemia, hypomagnesemia, hyperlactatemia, or hypoxia (36). After repletion of the anion, the severity of arrhythmias improves. Arrhythmias have been described in patients with anorexia nervosa who become hypophosphatemic (37). Hypophosphatemia in patients with acute myocardial infarction increases the risk for ventricular tachycardia (38).

In vivo metabolism of inorganic phosphorus and its compounds can be studied using ^{31}P nuclear magnetic resonance spectroscopy. Using this technique the concentrations of phosphocreatine and ATP in the normal human heart have been estimated to be 11.0 ± 2.7 (SD) and 6.9 ± 1.6 mmol/g wet weight, respectively (39). This technique should be useful for studying disorders of the heart associated with phosphorus deficiency and hypophosphatemia.

Respiratory Insufficiency

Several clinical reports have described patients treated with TPN who developed respiratory failure (2, 40). These patients became seriously ill because of respiratory acidosis and hypoxia. Most were in intensive care unit settings and were desperately ill, receiving glucose or amino acids intravenously. Some demonstrated abnormalities of central nervous system function or peripheral neuropathy. Although profound weakness or muscle paralysis in some of the patients suggested the Guillain-Barré syndrome, usually the cerebrospinal fluid was normal. Some could not be weaned off ventilators at the anticipated time.

Most patients who developed acute respiratory failure due to hypophosphatemia induced by TPN had serious preexisting conditions. These include chronic intestinal fistulas, malabsorption syndrome, Crohn's disease, ulcerative colitis, small bowel resection, exocrine pancreatic insufficiency, chronic alcoholism associated with malnutrition, and gastrointestinal cancer. Others have suffered from chronic respiratory acidosis or cor pulmonale. Serum phosphorus concentrations have been below 1.0

mg/dL when respiratory failure occurred. In some cases, the patients were also hypokalemic. However, respiratory failure persisted despite correction of hypokalemia, responding to subsequent administration of phosphate salts and correction of hypophosphatemia (41). Phosphorus-deficient dogs also show diminished diaphragm function as a result of muscular weakness (42).

One important study was conducted on eight such patients with a mean serum phosphorus level of 1.65 ± 0.54 mg/dL, to characterize contractility of the diaphragm during electrical phrenic nerve stimulation (43). Correction of hypophosphatemia resulted in a twofold increase in transdiaphragmatic pressure generated by phrenic nerve stimulation.

Oddly enough, frank clinically evident rhabdomyolysis almost never occurs in patients who have developed respiratory failure. As pointed out in the section dealing with rhabdomyolysis, the latter apparently does not appear to occur as a consequence of acute hypophosphatemia per se unless significant muscle cell injury preexists. Thus, almost all cases of hypophosphatemic rhabdomyolysis occur in alcoholics, who probably all have preexisting muscle cell damage. This relationship may also explain the observation that the respiratory insufficiency and hypophosphatemic neurologic syndromes are hardly ever seen in alcoholics after admission to the hospital, because rhabdomyolysis usually corrects their hypophosphatemia spontaneously. Chronic alcoholism apparently protects against hypophosphatemic respiratory failure. Most patients who develop hypophosphatemic respiratory insufficiency have slowly become hypophosphatemic during administration of nutrients following correction of respiratory acidosis. In these patients, muscle cells have presumably not been damaged sufficiently for hypophosphatemic rhabdomyolysis to occur.

Erythrocyte Dysfunction

Phosphorus deficiency impairs oxygen release from hemoglobin (44) and rarely causes hemolysis (45, 46). The red cell is the only tissue in the body that produces 2,3-diphosphoglycerate (44). 2,3-DPG is bound to hemoglobin and serves to enhance dissociation of oxygen from the hemoglobin molecule. The interaction of 2,3-DPG with oxyhemoglobin has been well characterized. Deficiency of erythrocyte 2,3-DPG impairs release of oxygen from oxyhemoglobin, thus causing hypoxia (44). Coexistent acidosis reverses this effect by the Bohr effect (47). Reduced 2,3-DPG in erythrocytes may play an important role in neurologic disturbances that occur in hypophosphatemia (44).

As pointed out above, the vast majority of patients with DKA become hypophosphatemic during treatment. However, in most, there has not been adequate time for development of severe phosphorus deficiency. Because they usually recover rapidly with appropriate treatment, serum phosphorus levels recover spontaneously upon resumption of food intake and 2,3-DPG levels ordinarily do not fall (2). On the other hand, newly discovered diabetics who have been out of control for prolonged periods have more opportunity to develop serious phosphorus depletion (2).

Hemolysis in hypophosphatemia is rare. Superimposed events, such as alcoholic ketoacidosis or coincidental aspirin poisoning requiring hemodialysis, have also been

present (2). Serum phosphorus concentration was less than 0.5 mg/dL. Severe acidosis, quite independently of hypophosphatemia, may inhibit phosphofructokinase and in turn inhibit synthesis of 2,3-DPG and ATP (47). If ATP levels fall below 15% of normal, hemolysis may supervene (48). That the bulk of patients with DKA are not severely phosphorus deficient probably explains why frank hemolysis has never been reported in such patients. Simple improvement of acidosis in most patients with DKA leads to correction of the metabolic abnormalities despite hypophosphatemia.

Leukocyte Dysfunction

Hypophosphatemia and phosphorus deficiency cause a 50% reduction in chemotactic, phagocytic, and bactericidal activity of granulocytes. Leukocyte ATP levels fall (49). All abnormalities are corrected by phosphate repletion or in vitro by incubation of the leukocytes with adenosine and phosphate. These effects are seen only when hypophosphatemia is severe.

The mechanism by which hypophosphatemia impairs granulocytic function is probably related to impaired ATP synthesis. Microtubule contractions regulate the mechanical properties of leukocytes, thus pseudopod and vacuole formation. Microfilaments require ATP as their source of energy (2, 50). Actin and myosin are found in the cytoplasm of granulocytes. Phosphorus deficiency is also associated with a rise in intracellular calcium, which may independently impair phagocytosis (51). Hypophosphatemia not only limits mechanical functions of the granulocyte but also may impair the requirement for increased rate of synthesis of phosphoinositides and other organic phosphate compounds that are necessary for bactericidal activity during phagocytosis (52).

Platelet Disorders

Malnourished dogs treated with parenteral hyperalimentation without adequate phosphate become hypophosphatemic and show seven abnormalities of platelet function and structure (53): (a) thrombocytopenia; (b) increased platelet diameter suggesting shortened platelet survival; (c) megakaryocytosis of the marrow; (d) 5- to 10-fold acceleration of the rate of labeled platelet disappearance from blood; (e) impaired clot retraction; (f) a 50% reduction in platelet ATP content; and (g) hemorrhage into the gut and skin. Of note, none of these abnormalities is seen if phosphorus supplements are provided. Despite these abnormalities, there appears to be little evidence that hypophosphatemia is a primary cause of hemorrhage in man.

Metabolic Acidosis

Three mechanisms permit urinary excretion of hydrogen ions. First, disodium hydrogen phosphate (Na_2HPO_4) is converted to monosodium dihydrogen phosphate (NaH_2PO_4) by exchange of luminal Na^+ for cellular H^+ , and the hydrogen ions thus excreted are measurable as titratable acidity. Second, ammonia produced in the tubular cell diffuses into the tubular lumen and combines with H^+ to become NH_4^+ . Third, a small quantity of hydrogen is excreted as free hydrogen ion, thus accounting for the acid pH. The acid pH

facilitates formation of NH_4^+ in the tubular lumen. Since the ammonium ion is essentially not reabsorbable, ammonium excretion is enhanced in proportion to urinary acidification.

Severe metabolic acidosis may occur in the presence of phosphate deficiency and severe hypophosphatemia (54). Removal of phosphorus from the diet and simultaneous administration of phosphate-binding antacids leads to prompt mobilization of bone mineral and hypercalciuria (55). As hypophosphatemia becomes more severe, phosphate ions virtually disappear from the urine, thereby eliminating the capacity to excrete hydrogen ions as titratable acid.

Ordinarily, metabolic acidosis would be expected to augment renal production of ammonia. However, in phosphate deficiency, NH_3 formation decreases, presumably as a result of higher intracellular pH (56), and reduces urinary acidification by formation of NH_4^+ (57). Thereby, the decrease in ammonia production and unavailability of buffer phosphate in the urine substantially reduce excretion of metabolic acids.

One would predict that metabolic acidosis would regularly develop when excretion of titratable acid or ammonium into the urine is severely limited. However, metabolic acidosis in phosphorus deficiency is rare. The explanation lies in the fact that during mobilization of bone mineral, there also occurs mobilization of carbonate, which is an important component of bone apatite. During osteolysis associated with phosphorus deprivation, sufficient carbonate is mobilized from bone to titrate all metabolic acid retained in the body. However, should something prevent mobilization of bone mineral, then severe metabolic acidosis may occur. This has been described in experimental vitamin D deficiency and in children with severe lactase deficiency and protein-calorie malnutrition during refeeding without adequate phosphate in the diet (54). Addition of phosphate to their diet increased excretion of titratable acid into the urine and corrected metabolic acidosis. In experimental phosphorus deficiency, administration of diphosphonate or colchicine to impede calcium mobilization from bone causes metabolic acidosis (18).

Nervous System Dysfunction

Nervous system dysfunction is a well-recognized complication of severe hypophosphatemia. Hyperalimmented malnourished dogs become hypophosphatemic and develop ataxia, convulsions, and death (21, 58). Experimental human phosphorus deficiency caused weakness, apathy, and intention tremors (16) and made patients bedridden.

A wide spectrum of clinical manifestations have been reported involving almost all levels of the nervous system from higher cortical function, brainstem, to peripheral nerves and muscle. The most florid examples of hypophosphatemia-induced nervous system dysfunction have been reported during the course of nutritional recovery syndrome. In such patients, hypophosphatemia usually occurs after approximately 1 week or more of hyperalimentation with solutions of glucose and/or amino acids not containing enough phosphorus to prevent hypophosphatemia. The sequence of abnormalities consists of

irritability, apprehension, muscular weakness, numbness, paresthesias, dysarthria, confusion, obtundation, convulsive seizures, coma, and death (59, 60). Such a clinical state could be confused with that of delirium tremens in the alcoholic, because even lucid visual and auditory hallucinations may occur (61, 62). One report (44) described paresthesias about the mouth and limbs, mental obtundation, and hyperventilation in three of eight patients who became hypophosphatemic during hyperalimentation. At the same time, these patients displayed a sharp drop in red cell 2,3-DPG content that correlated with slowing of the electroencephalogram. Both abnormalities disappeared and the patients recovered symptomatically when hypophosphatemia was corrected. Most notably, such symptoms do not occur when adequate phosphorus is provided to prevent hypophosphatemia during hyperalimentation. Emphasis has been placed upon the importance of central nervous system complications in patients who slowly develop severe hypophosphatemia during the course of TPN (2, 44, 58, 59 and 60).

Symptoms of brainstem dysfunction, such as ptosis, dysphagia, dysphonia, impaired ability to swallow secretions, respiratory weakness, and hypercarbia in a setting of profound muscle weakness, have been reported. Distortions in color perception and even amblyopia may occur. Some patients with slowly developing hypophosphatemia develop all clinical features of the Guillain-Barré syndrome with ascending paralysis, areflexia and respiratory muscle paralysis (2). Other cases closely resemble Wernicke's encephalopathy, in which dramatic improvement has been observed following correction of hypophosphatemia. However, when hypophosphatemia is prolonged, recovery after correction may be delayed. Asterixis has also been described. Peripheral neuropathy documented by nerve conduction studies has also been reported. Psychiatric manifestations may include paranoid delusions, extreme anxiety, and visual and auditory hallucinations. A syndrome resembling encephalitis has been described in children with malnutrition who became ill after 1 week of refeeding. Although phosphorus levels were not measured, the possibility of hypophosphatemia seems likely. These children developed coarse tremors resembling parkinsonism, mainly involving the upper extremities but also the legs, neck, and tongue. They remained alert. Hypotonia has also been described in infants undergoing treatment for protein-calorie malnutrition (63). There appeared to be a positive correlation between the reduction in serum phosphate and the occurrence of death during treatment. Obviously, all levels of nervous system dysfunction may be seen. As one might suspect, smooth muscle function is also apparently affected by severe hypophosphatemia as evinced by ileus.

In patients who develop syndromes of central or peripheral nervous system dysfunction and also in those who develop respiratory failure as a result of hypophosphatemia, rhabdomyolysis is virtually nonexistent. Presumably, the apparent requirement for preexistent skeletal muscle injury is missing. Failure to develop rhabdomyolysis results in inexorable and progressive hypophosphatemia and thus permits full expression of nervous system failure.

Treatment of Hypophosphatemia

Milk is an excellent source of phosphorus, containing 33 mmol/L (100 mg/dL). Phosphate salts are also available for oral use. They are less likely to cause diarrhea in phosphorus-deficient patients than in normal persons. Phosphorus salts cannot be

given by intramuscular or subcutaneous injection, but sodium phosphate and potassium phosphate are available for intravenous use. The potassium salt should be given when hypokalemia and hypophosphatemia coexist. Two recent prospective studies on hypophosphatemic patients in acute intensive care unit situations show that a 15-mmol dose of either sodium or potassium phosphate may be given in 100 mL of 0.9% sodium chloride intravenously over a period of 2 hours (64). A second study shows that depending on the severity of hypophosphatemia, doses ranging from 0.16 to 0.64 mmol/kg may be given over a period of 1 or 2 hours as a single dose on a daily basis (65). Serum phosphorus should be measured within several hours after the infusion and at least daily under such conditions. Oral administration of phosphate salts or milk should be resumed as quickly as possible (2). A safe dosage regimen for treatment of alcoholics who are hypophosphatemic, phosphorus deficient, hypokalemic, and hypomagnesemic is the infusion each 8 to 12 h of 1 L of 0.5 normal sodium chloride in 5% glucose containing 9 mmol of potassium phosphate and 4.2 mmol of magnesium sulfate (2.0 mL of 50% MgSO₄ solution).

Hyperphosphatemia should be avoided because it can cause severe hypocalcemia and crystal deposition in important structures including blood vessels, the eye, lung, heart, and kidney. Fatal alveolar diffusion block has occurred, especially if the patient is alkalotic. Patients treated with parenteral nutrition should receive adequate amounts of phosphate to prevent hypophosphatemia (see [Chapter 101](#)).

HYPERPHOSPHATEMIA

Hyperphosphatemia in adults is defined as an elevation of serum phosphorus above 5 mg/dL (1.67 mmol/L) and is a common finding with many causes. Spurious hyperphosphatemia may occur in patients with thrombocytosis when blood is allowed to clot to obtain serum. Undelayed collection of plasma from heparinized samples will show lower values. Certain autoanalyzers cause spurious hyperphosphatemia because of chemical interference. Abnormal positively charged serum proteins, as in plasma cell dyscrasias, may bind phosphorus and cause marked elevations exceeding 13 mg/dL (4.3 mM).

Decreased renal excretion of phosphorus is the most common cause of hyperphosphatemia. Since parathyroid hormone (PTH) is phosphaturic, hyperphosphatemia is a cardinal feature of hypoparathyroidism, either as a primary disorder or in patients whose renal cAMP response to PTH is abnormal (pseudohypoparathyroidism type I) or those whose phosphaturic response to PTH is suppressed (pseudohypoparathyroidism type II) (2).

Severe hypomagnesemia causes marked suppression of PTH in plasma despite hypocalcemia but does not usually cause hyperphosphatemia (66, 67). Hyperphosphatemia occurs in tumoral calcinosis, pseudoxanthoma elasticum, infantile hypophosphatasia, and hyperostosis because of decreased renal excretion. Untreated severe hyperthyroidism apparently increases cellular catabolism sufficiently to elevate serum phosphorus in some patients despite increased phosphorus loss in the urine. Acromegaly or administration of growth hormone causes hyperphosphatemia. Presumably, the higher phosphorus levels in children partly reflect growth hormone

activity (68) or insulin-like growth factor I activity (69). Hyperphosphatemia occurs in untreated adrenal insufficiency because of volume-contraction metabolic acidosis and possibly reduced glomerular permeability. Mild hyperphosphatemia may occur with biphosphonate therapy because of increased tubular reabsorption of phosphorus.

Hyperphosphatemia, sometimes with levels up to 46 mg/dL, has occurred secondary to increased absorption from the gut following administration of excess phosphate salts by mouth or from the colon as a result of enemas that contain phosphorus. Overmedication with vitamin D and production of vitamin D by granulomatous tissue as in sarcoidosis and tuberculosis can cause hyperphosphatemia (2). Both acute metabolic and acute respiratory acidosis may decompose cellular organic phosphates, reduce phosphorylation, and result in diffusion of phosphorus from the cell and hyperphosphatemia. Lactic acidosis is especially important as a cause of hyperphosphatemia. Reduced insulin levels secondary to clonidine administration also can cause hyperphosphatemia. Cellular release of phosphorus may cause hyperphosphatemia, particularly in rhabdomyolysis, infarction of other tissues, or hemolysis. The tumor lysis syndrome, usually seen in patients whose tumor responds briskly to chemotherapy, consists of hyperphosphatemia, hypocalcemia, hyperkalemia, metabolic acidosis, hyperuricemia, and, in many cases, acute renal failure. Severe hyperphosphatemia after intravenous infusion of phosphate salts is a particular danger in patients who are acidotic or oliguric. Finally, infusion of compounds containing phospholipids for parenteral nutrition has caused hyperphosphatemia.

Treatment of Hyperphosphatemia

Hyperphosphatemia is potentially serious because of potential metastatic calcification. Before initiating treatment for hyperphosphatemia, its cause should be identified and corrected whenever possible. Although only an approximate guide, a calcium-phosphorus product (serum Ca in mg/dL × serum P in mg/dL) above 70 indicates a potential threat of calcification. Calcification is more likely to occur in the presence of an elevated blood pH or elevated level of parathyroid hormone.

In the absence of renal insufficiency, hydration or volume expansion by infusing hypotonic saline will increase fractional clearance of phosphorus by the kidney. Aluminum-based antacids will bind phosphorus in the gut and prevent absorption. Although long-term use of these compounds may result in aluminum toxicity, their use for a short time in acute hyperphosphatemia is safe and may be very helpful. Hyperphosphatemia in the presence of renal insufficiency often requires either peritoneal dialysis or hemodialysis.

[Selected Readings](#)

Magnesium plays an essential role in a wide range of fundamental biologic reactions. Hence, it is not surprising that deficiency in the organism may lead to serious biochemical and symptomatic changes. Kruse and associates made the first systematic observations of magnesium deficiency in rats and dogs in the early 1930s (1). The first description of clinical depletion in man, published in 1934, involved a small number of patients with various underlying diseases (2). In the early 1950s, Flink initiated studies

documenting depletion of this ion in alcoholics and in patients on magnesium-free intravenous solutions (3). Although the diets ordinarily consumed by healthy Americans do not appear to lead to clinically significant depletion, an increasing number of clinical disorders have been associated with depletion.

BIOCHEMISTRY AND PHYSIOLOGY

Magnesium is involved in more than 300 essential metabolic reactions, and the number increases with new discoveries in molecular biology. Magnesium ion (Mg^{2+}) forms complexes with a variety of organic molecules having biologic activities. The relatively high—in comparison with other electrolytes—extracellular and intracellular concentrations of Mg^{2+} tend to favor binding to such molecules. The binding of functional groups is, in descending order: phosphates > carboxylates > hydroxyls, in terms of both relative importance and binding affinities (4). Mg^{2+} is essential for many enzymatic reactions and has two general interactions: (a) Mg^{2+} binds to the substrate, thereby forming a complex with which the enzyme interacts, as in the reaction of kinases with MgATP, and (b) Mg^{2+} binds directly to the enzyme and alters its structure and/or serves a catalytic role (e.g., exonuclease, topoisomerase, and RNA- and DNA polymerases) (5, 6). Other divalent metal ions (especially Mn^{2+}) activate many of the same enzymes but usually have less specificity and/or are present in much smaller quantities. Because of the weak binding of Mg^{2+} to proteins, activated enzymes are not necessarily isolated in the metal-bound form. Consequently, Mg^{2+} must be added for in vitro reactions, whereas in vivo, the background Mg^{2+} concentration usually suffices to stimulate the enzyme.

Adenosine triphosphate (ATP) has a strategic position in “free-energy” currency for virtually all cellular processes by providing high-energy phosphate. It exists in all cells primarily as magnesium ATP^{2-} (MgATP).

Enzyme Interactions

Some examples of the numerous enzymes in both classes mentioned above will emphasize the important role of magnesium (7, 8 and 9). They include hexokinase, which phosphorylates glucose by way of MgATP and other enzymes necessary for the glycolytic cycle. Magnesium is required in steps of the citric acid cycle; three of the four key enzymes in the gluconeogenesis pathway from noncarbohydrate sources require magnesium. It is required in lipid metabolism; amino acid activation via RNA and DNA polymerases; the transketolase reaction involving thiamin; and the transfer of CO^2 to biotin in carboxylation reactions. Glutathione, a key intracellular antioxidant, has a Mg^{2+} requirement for its synthesis. The ubiquitin-proteasome pathway of protein degradation (see Chapter 2) also requires Mg^{2+} and ATP. Protein kinases, enzymes that catalyze the transfer of the α -phosphate from MgATP (e.g., in intracellular signaling), now number more than 100 (10).

The second messenger, cyclic adenosine monophosphate (cAMP), formed from MgATP and the enzyme adenylate cyclase, is activated by Mg^{2+} through its two binding sites (11). cAMP is involved in many reactions, including secretion of parathyroid hormone

(PTH) by its gland (12); in addition, PTH exerts at least some of its physiologic effects through the formation and actions of cAMP (13).

Structural Modifications

The negatively charged ribose phosphate structure of nucleic acids has an affinity for Mg^{2+} ; the resulting stabilization of numerous ribonucleotides and deoxyribonucleotides induces important physicochemical changes—all having biologic effects (4, 14, 15); hence “RNA science eventually became magnesium science” (14). In addition, the binding of hydrated Mg^{2+} by transfer RNA (tRNA) and modified tRNA and its DNA analogues results in structures that cannot be duplicated by the binding of other metals (4, 6, 14). Magnesium, calcium, and some other cations react with hydrophilic polyanionic carboxylates and phosphates of the various membrane components to stabilize the membrane and thereby affect fluidity and permeability.

Extracellular and Intracellular Magnesium Interrelations

In the early 1970s, it was noted that the magnesium ion modulated muscle tension (16) and that its intracellular concentration increased with epinephrine stimulation of lipolysis in adipocytes (17). The availability of ^{28}Mg enabled transport studies in cardiac cells and revealed that the free intracellular (cytosolic) magnesium concentration $[Mg^{2+}]_i$ was 1 mmol or lower (18), appreciably less than had been postulated. More-sensitive methods of measuring intracellular concentrations have advanced our understanding of magnesium transport, cellular homeostasis, and its regulatory role (19, 20). Of the approximately 500 mmol of total intracellular magnesium in the adult human, about 90 to 95% of that in the cytosol is bound to ligands such as ATP, ADP, citrate, proteins, and nucleic acids. The small remainder is free Mg^{2+} . What processes maintain or modify the relationships between total and ionized internal and external magnesium?

Transport across Plasma Membranes. $[Mg^{2+}]_i$ is maintained far from electrochemical equilibrium with external $[Mg^{2+}]$ ($[Mg^{2+}]_e$), indicating that the plasma membrane must contain transport mechanisms to extrude this ion; otherwise, magnesium would gradually accumulate intracellularly (21). Studies from a variety of tissues and species indicate that a Na^+ -dependent Mg^{2+} efflux is a common mechanism for maintaining the intracellular homeostasis. There are some exceptions and other evidence for a Na^+ -independent transport system (22, 23) as well as transporters that depend on hormones and others inhibited by calcium channel blockers, which suggests a role for Ca^{2+} in Mg^{2+} efflux (24). Because of the difficulties in studying the molecular aspects of Mg^{2+} transporters in eukaryocytes, investigations have been made in certain bacteria, in which four distinct regulating systems have been found (22, 25).

Ion Exchange across the Plasma Membrane. Cytosolic Mg^{2+} exchanges readily with extracellular magnesium; however, the level of the cytosolic free ion is highly regulated. For example, intact isolated cells from various rat tissues placed in a normal magnesium medium maintain their usual $[Mg^{2+}]_i$ despite a many-fold increase in external $[Mg^{2+}]$ (22, 26 and 27). Similarly, cells depleted of Mg^{2+} and then bathed in a medium of

supernormal Mg^{2+} concentration gradually accumulate Mg^{2+} until the normal concentration is reached and then maintain that level (27).

Stimulated Intracellular Magnesium Exchanges. Perfused rat livers and hearts and isolated hepatocytes and myocytes release Mg^{2+} into the medium upon stimulation with certain adrenergic agonists or cAMP (28). Reverse movement of Mg^{2+} occurred with carbachol stimulation of the muscarinic receptor, causing a decrease in cytosolic cAMP levels (28) (Fig. 9.1). The observed fluxes were rapid, the quantities released or taken up within a few minutes were equal and accounted for approximately 5 to 10% of total cellular ionized magnesium. Such data suggest that the flux mechanisms are activated by appropriate hormones and are associated with redistribution of ionized magnesium from or into various intracellular compartments.

Figure 9.1. Schema of regulation of cellular Mg^{2+} homeostasis in the mammalian cell. The pathways are indicated for cellular Mg_{2+} release (*upper section*) and for its uptake (*lower section*). Stimulated by b-adrenergic agonists, cAMP is increased in the cytosol, which modulates mitochondrial adenine nucleotide translocase and increases the efflux of Mg_{2+} from the mitochondrion by means of an exchange of one Mg-ATP for ADP. Activation of muscarinic receptors (in cardiac cells) or vasopressin receptors (in the liver) may stimulate a Mg_{2+} influx mechanism either by decreasing cAMP or by enhancing protein kinase C activity by diacylglycerol (*D.G.*). Vasopressin receptor activation is coupled with production of inositol triphosphate (*IP3*) from phosphatidylinositol biphosphate, which induces release of Ca^{2+} from the endoplasmic reticulum (*E.R.*) or the sarcoplasmic reticulum (*S.R.*). Calcium ion release may be associated with either Mg_{2+} influx or Mg redistribution in the nucleus or endoplasmic reticulum. (From Romani A, Marfella C, Scarpa A. *Miner Electrolyte Metab* 1993;19:282–289, with permission.)

Mg^{2+} plays a role in ion channels (see [Chapter 38](#)). For example, in myocardial cells, Mg^{2+} produces inward rectification in at least four different potassium channels by plugging the open channel as outward current begins to flow. It also modulates the

outwardly directed potassium current and the inwardly directed low-threshold calcium current (29). Stimulation of the K_{ATP} channel by MgATP activates this channel in intact pancreatic b cells; hence MgATP is an intracellular regulator of insulin secretion (30).

Cell Surface Receptors. Finding that ATP, ADP, and adenosine act directly on surface receptors led to the discovery of classes of such receptors, designated as purinoceptors (31, 32). These widely distributed receptors with many actions have been subdivided into P1 (adenosine-stimulated) purinoceptors and various subtypes of P2 purinoceptors, which are activated by ATP and ADP.

Cell Migration. Levels of extracellular Mg^{2+} and Ca^{2+} can affect the adhesive and migratory activities of many cell types. For example, in the early stages of cutaneous wound repair, in which cell migration into the wound is initiated, $[Mg^{2+}]$ increased and $[Ca^{2+}]$ decreased in the wound fluid. The data suggest that such ionic changes affect integrins and E-cadherins in activating the phenotypes of cells involved in wound healing (33).

ANALYTIC PROCEDURES

A variety of methods have been developed to measure magnesium in foods, excreta, blood, cells, and cell compartments.

Total Magnesium. Atomic absorption spectrometry (AAS) has been widely used to determine total magnesium in many sources and still remains the reference method (34). Clinical laboratories now almost exclusively use one of the various chromophores in automated instruments, with varying precision compared with AAS; however, with experience and proper calibration, these methods are acceptable (35). Inductively coupled plasma emission spectroscopy is useful for determination of a number of minerals including magnesium in serum, urine and, after wet ashing, stool or foods (36).

Ionized Magnesium and Ion-Selective Electrodes (ISEs). Electrodes have been developed with increasingly specific resins, which can measure ionized magnesium in serum, plasma, whole blood, and cells (21, 37). Calcium ion and lipophilic cations (e.g., acetylcholine and cation substitutes) may interfere. The current clinical chemistry literature indicates that ISEs from various manufacturers differ in accuracy from each other and from AAS and may give misleading results in sera with low magnesium concentrations (38, 39). Huijgen et al. have reviewed the combination of methods that allows measurement of all known serum magnesium parameters (37).

Magnetic Resonance Spectroscopy (MRS). A number of metabolites exist in equilibrium between uncomplexed and complexed Mg^{2+} . Because the resonances of such molecules may shift upon Mg^{2+} complexation, MR spectra can provide information on $[Mg^{2+}]_i$. ATP is the most useful endogenous indicator because of the ^{31}P nuclei and its high concentration and broad distribution in cells. The observed shift difference between a and b phosphate resonances is the parameter of choice. This method is used to measure $[Mg^{2+}]_i$ noninvasively in many tissues and cells. Technical issues in

methodology have been discussed (40, 41 and 42). Exogenous MRS indicators have been developed to measure cytosolic Mg^{2+} ; such indicators gain sensitivity and selectivity, for example, by using fluoridated compounds, because essentially no fluoride background resonance normally exists in cells. Biologic and technical issues with these indicators have been reviewed (40).

Fluorescent Indicators. Several indicators (e.g., FURAPTRA) undergo a change in fluorescence on binding to Mg^{2+} . The measurable shift in the excitation spectrum allows determination by a ratio method of the ion concentration in cell suspensions and in individual cells. Calibration and a number of metabolic issues must be considered in using this method (21, 40).

[α Citrate]:[α Isocitrate] Ratio. Free [Mg^{2+}] in cytoplasm can be measured from the variation in the [α citrate]:[α isocitrate] ratio in the aconitase reaction because this varies with [Mg^{2+}]_i (43).

Magnesium Isotopes. Isotopes have been used as biologic tracers to follow the absorption, distribution, and excretion of the magnesium ion. The radioisotope ^{28}Mg has been used in human studies (44). Its value is limited by its radioactivity, its short half-life of 21.3 h, and its short supply. The percentage of distribution of stable magnesium in nature is 78.99% ^{24}Mg , 10.0% ^{25}Mg , and 11.01% ^{26}Mg . The latter has been used for tracer studies (47), including absorption studies in man (45). The ^{25}Mg : ^{26}Mg ratio has been used to measure intestinal absorption (46).

Energy-Dispersive X-ray Analysis. Energy-dispersive x-ray analysis has been used to measure intracellular [Mg^{2+}] in sublingual epithelial cells and atrial biopsy specimens in various conditions (47).

BODY COMPOSITION

The distribution of magnesium in various body compartments of apparently healthy adult individuals is summarized in [Table 9.1](#). Somewhat more than half of the total is in bone, with almost all of the rest in soft tissue. Magnesium is the most abundant divalent mineral cation in cells and is second only in electrolyte quantity to monovalent potassium. Reference values for magnesium in serum, in blood cells, and in infants and children are given in references 48 and 48a. While bone has the largest amounts, much of this is either within the hydration shell or on the crystal surface (49). The amount of magnesium lost in sweat is very small in comparison to other cations. For example, in a 10-km run in 40.5 minutes with an average body weight (fluid) loss of 1.45 kg, the actual ion losses per kg of weight loss were Na, 800 mg; K, 200 mg; Ca, 20 mg; and Mg, 5 mg (50).

Tissue	Percentage of Total Body Mg	Concentration of Tissue
Bone	65	0.01% of bone ash
Soft tissue	27	10 mmol/kg wet weight
Extracellular fluid	1.5	0.1 mmol/kg wet weight
Intracellular fluid	1.5	1.0–2.0 mmol/L*
Red blood cells	1.5	0.1–0.2 mmol/L*
White blood cells	0.5	0.5–1.0 mmol/L*
Platelets	0.5	1.0–2.0 mmol/L*
Heart	0.5	0.5–1.0 mmol/L*
Spleen	0.5	0.5–1.0 mmol/L*
Liver	0.5	0.5–1.0 mmol/L*
Adipose tissue	0.5	0.5–1.0 mmol/L*
Brain	0.5	0.5–1.0 mmol/L*
Testes	0.5	0.5–1.0 mmol/L*
Ovaries	0.5	0.5–1.0 mmol/L*
Salivary glands	0.5	0.5–1.0 mmol/L*
Other	0.5	0.5–1.0 mmol/L*

*Figures are approximate and based on data from various sources. For example, the concentration of Mg in bone is 0.01% of the total weight of the bone (not the ash). The concentration of Mg in soft tissue is 10 mmol/kg wet weight. The concentration of Mg in extracellular fluid is 0.1 mmol/kg wet weight. The concentration of Mg in intracellular fluid is 1.0–2.0 mmol/L. The concentration of Mg in red blood cells is 0.1–0.2 mmol/L. The concentration of Mg in white blood cells is 0.5–1.0 mmol/L. The concentration of Mg in platelets is 1.0–2.0 mmol/L. The concentration of Mg in heart is 0.5–1.0 mmol/L. The concentration of Mg in spleen is 0.5–1.0 mmol/L. The concentration of Mg in liver is 0.5–1.0 mmol/L. The concentration of Mg in adipose tissue is 0.5–1.0 mmol/L. The concentration of Mg in brain is 0.5–1.0 mmol/L. The concentration of Mg in testes is 0.5–1.0 mmol/L. The concentration of Mg in ovaries is 0.5–1.0 mmol/L. The concentration of Mg in salivary glands is 0.5–1.0 mmol/L. The concentration of Mg in other tissues is 0.5–1.0 mmol/L.

Table 9.1 Distribution and Concentrations of Magnesium (Mg) in a Healthy Adult (Total body: 833–1170 mmol^a, or 20–28 g)

Most intracellular magnesium exists in bound form. Measured by ³¹P MRS, frog muscle cells contained 5.8 mmol/L magnesium bound to ATP, 1.7 mmol/L to phosphocreatine, and 0.3 mmol/L to myosin; the free [Mg²⁺]_i was 0.6 mmol/L (51).

HOMEOSTASIS

Homeostasis of the individual with respect to a mineral depends on the amounts ingested, the efficiency of intestinal and renal absorption and excretion, and all other factors affecting them. A schema for magnesium balance is given in [Figure 9.2](#).

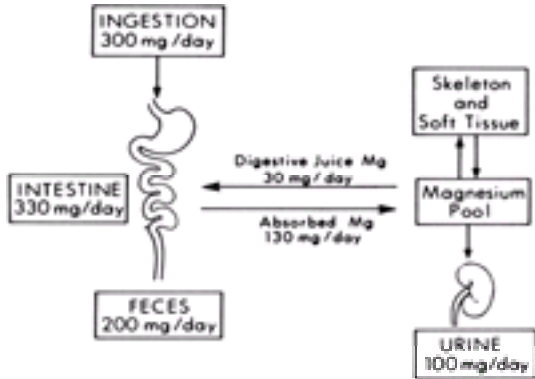

Figure 9.2. Magnesium homeostasis in man. A schematic representation of its metabolic economy indicating (a) its relatively poor absorption from the alimentary tract, (b) its distribution into a number of tissue pools with major distribution into bone, and (c) its dependence on the kidney for excretion. Homeostasis depends upon the integrity of intestinal and renal absorptive processes. (From Slatopolsky E. In: Klahr S, ed. Pathophysiology of calcium, magnesium and phosphorus metabolism in the kidney and

body fluids. New York: Plenum Publishing, 1984, with permission.)

Dietary Intake

Magnesium is widely distributed in plant and animal sources but in differing concentrations (see Appendix [Table IV-A-22](#)). The major food sources of the element beyond childhood to ages 60 to 65 in the United States as percentages of the daily intake have been listed ([52](#)). Vegetables, fruits, grains, and animal products accounted for approximately 16% each; dairy product contributions fell from about 20% in adolescents to about 10% for those beyond the third decade; beverages of various types yielded percentages of about 4% among adolescents, increasing to 15% in older age groups.

Daily per capita availability in the U.S. food supply increased by 9.4% from 1981 to 1990, at which date it was 350 mg (14.5 mmol) ([53](#) and Table 58 therein). This figure, based on disappearance data, differs markedly from actual intake data. For example, the mean daily *analyzed* intakes in the Total Diet Study for females ages 14 to 16 years, 25 to 30, and 60 to 65 were 194 mg (8.08 mmol), 189 mg (7.88 mmol), and 187 mg (7.79 mmol), respectively. For males in the same age groups, the intakes were 297 mg (12.38 mmol), 294 mg (12.25 mmol), and 250 mg (10.42 mmol), respectively ([54](#)).

When calculating individual intake from food composition tables, caution is advised because “there is less than 75% analytical data for important sources of this food component” ([55](#)). An example is the analyzed versus calculated values (using the USDA database) for the 234 foods in the U.S. FDA Total Dietary Study for eight age-sex groups, representing the core items of the U.S. food supply. The analyzed figures were 115 to 124% greater than the calculated values (unadjusted for missing values in the database) among the age groups reported ([52](#), [54](#)). Inadequate or few data exist for this ion in a number of products ([53](#) and Table 58 therein).

Intestinal Absorption

The fractional absorption of ingested magnesium by healthy humans is influenced by its dietary concentration and the presence of inhibiting or promoting dietary components. Based upon the time of appearance of ^{28}Mg in the blood following its oral ingestion, absorption began within 1 hour, stabilized at the rate of 4 to 6%/h from the 2nd to 8th hour, then decreased rapidly, and ceased at the 10th hour ([56](#)). When small amounts of magnesium were fed in the form of a standard meal supplemented by varying amounts of magnesium ([57](#)) or when Mg was given as ^{28}Mg ([58](#)), fractional absorption fell progressively from approximately 65 to 70% with intake of 7 to 36 mg (0.3–1.5 mmol) down to 11 to 14% with intake of 960 to 1000 mg (40 mmol). Absorption of magnesium as a function of intake is curvilinear ([Fig. 9.3](#)) and reflects a saturable process with passive diffusion. Estimates of the fractions absorbed by each process were 10 and 7%,

respectively (57). Similar absorptive processes appear to occur in children (59).

Figure 9.3. Net magnesium and calcium absorption in healthy humans. The data were obtained under conditions described in reference 57 and in the text. Mean values S.E. are indicated by *vertical bars*. The absorption data for magnesium represent a curved function compatible with a saturable process (at about 10 mEq/meal in this study) and a linear function reflecting passive diffusion at higher intakes. (From Fine KD, Santa Ana CA, Porter JL, et al. J Clin Invest 1991;88:396–402, with permission.)

Data on absorption fractions from balance studies using differing diets have been quite variable, ranging from 35 to 70% (60). When free-living adults eating self-selected diets were evaluated periodically over the course of a year, the mean absorptive fraction averaged 21% with average intake of 323 mg (13.4 mmol) by men and 27% with average intake of 234 mg (9.75 mmol) by women (61).

Sites of Absorption. Absorption studies in the rat by various techniques, including intact intestinal absorption, everted sacs, in vivo perfusion (summarized in [62, 63]), and stripped mucosa (64) show that magnesium is absorbed along the entire intestine, small and large; in some reports, colonic uptake is the greater. Evidence suggests that in the human, colonic absorption of magnesium is probable (63).

Influence of Other Ions. Long-term balance studies in healthy individuals, for the most part, indicate that increasing oral calcium intake does not significantly affect magnesium absorption or retention (65, 66 and 67). Some reports indicate decreased magnesium absorption at high levels of phosphate, whereas others found no consistent effect (62, 68).

A major increase in zinc intake (from 12 to 142 mg/day) decreased magnesium absorption and balance very significantly (69). Vitamin B₆ depletion induced in young women was associated with negative magnesium balance because of increased urinary excretion (70). Hypochlorhydria following short-term administration of the gastric

proton-pump inhibitor, omeprazole, did not change the intestinal absorption of magnesium, calcium, phosphorus, or zinc (71).

Increased amounts of magnesium in the diet have been associated with either decreased calcium absorption (65) or no effect (57, 72). Increased amounts of absorbable oral magnesium have been noted to decrease phosphate absorption, perhaps secondary to formation of insoluble magnesium phosphate (57). Although increased magnesium intake may not affect calcium absorption, renal tubular mechanisms may increase calcium excretion (57); conversely, decreased absorption of magnesium associated with high phosphate intake did not change magnesium balance because of associated decreased urinary excretion of magnesium (57).

Increased intakes of dietary fiber have been reported to decrease magnesium utilization in humans, presumably by decreasing absorption. However, the introduction of uncontrolled variables—including multiple differences between dietary components in addition to fiber contents—complicates interpretation of the data (72a, 72b). When isolated fiber has been added to a basal diet, the effects of fiber per se have been negative for dephytinized barley fiber (72c) and positive for cellulose (72d).

Absorbability of Magnesium Salts in Humans. The fractional absorption of a salt depends on its solubility in intestinal fluids and the amounts ingested, e.g., 5 mmol (120 mg) of the acetate in gelatin capsules has been found to be an optimal dose in terms of net absorption. Absorption of enteric-coated magnesium chloride is 67% less than that of the acetate in gelatin capsules (57). Magnesium citrate has high solubility, even in water, whereas magnesium oxide is poorly soluble even in acid solution. Magnesium oxide and various salts in large doses act as an osmotic laxative, with resultant diarrhea; the physician faced with a diarrhea of uncertain etiology should consider measuring fecal magnesium levels (72).

Magnesium Absorption: Any Relation to Calcitriol? While there is some uncertainty in the literature, there are data indicating that magnesium absorption in many individuals is not truly calcitriol dependent, as are calcium and phosphate. When patients with impaired calcium absorption were given vitamin D or its active form, those with both osteomalacia and osteoporosis had equivocal improvement in magnesium absorption (73), whereas those with osteomalacia or hypo- or hyperparathyroidism had only small increases, compared with calcium (74). Magnesium was absorbed by individuals with no detectable plasma calcitriol and, in contrast to calcium absorption, there was no significant correlation between plasma calcitriol and magnesium absorption (75). Individuals with absorptive hypercalciuria resulting from increased intestinal calcium absorption have normal magnesium absorption (76, 77).

Calcitriol did not increase net magnesium absorption in the stripped mucosa of the rat duodenum (78), ileum, or colon (64), but it markedly increased calcium absorption in the duodenum (78). The influence of magnesium depletion in rats on expression of the vitamin D-dependent protein in the proximal intestine that facilitates calcium absorption (calbindin D_{9k}) has been reported as negative (79) or positive (80). Other contradictory data from studies on this issue in the rat are reviewed in reference 62.

The effects of various gastrointestinal disorders on absorption are discussed below in the section on disease-related depletion.

Renal Regulation

Filtration and Tubular Absorption

The kidney plays a critical role in excreting the absorbed magnesium that is not retained for tissue growth or turnover replacement (26, 81). About 10% (roughly 100 mmol or 2400 mg) of the total body magnesium is normally filtered daily through the glomeruli in the healthy adult; of this only about 5% is excreted in the urine. Approximately 75% of the serum magnesium is ultrafilterable at the glomeruli. The fractional absorption of the filtered load in the various segments of the nephron is summarized in [Figure 9.4](#).

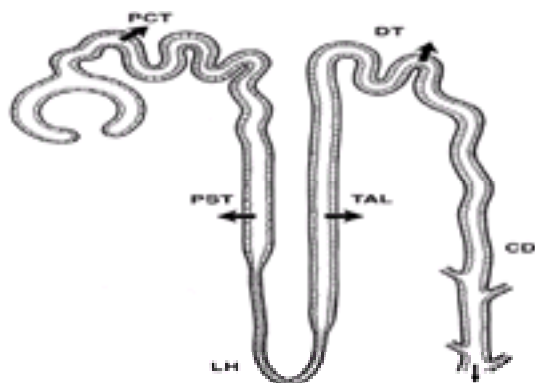

Figure 9.4. Fractional segmental reabsorption of filtered magnesium in the nephron. The percentage absorption of filtered Mg^{2+} has been determined by micropuncture techniques in various laboratory animals as the magnesium proceeds through the nephron. In the rat, approximately 10 to 20% of the Mg^{2+} is reabsorbed in the proximal convoluted tubule (*PCT*); this is only 25 to 30% that of Na^+ and Ca^{2+} in this segment. Magnesium reabsorption in the superficial and juxtamedullary proximal straight tubule (*PST*) is small, varying up to 5% depending on its luminal concentration. The major site for Mg^{2+} reabsorption is the thick ascending limb (*TAL*) of the loop of Henle (*LH*), primarily in its cortical portion. Here, 50 to 60% of magnesium leaves the lumen. The descending limb reabsorbs about 20% of the filtered load as a substantial amount of water is removed. In the distal convoluted tubule (*DT*) a little more than one-half of the magnesium remaining is absorbed, for a net fractional reabsorption of about 5%. Even less is reabsorbed in the collecting ducts (*CD*). There may be a balance in the ducts between absorption and secretion.

Hormonal and Other Regulator Influences on Absorption

Micropuncture studies in rodents showed that in the absence of hormonal influences, magnesium transport is a passive process occurring in the paracellular space and driven by transcellular transport of NaCl and the potential difference. Arginine, vasopressin, glucagon, calcitonin, PTH, and (to a lesser degree) an adrenergic agonist and insulin, when added individually to the bath of mouse segments of the cortical thick ascending limb of loop of Henle, significantly increased magnesium absorption (82). Proof that magnesium balance is normally regulated hormonally would require that certain changes in serum magnesium levels liberate one or more of these hormones into the blood and act on the tubule (82).

Although the regulatory mechanisms are unclear, a number of conditions affect absorption, principally in the ascending thick limb. Inhibition occurs with hypermagnesemia and hypercalcemia (26, 81). Decreased magnesium intake in experimental animals and humans rapidly decreases magnesium excretion, even before serum/plasma magnesium levels fall below the normal range (26, 83).

The close relationship between magnesium and potassium is clearly demonstrated in renal function. In the rat and man, magnesium depletion results in K⁺ loss. In the deficient rat, K⁺ entry into the tubule lumen occurs at a distal site and is associated with a rise in plasma aldosterone levels (84).

Tissue Sources

Extracellular and intracellular magnesium and that in bone compartments enter into the homeostatic mechanism. Human iliac crest changes indicate a broad range of loss during depletion with a weighted average of 18%, or 1.2 mmol/kg body weight (85). In young magnesium-deficient rats, the major body loss is from bone (approximately 15% of that in bone) with much less from muscle; however, age and duration of study affect the amounts lost (85). During starvation in a human obesity study, significant amounts of magnesium were lost, partly from loss of lean body mass, with an additional amount lost from bone as well as muscle, which was associated with acidosis (86). In an experimental human study of about 3-weeks' duration with resulting asymptomatic hypomagnesemia, there was no significant decrease in muscle magnesium; presumably bone and soft tissues were the sources of loss (87).

ASSESSING MAGNESIUM NUTRITURE

For public health as well as for individual need, procedures for assessing magnesium status are desirable. The available evaluation methods fall into five general classes.

Dietary Assessment

A dietitian or physician can do a rough but rapid evaluation of the probable level of

intake of individuals from information on the usual frequency of intakes of the food groups making major contributions to magnesium intake. However, other evaluation methods are necessary because inadequate dietary intake per se is usually not the primary cause of depletion in clinical situations.

Clinical Evaluation

Clinical evaluation includes a history and physical examination taken by a health practitioner sensitive to the causes, signs, and symptoms associated with magnesium depletion. This usually provides enough information to decide whether the individual is at no risk, is already at risk, or is symptomatically depleted. Risk factors are listed in [Table 9.2](#). Symptoms and signs of deficiency are given in [Table 9.3](#). Hypermagnesemia may also be a clinical problem (see last section). Laboratory tests are often key in establishing the correct diagnosis.

<p>Cardiovascular disorders (Heart failure, myocardial infarction, stroke, arrhythmias) (Hypertension, atherosclerosis, coronary artery disease, peripheral vascular disease) (Hypotension, hypovolemia, hypokalemia, hypocalcemia) (Myocardial infarction, stroke, arrhythmias) (Hypertension, atherosclerosis, coronary artery disease, peripheral vascular disease) (Hypotension, hypovolemia, hypokalemia, hypocalcemia)</p> <p>Neurological disorders (Headache, dizziness, vertigo, tinnitus, deafness, double vision) (Seizures, convulsions, tetany, chorea, dyskinesia, ataxia) (Parosmia, anosmia, taste blindness, taste aversion) (Hypertension, atherosclerosis, coronary artery disease, peripheral vascular disease) (Hypotension, hypovolemia, hypokalemia, hypocalcemia)</p> <p>Endocrine disorders (Hypertension, atherosclerosis, coronary artery disease, peripheral vascular disease) (Hypotension, hypovolemia, hypokalemia, hypocalcemia)</p> <p>Renal disorders (Acute renal failure, chronic renal failure, dialysis) (Hypertension, atherosclerosis, coronary artery disease, peripheral vascular disease) (Hypotension, hypovolemia, hypokalemia, hypocalcemia)</p> <p>Other disorders (Hypertension, atherosclerosis, coronary artery disease, peripheral vascular disease) (Hypotension, hypovolemia, hypokalemia, hypocalcemia)</p>

Table 9.3 Symptoms and Signs of Magnesium Depletion

Laboratory Analyses: Serum/Plasma, Urine, and Blood Cells

Total, Bound, and Ionized Serum Magnesium. In otherwise healthy laboratory animals and humans, instituting a magnesium-restricted diet results in a fairly early and progressive decline in total serum magnesium. In contrast, there are a number of reports of normal serum/plasma levels associated with a variety of illnesses but with low values in various blood cells and other organs (see below). Consequently, total serum/plasma magnesium values in such situations may be considered unreliable indicators of depletion. This has stimulated the search for more reliable laboratory markers for magnesium status.

Magnesium bound to protein and other serum/plasma ligands varies with changes in the concentrations of such ligands and in acid-base conditions; acidosis decreases bonding, and alkalosis increases it. The level of ionized magnesium may be more relevant under certain circumstances than that of total magnesium (37, 88). Improved ISEs for determining ionized magnesium in whole blood, serum, and plasma greatly simplify this determination; they are available commercially but require calibration (38, 39).

Erythrocytes. In experimental human magnesium deficiency, the magnesium content of red cells measured following hemolysis decreases more slowly and to a lesser extent than does total serum magnesium (89). Magnesium ion concentrations measured by ^{31}P MRS in erythrocytes of healthy volunteers on a magnesium-deficient diet for 3 weeks and in erythrocytes of other hypomagnesemic patients were significantly lower than those in the baseline period of normal magnesemic groups; in all subjects, $[\text{Mg}^{2+}]_i$ correlated with serum levels (90). Recent MRS data on erythrocytes of end-stage renal patients on dialysis did not support older data claiming that such patients have intracellular magnesium depletion (91).

Blood Mononuclear Cells. Reports indicate that magnesium concentrations in human mononuclear cells are a better guide to magnesium nutriture than is the serum level (92, 93), but there are contradictory reports (94, 95 and 96).

Urine Levels As Indicators. In an individual with normal renal function, 24-h magnesium excretion that is more than 10 to 15% of the amount ingested from an adequate diet suggests good nutriture. When there is a major reduction in the amounts ingested and/or absorbed, there is a fairly rapid and progressive reduction in urinary excretion of this ion by the normal kidney; in early stages of such depletion, total serum magnesium may still be within normal limits, but urine levels may be significantly reduced (24, 97). In situations in which renal magnesium wasting occurs (Table 9.4), the resulting hypomagnesemia (e.g., $[\text{Mg}^{2+}]_s$ 0.7 mmol/L) is associated with urinary magnesium excretion of more than 1 mmol/day (98, 101) (Fig. 9.5). Such a relationship suggests renal tubular dysfunction if the cause of the hypomagnesemia is otherwise uncertain.

Figure 9.5. Algorithm of a diagnostic approach to suspected magnesium deficiency, in which urine magnesium levels are emphasized to distinguish the key factors leading to magnesium depletion. (From Al Ghamdi SMG, Cameron EC, Sutton RAL. *Am J Kidney Dis* 1994;24:737–752, with permission.)

(The content of this table is extremely faint and illegible in the provided image.)

Table 9.4 Metabolic, Hormonal, and Drug Influences on Renal Magnesium Excretion

Magnesium Load/Retention Test.

The intravenous load or retention test provides an estimate of the proportion of infused magnesium that is retained over a given period (99, 100). Persons retaining more than the percentage retained by magnesium-replete individuals (e.g., 20–25%) are considered to have some body depletion. The test was initially validated in weanling rats and then in mature rats given differing amounts of magnesium, while magnesium was measured in plasma, urine, and bone (99). A suggested clinical protocol that has been tested in a relatively large number of hypomagnesemic patients, chronic alcoholics, and animal controls has been published (100). It is an invasive, time-consuming, nonstandardized, and expensive test, requiring hospitalization or other close supervision

for the partial or full 24 hours after infusion, with careful urine collection for laboratory analysis. This type of test again raises the important question of how much depletion must occur in various body pools before magnesium deficiency becomes biochemically and clinically significant.

Combined Laboratory Testing

An algorithm combining serum magnesium level with renal excretion and the load test is presented in [Figure 9.5](#). While blood and urine levels together with history usually suffice to make the diagnosis, the load test may be included when semiquantitative data on the severity of pool depletion is desired or when the urinary data are equivocal ([101](#)).

Enzymatic Reactions

Despite the numerous enzymatic reactions for which Mg^{2+} is essential, there is no clinically useful diagnostic enzymatic reaction for detecting deficiency.

Classic Balance Studies

The long-term and expensive metabolic studies used to estimate normal human requirements are not applicable to the study of sick patients. They are discussed in the next section.

NEEDS FOR HEALTH?

Intake Standards. For healthy older children, adolescents, and adults, the primary approach has been the balance study. For infants and young children, the figures are based primarily on estimates of magnesium intakes of milk and other foods that allow good development. Such data have been transmuted into the dietary reference intakes (RDIs) in the United States ([101a](#)) and similar standards in other countries. (See Appendix [Table A-2-a-1](#), [Table A-2-a-2](#), [Table A-2-a-3](#), [Table A-2-b-1](#), [Table A-2-b-2](#), [Table A-2-b-3](#), [Table A-2-b-4](#), [Table A-2-b-5](#), [Table A-2-b-6](#), [Table A-2-c-1](#), [Table A-2-c-2](#), [Table A-2-c-3](#), [Table A-2-c-4](#), [Table A-2-c-5](#), [Table II-A-3-a](#), [Table II-A-3-b](#), [Table II-A-4-b](#), [Table II-A-4-c](#), [Table II-A-4-d](#), [Table II-A-4-e-1](#), [Table II-A-4-e-2](#), [Table II-A-4-f](#), [Table II-A-5-a](#), [Table II-A-5-b](#), [Table II-A-5-c](#), [Table II-A-5-d](#), [Table II-A-6](#), [Table II-A-7-a](#), [Table II-A-7-c](#), [Table II-A-7-a](#), [Table II-A-7-d-1](#), [Table II-A-7-d-2](#), [Table II-A-7-d-3](#), [Table II-A-7-d-4](#), [Table II-A-7-d-5](#), [Table II-A-7-d-6](#), [Table II-A-8-a-1](#), [Table II-A-8-a-2-a](#), [Table II-A-8-a-2-b](#), [Table II-A-8-a-2-c](#), [Table II-A-8-a-3](#), [Table II-A-8-b-2](#), [Table II-A-8-b-2-a](#), [Table II-A-8-b-3](#) and [Table II-A-8-b-4](#).) The new U.S. reference intakes for magnesium are given in [Table 9.5](#) (see also Appendix [Table II-A-2-b-3](#)) with comparison to the 1989 RDA figures ([101b](#)). Both are based on estimates of intake that meet the needs of 97 to 98% of healthy individuals. The chief difference is in higher levels in the DRI for all ages beyond 8 years.

Age (years)	1989 ^a		Age (years)	1997 ^b	
	Male	Female		Male	Female

Table 9.5 Comparison of 1989 and 1997 Recommendations for Daily Intakes of Magnesium (mg)

Are Americans at Risk for Deficiency? Estimates of magnesium intakes in NHANES III (1988–91) indicated that children 2 to 11 years grouped by gender, age, and race/ethnicity had median intakes well above their RDA. Those ages 1 to 5 years in the lower fifth percentile took in about 90% of the RDA, which includes a safety factor (53, 54 and 55). On the other hand, males and females from 12 to more than 60 years, grouped by race and ethnicity, with the exception of non-Hispanic white males, had low median intakes in terms of the RDA (53).

The basis for the claims that many adolescents and adults in the United States are at risk of magnesium depletion rests on the accuracy of two indices: the dietary intake data summarized in NHANES and the RDA. If either or both of these are seriously inaccurate, the extent of potential depletion will be either higher or lower. The *Third Report on Nutrition Monitoring in the United States* (1995) analyzed intake in relation to the RDA for age and gender; it concluded that magnesium presents a potential public health issue requiring further study (53). One reason given was that in 1988–91, the median intakes of magnesium from food were lower than the RDAs in various population groups. The report accepts the dietary intakes as “low” without questioning the reliability of the RDAs. Interestingly, the 1989 nutrition monitoring report did not consider magnesium a current health issue (55). On the basis of the 1997 DRI (Table 9.5), a higher percentage of adolescents and adults will be deemed at risk by these criteria. The new tables for this nutrient and a brief explanation of the various reference intakes are given in Appendix Table II-A-2-b-2, Table II-A-2-b-3, and Table II-A-2-b-4.

The median magnesium intake of many Americans also appears inadequate to those who argue that the *median* magnesium intake should be approximately 600 mg/day. As was recently stated, “extensive metabolic balance studies done by the USDA Research Service showed that the ratio of dietary calcium to magnesium that best maintained equilibrium (i.e., output equaling intake) was 2:1” (102). The reference is to Hathaway, who reviewed publications on various aspects of magnesium and presented many tables, brief summaries, and detailed data (without any statistical analysis) from a large

number of balance studies performed in the 1930s to 1950s (many with USDA support) in various institutions around the world (103). Review of this report fails to reveal any statements claiming a preferred ratio of dietary calcium:magnesium of 2:1 or recommending a median daily magnesium intake of about 600 mg. In her brief summary and conclusions, Hathaway stated specifically that “Studies with adults indicate that young women require about 300 mg of magnesium a day and young men between 300 and 400 mg and protein intakes about 70 and 80 gms, respectively” (103). Her only summary statement relating magnesium and calcium was a general one: “Its [magnesium's] relation to calcium and phosphorus intakes and metabolism seems to be more complicated [compared with protein] as the requirements seem to be interrelated” (103). Later research supports Hathaway's opinion; magnesium and calcium are now known to be interrelated in a number of mimic/antagonist relations. However, chemical or metabolic evidence for a 2:1 dietary interrelationship does not exist.

Criteria for Evaluating Magnesium Nutriture in Health

Adequacy of Dietary Intake Data. The section on dietary intake noted that laboratory analysis of foods revealed a magnesium content 115 to 124% greater than those calculated by tables of food composition (52, 53 and 54) and that a number of foods have not yet been thoroughly analyzed. Dietary intake data must be considered only semiquantitative; they probably should have confidence limits applied on the basis of the variability of such data.

Lack of Evidence for Significant Depletion. Serum magnesium was determined by AAS in 15,820 individuals in the NHANES I (1971–74) survey; 95% of adults ages 18 to 74 years had serum levels in the range of 0.75 to 0.96 mmol/L (1.50–1.92 mEq/L) with a mean of 0.85 mmol/L. The levels of the fifth percentile were at or above the lower levels of normal (i.e., 0.70–0.73 mmol/L (104).

Adequacy of the Current RDAs. A recent critique of previous—including the 10th—RDAs for magnesium noted that most of the published human balance data referenced in its various editions often did not meet the criteria for acceptable methodology (105). The balance studies (usually short term) were done mostly in adolescents and younger adults, and balance data presented for pregnant women were less than adequate (105). Published data about the elderly were meager (106). The need was pointed out for improved definition of acceptable standards, evaluation of the optimum base (i.e., weight, fat-free mass, or lean body mass), documentation of the accepted data, and more awareness of the ways in which homeostatic mechanisms conserve body magnesium. While the database of the 1997 reference values (Table 9.5) has eliminated the poorer studies, a question remains as to the accuracy of many balance studies in terms of adherence to acceptable methodology.

EXPERIMENTAL MAGNESIUM DEFICIENCY

A large number of different laboratory and domestic animals, some subhuman primates, and human subjects have been studied in the course of magnesium deficiency induced

by diets low in this element ([107](#)).

Laboratory Animals

Hypomagnesemia is the hallmark of experimental magnesium depletion in all species, but other manifestations often vary. Although most studied, the rat is strikingly different from other species in certain of its acute deficiency signs, including hyperemia of ears and feet induced by histamine release from basophils, hyperirritability associated with characteristic and usually fatal tonic-clonic convulsions, high levels of serum calcium with low inorganic phosphate, and decreased circulating PTH in response to the hypercalcemia. Mice on the same diet did not have hyperemia, became hypocalcemic in association with hypomagnesemia, and often died with a single abrupt and massive convulsion ([108](#)). Deficient dogs and monkeys—also on diets of the same composition—developed spasticity, weakness, tremors, and occasionally nonfatal convulsions with hypocalcemia; increasing calcium intake did not increase serum calcium or prevent the neuromuscular changes ([109](#)).

Other changes in deficient young rats include reduced growth rate, alopecia, and skin lesions. Chronic deficiency in the rat leads to edema, hypertrophic gums, leukocytosis, and splenomegaly. Various thymic abnormalities have also been noted ([110](#)). Crystalluria in the kidney with calcification and degenerative changes in various organs, especially the kidney, muscle, heart, and aorta, are prominent in deficient rats ([111](#) and [112](#)), guinea pigs ([113](#)), dogs ([114](#)), and certain other species maintained on low-magnesium diets, particularly when the calcium content is high compared with that of human diets ([109](#), [113](#)).

Humans

Symptomatic human deficiency has been induced experimentally by dietary restriction. Deficiency also occurs in a number of predisposing and complicating disease states ([Table 9.2](#) and [Table 9.4](#)). In the single depletion study in which signs and symptoms occurred, plasma magnesium fell progressively in six subjects to levels that were only 10 to 30% those of control periods, while erythrocyte magnesium declined more slowly and to a lesser degree ([89](#)). Urine ([Fig. 9.6](#)) and fecal magnesium decreased to extremely low levels within 7 days. In one subject ([Fig. 9.7](#)) and the other four consistently symptomatic patients, hypomagnesemia, hypocalcemia, and hypokalemia were present. Good intestinal absorption of calcium and low urinary output resulted in positive calcium balance. Serum phosphate was variable. Negative potassium balance resulted from increased urinary loss. Serum sodium remained normal, and the subjects were in positive sodium balance. Abnormal neuromuscular function ([Table 9.3](#)) occurred in five of the seven subjects after deficiency periods ranging from 25 to 110 days. All symptoms and signs (including personality changes and gastrointestinal symptoms) reverted to normal with reinstatement of magnesium.

Figure 9.6. Plasma and urinary magnesium in the week following omission of magnesium from the diet in human experimental deficiency. Rapid decrease in urinary excretion occurred in six subjects. By the 10th day, all plasma values except that of subject Y were more than two standard deviations below the normal mean. (From Shils ME. *Medicine* (Baltimore) 1969;48:61–85.)

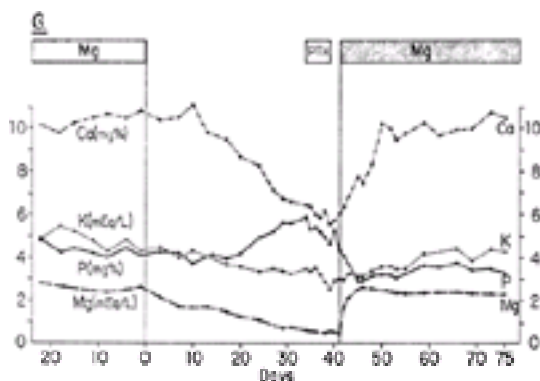

Figure 9.7. The course of blood chemistries in a subject subsisting before, during, and after a period on a diet very restricted in magnesium (*Mg*). *Mg* was omitted after the patient was on the control diet for 1 month. The rise in serum inorganic phosphate (*P*) with *Mg* depletion in this patient was unique among the depleted subjects. On depletion day 25, Trousseau's and Chvostek's signs first occurred, and the former became progressively stronger as plasma calcium (*Ca*), *Mg*, and potassium (*K*) continued to decline. These electrolyte changes were noted in all symptomatic subjects. On depletion day 35, PTH (*PTH*) was given i.m. at 50 units t.i.d. for 5 days; this had no effect on plasma *Ca* but appeared to decrease *P*. On day 41, anorexia, nausea, paresthesias, and generalized muscle spasticity developed; 17 mEq of *Mg* was then given i.v. with rapid improvement. This was followed by similar amounts of *Mg* i.m. 12 and 15 hours later. Dietary *Mg* (40 mEq/day) was resumed on the third repletion day. Note the characteristic delay in the return to normal of serum *Ca* and *K*. (From Shils ME. *Medicine* (Baltimore) 1969;48:61–85.)

In other detailed investigations of experimental magnesium depletion in human subjects in 1958, 1960, and 1966 (reviewed in [89]), marked decreases in fecal and urinary output occurred, but symptoms and signs of deficiency did not. More recently, hypomagnesemia has been induced by formula feeding for 3-week periods for physiologic studies (100, 115).

The signs and symptoms noted above in experimental deficiency and still others have been described individually or in various combinations in clinical cases of hypomagnesemia (Table 9.3). The closest disease-related condition to uncomplicated experimental human magnesium deficiency is congenital primary (idiopathic) hypomagnesemia related to a specific defect in intestinal absorption of this ion (59, 116). Hypomagnesemia, hypomagnesuria, hypocalcemia, and hypokalemia with tetany (often with convulsions), occurred in infants and were corrected or prevented with magnesium supplements. Calcium and vitamin D supplements without magnesium were ineffective in maintaining normocalcemia (116).

Metabolic Correlates

Sequence of Changes in Human Deficiency

Observations made during experimental studies and during clinical deficiency are the bases for this schema of changes during deficiency and repletion. The initiating factor appears to be failure of the normal heterionic exchange of bone calcium for magnesium at the labile bone mineral surface (117). Impaired receptor responsiveness to PTH of the osteoclasts follows, with reduced active bone resorption (118). Hypocalcemia progresses despite the increasing levels of circulating PTH that may occur at this stage (109, 119).

As depletion progresses, PTH secretion diminishes to very low levels despite adequate intraparathyroid gland hormonal reserves (119, 120). Signs of severe magnesium depletion are now present: hypomagnesemia with very low circulating PTH, hypocalcemia and hypocalciuria with positive calcium balance, hypokalemia with loss of body potassium, sodium retention, and neuromuscular and other clinical signs and symptoms (89).

Following administration of adequate magnesium, serum magnesium levels rise rapidly, presumably with increased heterionic calcium exchange but with little or no detectable change in circulating calcium in this early phase. Despite an increase in circulating PTH, the serum calcium response is delayed, presumably until osteoclast receptors to PTH regain responsiveness (118). When calcium levels increase, plasma PTH levels decline appropriately. The delayed rise in serum potassium is presumably secondary to the period required to restore the normal activity of the cellular membrane Na-K ATPase, Na-K-Cl cotransporter, or K channels (121). Clinical signs and symptoms tend to disappear in a matter of hours to a few days, although serum calcium and potassium

usually have not reached normal levels.

Additional Effects of Deficiency

Magnesium, Calcium, and PTH Interactions. Extracellular Mg^{2+} plays various roles, including regulation of PTH secretion. It is essential in the formation of cAMP through its binding at two sites in adenylate cyclase, which in turn stimulates PTH secretion (10). When Mg^{2+} is absent or present at very low levels in culture medium for explants of bovine parathyroid glands or rat parathyroid tissue, there is little PTH secretion despite a low $[Ca^{2+}]$, which suggests that Mg^{2+} is essential for hormone synthesis. However, when the minimum $[Mg^{2+}]$ necessary for such synthesis is present, increasing $[Mg^{2+}]$ and/or $[Ca^{2+}]$ progressively suppresses secretion (reviewed in [122, 123]). Extracellular Ca^{2+} and Mg^{2+} do not act directly but rather modulate a cell-surface, extracellular, Ca^{2+} -sensing receptor; the resulting inward current mobilizes intracellular Ca^{2+} stores, presumably by activating phosphoinositide-specific phospholipase C on a pathway to inhibition of PTH secretion (124). These results support the in vitro and in vivo findings that extracellular $[Mg^{2+}]$ has an appreciably smaller effect than $[Ca^{2+}]$ in suppressing PTH secretion (122).

PTH Levels in Deficient Human Subjects. Development of the immunologic method for measuring the circulating PTH level (the iPTH assay) was a major advance in understanding the magnesium–parathyroid gland relationship. The earliest reported use of this method on a deficient individual with idiopathic malabsorptive defect suggested a failure of synthesis or secretion (or both) of PTH (125). As more iPTH assays were performed on deficiency patients, a more complex situation became apparent: magnesium deficiency resulted in high, low, or normal PTH levels (119, 122), depending in part on the severity of the deficiency and the reaction of osteoclast receptors to PTH (118) (see below).

Patients with marked hypomagnesemia and hypocalcemia respond to a rapid intravenous injection of a magnesium bolus with a major rise in serum iPTH levels within 1 minute, from an undetectable baseline; very rapid elevation of serum magnesium levels is not associated with any detectable rise in serum calcium levels over the next 0.5 to 6 hours. It was concluded that the magnesium-depleted parathyroid gland could synthesize PTH but needed magnesium to induce secretion (119, 120). Eumagnesemic normal subjects given the same magnesium infusion had the expected rise in serum magnesium levels, but their iPTH level declined significantly (119).

PTH Response in Depleted Rats. Circulating PTH in rats, in contrast to humans and other species, responded appropriately to the rising calcium levels induced by magnesium deficiency (126, 127). Severely magnesium-depleted rats could secrete large amounts of iPTH when hypocalcemia was induced by depletion of either calcium or vitamin D (127).

Bone Changes and Resistance to PTH. Resistance to PTH was predicted from the normal or elevated iPTH levels found in some hypomagnesemic and hypocalcemic patients and also by the relative refractoriness of deficient laboratory species and

humans after administration of parathyroid extract (reviewed in [122]). Such resistance has been confirmed in dogs with chronic magnesium depletion, which show markedly reduced uptake of synthetic bovine PTH perfused into isolated tibias (118). This correlated with a significant depression in cAMP production by the deficient dogs, whose bones had a histologic picture of skeletal inactivity with virtually no osteoid.

Wallach reviewed the multiple effects of magnesium deficiency on skeletal morphology and composition. Depressed bone growth, abnormal bone formation, and osteopenia occur, with some species variability (49). In vitro rat bone studies conducted years ago suggested that magnesium somehow stimulated the normal process of bone resorption (128). Studies with cultured rat osteoclasts demonstrated that Mg^{2+} is essential for their adhesion to bone (an early critical step in bone resorption) and that Ca^{2+} diminishes such adhesion (129).

Vitamin D Resistance. The usual calcemic effect of vitamin D and its active metabolites calcidiol and calcitriol is blunted—even with high doses—in the presence of magnesium deficiency induced under a variety of conditions in humans, including rickets (130), intestinal malabsorption (131), and idiopathic (132) or surgically induced hypoparathyroidism (133). Hypomagnesemic hypercalcemic rats were also resistant (133). Although serum calcitriol levels were low in most depleted humans, serum magnesium, PTH, and calcium levels rose in response to magnesium administration (114, 134, 135 and 136). Low calcitriol levels were frequent in magnesium-deficient patients and persisted for 5 to 13 days after magnesium therapy, despite normal magnesium, PTH, and calcium responses (135). It has been suggested that magnesium depletion may partially impair the stimulatory effect of PTH on hydroxylation of calcidiol to calcitriol (115). Others found that administering magnesium together with calcidiol resulted in a rise in serum calcitriol levels to normal, but magnesium administration without the calcidiol elicited little or no rise in this hormone (137). Further study is necessary to determine the cause and significance of the depressed calcidiol and calcitriol concentrations in magnesium-depleted patients. Nonetheless, normal calcitriol levels are clearly not essential for correction of hypomagnesemic hypocalcemia.

Magnesium depletion in rats did not affect normal conversion of calcidiol to calcitriol in vivo nor did it modify the in vitro activity of the 1 α -hydroxylase in renal mitochondria (133). It was concluded that vitamin D resistance induced by magnesium depletion is the consequence of impaired skeletal response to calcitriol.

Renal Citrate Reabsorption. Magnesium-deficient patients have markedly lower urinary citrate content secondary to increased renal tubular citrate reabsorption (138). The low urinary citrate is an additional risk factor for renal stone formation in hyperoxaluric hypomagnesemic patients.

Lipids, Lipoproteins, and Prostanoids. Magnesium deficiency in rats has been associated with increased serum/plasma phospholipid (139, 140) and triglyceride (140) levels, variable total cholesterol (139, 140) levels, low free cholesterol (140) levels, increased levels of oleic and linoleic acids, decreased stearic and arachidonic acid levels, and modifications of lipoprotein concentrations (140) Plasma prostanoid (PGE₂,

PGF_{2a}, 6-keto-PGF_{1a}, and TBX²) levels were significantly higher in both plasma and tissues of deficient rats than in controls (141). In contrast to pair-fed controls, the hyperlipidemia in magnesium-depleted young rats was associated with increased oxidation of very low density (VLDLs) and low-density lipoproteins (LDLs). Increased lipid oxidation occurred in liver, heart, and muscle of the deficient rats (142). Magnesium depletion, by inhibiting adenylate cyclase activity and thereby lowering cAMP levels, may permit increased cyclooxygenase activity and stimulation of prostanoid synthesis (140).

Because certain biochemical and pathologic changes differ in the magnesium-deficient rat and in other species, experimental comparison with other species is necessary before generalizing the lipid and prostanoid changes noted above. Lipid alterations have been reported in hypomagnesemic human subjects; however, they are often complicated by factors related to underlying lipoprotein abnormalities occurring in diabetes, coronary artery disease, myocardial infarction, and other diseases.

DISEASE-RELATED (CONDITIONED) DEPLETION

Experimental versus Clinical Depletion

Unlike experimental magnesium depletion in humans and various species of laboratory animals, the clinical literature dealing with magnesium deficiency reports large variations in the concentrations of magnesium found in serum, various blood cells, and biopsy specimens of muscle and bone (reviewed in [143]). These marked and inconsistent variations emphasize the difficulty in ascribing cause and effect to a specific nutrient deficiency in uncontrolled situations in sick individuals. Normal cellular metabolism and homeostasis depend critically on an adequate supply of energy and essential nutrients. A deficiency of any one nutrient (e.g., magnesium, sodium, potassium, phosphate, or nitrogen) has a negative impact on retention of others (144). Magnesium deficiency depletes potassium (89), and potassium depletion reduces cellular magnesium (145). The adverse effects of major loss of lean body mass and acidosis on magnesium status have been noted (86). The clinical situation may be further complicated by a hypercatabolic state, hormonal imbalance, and various medications.

Prevalence

The many risk factors for magnesium depletion (Table 9.2 and Table 9.4) suggest that this condition is not a rare occurrence in acutely or chronically ill patients. Of 2300 patients surveyed in a Veterans Administration hospital, 6.9% were hypomagnesemic; 11% of patients having routine magnesium determinations were hypomagnesemic. When patients were hypokalemic, hypomagnesemia occurred in 42%; 29% of those with hypophosphatemia were hypomagnesemic, 27% of those with hyponatremia, and 22% of those with hypocalcemia (146). The true prevalence of magnesium depletion is not known, because this ion is not included in routine electrolyte testing in many clinics or hospitals (147). Similar high rates of depletion have been reported in studies of ICU patients (148, 149 and 150).

Gastrointestinal Disorders

Gastrointestinal disorders ([Table 9.2](#)) may lead to magnesium depletion in various ways. Persistent nausea, cramping, or abdominal pain may seriously impair intake. Vomiting of upper tract (stomach) contents is not associated with significant losses of magnesium, but persistent loss of large volumes from the small intestine for any reason will cause serious loss of magnesium (5–10 mmol/L). Crohn's and Whipple's diseases, gluten-induced enteropathy (celiac disease), lymphangiectasia, enteral fistulas, radiation enteritis, and surgically induced bowel resection, as well as other malabsorption syndromes impair magnesium absorption. These conditions are among the more common disease-related causes of depletion, in part, because of their chronic nature. Any condition that significantly increases the amount of unabsorbed fatty acids in the lumen will significantly reduce magnesium (and calcium) absorption by precipitating them as fatty soaps (i.e., bile insufficiency secondary to biliary obstruction or to damage or resection of the terminal ileum). Additional resection or disease of the colonic epithelium probably contributes to magnesium loss, because evidence suggests that the colon is a site of magnesium absorption. A large number of infections by bacteria, protozoa, and other parasites and viruses induce loss of magnesium by all of these mechanisms. Gastrointestinal damage (gastritis, cirrhosis, pancreatitis) induced by chronic alcoholic intake also affects magnesium status adversely in other ways.

Renal Disorders

Magnesium Wasting

Clinical depletion is induced by metabolic disorders that lead to renal magnesium wasting, including the hypercalcemia of hyperparathyroidism and malignancy, genetic disease, alcoholism, and diabetes mellitus. Thiazide diuretics in medium-strength dosages generally cause relatively little magnesium loss but may do so if ingested in large amounts over long periods; potassium loss may be more significant. Loop diuretics (e.g., furosemide) acting on the main site of tubular absorption are more likely to induce magnesium losses with chronic use ([98](#), [121](#)). Cisplatin nephrotoxicity has caused magnesium and potassium losses, which may occur rapidly and may persist for months or even years after discontinuation of the drug ([98](#), [151](#)). Provision of the drug with extensive hydration provides some protection.

Not all hypercalcemic conditions are associated with magnesium wasting. Familial hypocalciuric hypercalcemia ([152](#)) and lithium carbonate ([153](#)) used in the treatment of manic depression are associated with hypercalcemia, hypermagnesemia, and decreased excretion of calcium and magnesium.

Following release of a unilateral or bilateral ureteral obstruction, absolute and fractional urinary magnesium excretion increases from the obstructed kidney(s). This parallels the increase in sodium and calcium during the postobstructive diuresis; however, the magnesuria persists well beyond the sodium and water diuresis ([154](#)). Magnesium

wasting may also occur with various nephritides and following kidney transplant.

Primary hypomagnesemia (59) and congenital renal wasting syndromes (98) reflect deficiencies secondary to malabsorption in the intestine and kidney tubule, respectively. They are differentiated clinically by a very low urinary output in the former and a relatively high output in the latter.

Hypomagnesemia may occur in Bartter's syndrome (presenting below the age of 6 years with urinary potassium wasting, hypokalemia, alkalosis, normal or increased urinary calcium, and hyperaldosteremia, hyperreninemia, and increased urinary PGE_2), but usually in a minority of 20 to 36% (96, 98). A similar syndrome has been described with normal juxtaglomerular apparatus and severe hypokalemia that responded to large amounts of magnesium (155). The milder Gitelman's (or Welt's) syndrome frequently presents in adult life; it also has renal potassium wasting with resultant hypokalemia and alkalosis but with hypocalciuria and with most having hypomagnesemia with magnesium wasting (98). These and other related conditions have been summarized (98).

Chronic Renal Failure

While filtration through the glomeruli is progressively reduced, magnesium excretion continues to balance intake until the filtration rate falls below approximately 30% of normal; consequently, serum magnesium levels are within the normal range up to this time. Renal balancing factors include an increasing osmotic load, increased sodium excretion, increased calcium concentration in the tubule, and acidosis, all of which increase fractional magnesium excretion (156). If there is also tubular damage, magnesium wasting may occur; hypomagnesemia may result despite concomitant azotemia.

Magnesium in Dialysis Patients. Hemo- and peritoneal dialysis decrease magnesium together with other substances accumulated in blood because of severely impaired filtration. When the fluxes of plasma magnesium were determined using high-efficiency hemodialysis, a magnesium-free dialysate reduced the plasma magnesium from a high level (mean, 1.35 mmol/L [3.3 mg/dL]) to low normal (mean, 0.66 mmol/L [1.6 mg/dL]) in 2.5 h. A magnesium level of 0.6 mg/dL in the dialysate was well tolerated (157). It was suggested that approximately 0.5 g/day of magnesium carbonate be given orally with this dialysate level to minimize hypercalcemia and allow a doubling of intravenous calcitriol (157a).

Alcohol and Alcoholism

Magnesium depletion has been noted with high frequency in chronic alcoholics. The many causes include poor intake (as alcohol calories replace nutritious foods by choice or necessity) exacerbated by gastrointestinal problems such as nausea, vomiting, gastritis, and diarrhea, and increased urinary loss as the result of the direct action of alcohol, ketosis, and the frequent use of diuretics (158, 159).

It has been suggested that magnesium depletion in chronic alcoholics may play a role in

cardiovascular disease by increasing the platelet aggregation that occurs with deficiency (159); in addition, osteoporosis, which is common in alcoholics, may be partly due to alcohol-induced transient cycles of hypoparathyroidism followed by rebound hyperparathyroidism (160). With age and relative weight, alcoholism is among the three most common associations for hypertension in men and women (161, 162).

Diabetes Mellitus

Diabetes mellitus is probably the most common disorder associated with magnesium depletion (100, 163). More than 30% of ambulatory diabetic patients without renal insufficiency were hypomagnesemic on a multifactorial basis (163). A significant negative correlation was noted between serum/plasma magnesium and blood glycohemoglobin levels in insulin-dependent pregnant women, with significant relationships to the rates of spontaneous abortion and malformation (164). About one-third of infants born to diabetic mothers were hypo-magnesemic during the first 3 days of life. Similar negative correlations were noted between plasma and muscle magnesium and glycohemoglobin levels in adult insulin-dependent diabetes mellitus (IDDM) (165). In one group of children with IDDM, serum magnesium, calcium, PTH, calcitriol, and osteocalcin levels were lower than in age- and sex-matched controls (166); in another series, magnesium and potassium were low in skeletal muscle (167). Following oral magnesium supplementation, these values increased significantly. Supplementation also decreased the insulin requirement (168). When very elderly patients with normal serum magnesium and glucose levels but subnormal erythrocyte magnesium concentrations were given oral daily magnesium supplements, their erythrocyte magnesium levels rose, accompanied by net increases in insulin secretion and action (169).

Magnesium depletion in diabetic ketoacidosis occurs in part because of acidosis-induced cellular loss. Many such patients have normal or elevated serum magnesium (because of decreased glomerular filtration with volume contraction), but administration of fluid and insulin (particularly with intermittent relatively large amounts of the latter) without supplementary magnesium soon induces low serum levels indicating low tissue levels (170).

Intracellular magnesium concentration is reduced in muscle and in various blood cells of type II diabetics (100, 171). One cause of depletion appears to be increased urinary losses accompanying glycosuria-induced osmotic diuresis. Because insulin normally increases intracellular magnesium concentration, the insulin lack or resistance of the two types of diabetics has been suggested as a cause of reduced intracellular magnesium. Magnesium-deficient type II diabetics with decreased red cell magnesium had increased sensitivity to platelet aggregation, which was reduced by magnesium supplements (159).

Hypertension

The possible relationship of hypertension to magnesium nutriture has been examined by a number of approaches. In epidemiologic studies in which hypertension was correlated with dietary food records, magnesium intake was not associated with blood pressure in

black girls 9 and 10 years old. In white girls of the same age, higher magnesium intake was associated with decreased diastolic pressure; however, this effect disappeared after adjustment for dietary fiber intake (172). In a 4-year follow-up of 1248 male health professionals, the same relationship was noted; namely, hypertension was inversely related to the intakes of magnesium and dietary fiber. Only dietary fiber, however, had an independent inverse association (161). With adult females in a similar type of study, dietary magnesium (and calcium) was independently inversely related to hypertension (162). Reports relating serum magnesium levels in hypertensives to those in nonhypertensives are inconsistent; magnesium levels were lower in both sexes with hypertension (173), were lower in men but not in women (174), or did not differ in either gender from controls (175, 176).

The results of intervention studies are much more relevant. In uncontrolled studies, hypertensive patients on thiazide diuretics given magnesium supplements exhibited subsequent drop in blood pressure (177, 178), whereas in a controlled study, magnesium supplements had no significant effect after 6 months (179). When a magnesium supplement was compared with placebo in patients not on diuretics who had either mild-to-moderate (180) or mild hypertension (181), there was no decline in blood pressure at 1 or 3 months, respectively; in contrast, the same magnesium salt in another study produced a small but significant decrease only in the diastolic pressure of women with mild-to-moderate hypertension (182). An 8-month controlled study in subjects with mild hypertension compared placebo with either magnesium or potassium salts alone or together; potassium alone or given with magnesium caused a significant reduction in pressure, but magnesium had no added effect (183). In yet other controlled clinical trials, supplemental magnesium had no effect on the blood pressure of individuals with high-normal or mild hypertension (184, 186). In this study, when some of the subjects with low pretreatment urinary magnesium levels were given magnesium, their blood pressure fell significantly; however, this change was observed mainly in association with increased urinary excretion of sodium (186).

Erythrocytes of patients with essential hypertension had elevated levels of intracellular calcium and sodium, but the magnesium level and pH were low; these differences were exacerbated by salt loading salt-sensitive individuals and blunted by a calcium channel blocker (187). Hypertensive patients with left ventricular hypertrophy (LVH)—a prognostic factor for congestive heart failure and a risk factor for myocardial infarction and sudden death—had lower erythrocyte magnesium levels than hypertensive patients without LVH. The LVH patients had evidence of insulin resistance; insulin infusion increased their intracellular magnesium levels significantly over those of patients without LVH (188). Lack of insulin rather than hypertension appeared to cause the low red cell magnesium concentration.

The *Third Report on Nutrition Monitoring in the United States* (53) classified magnesium as a potential public health issue. This claim was made in part “because epidemiological and clinical studies have suggested that certain of these minerals are associated with hypertension (potassium and possibly magnesium)” (53). The stated support for this “possible” relationship is: “Limited evidence suggests that low serum levels of magnesium may be associated with an increased risk of hypertension” (53), and only two papers were cited (161, 162). These references were cited inaccurately in the third report; they did not report serum magnesium levels, nor did the authors of reference

[161](#) find an association between dietary magnesium intake and hypertension in males when dietary fiber was factored into the data.

Protein-Energy Malnutrition

Magnesium depletion has occurred in children with inadequate food intakes in association with malabsorption, persistent vomiting and/or diarrhea, and infection. Serum or plasma magnesium was noted to be low in a significant proportion of such children in various studies in Africa ([189](#)), whereas in a study in Central America, 50% of serum magnesium values were below 0.65 mmol/L on admission ([190](#)).

Postparathyroidectomy Hypomagnesemia

Symptomatic hypomagnesemia may follow parathyroidectomy for primary hyperparathyroidism in association with the expected hypocalcemia, presumably as part of the “hungry bone” syndrome that results from rapid uptake of calcium and magnesium by bone. Muscle weakness, tremor, and mental changes can be reversed by magnesium supplementation despite continuing low calcium levels ([191](#)).

Cardiovascular Disease

Various statements above have indicated the importance of magnesium in cardiovascular function. This section evaluates the literature on the possible relationship of this nutrient to various aspects of heart disease, particularly coronary artery disease (CAD). For many years, researchers have tried to assess the relationship between CAD prevalence and ingestion of “hard” water (i.e., water relatively high in calcium but also containing, in various proportions, magnesium, fluoride, phosphates, and other ions). An inverse relationship between the magnesium content of water and CAD has been claimed ([192](#), [193](#)), denied ([194](#), [195](#)), or stated to be uncertain ([196](#)). Serious difficulties exist in collecting accurate data about water composition and consumption over long periods, changes in water sources and treatment methods, population shifts, intakes of other sources of magnesium, and a large number of other variables, such as diet, and in proper execution of case-controlled or randomized studies ([196](#)).

Depressed magnesium status has been implicated as a causative factor for both dysrhythmias and myocardial infarction. Older literature cited low serum/plasma magnesium levels in individuals complaining of chest pain or with proven myocardial infarction upon, or soon after, admission; most of these reports were either uncontrolled or otherwise inadequate. More-recent studies suggest that other significant events contributed to the reported low serum values (reviewed in [[143](#)]): (a) the time blood is drawn following onset of chest pain is important, since magnesium leaves the infarcted myocytes; (b) the prior and often chronic use of diuretics and cardiac glycosides by patients with heart disease may induce depletion of magnesium as well as potassium and contribute to arrhythmias; (c) postinfarction lipolysis (also induced by ethanol withdrawal, epinephrine, and surgery) releases serum fatty acids that lower serum magnesium levels; and (d) the degree of pain per se affects magnesium levels. Similarly, the decreased magnesium content of ischemic hearts at postmortem examination is attributable to many factors, including previous medications, extent of

previous myocardial damage, and sampling sites.

Dietary magnesium intakes (comparing those of highest and lowest quartiles) were not a significant predictor of the occurrence of ischemic heart disease in a 16-year observation period of 2512 males, ages 45 to 59, when age, smoking, and energy and alcohol intakes were considered ([196a](#)).

Magnesium Infusion in Myocardial Infarction

A number of controlled studies supported the conclusion that intravenous magnesium given early after suspected myocardial infarction reduced the frequency of serious arrhythmias and mortality ([197](#), [198](#), [199](#) and [200](#)). These observations were supported by several metaanalyses ([201](#), [202](#)). In addition, the report of a major, randomized, double-blinded, placebo-controlled study, the Leicester Intravenous Magnesium Intervention Trial (LIMIT-2), indicated some benefit with magnesium ([203](#)). Mortality from all causes was 7.8% in the magnesium-treated group of 1019 patients and 10.3% in the placebo group of 1002 patients ($P = .04$). Left ventricular failure was reduced by an average of 25% ($P = .009$) in the magnesium group, as followed in the coronary care unit. The authors also concluded that magnesium was acting pharmacologically rather than correcting an existing deficit, that it did not affect progression to acute infarction in those with unstable CAD, and that it did not have antiarrhythmic action. A follow-up report on those who survived this study for 1.0 to 5.5 years indicated that the magnesium-treated group had 21% lower mortality from ischemic heart disease and 16% lower all-cause mortality than the controls ([204](#)).

The Fourth International Study of Infarct Survival (ISIS-4) was a much larger randomized trial than LIMIT-2 of patients having suspected myocardial infarction. This study compared the benefits of three different treatments with each other and with placebo-treated or “open” control groups ([205](#)). In comparing intravenous magnesium sulfate (2216 patients) with open controls (2103 patients), no significant reduction was found in 5-week mortality, either overall (magnesium, 7.64%; controls, 7.24%) or in any subgroup examined (i.e., treated early or late, presence or absence of fibrinolytic or antiplatelet therapies, or high risk of death). There was a significant excess of mortality with magnesium treatment in heart-failure patients or in those suffering from cardiogenic shock. Intravenous magnesium was concluded to be ineffective. The differences among the metaanalyses, LIMIT-2, and the ISIS 4 megatrial have led to continuing and divergent opinion on this subject ([206](#), [207](#) and [208](#)).

Rasmussen and colleagues, who had been proponents of magnesium infusion at the time of suspected infarction ([200](#)), found that daily oral administration of magnesium hydroxide (15 mmol, or 360 mg, over a 1-year period) to survivors of an acute myocardial infarction resulted in no differences in the incidences of reinfarction, sudden death, or coronary artery bypass grafting, compared with placebo ([209](#)).

Magnesium in Cardiac Surgery or Organ Transplantation

Cardiopulmonary bypass (CPB), used in cardiac and organ transplant procedures greatly expands the extracellular fluid volume (ECF) because of infusion of blood and/or

blood derivatives (e.g., up to 2500 mL/m² increases the ECF volume between 20 and 30%). Associated with this procedure are lactic acidosis, metabolic alkalosis, hemodilution, extracellular ion shifts, binding of Ca²⁺ and Mg²⁺ to stored blood products, and decreased serum [K⁺], [Na⁺], [Ca²⁺], and [Mg²⁺] (210). A significant number of candidates for cardiac surgery (211) or liver transplantation (212) are hypomagnesemic preoperatively, primarily because of poor intake and medications. Magnesium levels decrease further with ECF expansion and increased excretion stimulated by loop diuretics. Magnesium administration given once intraoperatively after the termination of CPB elevated the depressed serum magnesium transiently; this treatment was associated with a reduced frequency of clinically significant postoperative ventricular dysrhythmias and an increased cardiac index (211).

Cardiac Arrhythmias and Magnesium

The contradictory findings of LIMIT-2 and ISIS-4 raise uncertainties about the effectiveness of intravenous magnesium in preventing deaths from serious arrhythmias in patients with acute myocardial infarction. Nevertheless, the intimate roles of Mg²⁺ in cellular biochemistry, including its functions in association with Na-K ATPase (213), Ca ATPase (214), transport via multiple-ion channels (29), and hormonal regulation, provide evidence for its importance in cardiac function. Its deficiency—often combined with that of potassium—may result in electrophysiologic and other abnormalities leading to arrhythmias that are reversible by magnesium (100). Magnesium has proven effective in suppressing a ventricular arrhythmia, torsade de pointes, which is potentially life threatening (212, 215).

MANAGEMENT OF DEPLETION

The physician should consider all predisposing factors in patients at risk, to anticipate hypomagnesemia and institute early treatments to *prevent* its occurrence or minimize its severity. These include instituting control of underlying disease, minimizing therapeutic insult, and initiating medical and dietary changes designed to maximize magnesium retention by the intestine and kidney. When magnesium depletion is evident, its cause must be determined (see [Assessing Magnesium Nutrition](#) above). Prior to initiating treatment, magnesium, calcium, potassium, and sodium levels in the blood and urine and the acid-base balance in blood must be determined. The amount, route, and duration of magnesium administration depend on the severity of depletion and its causes.

Adolescents and Adults. Seizures, acute arrhythmias, and severe generalized spasticity require immediate intravenous infusion with one of several protocols, depending on the state of renal function. One to 2 g MgSO₄ • 7H₂O (8.2–16.4 meq Mg²⁺) is usually infused over 5 to 10 min, followed by continuous infusion of 6 g over 24 h or until the condition is controlled (93). Infusion of calcium gluconate should accompany the magnesium if blood levels are low. Alternatively, 2 g of the sulfate are given over 1 min, followed by 1.0 meq/kg (0.5 mmol) during the first 24 h, followed by 0.5 meq/kg for the next 3 days (215). A similar protocol (216) and others (217) have been used to suppress the ventricular arrhythmia torsade de pointes. In all instances, correction of

electrolyte (especially potassium) and acid-base imbalances should accompany the magnesium therapy. Additionally, levels of serum and urine magnesium and other electrolytes should be determined at least twice daily in such patients.

Less severe manifestations (e.g., paresthesias with latent or active tetany associated with persisting intestinal or renal losses) are likewise best treated by the intravenous route, again in conjunction with appropriate therapy for the underlying condition and with correction of other electrolyte and acid-base abnormalities. When renal function is good, 3 g (25 meq) of magnesium sulfate may be given intravenously over 2 or 3 h in saline or dextrose solutions, with other nutrients as required. Another 3 or 4 g are then given by continuous infusion over the remaining 24 h. When the intravenous route cannot be used, equivalent periodic intramuscular injections can be given, although these are painful and may lead to fibrotic reactions. This regimen is continued for 2 or more days, and the situation is then reassessed. The dosages given must always exceed the daily losses as indicated by serum levels and urinary excretion. Intravenous calcium administration in the treatment of hypocalcemia secondary to magnesium deficiency is usually desirable for 1 or 2 days when tetany is initially apparent.

The return to the normal or slightly higher range of serum magnesium levels with any of these schedules is relatively rapid. However, repletion of magnesium lost from bone and other tissues requires more prolonged magnesium therapy at lower and/or less frequent doses, preferably by mouth. This regimen is continued until—or, if necessary, beyond—the time necessary to attain a persisting, relatively normal serum magnesium concentration and a urine output of 20% or more of the oral intake in the case of intestinal malabsorption. When intestinal absorption is normal and renal magnesium wasting is present, supplements should be added to the usual diet to maintain normal serum levels; this supplement should be 20% or more above the amount of magnesium lost in fecal water plus urine, as measured when only the diet is given.

For the asymptomatic patient with serum levels below approximately 0.5 mmol/L (1.0 meq/L), a trial of increased oral intake is prescribed, as tolerated and effective (see below); otherwise, injectable magnesium sulfate is given intramuscularly for a trial period. Those with continuing severe magnesium and potassium losses in the urine (as in cisplatin nephrotoxicity) may require long-term supplements. If this is not possible solely by increased oral intake, an alternative to painful intramuscular injections of magnesium salts is either intravenous infusion via an indwelling central catheter for home administration or a trial of the old-fashioned, but useful, hypodermic clysis. In the latter procedure, 2 g of 50% magnesium sulfate is diluted in 250 mL of 0.45% saline with potassium as indicated. This solution is then infused as rapidly as possible, through a very small bore needle inserted just under the abdominal skin, as often as is necessary to meet the patient's magnesium requirement.

When depletion is modest and persistent, initial efforts should be directed to increased intake of magnesium-rich foods. When necessary and feasible, supplementary oral magnesium may be taken as small gelatin capsules packed with the sulfate, chloride, acetate, citrate, or other salts with good solubility in enteric fluids. Several small capsules may be given 3 to 6 times per day, with a full glass of water to prevent or minimize magnesium-related diarrhea (60) and to ensure solubilization. For the

individual on enteral feeding, one of these salts may be dissolved in the formula. Improvement of existing steatorrhea by dietary or other medical means will decrease fecal magnesium losses. Again, treatment of underlying disease and replacement of potassium deficits are essential.

Infants and Young Children. Symptomatic magnesium depletion in infants responds well to relatively small amounts of intravenous or intramuscular magnesium. When renal function is normal, parenteral administration is recommended: 3.6 to 6.0 mg (0.15–0.25 mmol or 0.3 to 0.5 meq)/kg body weight as 50% magnesium sulfate over the first several hours, followed by an equal amount, either intramuscularly or intravenously, over the remainder of the day (218). Calcium should also be infused initially, together with potassium and other electrolytes as indicated. When convulsions or arrhythmias are present in those beyond infancy, treatment may be initiated with an oral bolus of the 50% magnesium sulfate at a dose of 20 to 100 mg (1.65–8.25 meq/kg) over 1 min; this is followed by 1.0 meq/kg given continuously thereafter (219).

In patients with chronic malabsorption (e.g., primary hypomagnesemia), 12 to 18 mg/kg (0.5–0.75 mmol) in multiple, divided oral doses is suggested; this dosage schedule raises serum levels to near normal without inducing diarrhea (218).

HYPERMAGNESEMIA AND MAGNESIUM TOXICITY

Physiologic Effects of Hypermagnesemia

Magnesium at levels above normal relaxes vascular smooth muscle in vitro and reduces pressor responses (220). In humans, when serum magnesium levels were roughly twice normal, systolic and diastolic blood pressures fell by an average of 10 and 8 mm, respectively; renal blood flow increased significantly; and the pressor effect of angiotensin II was blunted (221). Urinary excretion of 6-keto-PGF_{1a} increased markedly. Cyclooxygenase inhibition with indomethacin or ibuprofen completely blocked the magnesium-induced fall in blood pressure, the rise in urinary 6-keto-PGF_{1a}, and the rise in renal blood flow. The calcium-channel blocker nifedipine also prevented the magnesium-induced rise in 6-keto-PGF_{1a} and fall in blood pressure. These findings indicate that the effect of magnesium was mediated by prostacyclin release and increased Ca²⁺ flux. When magnesium chloride was infused acutely in healthy subjects to the point of doubling the plasma magnesium, PTH levels fell and plasma renin activity and renin levels increased (222).

Induced Hypermagnesemia As Therapy

Preeclampsia and Eclampsia

Preeclampsia and eclampsia are the most important causes of maternal death in the United States and many other countries (223). For many years, high-dose parenteral magnesium sulfate has been the drug of choice in North America for preventing eclamptic convulsions that may occur in association with severe hypertension and other

problems in late pregnancy or during labor (224). Since 1995, magnesium sulfate has begun to replace phenytoin and diazepam in Europe and elsewhere (225). Despite many clinical trials and several metaanalyses suggesting that calcium supplements reduced the incidence of preeclampsia, a major double-blinded randomized study found that 2 g of elemental calcium given daily to healthy pregnant women did not prevent preeclampsia, pregnancy associated–hypertension, or adverse perinatal outcomes (225a). Magnesium is believed to reverse the cerebral vasospasm and ischemia that appear to be the genesis of eclampsia. A similar program of magnesium administration has been used in an effort to prevent premature labor (226); this use of magnesium as a tocolytic agent is disputed (see below). A loading dose and then maintenance doses are given to maintain a high serum level of approximately 2 to 3 mmol/L (4–6 meq/L) (224) or slightly above (226). With increased serum magnesium levels, circulating PTH levels may drop, with associated hypocalcemia (226, 227).

Patients with normal kidneys can excrete 40 to 60 g of magnesium sulfate \times 7H₂O per day when it is given constantly by infusion. The high doses used are rarely associated with serious side effects, because patients are closely monitored with modification of dosage as indicated.

Fetuses delivered from mothers receiving high-dosage magnesium had hypermagnesemia of the umbilical vein and artery blood at about the elevated levels of the mother; however, serum levels fell progressively to normal levels in neonates by 48 hours (228). With maternal hypocalcemia, the fetus at delivery may have normal (228) or low serum calcium (229). Abnormal radiographic findings have been noted in the proximal humeral metaphysis in infants of mothers who were on high-dose magnesium therapy to delay labor; they resolved completely within the first few months (230).

Effect on Cerebral Palsy and Asthma

An increasing number of reports have associated prenatal exposure of the fetus to increased levels of magnesium sulfate (as in the treatment of preeclampsia) with a major reduction in the risk of cerebral palsy and, possibly, of mental retardation in very low birth-weight (VLBW) children (231). However, a preliminary report in a well-controlled randomized study is contradictory. Women in preterm labor at less than 34 weeks gestation who were not pre-eclamptic were given MgSO₄ as one of the randomized treatments. Its use was associated with increased pediatric mortality and the trial was stopped (231a). This observation “tilts the balance of evidence firmly away from magnesium use as a tocolytic or cerebroprotectant agent in preterm labour” (231b).

Induced hypermagnesemia may be potentially useful in the management of status asthmaticus in children (232).

Magnesium in Treatment of Suspected Drug Overdose

Magnesium-containing cathartics have been given orally with activated charcoal in single or multiple doses (each of 30 g MgSO₄ \times 7H₂O [245 meq Mg²⁺]) in an effort to

decrease blood levels of drugs, as part of the treatment of patients with suspected drug overdose. Despite initially normal serum creatinine concentrations (233), 9 of 14 patients were hypermagnesemic by the third dose at 8 hours, including 4 with magnesium levels of 3.0 meq/L and one of 5.0. The presence of drugs that decreased gut motility (e.g., anticholinergics or opioids) appeared related to the higher levels (231).

Disease-Related Hypermagnesemia

Hypermagnesemia may occur at symptomatic levels in patients with gastrointestinal disorders such as obstipation, severe constipation, ulceration, obstruction, or perforation when magnesium-containing cathartics or antacids are taken, even in moderate dosages, and renal insufficiency is mild or moderate (232).

Advanced Renal Failure with Exogenous or Endogenous Magnesium Load

In addition to the planned therapeutic hypermagnesemia noted above, elevated serum levels occur when magnesium-containing drugs, usually antacids or cathartics, are ingested chronically and in relatively large amounts by individuals with advanced renal insufficiency. Because 20% or more of Mg^{2+} from various salts may be absorbed, impaired renal clearance can induce significant hypermagnesemia. The common association of age or disease-related impairment of glomerular filtration, which may be exacerbated by ingestion of potentially nephrotoxic medications (such as steroidal antiinflammatory drugs for arthritic pain), and the chronic use of magnesium-containing antacids and/or laxatives, contribute to the danger of significant hypermagnesemia in such individuals. Uncommonly, *hypomagnesemia* may occur when there is tubulointerstitial nephropathy–induced magnesium wasting or severe intestinal malabsorption (235).

Magnesium Toxicity

The many potentially toxic and even lethal effects of magnesium excess are summarized in [Figure 9.8 \(236\)](#). One of the earliest effects is a fall in blood pressure, progressing with increasing hypermagnesemia; this appears to result from inhibition of Ca^{2+} flux and the vasoconstrictive action of norepinephrine and angiotensin II (221). Some of the later effects, such as lethargy, confusion, and deterioration in renal function, may be related to the hypotension (234). ECG changes, such as prolongation of the P-R and Q-T intervals, occur at 5 meq/L (2.5 mmol). Tachycardia (probably secondary to hypotension) or bradycardia may occur. At 6 meq/L and above, muscle weakness and hyporeflexia may occur, presumably resulting from decreased release of acetylcholine and impaired transmission at the neuromuscular junction; hypocalcemia and hypokalemia may contribute to the progressive muscle weakness and respiratory difficulty. Complete heart block and cardiac arrest may occur at about 15 meq/L (236).

Figure 9.8. The progression in toxic effects as hypermagnesemia becomes more severe. An early sign is a lowering of blood pressure (*BP*). Nausea, vomiting, and hypotension may occur in the range of 3 to 9 mEq/L; bradycardia and urinary retention also occur in this range. Electrocardiogram (*ECG*) changes, hyporeflexia, and secondary central nervous system depression may appear in the 5 to 10 mEq/L range, followed at higher concentrations by life-threatening respiratory depression, coma, and asystolic cardiac arrest. (From Mordes JP, Wacker EC. *Pharmacol Rev* 1978;29:274–300, with permission.)

Management of Hypermagnesemia

Prevention or treatment of mild-to-moderate hypermagnesemia (≥ 1.5 mmol) requires reducing magnesium intake when absorption from all sources exceeds the renal excretory capability. At higher levels, when hemodynamic instability and muscle weakness are apparent, all magnesium intake should be stopped and an acute infusion of 5 to 10 meq of calcium should be given (234). Continued saline and calcium infusion will increase magnesium excretion. Dialysis will remove magnesium readily in the patient with poor renal function (234).

HISTORY OF IRON IN MEDICINE AND NUTRITION

Iron was a familiar metal in most of the ancient civilizations of the Mediterranean littoral

and was used in numerous tools and weapons. This familiarity with iron may also have led to its early medicinal use. In the earliest extant manuscript, the Ebers papyrus of Egypt, rust was prescribed in an ointment to prevent baldness. In early Greece, a solution of iron in wine was esteemed as a means of restoring male potency. In the 17th century of our era, the most important clinical application of iron was discovered: the treatment of chlorosis, a disorder later shown to be due to iron deficiency (1).

Even before the role of iron in nutrition was firmly established, the first clinical description of iron overload disease was reported in 1871 (2). The earliest objective study of iron in human nutrition, performed nearly a century ago and published in 1895, showed that the diets of young women with chlorosis only provided 1 to 3 mg of iron daily, whereas the average iron content of diets of normal persons ranged from 8 to 11 mg daily (3). Yet, it was not until 1932 that a centuries-long controversy concerning the value of iron for treatment of chlorosis was finally resolved beyond doubt (4). The major aspects of iron metabolism were elucidated before 1960. Thousands of subsequent investigations have filled in important details.

Biologic Importance

More than any other metal, iron is a key element in the metabolism of all living organisms. The iron-sulfur complex of ferredoxins is required for an early step of photosynthesis. The iron-sulfur complex of aconitase in the tricarboxylic acid (Krebs) cycle intimately links the iron content of cells with energy production via oxidative phosphorylation both in carbohydrate and in lipid metabolism. Iron is a part of heme, which is the active site of electron transport in cytochromes and cytochrome oxidase. Heme is also the site of oxygen uptake by myoglobin and hemoglobin, thereby providing the means of transporting oxygen to tissues and within muscle cells. Hemoglobin in the root nodules of legumes protects nitrogen-fixing enzymes of symbiotic bacteria from oxidative inactivation. The ammonia formed is important in the synthesis of amino acids and proteins. The amino acids and proteins of legumes are transferred through the food chain to herbivores and thence to humans; we depend on them. Heme is also the active site of peroxidases that protect cells from oxidative injury by reducing peroxides to water. Figure 10.1 shows the structure of heme, a molecule vital to energy metabolism, electron transfer, nitrogen fixation, and oxygen transport.

Figure 10.1. Structure of heme, showing iron at the center of a porphyrin ring. Heme is a component of hemoglobin, myoglobin, cytochromes, peroxidases, and cytochrome oxidase. In each of these, it is the functional site of the molecule, reversibly binding oxygen in hemoglobin and myoglobin, and serving as the site of the electron transfer in the oxidation-reduction reactions for which the other heme proteins are either enzymes or coenzymes.

Aconitase, a key enzyme of the Krebs cycle, catalyzes the interconversion of citrate, *cis*-aconitic acid, and isocitrate. This is the first step in the Krebs cycle, after condensation of acetyl-CoA and oxaloacetate to form citrate. Without aconitase, energy production becomes inefficient. Aconitase has an iron-sulfur cluster at its active site (Fig. 10.2). When there is sufficient iron in mitochondria or in cytosol, the iron-sulfur cluster of aconitase has a cubane, or cubelike, structure, with four atoms of iron and four atoms of sulfur at alternate apices (5, 6). This is the enzymatically active form of aconitase. On the other hand, when there is a deficiency of iron, the iron-sulfur complex is modified, with iron at only three apices (Fig. 10.2). In this form, aconitase is enzymatically inactive but becomes the iron-regulatory protein (IRP), binding to the iron-responsive elements of mRNA molecules for apoferritin, d-aminolevulinic synthase, and transferrin receptor. By doing so, it inhibits synthesis of apoferritin but stimulates synthesis of the other two proteins. In this way, iron uptake and heme synthesis are regulated at the cellular level to meet the needs of oxidative phosphorylation via the Krebs cycle. Further details of this mechanism are presented below. Aconitase exists in both mitochondria and cytosol and both mitochondrial and cytosolic aconitase have the properties and functions described here.

Figure 10.2. Iron-sulfur cluster of aconitase. This protein is involved both in glucose and fat metabolism and in regulation of iron metabolism. When iron is in abundance, it assumes the cubane structure shown on the *left*; when there is little iron in the cytosol, it loses an atom of iron, and it then has a more open structure as shown on the *right*. These changes in configuration are involved in its interaction with the stem-loop IREs shown in Figure 10.8 and Figure 10.9. It functions in glucose and fat metabolism only in

the iron-rich cubane configuration. (From Beinert H, Kennedy MC. FASEB J 1993;7:1442–9, with permission.)

Figure 10.8. Stem-loop structure, the basic unit of the iron-responsive elements of mRNA. (From Hentze MW, Seuanez HN, O'Brien SJ, et al. Nucleic Acids Res 1989;11:6103–8, with permission.)

Figure 10.9. Regulation of iron metabolism within the cytosol by interaction of aconitase with iron response elements (*IREs*) on mRNA. IREs are stem-loop structures that are activated or inhibited by iron-depleted aconitase (iron-regulatory protein, or IRP, formerly called IRE-BP, or iron responsive element-binding protein) within the mitochondria or the cytosol. Synthesis of proteins critical to iron metabolism is regulated by the aconitase-IRE mechanism. (A similar mechanism may exist for Nramp2). The *upper panel* represents apoferritin mRNA, the *lower panel*, transferrin receptor mRNA. When there is little iron within the cytosol, desferriaconitase binds to the IREs of mRNA for each of these proteins, stabilizing the mRNA, to increase the number of transferrin receptor molecules on the cell surface, to decrease the synthesis of apoferritin, and to increase the synthesis of ALA-S, thus facilitating uptake of iron at the cell membrane and synthesis of protoporphyrin so more is available for heme synthesis. When iron is

abundant within the cytosol, aconitase is displaced from the IREs, thereby stimulating apoferritin synthesis, inhibiting synthesis of transferrin receptor and ALA-S, and accelerating degradation of the mRNA. This results in enhanced synthesis of apoferritin and reduced synthesis of transferrin receptor, thus reducing iron uptake at the cell membrane and increasing storage capacity for the iron in the cytosol; there is also decreased synthesis of ALA-S and thus of heme. IRP, iron-regulatory protein, or desferriaconitase. (Modified from Knisely AS. *Adv Pediatr* 1992;39:383–403, with permission).

Although iron is one of the most abundant metals on earth and in the universe, nearly all the iron in the environment is insoluble, existing as iron oxides or as metallic iron. Thus, little iron is available for biologic needs, and living organisms treasure iron as if it were a trace element. Our bodies zealously defend the few grams of iron that are within each of us—for iron, in its extraordinary variety of biologically active forms, is the metal of life.

IRON METABOLISM

Compartments

In humans, the total quantity of body iron varies with weight, hemoglobin concentration, sex, and size of the storage compartment. [Table 10.1](#) shows approximate normal values for iron in various compartments. Of these, the largest is the iron in hemoglobin, contained within circulating erythrocytes. The size of this compartment varies considerably according to body weight, sex, and blood hemoglobin concentration. For example, a person weighing 50 kg (110 lb) whose blood hemoglobin concentration is 120 g/L (12.0 g/dL) would have a hemoglobin compartment iron content of 1.4 g. The size of the storage compartment, in which iron is contained in ferritin and hemosiderin, is also markedly influenced by age, sex, body size, and whether there has been excess iron loss (e.g., from bleeding or pregnancy) or iron overloading (e.g., hemochromatosis). Women and children often have very little storage iron. The tissue iron pool includes myoglobin and the tiny but essential fraction of iron in enzymes. The “labile pool,” a rapidly recycling component defined by iron kinetic studies, does not have a definable anatomic or cellular location. The transport compartment is iron bound to transferrin, the iron-transport protein in plasma. This compartment is small but quite active; normally 20 to 30 mg cycles through the transport compartment daily. The main metabolic pathways of iron metabolism are illustrated in [Figure 10.3](#) and [Figure 10.4](#). Further details concerning cellular iron metabolism and the proteins of the storage and transport compartments are given below.

Compartment	Iron Content (mg)	Total-Body Iron (%)
Hemoglobin iron	2000	67
Storage iron	1000	27
Tissue iron		
Myoglobin iron	130	3.5
Enzyme iron	8	0.2
Labile iron pool	80	2.2
Transport iron	3	0.08

^aThese values represent estimates for an "average" man: 70 kg, 177 cm (70 in). They are derived from data in several sources.

Table 10.1 Iron Compartments in Normal Man^a

Figure 10.3. Scheme for the metabolic pathways of iron. Iron intake (1) is normally about 1 mg/day, by absorption from the upper intestinal tract, and is balanced by 1 mg of iron loss (8), predominantly by exfoliation of epithelial cells of the intestinal mucosa. When iron loss exceeds 1 mg/day (e.g., during the reproductive years in women or from other blood loss), iron absorption must be proportionately increased. Iron absorbed by the small bowel is transported by transferrin in plasma predominantly (normally ~80% of absorbed iron) to hematopoietic bone marrow (2), where hemoglobin is formed in erythrocytes later released into circulating blood. A smaller amount of iron enters other compartments, iron stores as ferritin and hemosiderin in many organs (3), myoglobin in muscle cells, and enzyme iron in all cells (5). A "labile pool" (4) may be iron that passes from plasma to lymph and then recycles into plasma via the lymphatic duct. When erythrocytes have completed their normal life span of 4 months in circulation, the metabolically "rundown," or senescent, red cells are phagocytized and digested by monocytes and macrophages of bone marrow, spleen, liver, lymph nodes, and other organs (6). Some of the iron released in macrophages by hemoglobin catabolism is retained as storage iron, but most is reused by recycling to plasma and then to hematopoietic bone marrow (3 to 2), where this cycle begins anew. In the storage compartment (7), iron exists in a rapidly exchanging pool (a) and a slowly exchanging pool (b). The former corresponds to ferritin, and the latter to hemosiderin. A small amount of both hemosiderin and ferritin may be lost in feces as a result of exfoliation of

intestinal epithelial cells (8). Normally, a minute amount of blood is also lost in feces.

Figure 10.4. Iron cycle in humans. Iron is tightly conserved in a nearly closed system in which each iron atom cycles repeatedly from plasma and extracellular fluid (*ECF*) to *bone marrow*, where it is incorporated into hemoglobin. It then enters the peripheral blood within *erythrocytes* and circulates in the blood for 4 months. It then travels to *phagocytes* of the reticuloendothelial system, where senescent erythrocytes are engulfed and destroyed, hemoglobin is digested, and iron is released to *plasma*, where the cycle continues. With each cycle, a small proportion of iron is transferred to *stores*, where it is incorporated into ferritin or hemosiderin. A small proportion of storage iron is released to plasma; a small proportion is lost in urine, sweat, feces, or blood; and an equivalent small amount of iron is absorbed from the intestinal tract. In addition, a small proportion (about 10%) of newly formed erythrocytes normally is destroyed within the bone marrow and its iron released, bypassing the circulating blood part of the cycle (*ineffective erythropoiesis*). Numbers indicate the approximate amount of iron (in mg) that enters and leaves each of these iron compartments every day in healthy adults who do not have bleeding and other blood disorders.

Intake

The average daily intake of iron in North American and Europe is between 10 and 20 mg, about 5 to 7 mg of iron per 1000 calories. A weight-conscious young woman who limits her intake to between 1000 and 1500 calories/day may consume only 6 to 9 mg of food iron, and if her diet consists largely of snack foods, pizza, and soft drinks, which have negligible iron content, it will be well below that.

Some natural fruit juices contain significant amounts of iron, but beer and soft drinks are generally quite poor in iron. Distilled alcoholic beverages are also iron poor. Some European ciders and wines may contain 16 mg of iron or more per liter. The iron content of city water supplies is usually less than 5 mg/L, but water from some deep wells may

have a higher iron concentration. [Table 10.2](#) shows the iron content of many commonly eaten foods ([7](#), [8](#) and [9](#)). Since the quantity of food eaten is driven mostly by caloric need, it is most sensible to consider the iron content of foods as a function of their caloric value. The last column of the table shows this relationship. In this table, food groups are ranked according to their iron content per kilocalorie. Green vegetables and legumes provide the highest iron:calories ratios; milk products, snack foods, and soft drinks, the lowest. To the extent that the diet contains generous amounts of green vegetables or legumes, iron intake should be sufficient; to the extent that milk products, snack foods, and soft drinks predominate, iron nutrition will be poor.

Food Group	Food Item	Iron (mg/100g)	Iron:Calories (mg/1000 kcal)
Green Vegetables	Spinach	2.9	10.0
	Kale	2.7	9.0
	Broccoli	2.6	8.7
	Brussels sprouts	2.5	8.3
	Cauliflower	2.4	8.0
	Green beans	2.3	7.7

	Water	0.00001	0.00003

Table 10.2 Iron Content of Some Commonly Consumed Foods, Ranked by Food Group in Approximate Order of Iron Content per 1000 kcal

In recent decades, there has been a marked shift in food consumption patterns in the United States, with progressive decline in consumption of meat or other sources of readily assimilable iron, and an increase in consumption of foods that are either low in iron content or contain iron in a form that is not readily assimilated. This trend since 1980 is shown in [Figure 10.5](#) ([10](#), [11](#) and [12](#)). For example, during the 25 years prior to 1995, the annual consumption of mozzarella cheese in the United States increased from 224 million pounds to 2.09 billion pounds, a compound rate of increase of 9.3% annually, and a 933% increase in mozzarella cheese consumption during this interval ([13](#)). At least 80% of the mozzarella cheese is consumed in the form of pizza. From 1985 to 1995, the consumption of pizza more than doubled. Pizza is now a major “fast food” in the American diet. It is predominantly a milk-and-flour product, with variable amounts of sausage. There is a negligible amount of iron in milk or cheese, and only a small amount of poorly absorbed metallic iron in flour. The same may be said of many other “fast food” products.

Figure 10.5. Changes in dietary patterns in the United States during the 12-year interval 1980–1992. (Based on data from ref. [10](#), [11](#), [12](#) and [13](#).)

Surveys indicating that the total iron content of the average American diet has slightly increased during this decade must be considered in the context of the increasingly poor nutritional quality of the iron in the American diet. Approximately half the iron ingested in the average American diet is in the form of bread or other grain products from which it is poorly absorbed. In 1988 to 1991, median intakes of iron from food were less than recommended dietary allowance (RDA) values for children aged 1 to 2 years and for adolescent and adult women ([13](#)). Furthermore, for women aged 18 to 44 years, the population group most at risk of iron-deficiency anemia, the mean daily iron intake has been one-third less than the RDA of 15 mg. Non-Hispanic white women in this age group had a mean iron intake 24% below the RDA in 1989; African American and Hispanic women had mean iron intakes that were only 67 and 65% of the RDA, respectively ([10](#), [11](#) and [12](#), [14](#)). During the reproductive years, most women cannot avoid negative iron balance, and many cannot avoid becoming anemic at these inadequate levels of iron intake.

Absorption

Mechanisms

In healthy persons who do not lose iron by bleeding, iron loss is very limited. Therefore, normal iron balance is maintained largely by regulation of iron absorption. Ingested inorganic iron is solubilized and ionized by acid gastric juice, reduced to the ferrous (FeII) form, and chelated. Iron absorption is promoted by substances that form low-molecular-weight iron chelates, such as ascorbic acid, sugars, and amino acids. The mucin of normal gastric juice chelates and stabilizes iron, thereby reducing its precipitation at the alkaline pH of the small intestine. Impaired iron absorption in achlorhydric or gastrectomized persons reflects decreased solubilization and chelation of the ferric iron in food.

Absorption may occur at any level of the small intestine, but it is most efficient in the

duodenum. Prior to uptake by the brush border of the mucosal cell, the iron atom must first traverse the mucous layer. Passage of iron through this layer is facilitated by organic acids (15 and 16) or taurocholic acid (17) in normal bile or by polypeptides containing cysteine from digestion of meat, fish, or poultry (18 and 19). The divalent, or Fe(II), form of iron is more readily soluble than the trivalent, or Fe(III), form because of the low solubility of ferric hydroxides and phosphates at the alkaline pH of intestinal fluid. Thus, Fe(II) more readily traverses the mucous layer to reach the brush border of intestinal epithelial cells.

From mucin, iron is taken up by one or more proteins on the luminal surface of the mucosal epithelium of the duodenum (20 and 21) (Fig. 10.6). Cell membrane proteins that have been postulated to function in this way are (a) an iron-binding protein that is a trimer of 54-kDa subunits (22); (b) a b_3 -integrin of approximately 160 kDa that spans the cell membrane, and which consists of subunits of 150 kDa and 90 kDa (23); (c) the Hfe protein of approximately 44 kDa that also spans the cell membrane and functions together with b_2 -microglobulin, a small protein of approximately 11 kDa (also see Fig. 10.14, in the section on hereditary hemochromatosis); (d) Nramp2, also a transmembrane protein. Each of these iron-binding proteins of the cell surface has been described by different investigators. It is not yet clear how they interact in determining the rate of iron absorption. It is also possible that different investigators have described the same iron-binding protein but given it different names. Integrins are known to bind cations and facilitate their absorption. By analogy with calreticulin, a related integrin, the b_3 -integrin of the intestinal mucosal epithelium may interact in some manner with b_2 -microglobulin and the Hfe protein to effect the uptake of iron from the intestinal lumen. This process remains to be elucidated.

Figure 10.6. Scheme for the mechanism of iron uptake by duodenal epithelial cells and its transport across the epithelial cell to plasma of the subepithelial capillaries. At least eight proteins appear involved in this mechanism: *mucin* in the gastric and *duodenal lumen*, b_3 *integrin*, *Nramp2*, and *Hfe* proteins in cell membranes, *mobilferrin* and *parafeerritin* within the cytosol, *ceruloplasmin* and *transferrin* in plasma. Either an iron-Nramp2 complex or an iron-integrin complex is internalized and complexed with mobilferrin; the iron is then transferred to parafeerritin, which acts as the cytoplasmic iron-transport protein that delivers iron to the serosal side of the cell, where it is released as Fe(II), oxidized by ceruloplasmin to Fe(III), and taken up by transferrin in capillaries

for transport to the rest of the body. Heme is also taken up by epithelial cells, but the iron must then be released by heme oxygenase before it is bound to paraferitin. It is not yet clear how the Hfe protein normally regulates this mechanism. Some of the complexities in this model may become better resolved in the next few years. (Based in part on Conrad ME, Umbreit JN, Raymond DA, et al. *Blood* 1993;81:517–21, with permission.)

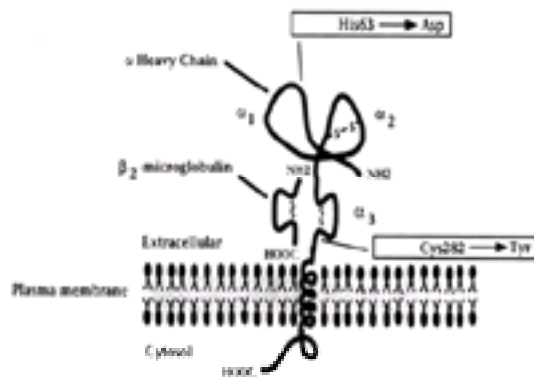

Figure 10.14. Postulated structure of the hemochromatosis protein. *Note:* The hemochromatosis protein and its gene are now designated Hfe rather than HLA-H. (From Feder JN, Gnirke A, Thomas W, et al. *Nature Genet* 1996;13:399–408, with permission.)

Recently described is Nramp2, a transmembrane protein that is particularly expressed in epithelial cells of the upper duodenum but occurs also in most other cells, including the erythroblasts of bone marrow (24 and 25). Nramp2 is a member of a class of proteins designated *natural resistance-associated macrophage proteins*. Nramp1 is responsible for resistance to mycobacterial and leishmanial infections, particularly by macrophages. However, the structurally similar protein Nramp2 is essential for iron absorption by intestinal epithelial cells and may also be the intracellular iron transport protein in the erythroblast. Inbred mice with hereditary microcytic anemia that are mk/mk homozygotes have a mutation in the Nramp2 gene that renders them unable to absorb iron from the diet. They also do not respond to parenterally administered iron, which implies impaired iron uptake by both intestinal epithelium and erythroblasts. Lack of this protein in erythroblasts causes hereditary microcytic anemia in Belgrade laboratory rats.

Once inside the mucosal epithelial cell, the iron is transferred successively to cytosolic proteins designated mobilferrin (26) and paraferitin (27). It is then transported to the serosal surface of the epithelial cell, and it passes through this side of the cell membrane in the Fe(II) state. As it enters the blood of the subendothelial capillary network, it is oxidized by ceruloplasmin to Fe(III), and it is then bound to transferrin,

which carries it in the portal venous system, first to the liver and then to all the tissues of the body.

A major source of iron in the diet is heme iron derived mostly from hemoglobin trapped in capillaries and myoglobin of muscle. Much lesser amounts of iron are obtained from peroxidases and cytochromes in the diet. To be absorbed, iron contained in heme proteins must be successively liberated, first by digestion of the protein, with liberation of heme ([26](#), [27](#), [28](#) and [29](#)). Heme is absorbed as such by the mucosal epithelium of the small bowel, although exactly how this occurs is not yet known. Within the cytosol, iron is liberated from protoporphyrin by the microsomal enzyme heme oxygenase, which breaks the porphyrin ring, yielding Fe(III), biliverdin, and CO. Fe(III) is then bound by paraferitin and transported to the serosal side of the cell, as described above. Biliverdin is converted to bilirubin, which is transported in plasma to the liver for excretion. The carbon monoxide released by heme catabolism is transported to the lungs for excretion in exhaled air.

Absorption of heme iron is not increased by ascorbic acid nor is it depressed by such substances as phytates and desferrioxamine. Its absorption is only slightly inhibited by simultaneous administration of inorganic iron and nonheme iron ([30](#), [31](#) and [32](#)).

In mid-1996 the gene was identified for the major hereditary iron-overloading disorder, hereditary hemochromatosis (European or HLA-linked type) ([33](#)). This gene is responsible for synthesis of an MHC class I protein that spans the membranes of all cells that have been examined. On the cell surface it is associated with b₂-microglobulin, and together these proteins have homologies with immunoglobulins. This protein, which commonly is structurally altered in hereditary hemochromatosis, has been designated Hfe protein. It is presently unknown how it serves to regulate the absorption of iron by intestinal mucosal cells, although clearly, it must do so. As stated above, this mechanism may involve an interaction with b₃-integrin and Nramp2. Quite likely, this Hfe protein normally restricts uptake of iron when there is sufficient iron in the cytosol and permits iron uptake when there is not. The Hfe protein and its gene mutations are considered further in the section on [hereditary hemochromatosis](#).

Intraluminal Factors

Intraluminal factors that decrease absorption include rapid transit time, achylia, malabsorption syndromes, precipitation by alkalization, phosphates, phytates, and ingested alkaline clays or antacid preparations. Milk proteins, albumin, and soy proteins reduce iron absorption ([34](#), [35](#) and [36](#)). However, ingestion of milk together with cereals neither enhances nor reduces the effect of cereal on iron absorption in humans. Tea and coffee both reduce iron absorption substantially, in proportion to the amount of tea or coffee ingested. Iron absorption is reduced about 60% by tea and about 40% by coffee ([37](#), [38](#) and [39](#)). Phytate is inositol hexaphosphate, a substance that normally occurs in the fiber or bran component of wheat, rice, maize, psyllium, walnuts, peanuts, hazelnuts, and plant lignins, and which chelates iron, reducing its absorption ([40](#), [41](#), [42](#), [43](#), [44](#), [45](#) and [46](#)). As little as 5 to 10 mg of phytate in bread can reduce nonheme iron absorption by 50% ([42](#)), and this effect of phytate on iron absorption can be maintained indefinitely ([43](#)). Addition of meat or ascorbic acid to the diet reverses the iron-chelating

effect of phytate (42). Some other plant fibers such as that derived from yod kratin (leaves of the Southeast Asian lead tree) also reduce iron absorption (47), but cellulose does not (48). Beet fiber (b fiber) also does not appear to inhibit iron absorption (44). In contrast with the effect of phytate in retarding food iron absorption in humans, both rats and anemic pigs seem to absorb iron equally well from phytate-rich and phytate-poor diets (49). Concomitant ingestion of zinc and iron salts reduces iron absorption in humans (50).

As the ingested dose of iron increases, the total amount retained by the body rises steadily, although the percentage absorbed decreases. Plotting the logarithm of iron dosage against the logarithm of iron absorbed yields a straight line (51). For each twofold increment in iron dosage, a 1.6-fold increment in absorption can be anticipated. Uptake is increased by large oral doses of ascorbic acid, by certain weak chelating substances (e.g., citric acid, succinic acid, sugars, sulfur-containing amino acids) and by mucin. Digestion of meat or poultry enhances the absorption of iron by releasing cysteine or cysteine-containing small polypeptides (18, 19). The effects of ethanol ingestion and of deficient pancreatic exocrine function on iron absorption have been disputed. Whether ingested or administered parenterally, ethanol has little, if any, direct effect on iron absorption in humans and may even retard it (52). In rats, addition of alcohol to the diet increased iron absorption (53). In humans, acute or chronic alcohol consumption does not appear to increase iron absorption (54).

Systemic Regulation

The systemic regulatory mechanisms that influence iron absorption have never been identified despite intensive search. They operate to (a) increase absorption in iron deficiency and in hemochromatosis, during the latter half of pregnancy and when erythropoiesis is stimulated (including ineffective erythropoiesis) as in anemias or hypoxic states, and (b) decrease absorption in iron overload, in chronic disease such as rheumatoid arthritis, or in other circumstances when erythropoiesis is depressed. With elucidation of Hfe and Nramp2 proteins, regulation of the rate of iron absorption may become better understood in the next few years.

Absorption of iron is modulated by intestinal mucosal cells. The columnar mucosal cells formed in crypts at the base of villi contain a variable amount of iron, which helps to regulate the quantity of intraluminal iron that enters cells. The iron in intestinal epithelial cells may enter the body according to need or may remain in ferritin within these cells to limit absorption and be lost when the cells are sloughed from the tips of villi at the end of their brief life spans. Little iron is incorporated into ferritin in the mucosal cells of iron-deficient subjects, and absorption is enhanced. Conversely, in iron-loaded subjects, the mucosal cells formed are well endowed with iron in ferritin; transport of iron into plasma is limited, and cellular iron is excreted when desquamation occurs.

Absorption from Foods

Healthy persons absorb about 5 to 10% of dietary iron, and those who are iron deficient absorb about 10 to 20%. The maximum amount of iron absorption expected from an average diet in the United States is about 1 to 2 mg in normal adults and 3 to 6 mg in

iron-deficient patients.

The earliest measurements of iron absorption were made with balance techniques. The small difference between oral intake and fecal loss is difficult to measure with precision by chemical methods. Furthermore, such methods cannot distinguish excreted iron from iron contained in mucosal epithelial cells that have been desquamated into the intestinal lumen. Such balance studies were done using mixed diets fed over a period of several weeks; the effect of daily variation on results was minimized. Iron absorption, calculated on the basis of positive balance, ranged from 7.3 to 21% (55).

Single foods prepared or grown to contain a radionuclide of iron have been used to measure absorption of iron from these foods after they are prepared and fed as in a normal diet. Table 10.3 presents typical results (56). Overall absorption in 219 normal subjects approximated 10%, and that in 148 iron-deficient patients, 20%. Absorption of iron from food varies widely. It is greatest from meat of mammalian origin (e.g., beef), less from poultry or fish, and least from liver, muscle, eggs, milk, and cereals (57). It is generally greater in children than in adults.

Food	Adult		Infant or Child	
	Normal	Fe Deficient	Normal	Fe Deficient
Liver	1.0	2.7		
Beef	1.0	3.0		
Veal	2.2			
Fish	1.2			
Eggs	0.3	0.8	0.7	
Soybeans	1.2	2.7		
Breakfast cereal and milk			1.2	
Lettuce	0.3	2.8		
Green vegetables	0.3	2.8		
Wheat	0.5	0.7		
Enriched bread	0.7	5.0		
Corn	0.4	0.8		
Milk	0.2		0.8	1.6
Beans	0.2			
Spinach	0.1			
Rice	0.08			

(Based on data cited in ref. 56)

Table 10.3 Approximate Amount of Iron (mg) That May Be Absorbed from 10 mg of Iron Ingested in Various Foods

Figure 10.7 summarizes results obtained in 520 subjects using seven foods of vegetable origin and five of animal origin (58). Iron absorption from meat exceeded 10%. Iron absorption from rice and spinach was poor, but that from soybeans exceeded iron absorption from other vegetable sources. Since radioiron-tagged foods were given as a single test dose, daily variations in absorption were not measured, nor was the effect of possible interactions between specific foods and iron absorption determined. For example, ascorbic acid increased, and eggs decreased, uptake of iron from some foods.

Figure 10.7. Absorption of iron from foods. (From Layrisse M, Cook JD, Martinez C, et al. *Blood* 1969;33:430–43, with permission.)

Polyphenols (e.g., plant tannins) and phytate retard absorption of food iron. The effects of organic acids, phytates, and polyphenols on absorption of dietary iron were studied by a radionuclide tag method in which $^{59}\text{FeSO}_4$ was mixed with food prior to ingestion by human subjects and the amount of ^{59}Fe retained was measured. Iron was poorly absorbed from wheat germ, lima beans, spinach, lentils, and beet greens, all foods with high phytate or oxalic acid content. In contrast, there was good-to-moderate iron absorption from carrots, potatoes, beet roots, pumpkin, broccoli, tomatoes, cauliflower, cabbage, turnips, and sauerkraut, all vegetables that contain substantial amounts of malic, citric, or ascorbic acids (59).

In Western-type whole meals, iron absorption is enhanced by inclusion of beef, poultry, or fish and by ascorbic acid. Meals that include principally pizza, hamburger, or spaghetti and cheese result in poor iron absorption, whereas those containing cod, beef, shrimp, or chicken result in good iron absorption. (It is not clear why iron absorption from the hamburger-based meal is poor; perhaps phytates in the bun or the milk in the milkshake inhibit iron absorption.) In one study, the best iron absorption resulted from an Italian meal of antipasto misto, spaghetti, meat, bread, oranges, and wine (60). In addition to the dietary factors enumerated above, soy flour proteins have been reported to retard (61) or enhance (62) iron absorption, while soy sauce enhances iron absorption (63).

The effects of food mixtures on iron absorption have also been investigated (64, 65 and 66). One vegetable (maize or black beans) and one animal food (fish or veal muscle) tagged with different radionuclides (^{55}Fe and ^{59}Fe) were fed to the same subjects separately and mixed in the same meal. Iron absorption from veal was diminished about 20% when veal was combined with vegetable foods; iron absorption from either maize or black beans was almost doubled when these foods were mixed with animal meat, such as veal, poultry, or fish. Furthermore, the enhancing effect could be duplicated by substituting amino acids in the same composition as in fish muscle. Cysteine seemed

primarily responsible for the enhancing effect (19, 20).

Thus, overall iron absorption from a meal that contains many components cannot be estimated reliably from the percentage of iron absorption that would occur if single foods are separately fed. This is particularly true of attempts to estimate the adequacy of iron nutrition by tabulating iron content of foods without considering two facts: (a) some forms of iron, such as heme, are readily absorbed, whereas metallic iron and trivalent iron are not, and (b) phytates and other inhibitors of iron absorption are commonly present in foods and beverages and will significantly decrease iron absorption.

Table 10.4 shows the effect of various combinations of food on iron absorption. The authors of this study (67) thoughtfully observed, with respect to the amount of iron that could be absorbed daily from different diets, that

Dietary Components	Bioavailability of Iron		
	Low	Medium	High
Cereals	Millet Oat meal Rice Sorghum Wheat wheat flour	Corn flour White flour	
Fruits	Apple Avocado Banana Grape Peach Pear Pine Rhubarb Strawberry Eggplant	Cantaloupe Mango Pineapple	Grape Lemon Orange Pawpaw Tomato
Vegetables	Lima beans Fava beans Lentils Spinach	Carrot Potato	Beets Broccoli Cabbage Cauliflower Pumpkin Turnip
Nuts	Almond Brazil Coconut Peanut Walnut		
High-protein foods	Egg Isolated soy protein Soy flour		Fish Meat Poultry

Adapted from Rothwell 1991, J Intern Med 1990;228:317-89, with permission.

Table 10.4 Relative Bioavailability of Iron in the Presence of Various Dietary Components

a diet of low bioavailability supplies only about 0.7 mg of iron daily, which is insufficient to meet the normal physiological requirements of females and many males. The diet of intermediate bioavailability supplies about 1.4 mg daily, which is sufficient to meet the needs of more than 50% of women. The diet of high bioavailability supplies 2.1 mg daily, which meets the requirements of most adult members of the population . . . none of the diets is sufficient to match the daily requirements of 5–6 mg daily, which occur during the second and third trimesters of pregnancy.

Transport

In blood or other body fluids, iron is transported by a protein called transferrin. Transferrin binds iron that either is released from intestinal epithelium into the blood or lymph or is secreted from macrophages following degradation of hemoglobin. It distributes transferrin iron throughout the body to wherever it is needed, mostly to erythrocyte precursors in the bone marrow for new hemoglobin synthesis.

Transferrins and lactoferrins comprise a group of iron transport proteins that are structurally and functionally quite similar. They are single polypeptide chains of approximately 679 amino acids, approximately 80 kDa in mass (68, 69, 70 and 71). Transferrin is the normal plasma protein that transports iron between various iron compartments. Lactoferrin occurs in a variety of body fluids including milk, semen, and the cytosol of granulocytes. It may function as an intracellular iron trap that protects the cytosol from potential superoxide injury induced by Fe(II).

Transferrins and lactoferrins are carbohydrate-rich globular proteins with single polypeptide chains. Each molecule has two binding sites for trivalent iron and two for bicarbonate. Each is bilobed, and within each lobe the iron-binding site is in a cleft between two domains designated N and C (for amino terminal and carboxy terminal) (70, 71 and 72). Thus, each complete transferrin or lactoferrin molecule has two N domains and two C domains (e.g., N-C-hinge-N-C). The two lobes, or half molecules, consist of a complex of helices and β -pleated sheets, and the two lobes are connected by a “hinge” consisting of two linked helical segments. Within each lobe, Fe (III) is bound to both the N and C domains, which fold over the iron to bind it tightly. Each of the two C domains has a polysaccharide sialic acid side-chain that is so branched that it may be two-pronged or three-pronged, called *biantennary* or *triantennary*, respectively. Human transferrin is predominantly (80%) biantennary. The polysaccharide chains are bound to asparagine at amino acid positions 413 and 510. The polysaccharide chains may represent a signal for binding to the cell membrane. The transferrin gene is on chromosome 3. The complete DNA sequence of the gene has been determined (70).

Congenital deficiency of transferrin is extremely rare; only 9 cases are known worldwide (see below). Congenital inability to sialylate apotransferrin, the “carbohydrate-deficient transferrin syndrome,” is associated with severe neurologic abnormalities, including seizures, hyperreflexia, peripheral neuropathy, and mental retardation (72, 73). Chronic alcoholics also have reduced sialylation of transferrin, but the alterations are difficult to demonstrate, so measurement of this analyte in serum is not a reliable test for chronic alcoholism.

One atom of Fe(III) can be bound, together with a bicarbonate ion, at each of the two binding sites. In humans, the two iron-binding sites seem to be functionally equivalent. When no iron is bound to the transferrin molecule, it is designated apotransferrin. Monoferric transferrin has one Fe(III), diferric transferrin, two. When all iron-binding sites are occupied by Fe(III), transferrin is said to be saturated. Normally, plasma transferrin is approximately one-third saturated; it is a mixture of monoferric and diferric transferrin.

The normal concentration of transferrin in plasma is about 2.2 to 3.5 g/L. Since iron is the natural ligand of transferrin, the plasma concentration of transferrin may be measured by the amount of iron that it will bind. This is called the total iron-binding capacity, or TIBC. The normal serum TIBC is about 45 to 80 $\mu\text{mol/L}$ (250–450 $\mu\text{g/dL}$). The amount of iron actually bound to transferrin is measured as the serum iron concentration, or SI. The SI normally ranges from 12 to 31 $\mu\text{mol/L}$ (70–175 $\mu\text{g/dL}$) in males and 11 to 29 $\mu\text{mol/L}$ (60–165 $\mu\text{g/dL}$) in women. Percentage transferrin saturation (Tsat) is calculated as $(100 \times \text{SI}) / \text{TIBC}$. The serum iron concentration normally exhibits

diurnal variation. Highest values occur in midmorning (6–10 AM). Values are lower in midafternoon, and lower yet in the evening, with a nadir near midnight. In iron-deficiency anemia, SI is usually diminished, TIBC may be increased, and Tsat may be less than 15%. In iron-overload disorders, SI often exceeds 40 $\mu\text{mol/L}$, TIBC is usually normal or diminished, and Tsat may be 100%. In acute diseases (e.g., acute infections or myocardial infarction) and probably following immunizations, SI is diminished, TIBC is normal, and Tsat is diminished. In chronic disorders (e.g., chronic infections, rheumatoid arthritis, or malignancies), SI is diminished, TIBC is often diminished as well, and Tsat may be normal or low.

When transferrin is 100% saturated, iron absorbed by the intestinal mucosa cannot be bound by transferrin; most of this excess iron is deposited in hepatocytes of the liver, the first organ encountered by blood containing absorbed nutrients (including iron). In an extremely rare disorder called congenital atransferrinemia, there is no transferrin in plasma to carry the iron that enters plasma. Consequently, absorbed iron is rapidly deposited in hepatocytes of the liver and in other organs. In this condition, SI and TIBC are quite low, and transferrin cannot be measured. Because the normal mechanism for transport of iron to erythrocyte precursors is lacking, a severe microcytic anemia develops in addition to iron overload of many organs.

The normal plasma half-time for transferrin is 8 to 10.5 days. However, the transit time of iron through plasma is much shorter; the normal plasma iron clearance half-time for transferrin-bound radioiron is about 60 to 90 min. As shown in [Table 10.1](#), only about 3 mg of iron is transferrin-bound at any time. Yet turnover is very rapid, as 25 to 30 mg of iron are transported daily from sites of absorption or release to cells where iron is needed. Normally, 70 to 90% of this iron is taken up by the erythropoietic cells of bone marrow for hemoglobin synthesis. Smaller quantities are delivered to other cells for formation of myoglobin, cytochromes, peroxidases, or other functional iron proteins and, in pregnant women, to the placenta for fetal needs. A small amount of iron is exchanged with iron released from ferritin and hemosiderin in macrophages.

Transferrin exhibits considerable heterogeneity. At least 19 molecular variants have been recognized in humans. All appear to be functionally identical.

Uptake by Cells

Cell membranes contain a protein called *transferrin receptor*. Early erythrocyte precursors have abundant transferrin receptors on their membranes; the number diminishes as these cells mature and fill with hemoglobin. On the cell membrane, diferric transferrin binds to transferrin receptors, and the iron-transferrin–transferrin receptor complex is internalized by endocytosis. Binding to transferrin receptors occurs in pits on the surface of the cell. Upon endocytosis, the pits become coated vesicles, within which iron is released from transferrin ([74](#), [75](#), [76](#), [77](#), [78](#), [79](#), [80](#), [81](#), [82](#), [83](#), [84](#) and [85](#)). Most other cells also have transferrin receptors on their membranes, although in smaller numbers. The same mechanism is involved in the internalization of iron in erythrocytes and other cells.

Transferrin receptor is a transmembrane glycoprotein with a molecular mass of

approximately 90 kDa. It is 760 amino acids long and consists of two subunits linked by disulfide bonds. It is a group II membrane protein; that is, its amino terminus is on the cytoplasmic side of the membrane, and its carboxy terminus, on the outer surface ([86](#), [87](#), [88](#) and [89](#)).

The transferrin receptor gene is at the end of the long arm of chromosome 3. The gene has been cloned and much of its structure elucidated ([90](#), [91](#) and [92](#)).

Belgrade laboratory rats are unable to remove iron rapidly from the internalized vesicles; most of the iron returns to the plasma still attached to transferrin. A somewhat similar disorder in an inbred strain of anemic mice is associated with a mutation in a gene called *Nramp2*, which may code for an intracellular iron-transporter protein. *Nramp2* is also deficient in Belgrade laboratory rats. Similar disorders have not yet been described in humans.

Regulation of Iron Metabolism in Cells

Cellular regulation of the iron balance depends on the effect of iron (or its lack) in stimulating or inhibiting synthesis of apoferritin within the cytosol, of transferrin receptors on the cell membrane, and of d-aminolevulinic acid synthase (ALA-S) within mitochondria. These three proteins determine the availability of iron to meet the needs of cellular metabolism. Regulation of the rates of synthesis of these three critical proteins involves the interplay of iron and aconitase (also called iron responsive element-binding protein, or IREBP, or iron-regulatory protein, IRP-1) on iron-responsive elements (IREs) in the untranslated regions of transferrin receptor mRNA, apoferritin mRNA, and ALA-S mRNA. IREs are stem-and-loop structures in the mRNA. The loop is the short nucleotide segment CUGUGX on a short stem of nucleotides, where X can be C, A, G, or U ([Fig. 10.8](#)) ([93](#)). The IRE for transferrin receptor consists of as many as five loops and stems in the 3' (downstream) untranslated portion of transferrin receptor mRNA ([83](#), [84](#), [85](#), [86](#), [87](#), [88](#), [89](#) and [90](#)). Synthesis of transferrin receptor is induced by iron deficiency or, experimentally, by incubation of cells with an iron-chelating agent such as desferrioxamine. Synthesis of transferrin receptor is inhibited by heme, and this inhibition can be blocked by desferrioxamine ([89](#)). Another locus in the 5' (upstream) untranslated region of transferrin receptor mRNA also contributes to control of transferrin receptor synthesis ([90](#)).

Aconitase has been described as a “two-faced protein,” because it both controls oxidation of glucose and fat in the Krebs cycle and regulates the iron economy of the cell. Thus, it fine-tunes cellular iron metabolism to meet the needs of energy metabolism. In the Krebs cycle, aconitase catalyzes the interconversion of citric acid, *cis*-aconitic acid, and isocitric acid. It can do this only when the cell contains enough iron to put the iron-sulfur cluster of aconitase in the cubane, or cubelike, configuration, with four atoms of iron and four atoms of sulfur alternating at the apices ([5](#), [6](#), [94](#), [95](#)) (see [Fig. 10.2](#)).

When iron is in short supply, the cubane structure breaks open for lack of an iron atom at one apex ([94](#), [95](#)). Then aconitase loses its enzymatic function and becomes instead the IRP that binds to the stem-loop structures of the mRNAs for apoferritin, transferrin

receptor, and ALA-S ([Fig. 10.9](#)). Here it prevents degradation of the mRNA by RNAase, and it accelerates synthesis of transferrin receptor on the cell membrane and of ALA-S within mitochondria. This results in increased iron uptake from transferrin in plasma and increased synthesis of protoporphyrin so that more heme, more cytochrome, and more hemoglobin can be formed, at least in bone marrow erythroblasts. Conversely, the binding of IRP to the IRE of apoferritin mRNA results in reduction of apoferritin synthesis. Thus, the iron that the cell takes up is less likely to be trapped in ferritin and rendered metabolically inactive.

When there is sufficient iron within the cytosol or mitochondria, IRP is displaced from the IREs, and the Fe-S cluster resumes the cubane configuration, again becoming the active enzyme aconitase that functions in the Krebs cycle ultimately to generate the high-energy bonds of ATP. These relationships are portrayed in [Figure 10.2](#) and [Figure 10.9](#).

There are at least two structurally different aconitases in cells, c-aconitase in cytoplasm and m-aconitase in mitochondria. Both function as described above. Of course, m-aconitase regulates the synthesis of ALA-S, as the latter is a mitochondrial enzyme that catalyzes the first step in heme synthesis, and it is m-aconitase that is involved in energy metabolism. Aconitase is encoded by a gene in human chromosome 9.

Iron in the Erythroblast

Following endocytosis of the iron-transferrin–transferrin receptor complex in the coated vesicles, iron is released into the cytosol, and apotransferrin is returned to extracellular fluid. The release of iron from transferrin is stepwise: one atom may be released by low pH; the other may require mediation by ATP, hemoglobin, or other substances ([96](#), [97](#), [98](#), [99](#), [100](#) and [101](#)). Within the cytosol of the erythroblast, iron either is transported to mitochondria for incorporation into heme or is taken up by ferritin within siderosomes. Either transferrin itself or other iron-binding substances ([101](#), [102](#), [103](#) and [104](#)), such as the Nramp2 protein ([24](#), [25](#)), may participate in iron transport in the cytosol ([Fig. 10.10](#)). The mechanism of iron entry into mitochondria is unknown. In iron deficiency, sideroblasts almost disappear from the marrow. Conversely, in some states of iron overload, they may become more numerous and contain more siderotic granules than normally.

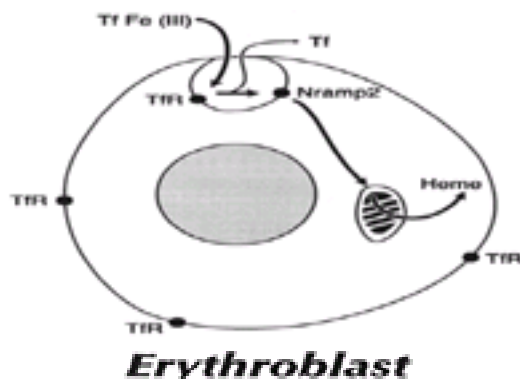

Figure 10.10. Cellular uptake of iron in an erythroblast in bone marrow. The Fe(III)-transferrin complex [$T_2Fe(III)$] binds to transferrin receptor (*TfR*) on the cell membrane. The Fe(III)-transferrin TfR complex is then internalized in a pit that becomes an endosome. Within the acidic interior of the endosome, Fe(III) is released from transferrin and is transferred to *Nramp2*, which transports it to mitochondria, where Fe(III) is inserted into a porphyrin ring to form *heme*. The transferrin, now unburdened of Fe(III), is returned to the plasma ready to take up more Fe(III).

Within the mitochondria, iron is inserted into protoporphyrin to form heme in a reaction catalyzed by the enzyme heme synthetase (ferrochelatase). Heme inhibits release of iron from transferrin (105). This may be one of the feedback mechanisms for adjusting the iron supply to the rate of hemoglobin synthesis in the erythroblast.

Iron Utilization

A normal adult uses approximately 20 to 25 mg of iron per day for hemoglobin synthesis. These values can be calculated as follows: A man with a blood volume of 5000 mL and a hemoglobin level of 150 g/L has 750 g of circulating hemoglobin or 2.55 g of circulating hemoglobin iron (total blood hemoglobin in grams multiplied by 0.34%). Since the normal life span of the red cell in circulating blood is about 120 days, 2.55 g / 120, or 21 mg of iron, would be required daily to replace the catabolized hemoglobin. Iron use can also be determined after a tracer dose of radioiron is given intravenously. The amount of injected radioactive iron used for hemoglobin synthesis and delivered to the peripheral blood in newly formed erythrocytes is then measured. Normally, erythrocyte radioactivity rises for 7 to 14 days and then levels off at 75 to 90% of the injected amount. Iron-deficient persons typically use more than 90% of the injected ^{59}Fe .

Normally functioning bone marrow can effect a sixfold increase in its production of red blood cells and hemoglobin. Under maximal stimulation, therefore, as much as 100 to 125 mg of iron can be used for hemoglobin synthesis per day.

Iron Reutilization

The avid manner in which the body conserves and reutilizes iron is an important characteristic of iron metabolism. A normal adult catabolizes enough hemoglobin each day to release 20 to 25 mg of iron, most of which is promptly recycled by formation of new hemoglobin molecules. More than 90% of hemoglobin iron is repeatedly recycled by phagocytosis of old erythrocytes, which occurs chiefly in macrophages of the liver and spleen.

Phagocytized red cells are digested at a rate sufficient to release approximately 20% of the hemoglobin iron within a few hours, and the remainder more slowly. The iron released by the action of the monocyte-macrophage system is bound to transferrin and

is ultimately redistributed. About 40% of the hemoglobin iron of nonviable erythrocytes reappears in circulating red cells within 12 days. The rate of reutilization varies considerably. In normal persons there is 19 to 69% reincorporation in 12 days. The rate of reutilization of iron is more variable in the presence of disease. The remainder of the iron derived from hemoglobin catabolism enters the storage pool as ferritin or hemosiderin and normally turns over very slowly: approximately 40% remains in storage after 140 days. When the rate of erythropoiesis increases, however, storage iron may be released more rapidly from the storage pools to plasma transferrin. Conversely, in the presence of chronic disease such as infection, rheumatoid arthritis, or malignancy, the storage iron derived from hemoglobin catabolism is reused much more slowly.

These alterations in the rate of iron reuse seem to be determined by the rate of iron release from cells of the monocyte-macrophage system to plasma transferrin. Thus, in the presence of chronic disease, the rate of release of iron by macrophages decreases, and iron storage in the monocyte-macrophage system increases. The effect is a reduced rate of iron delivery to developing erythroblasts, an accelerated rate of transport to the bone marrow of the iron available in the plasma pool, a reduced plasma iron concentration, and a reduced rate of erythropoiesis. Microcytic erythrocytes may result from the reduced flow of iron from the monocyte-macrophage system to the developing erythroblasts.

In addition to its role in regulating the size of iron stores, the monocyte-macrophage system appears to participate in regulation of the concentration of transferrin. Macrophages of this system can both synthesize apotransferrin and take up and degrade transferrin.

Storage Iron

Iron in excess of need is stored intracellularly as ferritin and hemosiderin, principally in the macrophage ("reticuloendothelial") system of liver, spleen, bone marrow, and other organs. Ferritin is the basic storage molecule for molecular iron; hemosiderin is aggregated ferritin partially stripped of its protein component. A complete ferritin molecule has an apoferritin protein shell that is 13 nm in outer diameter with an internal cavity 7 nm in diameter ([106](#), [107](#), [108](#), [109](#), [110](#), [111](#), [112](#) and [113](#)). The internal cavity holds one or more crystals of ferric oxyhydroxide (FeOOH) together with trace amounts of phosphate that may occur at imperfections or cleavage planes in the FeOOH crystals ([Fig. 10.11](#)). The cavity of each ferritin molecule can hold at maximum 4300 iron atoms as FeOOH crystals, although most ferritin molecules contain 2000 iron atoms.

Figure 10.11. A scheme for the quaternary structure of the apoferritin molecule. It consists of 24 subunits, or apoferritin monomers, joined together to form a snubbed cube, or a cube with rounded apices. Four monomers comprise each facet of the cube, and at the center of the facet, where the ends of the monomers join, there is a pore through which may pass Fe(II), and possibly other small molecules, to enter the interior cavity of the molecule. Here, FeOOH forms one or more crystals, and it is in this crystalline form that iron is held in storage. (From Harrison PM, et al. In: Jacobs A, Worwood M, eds. *Iron in Clinical Medicine*. New York: Academic Press, 1980;131–171.)

The apoferritin protein shell is composed of 24 monomers, each with a molecular mass of approximately 20 kDa, and each formed in turn by four long, nearly parallel helical chains of amino acids, two short helical segments, and connecting nonhelical segments. The monomers are arranged in a nearly spherical structure—the apoferritin shell—with groups of four monomers aligned so that their short helices form pores. These six pores permit passage of small molecules to and from the interior of the apoferritin shell. The pores are large enough to permit iron, water, and possibly other small molecules, such as ascorbic acid, to enter the interior cavity ([Fig. 10.10](#)) ([109](#), [110](#) and [111](#)). Furthermore, the pores appear to function as catalytic sites for the binding of Fe(II), its oxidation to FeOOH, and facilitated passage of the FeOOH to the interior, where it is added to the growing core crystal ([Fig. 10.12](#)) ([111](#) and [112](#)). Thus the apoferritin shell not only is an efficient iron trap but also functions enzymatically.

Figure 10.12. Scheme for uptake and deposition of iron by ferritin. Two pairs of iron-binding sites are envisioned, located near the inter-monomeric pores of the apoferritin shell. See text for a more complete explanation. (From Crichton RR, Roman F. *J Mol Catal* 1978;4:75–82, with permission.) Currently it is believed that oxidation of iron from Fe(II) to Fe(III) involves sites only on the H monomer.

Oxidation and uptake of iron by apoferritin is very rapid. Similarly, the release of iron is rapid (113). Iron release from ferritin may be mediated by reduced flavin mononucleotide, although an enzymatic mechanism has not been excluded (111). Human ferritins may exist in multiple isomeric states (114). H and L monomers differ in mass, the former being about 20 kDa and the latter about 18 kDa. There are as many as 25 isoforms, depending on the proportion of H and L monomers. Ferritin that contains mostly H monomers is relatively acidic, contains relatively more iron, and is found predominantly in heart. Ferritin that contains mostly L monomers is relatively basic, contains little iron, and is characteristically found in liver. Ferritin predominantly of the H type is increased in the serum, especially in patients with malignancies such as carcinoma of the breast, embryonal carcinomas, and lymphomas.

Hemosiderin, unlike ferritin, is insoluble in aqueous media. Hemosiderin contains slightly more iron (~30% by weight) than does ferritin. Immunologically, they appear to be identical. On electron microscopy, the apoferritin shell of ferritin is not seen, but the electron-dense FeOOH crystalline core appears as a tetrad because of its octahedral shape. Electron microscopy shows great numbers of ferritin core crystal tetrads in hemosiderin; thus, a molecular weight cannot be given for hemosiderin. The molecular mass of ferritin, which depends partly on its iron content, is usually stated as 620 kDa.

Within cells, apoferritin monomers are synthesized by ribosomes in response to the presence of iron. Regulation of apoferritin synthesis depends on the binding of IRP to the apoferritin mRNA. Iron in the cytosol relieves the inhibition of apoferritin synthesis by causing IRP to convert to aconitase with the iron-sulfur cluster in the cubane form. In this form it does not bind to the IRE. Iron also causes translocation of preformed ferritin messenger RNA to polyribosomes where ferritin synthesis occurs (115, 116, 117, 118 and 119).

In the liver and spleen of normal animals, there is a slight preponderance of ferritin iron over hemosiderin iron. With increasing concentrations of tissue iron, this ratio is reversed, and at high levels, the additional storage iron is deposited as hemosiderin. Both forms can be mobilized for hemoglobin synthesis when the need for iron exists. Reducing substances such as ascorbate, dithionite, and reduced flavin mononucleotide (FMNH₂) cause rapid release of iron from ferritin. Thus, FMNH₂ might serve as the physiologic mediator of iron release (111, 112 and 113).

Quantitation of normal iron stores has proved difficult, but reasonable estimates derived

from available data are 300 to 1000 mg for adult women and 500 to 1500 mg for adult men. More individuals appear to fall into the lower half of these ranges than into the upper half, and many healthy women have virtually no iron reserves. Iron is released from ferritin as Fe(II) and as such traverses the cytosol and cell membrane to enter plasma, where it is again oxidized by ceruloplasmin to Fe(III) and is taken up by transferrin. The amount of stored iron may increase as a result of a shift of iron from the red cell mass to the stores. This occurs in all anemias except those due to iron deficiency. A true increase in total body iron is found in patients with hemochromatosis, transfusional hemosiderosis, or (rarely) after excessive and prolonged iron therapy. The total body burden of storage iron may exceed 30 g. An assessment of whether iron stores are deficient or excessive may be made from the serum iron, TIBC, serum ferritin, and stainable iron in bone marrow aspirates.

Enzyme Iron

It was once believed that iron enzymes were “inviolable” in iron-deficiency anemia. Extensive studies in experimental animals have shown that iron enzymes are in fact quite sensitive to iron deficiency. The degree of loss varies from enzyme to enzyme and from tissue to tissue. Cytochrome c and aconitase are quite readily depleted, cytochrome oxidase appears to be less susceptible, and catalase is the most resistant of all to depletion. Investigations of human leukocytes and buccal mucosa have shown depletion of cytochrome oxidase, however, even in relatively mild iron deficiency ([120](#) and [121](#)). Iron deficiency in rats is associated with marked (~70%) reduction in activity of the iron-sulfur enzymes succinate-ubiquinone oxidoreductase and NADH-ubiquinone oxidoreductase in rat skeletal muscle mitochondria. These important enzymes of the respiratory chain appear to be reduced in quantity rather than impaired in function, since both the peptide components and the flavin prosthetic groups were reduced ([122](#)).

Iron-deficient rats also have hyperphenylalaninemia that is directly proportional to the severity of anemia. The mechanism of this effect is uncertain, as the hepatic activity of the iron-containing enzyme phenylalanine hydroxylase is not reduced. It is suggested that iron deficiency results in metabolism of phenylalanine by an alternative pathway that might generate increased quantities of phenylpyruvic acid and thereby disturb brain function. Treatment of iron deficiency with iron dextran resulted in normal serum concentrations of phenylalanine within 1 week ([123](#)).

Poor work performance in iron-deficient rats has been attributed to reduced activity of muscle α -glycerophosphate dehydrogenase, as noted below (see “Clinical Manifestations”). Mitochondrial α -glycerophosphate dehydrogenase, a flavoprotein that contains nonheme iron, plays an important electron transport role in aerobic metabolism. That iron deficiency results in impairment of activities of cytochromes and of so many iron-containing enzymes is understandable. However, iron deficiency is also associated with reduced activity of many enzymes that do not contain iron. The activity of monoamine oxidase (MAO), a copper-containing enzyme important in the synthesis of neurotransmitters, is diminished in the liver and in platelets of iron-deficient humans ([123](#), [124](#) and [125](#)). However, MAO activity was normal in the brains of iron-deficient rats ([125](#)).

Some diminution in the activities of other enzymes has also been reported in association with iron deficiency in rats. These include hepatic glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, and various transaminases ([126](#), [127](#) and [128](#)). These alterations appear to be minor and are probably of no physiologic import. Further, it is puzzling that activities of these enzymes should be affected, as none of them contains iron or requires iron as a cofactor.

Iron Loss

Excretion

The body has a limited capacity to excrete iron. Daily iron loss in adult men is between 0.90 and 1.05 mg, or approximately 0.013 mg/kg body weight, irrespective of climate-dependent variation in perspiration ([130](#), [131](#)). The daily external loss is distributed roughly as follows: gastrointestinal blood (hemoglobin), 0.35 mg; gastrointestinal mucosal (ferritin), 0.10 mg; biliary, 0.20 mg; urinary, 0.08 mg; and skin, 0.20 mg.

A slight increase in iron excretion—principally fecal, and not exceeding about 4 mg/day—may occur in persons with iron overload, in partial compensation for increased iron stores ([132](#)). Urinary iron excretion may be increased significantly in patients with proteinuria, hematuria, hemoglobinuria, and hemosiderinuria. Hemosiderinuria may cause iron deficiency in patients with artificial heart valves or calcific aortic stenosis. The iron excreted in feces is derived from blood lost into the alimentary canal (1.2 ± 0.5 mL whole blood/day) ([133](#)), from unabsorbed iron in bile, and from desquamated intestinal mucosal cells.

Menstruation

It is difficult to quantitate the “normal” iron loss due to menstruation or pregnancy, because of the wide variation encountered. While menstrual blood loss for any individual normal woman does not vary much from month to month, the difference between women is considerable. In studies of Swedish women, the mean menstrual loss was found to be 43 mL, equivalent to an average of about 0.6 to 0.7 mg of iron daily ([134](#), [135](#) and [136](#)). The upper normal limit of menstrual loss was about 80 mL per period. However, women who consider their menses normal may lose more than 100 mL and occasionally more than 200 mL per period. Menstrual blood losses are increased by intrauterine devices and reduced by contraceptive pills.

Pregnancy

The iron “cost” of pregnancy is high. The external loss in urine, feces, and sweat amounts to about 170 mg for the gestational period. About 270 mg (200–370 mg) is contributed to the fetus, and another 90 mg (30–170 mg) is contained in the placenta and cord. The amount of iron lost in hemorrhage at delivery was underestimated in the past and is now believed to average about 150 mg (90–300 mg). Iron is required for the

expansion of blood volume that occurs normally during the last half of pregnancy, but this amount is largely recovered when the circulating red blood cell volume is returned to normal after delivery. Lactation causes an additional drain of approximately 0.5 to 1 mg of iron daily. The volume of blood loss is roughly equal to a year's menstrual loss. Furthermore, the iron needed for the expanded blood volume and the enlarging uterus is mostly conserved. Therefore, the net iron "cost" of a normal pregnancy is in the range of about 420 to 1030 mg ([Table 10.5](#)), or an additional requirement of 1 to 2.5 mg/day, spread over the 15-month period of pregnancy and lactation.

Iron contributed to fetus	200-370
In placenta and cord	30-170
In blood loss at delivery	90-310
In milk, lactation 6 months	<u>100-180</u>
Total	420-1030
Average per day (pregnancy, 9 months; lactation, 6 months)	1-2.5

Table 10.5 Iron "Cost" of a Normal Pregnancy (mg)

Iron Transfer to the Fetus

The fetus has a highly effective acceptor system for assimilating iron. Iron from maternal transferrin is transferred to the placental tissue, to the plasma transferrin of the fetus, and then to the fetal tissues, by a unidirectional pathway that operates against increased maternal requirements for iron, even despite maternal iron deficiency. During the last trimester of pregnancy 3 to 4 mg of iron is transferred to the fetus each day.

Bleeding

Pathologic bleeding from any site constitutes an important form of iron loss: 1 mL of blood with a hemoglobin concentration of 150 g/L contains 0.5 mg of iron. A rough but useful rule-of-thumb is that 1 mL of packed red cells contains 1 mg of iron. The chronic loss of only a small volume of blood, therefore, may significantly increase iron requirements. For blood donors, each 500 mL of blood donated contains between 200 and 250 mg of iron. Spread equally over a year, that amounts to roughly 0.6 to 0.7 mg/day. A donor who gives blood every 2 months will have an increase in the average daily iron loss of 4 mg and will require at least a fourfold increase in iron intake to avoid becoming anemic. This is especially problematic for women who are blood donors. If they do not receive iron supplementation, many may cease being blood donors because of anemia. In a controlled study of the effects of iron supplementation for women blood

donors, the dropout rate due to anemia was 32% for those not receiving iron supplements and only 4.5% for those given regular oral iron supplement. As little as 39 mg of iron daily (120 mg of ferrous sulfate) in a single dose sufficed to prevent anemia and allow 96% of adult women to donate blood at 8- to 12-week intervals (137). Despite this finding, many blood banks in the United States are unwilling to provide iron supplements to their regular blood donors.

IRON REQUIREMENTS

Growth

The iron required for growth and its attendant increase in circulating hemoglobin mass depends upon the rate of growth (i.e., the rapid growth during infancy and the growth spurt of adolescent males). The basis for estimating iron need is shown in [Table 10.6](#). The average daily iron requirement is 0.35 to 0.7 mg/day for boys and 0.3 to 0.45 mg/day for girls prior to menarche. Other studies have shown a daily iron requirement of 38 mg/kg of optimal body weight, for both males and females between ages 4 and 14 years (138).

	Amount That Must Be Absorbed for Hemoglobin Synthesis (mg)
Infants	1
Children	0.5
Young nonpregnant women	2
Pregnant women	3
Men and menopausal women	1

Table 10.6 Minimum Daily Iron Requirements

Nutritional Allowances

Estimates of the amount of iron required to maintain positive balance are shown in [Table 10.7](#) (139). (See also Appendix [Table A-2-a-1](#), [Table A-2-a-2](#), [Table A-2-a-3](#), [Table A-2-b-1](#), [Table A-2-b-2](#), [Table A-2-b-3](#), [Table A-2-b-4](#), [Table A-2-b-5](#), [Table A-2-b-6](#), [Table A-2-c-1](#), [Table A-2-c-2](#), [Table A-2-c-3](#), [Table A-2-c-4](#), [Table A-2-c-5](#), [Table II-A-3-a](#), [Table II-A-3-b](#), [Table II-A-4-b](#), [Table II-A-4-c](#), [Table II-A-4-d](#), [Table II-A-4-e-1](#), [Table II-A-4-e-2](#), [Table II-A-4-f](#), [Table II-A-5-a](#), [Table II-A-5-b](#), [Table II-A-5-c](#), [Table II-A-5-d](#), [Table II-A-6](#), [Table II-A-7-a](#), [Table II-A-7-c](#), [Table II-A-7-a](#), [Table II-A-7-d-1](#), [Table II-A-7-d-2](#), [Table II-A-7-d-3](#), [Table II-A-7-d-4](#), [Table II-A-7-d-5](#), [Table](#)

[II-A-7-d-6](#), [Table II-A-8-a-1](#), [Table II-A-8-a-2-a](#), [Table II-A-8-a-2-b](#), [Table II-A-8-a-2-c](#), [Table II-A-8-a-3](#), [Table II-A-8-b-2](#), [Table II-A-8-b-2-a](#), [Table II-A-8-b-3](#) and [Table II-A-8-b-4](#) for U.S. and other national and international dietary recommendations for iron.) It is evident that men and nonmenstruating women, in the absence of pathologic bleeding, should have little difficulty obtaining the iron they need from diets customary in the United States (12–18 mg Fe per day). Iron balance is precarious, however, in many menstruating women and adolescent girls who, because of concern about weight, restrict their diets and frequently have iron intakes below 10 mg/day. Requirements during pregnancy frequently exceed the amount available from diet alone. Particularly in women with depleted stores, supplemental iron therapy is necessary during the latter half of pregnancy and for 2 to 3 months postpartum, if iron deficiency is to be prevented. Full-term neonates do not require iron supplementation for the first 3 months but should have iron supplementation thereafter as long as they are being formula- or breast-fed. Premature neonates should begin iron supplementation earlier.

Category	Age	RDI (mg)	
Infants (full term)	0–3 months	—	
	3–6 months	6.6	
	6–12 months	8.8	
Children (male and female)	1–10 years	10	
	Males	10–18 years	12
	Females	>18 years	10
Nonpregnant	10–45 years	15	
	Pregnant	45	
	Postmenopausal	10

Table 10.7 Recommended Daily Intake (RDI) of Iron

IRON TOXICITY

Iron that is readily soluble, as ferrous salts in numerous medications, can be highly toxic or lethal to small children who ingest a small handful of iron tablets that look like candy. Such accidental ingestion by a child requires prompt and vigorous attention in a hospital emergency room. The small amounts of iron added to infant formula, to cereal, or given by dropper are quite safe and well tolerated. There has been much speculation in recent publications concerning a possible adverse effect in adults of either iron therapy or chronically high normal iron stores, since, by the well-known Fenton reaction, free ionic iron may catalyze generation of free radicals. It may be in part for this reason that iron in all biologic fluids, whether plasma or cytosol, is normally always protein bound.

Studies from Finland seemed to show that persons with high serum ferritin values had an increased risk of ischemic heart disease or acute myocardial infarction ([140](#)). The Finnish diet is high in meat (therefore in readily assimilated iron) and in saturated fats,

and ischemic heart disease has quite a high prevalence in Finland irrespective of levels of serum ferritin. Studies reported both from Finland and from the United States have cast much doubt on the postulated adverse effect of iron in promoting ischemic heart disease ([141](#), [142](#), [143](#) and [144](#)). Further, patients with severe iron overload (hemochromatosis) appear to have a reduced risk of ischemic heart disease ([144](#)). The hemochromatosis allele that occurs with high frequency elsewhere in western Europe, however, appears to be rare in Finland.

IRON DEFICIENCY AND IRON-DEFICIENCY ANEMIA

Epidemiology

Worldwide, caloric insufficiency, manifested in hunger, famine, and starvation, appears to be the dominant nutritional problem. Iron deficiency, which affects an estimated 40% of the world's population, or two billion persons, is second only to hunger as a major nutritional problem worldwide. In tropical areas of Asia, Africa, and Central and South America, where intestinal helminthiasis such as hookworm infestation is common, iron-deficiency anemia has a particularly high prevalence. In India, where hookworm disease is prevalent and vegetarianism is mandated by religion, iron deficiency is nearly universal.

In the United States, where the dominant nutritional problem now seems to be obesity, iron deficiency is also the second most common nutritional problem. During the past few decades, it has been a common perception that iron deficiency and iron-deficiency anemia are no longer important nutritional problems in the United States. Clearly, this perception is in error. The prevalence rates for iron deficiency and iron-deficiency anemia have not diminished in the United States during the past 30 years; on the contrary, available evidence strongly suggests that iron deficiency and iron-deficiency anemia have gradually become more prevalent during this interval, while the quality of iron nutrition has declined.

[Table 10.8](#) indicates the progressive declines in mean hemoglobin concentration and mean hematocrit values documented by the Centers for Disease Control since 1959 in successive Health and Nutrition Examination Surveys ([145](#), [146](#) and [147](#)). Progressive declines in these values have been consistent in every age, sex and ethnic group examined, altogether in more than 50,000 persons surveyed. The observed declines have been most marked in women aged 18 to 44 years and in African Americans of every age group, both males and females. Part of the explanation may be that the earlier surveys were performed with specimens obtained from sitting persons and the later surveys from recumbent persons. Fluid shifts with recumbency are known to reduce hemoglobin concentration and hematocrit values. Part of the explanation may also be a change in the anticoagulant used to collect blood specimens; a dry powder was used in the earlier studies, and a liquid anticoagulant in 0.05 mL volume in the later studies. However, it is unlikely that either or both of these differences in sampling methods can account for the threefold difference in rates of decline in hemoglobin concentration and hematocrit for specimens obtained from African Americans or white females of ages 20 to 44 compared with those obtained from white males of the same

age range.

Group	Age (years)	% Change
White males	19-44	-4.9
White males	44+	-3.3
White females	19-44	-5.5
White females	44+	-2.4
Black males	19-44	-8.6
Black males	44+	-5.7
Black females	19-44	-5.4
Black females	44+	-5.5

Data from ref. 145-147. The First National Health Examination Survey conducted between October 1959 and December 1962 was taken as baseline in these calculations. National Health and Nutrition Examination Surveys (NHANES) 1 and 2 were conducted in the years 1971-1974 and 1976-1980, respectively. Declines were consistently observed and were approximately proportional between the first and second of these studies and the second and third. Analyses of the data from NHANES-3, conducted in 1988-1994, were not available at the time of preparation of this table. Preliminary evaluations of NHANES-3 data are alleged to indicate no further declines in hemoglobin concentration or hematocrit between NHANES-2 and NHANES-3, although the data have not been released. Equivalent declines have been demonstrated in hemoglobin concentration during these 21 years.

Table 10.8 Changes (%) in Mean Values for Venous Hematocrit in Three National Surveys, 1959–1980

[Figure 10.13](#) shows the prevalence of anemia in one prosperous, largely middle-class, predominantly white, Midwestern U.S. community during the years 1987 to 1989 ([148](#)). A similarly high prevalence of both anemia and iron deficiency was reported in 1994 from a survey of 617 apparently healthy school children in Georgia ([149](#)). In that survey, the prevalence of iron deficiency was 30% among African American children and 33% among white children, although only 2% of the children were frankly anemic. St. Paul, Minnesota, a prosperous community with high employment, has a high incidence rate for iron-deficiency anemia in infants and children of economically disadvantaged status who are eligible for the WIC (Women, Infant and Children) program of nutritional supplementation. The incidence rates of anemia in children aged 18 months to 5 years who were previously nonanemic were 24% for white children, 22% for African American children, 24% for Asian children (predominantly Hmong), 16% for Hispanics, and 7.9% for Native American children ([150](#)). Incidence is specified for this group rather than prevalence because none of the children in this study had previously been anemic.

Figure 10.13. Prevalence of anemia in a prosperous community in Minnesota, predominantly of European derivation. Because pregnant women were not excluded, approximately half the prevalence of anemia in the age range 20–39 years may be due to the normal hydremia of pregnancy. Half of the other cases of anemia were due to blood loss, acute or chronic. Prevalence of anemia increases markedly after age 59 in both sexes; iron deficiency is the most common cause of anemia in this population. These observations refute the widely held view that at present, iron deficiency is a minor problem in North America. (Adapted from Anía BJ, Suman VJ, Fairbanks VF, Melton LJ III. *Mayo Clin Proc* 1994;69:730–5.)

In northern Europe, with a well-fed population and a lifestyle not unlike that of middle-class white Americans, surveys have shown high prevalence rates for anemia and iron deficiency despite longstanding efforts to improve iron nutrition by addition of iron to wheat flour and bread. Conversely, no harm seems to have been done by this practice. In recognition of the lack of benefit from this practice, flour and bread are no longer iron fortified in Sweden and much of Europe.

As represented in [Figure 10.13](#) and [Table 10.9](#), the prevalence of anemia increases markedly in persons above age 70, because of chronic illness, chronic blood loss, or both. Acute or chronic blood loss (i.e., iron deficiency) accounts for approximately half of the rapidly escalating frequency of anemia in the elderly. Some clinicians and some nutritionists have assumed that the anemia that is particularly common in elderly males is part of the normal process of aging. There is, however, no evidence to support this assumption.

Ages (years)	White Males % Anemic	White Females % Anemic
20–39	3	10
40–44	3	10
45–59	5	7
60–64	10	8
65–69	12	8
70–74	15	11

^aData shown are for Olmsted County, MN, with a population of slightly more than 100,000, >95% Caucasian, with high employment and ready access to medical care. The table is from the same database as Fig. 10.13 but has been corrected by assuming that approximately half the “anemia” prevalence in women in the age range 20–39 may be attributed to the “dilutional anemia” of pregnancy. Data were obtained in 53,887 Olmsted County residents above age 20 and are considered to represent 78% of the population above age 20.¹⁴⁴ Anemia was defined as Hb concentration <13 g/dL in males or <12 g/dL in females (World Health Organization criteria, which also correspond to values below the 2–5 percentiles in NHANES-2). The prevalence of anemia increases rapidly for both males and females over age 74 years.

Table 10.9 Prevalence of Anemia in an Affluent Midwestern U.S. Community, 1985–1989^a

Anemia is not a sensitive indicator of the prevalence of iron deficiency, nor is anemia solely due to iron deficiency. However, iron deficiency is by far the commonest cause of anemia. In most populations, the prevalence of iron deficiency may be estimated at 3 or 4 times the prevalence of anemia. One may reasonably assume that most of the economically deprived children of St. Paul, Minnesota, are iron deficient. Indeed, free erythrocyte protoporphyrin, a relatively sensitive indicator of iron deficiency (or of lead poisoning) was elevated in nearly half the white children, in nearly half the African American children, and in nearly 80% of Asian children who were admitted to the WIC program (150).

Poverty Remains a Major Determinant of Iron Malnutrition in the United States.

Iron-deficient children are likely to become iron-deficient teenagers and adults and to have a higher prevalence of iron-deficiency anemia as women, both during the reproductive years and specifically in pregnancy. Declining values for hemoglobin concentrations in women and in African American males, shown in successive NHANES studies, may thus be preconditioned by iron-poor nutrition during childhood. Indeed, this is evident from recent nutritional monitoring in the CATCH survey (151, 152), the Bogalusa, Louisiana, Heart study (153), and in reports from the Nutrition Monitoring Study of the Federation of American Societies for Experimental Biology (10, 11 and 12). In the first of these surveys, which was based on 24-h recalls of what middle-school students of northern states and California had eaten, nearly 90% of students were thought to have had iron intakes of at least 75% of the RDA (10 mg). The other two studies found that African American and Mexican American children were much less likely to have adequate iron nutrition. In low-income households, hunger was common and iron intake inadequate.

African Americans are particularly at risk of iron malnutrition because of the economic catastrophe that resulted from accelerating levels of unemployment since the 1950s (154). In the United States, the income gap between rich and poor has dramatically widened during the past few decades; poverty is increasing in the United States, although a small subset of the population is acquiring extreme wealth. Poor people have diets rich in fat and carbohydrate but poor in vegetables, fruits, and meat. The First (U.S.) Health and Nutrition Examination Survey, conducted between 1971 and 1974, found that the mean iron intake of American women of nearly every age group, irrespective of race or economic status, was less than optimal; for those below the poverty income level, dietary iron insufficiency was nearly universal (155). In that study, most males over 24 years of age had adequate iron intake.

In the 1980s, the U.S. federal government released large quantities of cheese and butter that had been stored by the Department of Agriculture (USDA) to the poor—a gift of calories, saturated fat, and protein that was nearly devoid of iron. Revision of the public welfare system of the United States will further worsen the nutritional status of poor children and young adults, who are mostly African American, Native American, and Hispanic. In early 1997, the USDA ruled that school lunch programs, primarily intended to improve the nutrition of poor children, can now substitute iron-poor yogurt for meat. This ruling will also adversely affect the iron nutrition of disadvantaged children.

By almost imperceptible steps, the diet of a large part of the U.S. population has come to consist predominantly of iron-poor dairy products, iron-poor snack foods and potato products, white bread and flour with only a little added iron that is poorly absorbed, and iron-poor soft drinks.

Prevalence of Iron Deficiency in the United States

The overall prevalence of iron-deficiency anemia in the United States in the last few years of the 20th century cannot be stated with certainty, but conservative estimates for middle-class white Americans are approximately 5% for children of ages 1 to 14 years, 10 to 20% for young women during the reproductive years, 30 to 60% for pregnant or postpartum women, 5 to 10% for postmenopausal women, 1 to 5% for males of ages 20 to 44 years, 5 to 10% for males of ages 45 to 70 years, and 10 to 30% for both males and females over 70 years of age ([146](#)). African Americans of both sexes, Mexican Americans, Native Americans, and poor people of any ethnic group have a higher prevalence of iron-deficiency anemia. A particularly high prevalence of iron deficiency that occurs among the Inuit people of Alaska and Canada has been related to a high prevalence of duodenal infestation with *Helicobacter pyloris*.

African Americans have a high prevalence of α -thalassemia, which is associated with slight microcytosis of the erythrocytes and may be responsible for slightly lower mean hemoglobin concentrations in non-iron-deficient persons than in Caucasians and Asians. The prevalence of α -thalassemia-2 trait in African Americans is 28%, and the prevalence of homozygous α -thalassemia-2 is about 3%. The mean hemoglobin concentration is approximately 7 g/L lower in African Americans than in Caucasians or Asians. There is a proportionately lower mean packed-cell volume (PCV or hematocrit). This systematically lower mean hemoglobin concentration in African Americans is considered in estimating prevalence rates for anemia.

Despite the long recognition of iron deficiency as a major nutritional problem in the United States and despite limited efforts to ameliorate it, the prevalence of iron-deficiency anemia seems to have remained essentially unchanged or perhaps increased during the past 30 years. Further reduction in the quality of iron nutrition seems inevitable.

Effect of Iron “Fortification” of Bread and Flour

Efforts to improve the iron nutrition of the U.S. population have been based mostly on iron fortification of cereal. These efforts have had little effect to date, because the principal means selected to increase iron intake was addition of “reduced” (i.e., finely powdered, metallic) iron to cereal. Metallic iron is poorly assimilated because it must be oxidized to Fe(III) and then reduced to Fe(II) while still in the upper small intestine, before it is absorbed ([Table 10.10](#)). Since the duodenum is the main site of iron absorption, most of the metallic iron in iron-fortified bread or other cereal products must arrive in the colon unchanged. Furthermore, whatever fraction of the metallic iron becomes oxidized, at any level of the intestinal tract, is likely to be chelated by phytate in cereal and thus be rendered nonabsorbable. In Sweden, where white flour was

“enriched” by addition of reduced iron for several decades, neither harm nor benefit was demonstrated, and the practice was discontinued (156, 157). In Germany, the practice is illegal. Some major American flour-milling corporations are aware that the iron used to fortify flour is poorly absorbed.

Form of Iron	Absorbability	Amount Added
Ferrous sulfate	Fair	None ^a
Metallic (“reduced”)	Poor	20 mg/lb (44.1 ppm)

^aSome local bakeries may fortify flour with ferrous sulfate. In this form, iron accelerates rancidification of fat, creating undesirable flavors and colors in bread, causing bread to spoil more quickly. Some frozen flour products may also contain ferrous sulfate rather than metallic iron. The major flour mills (General Mills, Pillsbury ADM, and Conagra) fortify white flour with insoluble metallic iron. Whole wheat flour does not contain iron as an additive but has a small amount of iron as a natural component (about 20 mg/lb).

Table 10.10 Iron Fortification of White Flour, White Bread, Rolls, and Buns in the United States

IRON OVERLOAD

An excessive body burden of iron can be produced by greater-than-normal absorption from the alimentary canal, by parenteral injection, or by a combination of both. Excess iron is deposited largely as hemosiderin in reticuloendothelial cells or in the parenchymal cells of certain tissues. The site of deposition depends in part on the portal of entry. Excess iron derived from intestinal absorption is carried to tissues, bound by plasma transferrin, and transferred to parenchymal and reticuloendothelial cells and developing erythroblasts. On the other hand, parenterally administered iron, given usually as transfused blood, accumulates largely in reticuloendothelial cells where the transfused erythrocytes are eventually destroyed and their hemoglobin degraded. In iron overload, serum iron concentration and transferrin saturation are usually increased, and the TIBC may be depressed. A simple classification based on the mechanism of iron overloading follows.

- I. Excessive gastrointestinal absorption of iron
 - A. Hereditary hemochromatosis
 1. Hereditary European (HLA-linked) hemochromatosis
 2. African hemochromatosis (once called “Bantu siderosis”)
 3. Hereditary sideroblastic anemia
 4. Congenital atransferrinemia
 5. Congenital aceruloplasminemia
 - B. Iatrogenic (from prolonged therapeutic administration of iron to subjects not iron deficient)

- C. Chronic alcoholism or chronic liver disease (usually alcoholic cirrhosis) and possibly pancreatic insufficiency
 - D. "Shunt hemochromatosis"
 - E. Certain types of severe chronic anemia, usually associated with ineffective erythropoiesis and increased hemolysis
- II. Transfusional hemosiderosis or hemochromatosis

Traditionally, the term *hemosiderosis* has denoted an increase in iron storage without associated tissue damage; *hemochromatosis* has indicated that such damage is present, particularly in the liver, that the iron overload is generalized, and that the amount of iron is greatly increased (usually 20–40 g). In present usage, however, *hemochromatosis* has come to mean a severe or potentially severe iron-overload disorder with or without evidence of tissue injury.

Hereditary Hemochromatosis (European or HLA-Linked Type)

Hereditary hemochromatosis (HH) is a relatively common, autosomal recessive, inborn error of metabolism in which increased intestinal absorption of iron results in slowly progressive accumulation of the metal throughout life.

Genetics

Efforts by several groups of investigators to identify the gene for hemochromatosis culminated in the observation in mid-1996 that the gene is located approximately 4 Mb (4 million nucleotide base pairs) telomeric to the major histocompatibility (MHC) complex on the short arm of chromosome 6. The gene has a sequence of 1029 base pairs arranged in 7 exons, of which 6 encode a protein, termed *Hfe*, that contains 343 amino acids. On the basis of the nucleotide sequence, the protein is quite similar to MHC class I molecules, including a signal sequence, a peptide-binding region, an immunoglobulin-like domain, a transmembrane region, and a small cytoplasmic portion (Fig. 10.14) (33). The extracellular portion of the molecule, as in other MHC class I proteins, has three domains, designated a1, a2, and a3. Each of these contains several β -pleated sheets. The a3 domain is closely associated with β_2 -microglobulin, which is encoded by a gene on chromosome 15. The *Hfe* protein appears to be expressed in nearly all cell lines tested.

The function of *Hfe* protein is presently unknown. Since it spans the cell membrane, it may have a role in sensing iron content in cytosol and thus in controlling uptake or exclusion of iron or iron-carrier protein complexes at the cell surface. The complex of the a3 domain with β_2 -microglobulin is structurally homologous with the constant region of immunoglobulin, and in MHC class I proteins, it is the site of binding to antigen. Thus, it is reasonable to conjecture that the postulated protein may bind another protein (possibly heme or mucin or another as yet unidentified protein) that carries iron and presents it to the cell membrane. The function of the *Hfe* protein might be to bind the iron-protein complex and exclude it from uptake by cells that have sufficient iron in the cytosol. Structural alteration of *Hfe* protein would then permit unregulated uptake of iron

by intestinal epithelial cells as well as by hepatocytes and other parenchymal cells.

Mutations in the Hfe Protein. Two mutations have been identified, at nt (nucleotide) 845, G®A and at nt 187, C®G. These correspond to amino acid substitutions 282 Cys®Tyr (C282Y) and 63 His®Asp (H63D), respectively ([33](#), [157](#), [158](#)). The cysteinyl residue normally present at amino acid position 282 is involved in a disulfide bridge; replacement by a tyrosinyl residue at this position would significantly alter the quaternary structure of the protein and thus its function.

Identification of these two mutations indicates that three genotypes can be defined:

Wild type (normal) with 187 C and 845 G Genotype 845 G (or 282C)

Mutant allele with 187 C, 845 A Genotype 845 A (or 282Y)

Mutant allele with 187 G, 845 G Genotype 187 G (or 63D)

Of 178 U.S. patients from numerous medical centers who were believed to be homozygous for HH, 5 of every 6, or 83%, were homozygous for genotype 845 A (282Y/282Y); thus, their Hfe proteins would have the substitution 282, Cys®Tyr. For a population in which there are three alleles for a gene, which occur together two at a time (because chromosomes are in pairs), six combinations may be predicted: there will be three sets of homozygotes and three sets of heterozygotes. These are shown in [Table 10.11](#), together with the genotype frequencies observed in a study of 193 control subjects who did not have iron overload and 147 subjects who had been diagnosed by other means as having hemochromatosis ([157](#)). In this study, no instances were observed in the control population of homozygotes for the 282Y mutation, an observation that indicates very strong penetrance of this hemochromatosis gene. Compound heterozygotes who had the major hemochromatosis allele 282Y on one chromosome and the minor hemochromatosis allele 63D on the other also were at high risk of having full expression of hemochromatosis, although a fifth of these compound heterozygotes were in the control group. No cases were observed of homozygotes for the minor hemochromatosis allele 63D, probably reflecting only that they are relatively uncommon (the expected 63D homozygote frequency in this population would be only about 3/100 to have a 282C/63D heterozygote frequency of 27%; no instances of 63D/63D homozygotes, in a sample of 193, is consistent with a homozygote frequency of 3%).

Genotypes ^a	Controls		Hemochromatosis	
	N	(%)	N	(%)
Homozygotes				
282C/282C	112	(58.0)	10	(7.8)
282Y/282Y	0		121	(82.3)
63D/63D	0		0	
Heterozygotes				
282C/282Y	27	(14.0)	2	(1.4)
282C/63D	52	(26.9)	6	(4.1)
282Y/63D	2	(1.0)	8	(5.4)

Data from Beutler E, Gelbart T, West C, et al. *Blood Cells Mol Dis* 1996;184:1975-85.
^aAs indicated in the text, the following are equivalent designations for the Hfe alleles: 282C = H63; the normal or "wild type" allele; 282Y = H45A, the major hemochromatosis allele; 63D = 187G, a minor hemochromatosis allele.

Table 10.11 Genotype Frequencies for the Hfe Alleles in Normal and Hemochromatosis Subjects

Clearly, elucidation of the molecular genetics of hemochromatosis has only begun. Genotypes 845A (282Y) and 187C (63D) account for 90% of cases of homozygous hemochromatosis. The other 10% of cases may represent iron overloading without a genetic basis or may be due to other mutations of this gene that remain to be identified. Furthermore, the molecular genetics of non-HLA-linked African hemochromatosis has yet to be elucidated. A strain of mice that lacks b₂-microglobulin has iron overload that closely resembles human HH (158). Absence of the Hfe a3 domain–b₂-microglobulin complex on the cell surface apparently results in loss of ability to prevent absorption of iron. An analogous mutation of the b₂-microglobulin gene has not been described in humans. However, if it does occur, it might account for some of the cases of hereditary hemochromatosis that appear not to be HLA linked. A constitutive mutation in the Nramp2 gene, might also lead to excessive absorption of iron (23, 24).

Geographic Distribution of HH. Extensive studies of the prevalence of HH indicate that the homozygous condition occurs with a frequency of about 3 to 5/1000 in Iceland, Norway, Denmark, Ireland, the United Kingdom, Sweden, France, the Netherlands, western and southern Germany, northern Spain, Canada, and the United States and in persons of predominantly European origin in South Africa, New Zealand, and Australia (159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170 and 171). HH appears to be quite rare in Finland, North Africa, Greece, Turkey, and the Middle East and in people of Asian origin. These prevalence rates imply a gene frequency of about 0.04 to 0.09 and a carrier rate of 10 to 15% for Caucasians of northern European derivation.

Furthermore, it implies that most cases of hemochromatosis are not correctly diagnosed during life. Very likely, many such cases are diagnosed as diabetes mellitus, rheumatoid arthritis, or idiopathic cardiomyopathy, without the underlying iron storage disease being recognized. The occasional observation of apparent autosomal dominant inheritance of hemochromatosis now appears to result from homozygote-heterozygote matings. The homozygous state may be manifest any time after puberty in males, but it is unusual prior to menopause in women, since iron loss through menstruation provides a "safety

valve.”

The mechanism of increased iron absorption in hemochromatosis remains a puzzle. The mucosal epithelial cells themselves do not appear to have increased iron content, although the macrophages of the subendothelial layers do, as do nearly all other cells of the body. Furthermore, although, in HH, the mucosal epithelial cells are capable of markedly reducing their uptake of inorganic iron, they exhibit an increased rate of absorption of heme iron despite systemic iron overload.

Linkage between Hfe and HLA-A Genes. Because of the tight linkage to the HLA-A gene, there is a linkage disequilibrium between HLA genotypes in persons with HH of the European type; 70% have the HLA-A3 specificity, which is observed in only 28% of the general Caucasian population. Some physicians may be tempted to use HLA typing as a screening test for hemochromatosis or in the attempt to differentiate it from alcoholic cirrhosis. Either application is illogical, wastes resources, and is meaningless, because any patient with alcoholic cirrhosis has nearly a 30% likelihood of having the HLA-A3 antigen and 30% of patients with hemochromatosis do not have HLA-A3. The odds are nearly 100:1 that any person in the United States whose cells have the HLA-A3 antigen is not homozygous for, and will never develop, hemochromatosis. Furthermore, HLA testing is time consuming and costly. However, the procedure has merit for examining siblings of a known patient with hemochromatosis, since siblings who are genotypically identical to an affected patient may be presumed also to be homozygous for hereditary hemochromatosis. As a consequence, those who are not genotypically identical may be reassured. In this application, it does not matter what the HLA type is—A3 or any other type. However, now that the HH gene has been identified, DNA methods can be used to test for homozygous HH.

Clinical Features. The classical “triad” of hemochromatosis—cirrhosis, diabetes, and hyperpigmentation of the skin—are only the most striking clinical features of a far-advanced state of this disorder. The other major clinical features of hemochromatosis are fatigue, cardiac arrhythmias, dilated or restrictive cardiomyopathy (due to iron deposition in heart muscle cells), cardiac failure, arthropathy that may mimic rheumatoid arthritis, hypothyroidism, gonadal failure secondary to marked reduction in pituitary hormone secretion, and testicular atrophy. Arthritis has most often affected the second and third metacarpophalangeal joints, the knee, or the hip joint. The diabetes, arthropathy, and sterility are usually irreversible, but cardiac function and hepatic function commonly improve following removal of excess iron. Patients with hemochromatosis have a substantially increased risk of hepatocellular carcinoma. Overall, about one of every seven hemochromatosis patients dies of hepatoma. Of those who have liver cirrhosis, approximately 30% develop hepatoma (hepatocellular carcinoma) ([172](#), [173](#)). If cirrhosis is avoided by timely diagnosis and aggressive phlebotomy therapy, the risk of hepatoma becomes minuscule. The risk of hepatoma is not affected by phlebotomy therapy once cirrhosis has developed. Aberrations in mental function may be observed in about a third of patients with hemochromatosis. These aberrations include marked lethargy, somnolence, confusion, and disorientation.

Patients with hereditary hemochromatosis manifest increased susceptibility to infection. Sudden onset of overwhelming sepsis and shock was once a common cause of death in

patients with this disorder. Persons with iron overload of any cause are especially susceptible to septicemia from the marine bacterium *Vibrio vulnificus*, a microorganism that grows rapidly when iron is readily available (174, 175 and 176). The infection is usually acquired by handling or eating raw shellfish such as oysters. Septicemia is rapidly progressive and commonly fatal. Cases have also been reported of peritonitis and of septicemia due to *Yersinia enterocolitica* in patients with hereditary hemochromatosis, thalassemia major, or oral iron overdosing. This microorganism appears to be an “opportunistic pathogen,” causing severe or fatal infections in persons debilitated from a variety of disorders. Sudden onset of, and death from, septicemia from *Escherichia coli*, a normal inhabitant of the gastrointestinal tract, has also been observed.

Diagnosis. Screening tests for hemochromatosis should include assay of serum iron concentration, TIBC, transferrin saturation (in %), and ferritin concentration. These should be performed on serum specimens from *everybody*, beginning at age 20. Extensive studies have proven universal screening for hemochromatosis to be highly cost effective in reducing the long-term costs of medical care, preventing morbidity, and saving lives.

The tests need to be repeated every few decades, since they may be falsely negative during early decades because iron overload develops very gradually. Taken together, these tests, when abnormal, provide a high level of confidence for identification of persons likely to have hemochromatosis, although many cases are missed even with these tests. Persons with serum iron concentrations above 32 $\mu\text{mol/L}$ and transferrin saturation above 60% on repeated assays (at least twice) must be assumed to be at risk of hemochromatosis until proven otherwise. The observation of persistently elevated SI and transferrin saturation is a hallmark of the homozygous state for HH; these findings may be present for years before elevation of serum ferritin or other clinical or laboratory features of HH are manifest. Elevations in SI and transferrin saturation may persist despite vigorous phlebotomy therapy and normalization of iron stores and serum ferritin (177). Very often, serum activity of aspartate aminotransferase (AST, SGOT) is elevated early in the course of HH. Alanine aminotransferase (ALT, SGPT) may also be elevated. Serum bilirubin concentration is normal.

Examination of bone marrow iron content is often misleading in HH, as the iron content may be normal. Noninvasive methods for demonstrating iron overload in liver, such as computer-assisted tomography (CAT) or magnetic resonance imaging (MRI) scans have had a limited role in diagnosis. However, recent development of MRI techniques seems to offer promise for a sensitive noninvasive method of assessing the degree of iron excess in the liver. They do not document presence or absence of cirrhosis.

The definitive diagnostic test is usually liver biopsy. The specimen should be sectioned and stained with hematoxylin and eosin and with Perls' Prussian blue stain for iron. It is also useful to divide the specimen and measure the iron content in one portion.

Microscopic examination of iron content generally correlates well with the chemical assay. In normal liver, the iron content is estimated to be 0 to 1+ histologically and less than 50 $\mu\text{mol/g}$ (2.8 mg/g) dry weight. In persons with alcoholic liver disease, the iron

content of liver is not more than 0 to 2+ microscopically and less than 100 $\mu\text{mol/g}$ (5.6 mg/g) dry weight. In hemochromatosis, liver iron content is 3 to 4+ by microscopic estimation and usually exceeds 100 $\mu\text{mol/g}$ by chemical assay. Most patients with cirrhotic hemochromatosis have a liver iron content of at least 200 $\mu\text{mol/g}$ (11 mg/g) dry weight. Since the iron content of liver normally increases slowly with age, a "hepatic iron index" (HII) can be calculated by dividing hepatic iron content in $\mu\text{mol/g}$ by age in years (178, 179). Persons who are homozygous for HH have HII values above 1.9 but rarely above 20. There is a little overlap in HII values between some persons with homozygous HH and some heterozygotes, but patients are clearly distinguished from normal controls and alcoholic cirrhotics.

Treatment. Hereditary hemochromatosis is treated by a vigorous program of phlebotomy: removal of 500 mL of blood one to three times weekly over the course of 1 to 2 years. Since each 500 mL of blood contains 200 to 250 mg of iron, such treatment removes, in time, 10 to 40 g of iron. The phlebotomy program must be continued until the iron excess has been removed. This is first evidenced by a falling venous hemoglobin concentration that does not return to 110 g/L (women) or 120 g/L (men) within a week. The serum ferritin concentration should then be below 20 $\mu\text{g/L}$. When this point has been reached, the initial phase of treatment has been completed. Thereafter, patients should have a 500-mL phlebotomy once every 2 to 6 months for the remainder of their lives, with the objective of keeping the serum ferritin concentration at 20 $\mu\text{g/L}$ or below. Measurement of SI, TIBC and T_{sat} in phlebotomy-treated patients is not warranted. The SI and T_{sat} will likely be high (172). These abnormalities are characteristic of hemochromatosis irrespective of the size of iron stores; SI and T_{sat} should not be used as guides to treatment.

The required phlebotomy frequency following the initial phase of treatment varies and must be determined individually. The dramatic improvement in longevity and reduction in complications that attend this treatment have been amply documented. If this program is undertaken before hepatic cirrhosis or diabetes mellitus has developed, survival is indistinguishable from age- and sex-matched normal subjects (180).

In addition to iron removal, the endocrine, cardiac, and joint manifestations of HH may require appropriate treatment. Patients with HH must abstain absolutely from alcohol consumption. However, attempts to reduce iron intake by reducing meat or bread consumption are rarely indicated. An ordinary well-balanced diet should be recommended.

Iron chelators such as desferrioxamine have no rational place in treatment of HH. In secondary hemochromatosis, as in transfusion-dependent thalassemia major, however, parenteral administration of iron chelators is essential.

African Hemochromatosis ("Bantu Siderosis")

Iron overload in black people of South Africa (first recognized in those of the Bantu linguistic stock, although not limited or predetermined by language) appears also to have a genetic basis, but it is usually associated with long-continued exposure to diets containing too much iron, derived largely from cooking pots and from the steel barrels

used in preparation of fermented alcoholic beverages. The prevalence of the carrier state in sub-Saharan African populations has been reported as 30%. This gene presumably also occurs in African Americans, but no prevalence data are available.

In adult males, the iron intake from beer brewed in steel drums may exceed 100 mg iron per day. The condition frequently becomes manifest in late adolescence and reaches its greatest severity between the ages of 40 and 60 years. It is usually more severe in males, whose alcoholic consumption tends to be greater. The histologic pattern of the iron overload is initially one of deposition of iron in reticuloendothelial cells, such as Kupffer cells of the liver. Portal cirrhosis becomes evident in most patients (but not in all) when the hepatic concentration of iron reaches 2 g or more per 100 g dry weight. Redistribution of iron takes place, so that parenchymal deposits of hemosiderin are found in epithelial cells of many organs, particularly pancreas and the myocardium. Approximately 20% of these subjects develop clinical diabetes, but myocardial failure has not been described. To what extent these changes are caused by iron alone, by chronic alcoholism, or by associated nutritional disturbances is unknown.

Hereditary Sideroblastic Anemia

Hereditary sideroblastic anemia, a rare sex-linked disorder, is typically associated with anemia that may be mild to severe. The disorder is rarely seen in its complete form in women. In the erythroblasts of the bone marrow one may demonstrate, by Perls' stain, the presence of large blue granules encircling the nuclei like a necklace. These are "ringed sideroblasts." The granules are mitochondria stuffed with iron, which is the reason for the blue stain. Iron accumulates in the mitochondria because of a deficiency of ALA-S, the first enzyme in heme synthesis. This metabolic "bottleneck" in mitochondrial metabolism results in accumulation of heme precursors, most conspicuously iron. The gene has been identified on the X chromosome. All of the features of organ injury from iron overload in liver, pancreas, joints, pituitary, etc., are encountered in this disorder.

Congenital Atransferrinemia

Congenital atransferrinemia is an exceedingly rare disorder (the author's patient is the only one known to be living in the Western hemisphere at present). It is due to an inability to synthesize transferrin. The nature of the mutation is as yet unknown, but since it has occurred in two pairs of siblings (in Japan and Mexico), it appears to be an autosomal recessive disorder. There is a moderate-to-severe anemia. Serum iron concentration and total iron binding capacity are near zero. Serum ferritin may be very high as a result of excessive iron absorption from the gastrointestinal tract. All manifestations of severe generalized hemochromatosis may be observed, including hypogonadism due to absence of pituitary gonadotropins. Since patients have no transferrin to bind iron, they are unusually susceptible to overwhelming bacterial infections, which are the usual cause of death. The author's patient has responded well to monthly administrations of plasma (to provide transferrin) preceded by removal of 500 mL of blood (to remove iron). Replacement hormonal therapy is also required, since there is hypothalamic, hypogonadotrophic hypogonadism, as often occurs in severe iron

overloading of any cause.

Congenital Aceruloplasminemia

Congenital aceruloplasminemia is a rare autosomal recessive disorder that leads to excessive iron accumulation in the brain, liver, and pancreas, with the clinical features of mental slowing or dementia and diabetes mellitus–induced retinal degeneration, dysarthria, blepharospasm, and “cogwheel” rigidity of the extremities. In contrast with Wilson's disease, a Kayser-Fleischer ring has not been observed. Serum iron concentration is low, total iron binding capacity is normal, and serum ferritin concentration is elevated (e.g., 1500 µg/L). There is a mild microcytic anemia. Ceruloplasmin is absent in serum; serum copper concentration is low, urinary copper excretion is normal; liver copper is normal. Liver biopsy specimens have shown 3+ deposition of iron in hepatocytes, indistinguishable from the pattern observed in European (HLA-linked) hemochromatosis ([182](#)).

Ceruloplasmin functions as ferroxidase in iron metabolism, catalyzing the interconversion of Fe(II) and Fe(III). It appears that in aceruloplasminemia, the divalent iron that enters plasma cannot be oxidized to trivalent iron, an essential conversion prior to uptake of trivalent iron by transferrin. Therefore, divalent iron is taken up by apoferritin in the cytosol of various tissues, and iron overloading ensues.

Because of the microcytic anemia and low serum iron and low transferrin saturation, such patients are at risk of being diagnosed as having iron deficiency and being treated with iron—clearly a therapy that is contraindicated. If clinicians rely on serum ferritin assay to diagnose iron deficiency, as they should, they will not make this mistake. It would be reasonable to treat these patients by phlebotomy to reduce the iron overload. However, such treatment has not yet been reported.

Alcoholic Cirrhosis, Chronic Alcoholism, and Pancreatic Insufficiency

Patients with alcoholic or nutritional portal cirrhosis of the liver frequently have slightly increased amounts of stainable iron in their livers. The total amount present rarely exceeds 1 g. Clinical similarity to hemochromatosis is accentuated by the occurrence also in alcoholic cirrhosis of increased skin pigmentation, a higher incidence of diabetes mellitus than can be ascribed to coincidence, testicular atrophy, and increased risk of hepatoma. Cardiac failure, when it occurs, can usually be accounted for on other grounds. More males than females are affected, and clinical manifestations are most prominent in late middle life.

A number of possible explanations for the iron overload have been cited. Patients with hepatic cirrhosis are frequently wine drinkers and may consume several liters daily. European wines may contain significant quantities of iron (although American wines may not), and several milligrams per day may be derived from that source alone. Patients with chronic liver disease or chronic pancreatitis may have greater than normal intestinal absorption of iron.

While the controversy over the genetic basis of “idiopathic” hemochromatosis has been resolved, there remains the issue of whether alcoholic cirrhosis per se can lead to serious iron overload. Seventy percent of cirrhotic patients with marked iron overload have the HLA-A3 allele, a frequency identical with that in hereditary hemochromatosis, whereas the frequency of HLA-A3 is 30% in cirrhotics without iron overload, identical to that in the general population ([183](#)). Thus, studies of HLA antigen frequencies in HH and in alcoholic cirrhosis show that all or most alcoholic cirrhosis patients with iron overload in fact have hereditary hemochromatosis, and ethanol abuse increases the risk of hepatic cirrhosis but is not the primary cause of iron overload.

Shunt Hemochromatosis

Many cases have been observed of “shunt hemochromatosis” that appears within a few years of establishment of a shunt between the portal and systemic venous systems. The shunt has usually been created surgically to relieve pressure in esophageal varices, and in most instances, iron loading has followed end-to-side anastomoses. However, the disorder has also developed spontaneously, presumably from formation of collateral channels between portal and systemic veins. Iron accumulation is astonishingly rapid. The mechanism is unknown. The manifestations are the same as those of hemochromatosis from other causes.

Prolonged Iron Therapy

A few cases have been reported in which inappropriate administration of iron, orally or parenterally, for decades, to non-iron-deficient patients has led to typical hemochromatosis. Since iron preparations are advertised widely in the United States, are available without prescription, and are consumed in large quantities, it is astonishing that so few cases have been reported. Therefore, the potential of iron preparations to cause iron overload deserves special attention. One can estimate mathematically the amount of iron that might accumulate in the body of normal persons when different amounts of medicinal iron are administered over long periods of time. These estimates, for which the calculations were shown in the seventh edition of *Modern Nutrition in Health and Disease*, are illustrated in [Figure 10.15](#). As can be seen from the uppermost curve of this illustration, even at a daily dose of 240 mg of iron (e.g., four ferrous sulfate tablets daily), which amounts to a total ingested dose of 1.3 kg in 15 years, the increase in body iron content is still well below that commonly encountered in HH. These facts emphasize the remarkable way in which modulation of iron absorption by the intestinal mucosa tends to protect normal persons from the adverse effects of excessive iron ingestion. In view of the high prevalence of hereditary hemochromatosis, the widespread use of iron supplements, and the rarity of cases in which hemochromatosis is attributed to chronic ingestion of iron, some of these patients may be homozygous for hereditary hemochromatosis.

Figure 10.15. Expected accumulation of iron in menstruating women receiving single daily doses of 30 to 240 mg. Data are based on the assumptions that iron absorption in females is $D^{0.668}$, where D is the dose of iron in grams, that iron absorption is modified by stores to the extent of $3^{-0.196(F-1)}$, and that excretion is $0.0009\sqrt{F} + 0.0005$, where F is the iron stores in grams. 1 g Fe = 17.9 mmol.

Clearly, there is some hazard from prolonged administration of large doses of iron to persons who are not iron deficient. This is particularly a problem for patients with thalassemias and other chronic anemias, for whom the ultimate development of hemochromatosis is a very serious complication of treatment. For premenopausal women who have normal menses and do not have thalassemia or other chronic anemias, the hazard of serious iron overload resulting from exogenous iron is slight. However, inappropriate and prolonged administration of iron, by oral or parenteral route, to adults who are not bleeding and not iron deficient needlessly exposes them to the risk of hemochromatosis with all its serious complications.

Severe Chronic Anemia

The amount of iron found in the tissues of patients with refractory anemia, particularly those with hypercellular marrows and ineffective erythropoiesis, is occasionally greater than can be accounted for by the transfusions they have received. In some cases, little blood was given during the course of the illness, yet excess iron was present. Some, but not all, of these subjects have been inappropriately treated with iron. Excessive absorption of dietary iron must have occurred, presumably because of the accelerated but ineffective erythropoiesis. Patients at risk include those with sideroblastic anemia, thalassemia major, pyruvate kinase deficiency, and paroxysmal nocturnal hemoglobinuria. The cardiac and hepatic complications of hemochromatosis are common causes of death in patients with sideroblastic anemias or β -thalassemia major.

Severe iron overload may occur in patients with congenital dyserythropoietic anemia. Hereditary spherocytosis and thalassemia minor are not usually associated with iron overload, except in patients misdiagnosed as having iron deficiency and given copious amounts of iron over many years. However, some cases have been reported in which

these disorders coexisted with hereditary hemochromatosis. In view of the high prevalence of the latter disorder in persons of European ancestry, the concurrence of these disorders is hardly surprising. In such patients, large amounts of hemosiderin are found in both parenchymal and reticuloendothelial cells.

Transfusional Hemosiderosis

Whenever chronic anemia that has been treated by numerous transfusions over many years is found in a patient who does not have chronic bleeding, iron overload is likely to occur. These patients may experience all the consequences described above for HH. This complication is most often found in severe thalassemias such as β -thalassemia major, in some sideroblastic anemias, and in hypoplastic or other refractory anemias. For many of these patients, long-term treatment with the iron chelating agent desferrioxamine is essential. The desferrioxamine must be administered daily by subcutaneous infusion for 12 to 16 h, a treatment that is cumbersome and expensive. Effective oral iron chelating agents are being developed and may become available within a few years. They should supplant parenteral desferrioxamine therapy for these patients.

Surprisingly, some patients with marked iron overload resulting from transfusion never manifest severe organ damage. However, some persons with HH and marked iron overload also do not exhibit evidence of organ damage. These paradoxes may reflect the fact that serious organ injury is more likely to occur in patients subjected to toxic substance(s) or hepatitis in addition to iron excess.

OTHER DISORDERS RELATED TO IRON METABOLISM

Porphyria Cutanea Tarda

Porphyria cutanea tarda is typified by hepatic dysfunction, neuropathy, behavioral aberrations, and cutaneous sunlight hypersensitivity. It is related to iron metabolism in an as yet unknown manner. Most patients exhibit moderate iron overload. The manifestations of this disease are ameliorated by phlebotomy therapy.

Congenital Cataract with Hyperferritinemia

A few families have been described in which congenital nuclear cataracts were associated with hyperferritinemia without iron overload. The condition is inherited as an autosomal dominant disorder. The serum iron, TIBC, and transferrin saturation are normal, but serum ferritin concentration may be several thousand micrograms per liter. The ferritin contains only the L subunit. Hyperferritinemia is due to mutations in the IRE of the mRNA for apoferritin, such that normal regulation of apoferritin synthesis by the IRP-IRE mechanism cannot occur. So far as is known, there is no iron deposition in the affected lenses. However, unbridled constitutive synthesis of a protein within cells of the crystalline lens that should only contain lens protein may have an adverse colloid osmotic effect. There is, as yet, no report that any other cells or organs are adversely

affected ([184](#), [185](#) and, [186](#)).

Superficial Hemosiderosis of the Central Nervous System

Superficial hemosiderosis of the central nervous system is a rare disorder that results from recurrent subarachnoid hemorrhages with deposition of iron in the meninges. It may be associated with ataxia and other central nervous system manifestations. It is not related in any way to disorders of iron metabolism ([187](#)).

HISTORICAL ASPECTS

Zinc (Zn) was recognized as a distinct element in 1509. Evidence of its essentiality was demonstrated in plants in 1869 and in animals in 1934 (1). Because of its wide prevalence in foodstuffs, naturally occurring Zn deficiency was considered unlikely until 1955, when swine parakeratosis was shown to be a Zn deficiency disease. That humans could suffer from Zn deficiency was suggested by observations that malnourished Chinese patients during World War II had low concentrations of plasma Zn. In 1956, a conditioned Zn deficiency syndrome in humans was demonstrated. Since 1961, when the endemic hypogonadism and dwarfism of rural Iran was suggested to be derived from Zn deficiency, there has been increasing appreciation of the magnitude of both the clinical and the public health significance of Zn deficiency states (1, 2 and 3).

CHEMISTRY

Zn is a IIB element with a completed d subshell and two additional s electrons. Zn has an atomic number of 30, an atomic weight of 65.37 (isotopic mean), and in pure form is a bluish white metal. Zn occurs naturally as five stable isotopes: ^{64}Zn , 48.89%; ^{66}Zn , 27.91%; ^{67}Zn , 4.11%; ^{68}Zn , 18.57%; and ^{70}Zn , 0.62%. Six radioisotopes have been identified, of which three, ^{65}Zn , $^{69\text{m}}\text{Zn}$, and ^{63}Zn are used often in tracer studies (half-lives of 245 days, 13.8 hours, and 38 minutes, respectively). In biologic systems, Zn is virtually always in the divalent state. Zn typically forms complexes with a coordination number of 4, with tetrahedral disposition of ligands around the metal. Zn readily complexes to amino acids, peptides, proteins, and nucleotides. Zn has an affinity for thiol and hydroxy groups and for ligands containing electron-rich nitrogen as a donor. Zn does not exhibit any direct redox chemistry.

BIOLOGIC ACTIVITY

Net delivery of Zn to an organism is a function of the bioavailability and the total amount of Zn in the diet. Bioavailability is defined as the proportion of Zn (or any other nutrient) in food that is absorbed and used. As with most minerals, Zn absorption typically exceeds the amount actually used; the excess absorbed is rapidly excreted.

Food Sources

Foods differ widely in their Zn content. Zn concentrations range from 0.02 mg/100 g for egg white to 1 mg/100 g for light chicken meat to 75 mg/100 g for oysters. Shellfish, beef, and other red meats are good Zn sources. Whole-grain cereals are relatively rich in total Zn. Most of the Zn is contained in the bran and germ portions, and nearly 80% of the total Zn is lost in the wheat milling process (2). There is no standard enrichment policy for Zn, but some breakfast cereal manufacturers fortify the Zn content of their product in amounts ranging from 25 to 100% of the United States recommended dietary allowance (RDA). Nuts and legumes are relatively good plant sources of Zn. Plant Zn concentrations may be enhanced if grown in Zn-rich soil or treated with Zn-rich fertilizers (4).

Zinc Intakes

Total dietary Zn intakes are influenced greatly by food choices. Animal products provide about 70% of the Zn consumed by people in the United States, with about half coming from meat (beef, veal, pork, lamb) (5, 6). Cereals are the primary plant source. Frequently, Zn intakes are correlated with protein intake, but the exact relationship is influenced by protein source. Diets consisting primarily of eggs, milk, poultry, and fish have a lower Zn:protein ratio than those composed of shellfish, beef, and other red meats. Similar variations occur in vegetarian diets. Diets with a rich Zn:protein ratio have liberal quantities of legumes, whole grains, nuts, and cheese, whereas those with a low ratio contain primarily fruits and vegetables. Drinking water is typically low in Zn, providing only 2% of the daily zinc intake (7). The mean daily intake from adult self-selected mixed diets in the United States ranges from 8.6 to 14 mg Zn (2). The mean or median intakes reported in 171 studies summarized by the International Atomic Energy Agency ranged from 4.2 to 19 mg/day; the 10th, 50th, and 90th percentiles of intake were 7, 10, and 14 mg/day, respectively (7). During the first 6 months of life, Zn intake varies with the mode of feeding. Reported intakes of breast-fed infants range from 0.03 mmol/day (1.9 mg/day) at 1 month of age to 0.04 mmol/day (2.7 mg/day) at 6 months (8); bottle-fed infants consumed 0.055 and 0.07 mmol/day (3.6 and 4.6 mg/day) at 1 and 6 months, respectively. The Zn content of commercial infant formulas depends on the fortification policy of the manufacturer. Typical zinc intakes of various population groups are reported in [Table 11.1](#).

Group	No. of Studies	Percentile of intake		
		10	50	90
Children	39	4.9	7.9	13.0
Males	36	6.6	12.0	15.4
Females	46	5.7	8.5	10.9
Pregnancy and lactation	17	8.1	9.6	12.9
Vegetarians	10	—	9.5	—
All adults	171	7.0	10.0	14.3

Modified from World Health Organization. Trace elements in human nutrition and health. Geneva: WHO, 1996. Based on a database maintained by the International Atomic Energy Agency.

Table 11.1 Daily Zinc Intakes of Various Population Groups

Factors Affecting Zinc Bioavailability

Zn bioavailability is defined as the fraction of zinc intake that is retained and used for normal physiologic functions. Zn absorption is a function of the solubility of Zn compounds at the absorption site and the body “status” or need. Zn in foods is relatively easily extractable at gastric pH; it tends to bind to organic compounds at higher pH (9).

Small-molecular-weight ligands, such as amino acids and other organic acids, can increase solubility and facilitate absorption; larger-molecular-weight compounds, such as phytic acid, form poorly soluble compounds and reduce absorption. Competition between Zn and other elements for binding sites on the mucosal cell can influence absorbability.

Meats, liver, eggs, and seafood are considered good sources of Zn because of the relative absence of compounds that inhibit Zn absorption and the presence of certain amino acids that improve Zn solubility. For example, the absolute amount of zinc absorbed was about 80% higher when a high meat diet (280 g meat/day) was consumed than with a low meat (42 g meat/day) diet (10). Cysteine and methionine enhance Zn absorbability by forming stable complexes with Zn (11). Whole-grain cereal products and plant proteins, such as soy protein, contain Zn in a less available form. The phytic acid (myoinositol hexaphosphate) content of plant foods explains, at least in part, the lower availability of Zn from these foods. Fermentation of whole-meal bread reduces the phytic acid content and significantly improves Zn absorption, indicating that dietary fiber has little or no effect on zinc availability. Fermentation and enzymatic treatments gradually degrade the hexaphosphate form. The penta form depresses absorption like the hexa form, but lower inositol phosphates are less depressing (9). Extrusion cooking, which is used for breakfast cereals, seems to inhibit degradation of phytic acid in the gut and causes less efficient absorption of Zn (12). Millimolar phytate:Zn ratios above 10 increase the risk of poor Zn utilization.

Zinc-Nutrient Interactions

Transport mechanisms into cells for cations are in part determined by their configuration and coordination properties (13). Thus, elements with similar physicochemical characteristics compete for common pathways. Zn, with a preferred coordination number of 4, competes with copper (Cu) and cadmium (Cd). Mutual affinity for a carrier protein can also result in metal competition. This type of interaction may underlie reported Zn-iron (Fe) interactions.

Zinc-Copper

Large quantities of ingested Zn can interfere with Cu bioavailability (12). One explanation is that a high intake of Zn induces synthesis of the Cu-binding ligand metallothionein (MT) in the mucosal cell. This protein sequesters Cu, making it unavailable for serosal transfer, and thus decreases Cu absorption. Clinical signs of Cu deficiency developed in individuals taking 2.3 mmol/day (150 mg/day) of Zn for 2 years. Pharmacologic doses of Zn (3–4.6 mmol/day; 200–300 mg/day) are used to treat Wilson's disease, a rare inborn error of Cu metabolism that causes excessive tissue accumulation of Cu (14). Lower, more typical Zn intakes do not affect copper absorption (15). A high Cu intake does not inhibit Zn absorption (2).

Zinc-Iron

Fe given as a supplement or in a liquid solution inhibits Zn absorption (2). Ferrous Fe has a greater impact than ferric Fe, and heme Fe does not cause any intestinal

manifestation, suggesting that Fe and Zn compete at the same site for uptake into mucosal cells. Several studies showed that supplemental Fe lowers plasma Zn concentrations during pregnancy (2). The Institute of Medicine recommends that all pregnant women receiving more than 60 mg Fe/day also take supplemental Zn (16).

Zinc–Other Elements

High levels of dietary calcium impair Zn absorption in animals, especially from phytate-rich diets (12). Whether this occurs in humans is uncertain. High calcium intakes (34 mM or 1360 mg) reduced Zn absorption and balance in postmenopausal women but not in adolescent girls (17, 18). High intakes of tin (50 mg) increased fecal Zn excretion in a human balance study (19); but since the usual intake of tin is less than 8 $\mu\text{mol/day}$ (<1 mg/day), it is unlikely to have an adverse effect on Zn absorption from typical diets. Although high levels of dietary Cd can influence the distribution of Zn in the body, Cd does not seem to have a major effect on dietary Zn absorption.

Zinc–Folic Acid

Hydrolysis of dietary folates to their monoglutamate form requires the Zn-dependent enzyme pteroylpolyglutamate hydrolase (20). Administration of an oral dose of pteroylheptaglutamate to a group of Zn-depleted men prevented the usual rise in serum folic acid, whereas the serum response to an oral dose of pteroylmonoglutamate was normal (21). Several clinical studies show the converse, that folic acid supplementation impairs zinc use when zinc status is compromised (22). Supplementation with 800 μg folic acid/day for 25 days, however, did not alter zinc status in a group of students fed low-zinc diets (3.5 mg/day) (23). The interaction between zinc and folic acid needs further clarification.

METABOLISM

Zinc in the Human Body

Based on a total body concentration of about 0.3 $\mu\text{mol Zn/g}$ (20 μg), it is estimated that the newborn contains approximately 0.9 mmol (60 mg) Zn (24). During growth and maturation, the Zn concentration of the human body increases to approximately 0.46 $\mu\text{mol/g}$ (30 $\mu\text{g/g}$) (2). The adult total body Zn content ranges from about 2.3 mmol (1.5 g) in women to 3.8 mmol (2.5 g) in men.

Zn is present in all organs, tissues, fluids, and secretions of the body. Zn is primarily an intracellular ion, with well over 95% of total-body Zn found within cells. Zn is associated with all organelles of the cell, but about 60 to 80% of the cellular Zn is found in the cytosol. The Zn concentration and content of various tissues and the proportion of total-body Zn found in them are described in [Table 11.2](#).

Tissue	Approximate Zn Concentration		Total Zn Content		Percentage of Body Zn (%)
	Per Weight $\mu\text{Mg/g}$	$\mu\text{Mg/g}$	mg	μg	
Skeletal muscle	0.78	570	24	6733	57 (approx.)
Bone	1.54	1000	12	6771	26
Skin	0.49	320	2	6760	6
Liver	0.89	580	7	6713	5
Brain	0.11	770	0.6	6704	1.5
Kidneys	0.85	650	0.3	6703	0.7
Heart	0.25	320	0.15	6771	0.4
Hair	2.38	190	<0.15	<0.071	0.7 (approx.)
Body plasma	0.02	71	<0.15	<0.071	0.7 (approx.)

Wolfe GM et al. Zinc Nutrition. London: Springer-Verlag, 1988

Table 11.2 Approximate Zinc Content of Major Organs and Tissues in a Normal Adult Man

Zinc Uptake

Sites of Absorption. Zn is absorbed all along the small intestine; only small amounts are absorbed in the stomach and large intestine. Considering the length and surface area of the various segments of the small bowel, the transit time of digestion, and the endogenous secretion of Zn, most Zn is probably absorbed in the jejunum (25). After intake of a meal, the intraluminal quantity of Zn increases to about 1.5 to 3 times the amount ingested at the distal duodenum, presumably because of secretion of Zn-containing digestive juices. The luminal content of Zn declines substantially in the jejunum (26). In the postabsorptive state, Zn absorption was not affected by the quantity of Zn ingested until this exceeded 77 μmol (5 mg); Zn absorption from a meal providing 46 and 77 μmol (3 and 5 mg) was less than that from a 15- μmol (1 mg) meal (27).

Intraluminal Factors. During the process of digesting a meal, digestive enzymes release dietary Zn from food matrices and endogenous Zn from various binding ligands. As such, this free Zn can form coordination complexes with various exogenous and endogenous ligands, such as amino acids, phosphates, and other organic acids (9). Histidine and the sulfur-containing amino acids methionine and cysteine are the preferred amino acid ligands. Zn-histidine and Zn-methionine complexes are absorbed more efficiently than Zn sulfate (28, 29). Although widely discussed, citric acid and picolinic acid do not appear to enhance zinc absorption.

Cellular Factors. The mechanism by which Zn enters mucosal cells is unknown. Presumably, it traverses the unstirred water layer in an exchangeable or diffusible form. Zn uptake across the brush border surface occurs by both a carrier-mediated (saturable) mechanism and a nonmediated (nonsaturable) component. At low-normal luminal concentrations of Zn (less than about 80 $\mu\text{mol/L}$), the carrier mechanism predominates. This carrier-mediated uptake by the cell does not require energy. Specific receptor proteins for Zn have not been characterized. When the dietary supply of Zn is low, the carrier affinity for Zn is not changed, but the capacity for carrier-mediated

transport is greater, presumably due to a rise in the number of receptor sites (30). With high Zn intakes, the nonsaturable mechanism becomes prominent. This mechanism may involve passive diffusion and/or movement between mucosal cells. The positive, nonspecific effect of lactose and glucose polymers on Zn absorption may represent an increase in paracellular Zn movement.

Disposition of Zn within the cell is diverse. Intracellular Zn may be used by the cell for Zn-dependent processes, become bound firmly to MT and held within the cell, or pass through the cell. Cysteine-rich intestinal protein (CRIP) is associated with Zn absorption, but it is not likely to be involved in transcellular movement. MT gene expression is directly related to dietary Zn intake, however. Zn absorption declines as MT synthesis rises in response to dietary Zn (31). A vesicular transfer mechanism has also been proposed for transcellular Zn movement (32). Zn trapped within the cell is eventually lost in the feces in the normal course of mucosal cell turnover. Transport of Zn across the serosal membrane is carrier mediated and occurs by an adenosine triphosphate (ATP)-driven mechanism (33).

Portal Transport

Zn is released by the intestinal cells at the basolateral-serosal surface into the mesenteric capillary and is carried by the portal blood to the liver (33). The absorbed Zn is initially albumin bound.

Homeostatic Regulation

Total-body Zn content is controlled in part by regulating the efficiency of intestinal absorption and excretion from endogenous Zn pools. An inverse relationship between plasma Zn concentration and fractional Zn absorption has been reported (34, 35). As intestinal luminal concentrations of Zn rise, the fractional absorption of Zn decreases, but the actual amount of Zn absorbed rises. Thus, at high Zn intakes, regulation of intestinal absorption only provides “coarse control” of total-body Zn. Increased fecal excretion of endogenous Zn appears to provide the “fine control” needed to balance net retention of Zn with metabolic needs. Endogenous fecal Zn losses may increase severalfold to maintain Zn homeostasis with high intakes (36).

Homeostatic regulation of Zn is altered with changes in physiologic need. Experimental Zn deficiency in animals and humans enhances gastrointestinal Zn uptake (37, 38). In the rat, a specific increase in the efficiency of Zn absorption is observed in late pregnancy, possibly because of an increase in receptor sites (39). A similar increase has not been observed in pregnant women (34). Zinc absorption is enhanced during lactation, however, in both humans and experimental animals (34, 39).

The age of the individual influences absorptive capacity. Newborn animals absorb Zn to a higher degree than do older animals, perhaps because of a transport system with a higher affinity for Zn (40). Several studies show that Zn absorption decreases with age (41). Most report that Zn absorption in the elderly is approximately half that of young people, but one group found no difference in fractional Zn absorption in the elderly compared with young men. Moreover, old age does not appear to impair the ability of

the intestine to increase the efficiency of Zn absorption in response to ingesting a low-Zn diet. Among the elderly with lower Zn absorption, balance was maintained, suggesting a decline in endogenous Zn losses.

Hormonal influences associated with stress (corticosteroids and select cytokines) can increase the efficiency of Zn absorption (38). Acute bacterial infection and endotoxemia in the rat significantly increase Zn absorption (38).

Zinc Turnover and Transport

Kinetic modeling using stable isotopes of Zn provides information about Zn pools and their turnover in humans. A two-component model best explains the elimination of absorbed Zn from the body (2). The initial rapid phase has a half-life in humans of 12.5 days, and a slower turnover phase has a half-life of about 300 days. The initial rapid half-life primarily represents liver uptake of circulating Zn and its release. The slower turnover rate reflects differing rates of Zn turnover in various tissues other than liver (2). Zn uptake by the central nervous system and bones is relatively slow; the pancreas, liver, kidney, and spleen have the most rapid rates of accumulation and turnover; uptake and exchange of Zn in red cells and muscle are slower than in the viscera.

Kinetic data suggest an exchangeable zinc pool whose size depends on zinc intake (42). Size of this pool was estimated to be 2.4 to 2.8 mmol (157–183 mg) Zn, which decreases by 26 to 32% with severe Zn restriction for 1 week. The size of this exchangeable pool may provide a good measure of tissue zinc status.

About 0.05 mmol (3 mg) of Zn is normally circulating in the plasma at any given moment. This Zn is partitioned among α -2-macroglobulin (40%), albumin (57%), and amino acids (3%) (43). These loosely bound albumin and amino acid fractions of circulating Zn provide the transport and delivery of Zn to tissues. The amino acid-bound fraction determines the amount filtered by the kidneys. Because the total amount of Zn present in the major tissues is much larger than the total present in plasma, relatively small variations in the Zn content of tissues, such as the liver, can dramatically affect plasma Zn. For example, a 1% increase of liver Zn, caused by enhanced retention of Zn, could cause a 40% decline in plasma Zn. Because all absorbed Zn passes through the plasma to the tissues, the flux of Zn through the plasma is replaced approximately 130 times/day (44). [Figure 11.1](#) illustrates the metabolism of Zn.

Figure 11.1. Schematic representation of the metabolism of zinc in mammals. (From Beisel WR, Pekarek RS, Wannamacher RW Jr. Homeostatic mechanisms affecting plasma zinc levels in acute stress. In: Trace elements in human health and disease, vol 1. New York: Academic Press, 1976.)

Storage

There is no specific Zn “store.” In all species studied, a marked reduction in dietary Zn intake is quickly followed by signs of Zn deficiency. Nonetheless, growing chicks fed a high-Zn diet prior to depletion took longer to develop a deficiency than chicks fed a low-Zn diet previously (45). High Zn intakes increase bone, liver, and intestinal Zn. Release of Zn from those tissues during depletion may slow the rate of onset of Zn deficiency symptoms. Reduced food intake associated with Zn deficiency causes catabolism of muscle tissue and release of Zn into the plasma (46).

Excretion

The major route for endogenous Zn excretion is into the gastrointestinal tract, with ultimate loss in the feces. When tracer doses of Zn are given either orally or intravenously, only about 2 to 10% is recovered in the urine; the remainder is lost in the feces (2).

Fecal Zn losses are a combination of unabsorbed dietary Zn and endogenous Zn secretions. Pancreatic secretions are a major source of endogenous Zn. Other sources include biliary and gastroduodenal secretions, transepithelial flux of Zn from the mucosal cells, and sloughing of old mucosal cells into the gut (2). Perfusion studies show that about 0.04 to 0.07 mmol (2.5–4.8 mg) Zn is secreted into the duodenum following intake of a meal, presumably as meal-stimulated pancreatic secretions. Much of the Zn secreted into the gut lumen is absorbed and returned to the body. Maintenance of an intact enteropancreatic Zn circulation is important for maintenance of body Zn. The amount of Zn secreted into the gut varies with Zn intake. In humans, endogenous fecal losses may range from 15 $\mu\text{mol/day}$ (<1 mg/day) with extremely low

intakes to over 80 $\mu\text{mol}/\text{day}$ (>5 mg/day) with extremely high intakes (37, 47).

Normally, about 6 to 9 μmol (400–600 μg) of Zn is excreted daily in the urine. Urinary Zn arises largely from the ultrafilterable portion of the plasma Zn (2). Dietary Zn only influences urinary losses if intake is extremely low or extremely high. Under basal conditions, up to 95% of the filtered Zn is reabsorbed in the distal parts of the renal tubule (48). The amount of Zn excreted in urine is correlated highly with the rate of urine production (or urine volume) and creatinine excretion. Muscle catabolism, such as occurs with severe burns, major surgery, other trauma, or starvation, causes clinically significant increases in urinary Zn losses. Chelating agents, such as ethylenediaminetetraacetic acid (EDTA), also elevate urinary Zn levels (2).

Surface losses through desquamation of skin, outgrowth of hair, and sweat contribute up to 15 μmol (1 mg) of Zn daily. A marked reduction or marked increase in dietary Zn intake causes a concomitant change in surface losses (49). Other sources of loss include semen and menstrual secretions. An ejaculum of semen contains up to 15 μmol (1 mg) of Zn (37). Total menstrual loss is approximately 1.5 to 8.0 μmol (0.1–0.5 mg) per menstrual period (50).

BIOCHEMICAL AND PHYSIOLOGIC FUNCTIONS

Zn, the most abundant intracellular trace element, is involved in a multitude of diverse catalytic, structural, and regulatory functions. For example, Zn is found in numerous enzymes, is a component of biomembranes, is thought to be necessary for RNA, DNA, and ribosome stabilization, is involved in the binding of a number of transcription factors, stabilizes some hormone-receptor complexes, and may have a regulatory role in tubulin polymerization. Given its many functions, it is not surprising that a deficit of this element can pose serious physiologic challenges.

Biochemistry

With regard to metalloenzymes, Zn can have a catalytic, structural, or regulatory role. Examples are carbonic anhydrase, Cu, Zn–superoxide dismutase, and fructose biphosphatase, respectively. Over 200 Zn enzymes have been found in biologic systems, and Zn enzymes are found in all six International Union of Biochemistry (IUB) classes (2, 51). An enzyme is considered to be a zinc metalloenzyme if removal affects activity without irreversibly altering the enzyme protein, and zinc replacement restores activity. It is not known how zinc is donated to apometalloenzyme proteins, but posttranslational modification may be involved. For additional details on Zn enzymes, the reader is directed to several reviews (2, 51, 52).

A critical function of Zn is its role in the structure and function of biomembranes. Some investigators have argued that a reduction in the concentration of Zn in biomembranes underlies some of the disorders associated with Zn deficiency (53), with a loss of Zn from the membrane resulting in increased susceptibility to oxidative damage, structural strains, and alterations in specific receptor sites and transport systems. The influence of Zn on biomembrane structure and function may be due in part to its ability (α) to

stabilize thiol groups and phospholipids, (b) to occupy sites that might otherwise contain transition metals with redox potential (such as Fe), and (c) to be involved in the quenching of free radicals through its association with MT (54). Biomembrane accumulation of Zn can also alter membrane structure and function; for example, release of histamine from mast cells is reduced when Zn accumulates and blocks receptor sites for histamine-releasing agents (55).

The zinc-finger motif in proteins represents another extremely important structural role for zinc. Zinc fingers enable polypeptides that are too small to fold by themselves to fold stably when stabilized by bound zinc. The general structure of a zinc finger is repeated cysteine- and histidine-containing domains that bind Zn in a tetrahedral configuration. Several transcription factors have been reported to contain “Zn finger” regions (56). Up to 1% of the human genome (300–700 human genes) codes for these proteins. More than 10 classes of zinc fingers have been discovered and biochemically characterized. Zinc-finger proteins include transcription factors for DNA (i.e., retinoic acid and calcitriol receptors), the steroid-thyroid hormone–receptor superfamily, and the RING finger–protein family, which includes the breast and ovarian cancer susceptibility gene BRCA1. Zinc-finger proteins have also been found among signal transduction factors and may play a role in cell adhesion.

Zn also serves as a stimulator of *trans*-acting factors responsible for regulating gene expression (57). This function has been studied most extensively for the expression of MT or MT-like proteins. The metal-binding transcription factor for MT acquires Zn in the cell cytosol or nucleus and then can interact with the metal-response element to stimulate transcription. Dietary Zn is taken up by the cell nucleus in proportion to the Zn intake level, suggesting a close relationship between nuclear Zn and the dietary Zn supply.

Another regulatory role for Zn is in the polymerization of tubulin. Zn stabilizes neurotubules *in vitro*, possibly through formation of Zn mercaptide bridges between the tubulin dimer subunits. The rate of tubulin polymerization is decreased in brain extracts of Zn-deficient rats and pigs; Zn deficiency–induced reductions in the rate of tubulin polymerization have been postulated to underlie some of the developmental defects associated with Zn deficiency (58).

Physiologic Functions

To a great extent the appreciation of the physiologic roles of Zn is based on observations of signs of Zn deficiency in experimental animals and humans. Surprisingly, despite the long list of described Zn enzymes and nonenzymatic Zn-dependent processes, little consensus has been achieved on the precise biochemical lesions underlying development of the numerous signs of Zn deficiency. The following sections consider some of the signs of Zn deficiency, first in experimental animals and then in humans, and discuss some potential mechanisms that may underlie their development. At present, however, these mechanisms must be considered speculative.

ZINC DEFICIENCY IN EXPERIMENTAL ANIMALS

A Zn deficiency develops *differently* from most nutrient deficiencies. With most nutrients, insufficient dietary intake first causes mobilization of stores or functional reserves. Thereafter, tissue concentrations of the nutrient decline, and eventually, one or more specific functions or metabolic pathways that depend on the nutrient deteriorate. Thus, reduction in growth is a *late* manifestation of deficiency. In contrast, when dietary Zn intake is insufficient, the first responses are a reduction in growth by growing organisms and a decrease in endogenous losses of Zn to conserve tissue Zn. The important role of zinc in maintaining the structure of transcription factors and regulating gene expression provides a strong rationale for the avid conservation of tissue zinc. If the dietary deficiency is mild, Zn homeostasis may be reestablished after adjusting the rates of growth and excretion, and no further functional or biochemical changes occur. However, with a markedly deficient diet, the organism cannot reestablish homeostasis through adjustments in endogenous losses and growth, and as a consequence, generalized tissue dysfunction develops quickly. The prompt appearance of Zn deficiency signs in animals fed essentially Zn-free diets is attributed to loss of a small labile pool of Zn located within various tissues (59).

Zn deficiency can be induced rapidly. For example, within 12 hours of consuming a Zn-deficient meal, plasma Zn concentrations in the rat decrease by as much as 50% (60). Evidence that this reduction in plasma Zn is functionally significant is provided by the observation that feeding a Zn-deficient diet to pregnant rats for only a few days during the first trimester causes embryonic abnormalities (61). Administration of an excessive amount of dietary zinc to growing chickens permitted Zn accumulation in bone, liver, and intestine that was subsequently released for use during Zn deficiency (45). This was not true when the chicks were fed the minimum requirement of Zn. Although all species appear to lack any appreciable Zn stores or reserves that can be mobilized when needed, some reserves may be deposited in tissues when large quantities of Zn are fed. A homeostatic mechanism for release of that zinc is unknown; it may only become available when released in conjunction with cell turnover.

Early effects of Zn deficiency in many species are anorexia and cyclic feeding. Increased levels of norepinephrine and alterations in its receptor function in the hypothalamus of Zn-deficient animals have been suggested as mechanisms underlying the anorexia (62). Regardless of the biochemical explanation for the anorexia, the cyclic food pattern of Zn-deficient animals may represent adaptation of the animal to the low-Zn diet, because during periods of low food intake, the substantial muscle catabolism releases Zn into the plasma pool that can be used by hepatic and extrahepatic tissues for Zn-dependent processes (63).

If the period of Zn deficiency is prolonged, additional hallmarks of Zn deficiency are impaired growth, dermatitis, a compromised immune system, and decreased efficiency of food utilization. Although the lesions underlying these signs have not been defined, reduced cell replication is an early event in Zn deficiency. This reduced cell division has been related in part to the role of Zn in protein and nucleic acid synthesis, in chromatin decondensation, and in assembly of the mitotic spindle through its effect on microtubule

polymerization (63).

Associated with Zn-deficiency-induced reduction in cell division is impaired growth, which has been demonstrated for numerous species including humans (63). It has been suggested that a reduced growth rate may represent accommodation by the animal to the Zn deficit, thus making more Zn available for Zn-dependent metabolic processes. An alternative explanation is that the slower growth rate is secondary to the anorexia and the concomitant reduction in food intake. However, animals fed diets adequate in Zn, in amounts equivalent to those consumed by Zn-deficient animals, gain considerably more weight than the Zn-deficient animals. Thus, the lower weight gain observed with Zn deficiency cannot be ascribed solely to reduced food intake (62).

In addition to an overall reduction in body size, Zn-deficiency-associated reductions in cell division may also contribute to abnormal bone growth and maturation. Both the number of osteoblasts and the chondrocyte number in epiphyseal cartilage are reduced in Zn deficiency (64). A reduction in cell division rates may also underlie some of the effects of Zn deficiency on the immune system; deficient animals often have a small thymus and spleen, with resultant reductions in their capacity for T- and B-lymphocyte production (65). Zn-deficiency-induced reductions in cell replication rates may also underlie the teratogenicity of embryonic Zn deficiency, because an interruption in normal replication rates and patterns could lead to asynchrony in cell and tissue maturation.

As already indicated, a deficiency of Zn during early development can be highly teratogenic. Typical malformations associated with Zn deficiency in experimental animals include brain and eye defects, spina bifida, cleft lip and palate, and numerous malformations of the heart, lung, skeleton, and urogenital system (61). Biochemical lesions proposed to contribute to the teratogenicity of Zn deficiency include abnormal nucleic acid and protein synthesis, alterations in the differential rates of cellular growth needed for normal morphogenesis, impaired tubulin polymerization with resultant reductions in cell motility and division, chromosomal defects, excessive cell death in areas adjacent to regions where programmed cell death occurs, and excessive peroxidation of cell membrane lipids (61). Thus, the mechanisms leading to Zn-deficiency-associated abnormal development are probably multifactorial. In addition to its impact on the fetus, Zn deficiency during late gestation can result in parturition difficulties with delayed deliveries and excessive bleeding (61, 66). In Zn-deficient rats, the delay in delivery has been linked to an abnormally low normal activity of ovarian 20- α -hydroxysteroid dehydrogenase, an enzyme that catalyzes the degradation of progesterone, which is inhibitory to parturition (67). The subcellular distribution and metabolism of uterine estrogen-receptor complexes are altered in Zn-deficient rats. A poor response to estrogen priming may contribute to the delivery problems associated with Zn deficiency.

The influence of Zn on the reproductive process is not restricted to females. In Zn-deficient males, the testes are reduced in size with atrophy of the seminiferous epithelium. The resulting testicular dysfunction impairs spermatogenesis and the output of testosterone. It is thought that the primary defect underlying the effect of Zn deficiency on testicular function may involve impaired Leydig cell function, with a

secondary effect on the pituitary-gonadal axis (68).

Zn can induce as well as block apoptosis, or programmed cell death. High concentrations (500–1000 μM) block DNA fragmentation, whereas lower concentrations (80–200 μM) induce cell death (69). Although many mechanisms are likely to be involved, one pathway entails inhibiting the death signal by blocking binding of steroids to the glucocorticoid receptor. The significance of these effects is clouded by the fact that Zn does not provide long-term protection to cell survival.

A consequence of Zn deficiency can be marked alterations in several components of the immune system. Immune defects associated with Zn deficiency include reduced thymic hormone production and activity; impaired function of lymphocytes, natural killer cells, and neutrophils; impaired antibody-dependent cell-mediated cytotoxicity; altered immunologic ontogeny; and defective lymphokine production (65). As discussed above, Zn-deficient animals can be characterized by thymic atrophy and small spleens. Significantly, Zn deficiency reduces the mass of lymphoid tissues more than that of other tissues. The particular sensitivity of lymphoid tissue to Zn deficiency has not been clarified (65).

Impaired glucose tolerance has been reported by some investigators to occur in Zn deficiency. The impairment has been related to reduced insulin output, increased insulin degradation by glutathione insulin transhydrogenase, and increased peripheral insulin resistance (2).

Lipid metabolism is also affected by Zn deficiency. Reduced glucose use in Zn deficiency has been linked to an overall increased rate of lipid oxidation. Zn-deficient animals can be characterized by hypocholesterolemia (primarily caused by reduction in high-density-lipoprotein (HDL) cholesterol) and by an HDL fraction that is enriched in apo-E and low in apo-C content (2, 70). Moderate Zn deficiency in pregnant rats increased the use of linoleate for de novo lipogenesis and impaired whole body accumulation of polyunsaturated fatty acids (71). These changes in fatty acid metabolism explain why many of the signs of Zn deficiency are similar to those of essential fatty acid deficiency (72).

In addition to its putative effects on insulin and testosterone, the metabolism of several other hormones has been reported to be influenced by Zn. The synthesis, release, and binding of growth hormone, somatomedin, prolactin, thyroid hormone, corticosterone, luteinizing hormone–releasing hormone (LHRH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH) have all been reported to be affected by Zn deficiency, although these findings are not universal (2, 67).

ZINC DEFICIENCY IN HUMANS

Mild Deficiency

Although severe Zn deficiency in humans is well documented, whether a physiologically significant mild Zn deficiency exists in humans is controversial. It is inherently unlikely,

however, that human Zn deficiency is an “all-or-none” phenomenon. The concept of a graded response to progressive degrees of deficiency is supported by animal studies; for example, when weanling rats were fed graded amounts of dietary Zn ranging from 1 to 12 ppm, the 12-ppm diet supported normal growth, but impairment was increasingly severe with more severe dietary Zn restriction (73).

Demonstrating mild Zn deficiency is not as straightforward in humans as in experimental animals. If it is accepted that impaired growth velocity is the primary clinical feature of mild Zn deficiency, several studies in Denver, Colorado, provide convincing evidence (74, 75). Apparently healthy children with low height-for-age percentiles were selected for a double-blind, controlled trial of Zn supplementation. The treatment group received a small (0.08-mmol, 5-mg) Zn supplement. In all studies of these growth-retarded children, Zn supplementation increased the mean height increment and height-for-age percentile increment compared with those of placebo controls. Boys frequently had a greater response than girls. In one study, supplemental Zn improved the calculated energy and protein intake (76). Concurrently with these studies, Zn supplementation in children who were unselected with respect to growth percentiles did not increase their growth velocity (75).

Mild Zn deficiency may also affect the quality of growth. Zn supplementation of malnourished infants reduced the energy cost of growth, which was probably related to improved synthesis of lean body tissue (77). Idiopathic dysgeusia was improved in a single-blind trial of Zn therapy, but a subsequent double-blind trial failed to confirm this observation (78). Other functions that have responded to Zn supplementation include immune function in the elderly (79), oligospermia (80), and complications of pregnancy, such as pregnancy-induced hypertension, prematurity, prolonged labor, and intrapartum hemorrhage (81). However, these responses were generally to pharmacologic quantities of Zn and thus do not necessarily indicate a Zn deficiency. The response of these conditions to physiologic Zn doses (0.15–0.23 mmol/day, 10–15 mg/day) needs to be tested using double-blind, controlled designs.

Severe Deficiency

Severe Zn deficiency has been seen in patients with acrodermatitis enteropathica (AE), in patients fed total parenteral nutrition (TPN) solutions lacking Zn, and in experimental human Zn depletion. The clinical features of severe Zn deficiency in the three situations are similar. The symptoms of Zn deficiency in an individual depends on the severity of the deficiency and other factors.

Clinical Manifestations

The primary clinical manifestations of severe Zn deficiency are listed in [Table 11.3](#). In severe deficiencies, growth ceases, whereas a less severe deficiency state causes decreased growth velocity. If growth retardation is mild, the response to Zn supplementation is modest. Persons suffering from more severe reduction in growth velocity, as those with AE or Middle Eastern adolescents consuming high-phytate diets, show a greater response to Zn supplementation. The original observations of human Zn deficiency in Persian and Egyptian dwarfs included hypogonadism and delayed sexual

maturation (3). The effect of severe Zn deficiency on hypogonadism among patients with AE is unclear (82).

Growth retardation
Delayed sexual maturation and impotence
Hypogonadism and hypospermia
Alopecia
Acroecificial skin lesions
Other epithelial lesions, including glossitis, alopecia, and nail dystrophy
Immune deficiencies
Behavioral disturbances, including impaired hedonic tone
Night blindness
Impaired taste (hypogeusia)
Delayed healing of wounds, burns, and decubitus ulcers
Impaired appetite and food intake
Eye lesions, including photophobia and lack of dark adaptation

^aFeatures depend on the severity of the deficiency and other factors.

Table 11.3 Clinical Manifestations of Severe Human Zinc Deficiency^a

The skin lesions of severe Zn deficiency have a characteristic distribution, primarily at the extremities and adjacent to the body orifices. Lesions may occur elsewhere and can become generalized. Often the rashes are erythematous, vesiculobullous, and pustular (2, 82). Changes in the hair usually become apparent after the onset of dermatitis. The hair may become hypopigmented and acquire a reddish hue (82). Patchy loss of hair is common.

Diarrhea is a complication in AE and in patients receiving TPN. The mechanism(s) for diarrhea in Zn deficiency is unknown. Decreased mucosal disaccharidase activity and related carbohydrate malabsorption have been suggested (83), but the diarrhea seen in patients receiving TPN who are not ingesting meals clearly has a different origin. Other possible explanations include increased synthesis of prostaglandins, especially PGE₂, which can cause diarrhea, and a defect in enterocyte transport function.

Consistent with experimental animal data, Zn deficiency in humans alters several aspects of immune function. Thymic hypoplasia has been seen in patients with AE and in individuals suffering from protein-energy malnutrition. Impaired cutaneous responses to mitogens and in vitro lymphoblast responses have been noted, as have defects in monocyte and neutrophil chemotaxis (65).

The cornea, the tissue with the highest Zn concentration in the body, is affected by Zn deficiency. Corneal edema occurs and may progress to corneal clouding and opacities (82). Healing of more advanced lesions may leave residual scarring, but minor lesions may heal completely. A mild dry conjunctivitis may also occur and may progress to bilateral xerosis and keratomalacia. Vitamin A is ineffective in the treatment of these

disorders.

Behavioral changes can occur with Zn deficiency. Irritability, lethargy, and depression are common in children with AE (82). Administration of large doses of histidine to induce zincuria caused anorexia and dysfunction of smell and taste in adult subjects (78). The subjects then became irritable, depressed, easy to anger, lethargic, and sleepy. Some developed a fine tremor, ataxic gait, and slurred speech. Supplementation with 0.8 mmol (50 mg) of Zn quickly reversed these symptoms.

Biochemical Correlates

Although information on the biochemical functions of Zn is extensive, the biochemical correlates of the clinical features of Zn deficiency have not been determined satisfactorily. Disturbances in nucleic acid metabolism and protein synthesis may account for some of the features of Zn deficiency in humans. Elevated blood ammonia and reductions in circulating proteins with short half-lives have been reported in human Zn deficiency (84). It has been suggested that a relative excess of dietary nitrogen in subjects fed a Zn-deficient diet can cause anorexia (77).

As in experimental animal models, some of the effects of Zn deficiency in humans appear to be mediated through effects on hormonal function. Hormones reported to be affected by Zn status in humans include growth hormone, the gonadotropins and sex hormones, prolactin, thyroid hormones, corticosteroids, insulin, and the hormonelike substances, prostaglandins.

CONDITIONS PREDISPOSING TO ZINC DEPLETION

Mild-to-marginal states of Zn deficiency may go undetected because those individuals do not display the specific clinical features of Zn depletion. Individuals at risk include those with decreased absorption, increased losses, or increased needs caused by growth or reproduction, particularly if their dietary Zn intake is also low.

Primary and Diet-Induced Zinc Deficiency

The occurrence of isolated Zn deficiency in normal, healthy free-living adults has not been, and is unlikely to be, documented because of the remarkable ability of individuals to reduce Zn losses and to reestablish homeostasis when the dietary supply is low (85). However, if Zn need is increased, as in growing infants and children or in pregnant and lactating women, the potential for Zn deficiency may be increased. This is especially true if the dietary supply is inadequate. Although the increase in metabolic requirements for Zn during pregnancy appear to be modest (about 1.5 mmol, 100 mg) (24), certain complications of pregnancy have been linked to poor Zn status, as discussed below. Moreover, physiologic Zn supplements have improved growth velocity rates in growth-retarded infants who appeared otherwise healthy (86). A reliable, sensitive laboratory index of Zn deficiency is needed before the incidence of Zn deficiency in these vulnerable groups can be documented.

Patients receiving TPN have developed the clinical features of Zn deficiency. In many cases, patients who became Zn deficient had conditions that predisposed them to the problem, such as diarrhea, inflammatory bowel disease, or other conditions that increased Zn loss. Patients receiving TPN often have increased urinary Zn loss because of release of Zn from catabolized tissues (87) or because of increased levels of glycosylated amino acid–Zn complexes (88).

Conditions of semistarvation, such as anorexia and protein-energy malnutrition (PEM), may cause Zn deficiency. Insufficient intake combined with poor digestibility and absorbability caused by the effects of malnutrition on gastrointestinal function are precipitating factors. Poor bioavailability of Zn in the food supply, due to high levels of dietary phytate, may contribute to Zn deficiency with marginal diets. Other contributory factors include dermal loss caused by excessive sweating and Zn loss through chronic gastrointestinal hemorrhage among populations in developing countries. Because of high phytate intake, vegetarianism is considered a risk factor for Zn deficiency among individuals subsisting on cereal-based diets.

Inborn Errors of Zinc Metabolism: Acrodermatitis Enteropathica

AE is a rare, inherited, autosomal recessive disease affecting both sexes (82). The basic defect in AE is thought to be impaired intestinal uptake and transfer of Zn, although it has been hypothesized that poor absorption is secondary to impaired cellular processing (89). In young patients with AE, intestinal Zn absorption was reduced, as assessed by whole-body retention of an orally administered dose of ⁶⁵Zn (90). The basic defect in Zn absorption is unknown, but the mucosal mechanism for Zn uptake and transfer at customary luminal concentrations seems to be defective (82). The beneficial therapeutic effect of large oral doses of Zn may result from net uptake and transfer of Zn by a less specific mechanism.

Diagnosis of AE is made from the clinical features. Hyperpigmented skin lesions over the acral surfaces of elbows and knees, often also involving the face, buttocks, and other surfaces, are characteristic (76). The rash usually first occurs in early infancy, but onset of the disease usually does not occur until solid foods are started or breast-feeding is completely discontinued. Secondary infection is common. Intestinal disturbances and growth failure are usually present. Psychologic and behavioral abnormalities are prominent, with irritability, lethargy, and depression occurring even during relatively mild stages of the disease (91). Plasma and serum Zn concentrations are typically below 6 mmol/L (40 mg/dL).

Oral Zn therapy causes a rapid and complete remission of the clinical and biochemical symptoms of AE and must be continued indefinitely to sustain remission and normal Zn status. The quantity of Zn required is 0.5 to 0.7 mmol/day (30 to 45 mg/day); smaller quantities may be used initially in the very young child or infant (91).

Another syndrome of altered Zn metabolism is found in lactating women. This condition results from inability of the mother's mammary gland to secrete normal quantities of Zn into her milk. Apart from low milk Zn concentrations, maternal Zn status is normal. Zn

supplementation does not increase milk Zn concentrations (91). Infants who are entirely breast-fed by these mothers do not develop clinical features of severe Zn deficiency unless they were born prematurely. Temporary management with Zn supplements is required until breast-feeding is supplemented with other foods.

Secondary Acquired Zinc Deficiency

The major pathophysiologic abnormalities contributing to secondary Zn deficiency are Zn malabsorption and excessive urinary Zn loss. Any disease or condition altering the integrity of the mucosa cell can affect the efficiency of Zn absorption. Chelating agents and drugs can exacerbate the impact of a disease state on Zn metabolism. Penicillamine in the treatment of Wilson's disease and diethylenetriamine pentaacetate (DTPA) in the treatment of Fe overload in thalassemia patients have caused severe Zn deficiency (82). Moreover, anticonvulsant drugs, especially sodium valproate, may precipitate Zn deficiency. The antituberculous drug ethambutol has chelating properties and has been shown to increase Zn turnover rates in rats (92).

EVALUATION OF ZINC STATUS

Despite our knowledge of the biology of Zn and of factors promoting or predisposing persons to Zn depletion, assessment of the incidence of Zn deficiency in humans is impaired by the lack of sensitive, specific indicators of poor Zn nutriture. Approaches to assessing nutritional status in the laboratory involve measurement of static indices (e.g., concentration in tissues or fluids of Zn or surrogates for Zn, such as metal-containing enzymes and proteins) or functional indices (Zn-dependent physiologic functions). The problem is that many measurements do not accurately reflect nutritionally available Zn pool sizes.

Static Indices

Plasma/serum Zn concentration has been denigrated as a measure of Zn status because it does not fall with changes in Zn intake unless the dietary Zn levels are so low that homeostasis cannot be reestablished (59). Plasma Zn represents about 2% of a labile, or nutritionally available, total-body Zn pool that exchanges with isotopic Zn tracers in 24 hours (59). Because plasma Zn is the source of Zn for all tissues, plasma concentrations are maintained longer than other components of this labile body Zn pool. Plasma Zn kinetics or turnover tends to rise with Zn depletion. Thus, the rate of Zn turnover in the plasma compartment or in the total labile pool of the body might indicate Zn status (42, 93).

Metabolic states other than a change in Zn status alter plasma Zn concentrations. Stress, infection, food intake, short-term fasting, and the hormonal state all appear to influence the distribution of labile Zn among the tissues and thereby alter the amount in the plasma (94). Thus, plasma Zn can only be useful for assessment of Zn status if the effect of poor Zn nutriture can be differentiated from these other metabolic conditions. Erythrocyte metallothionein was suggested as a useful marker of tissue Zn distribution

(95), but analytic difficulties prevent widespread use.

Other static measures of Zn status hold little promise. Erythrocyte Zn is little affected by Zn deficiency and is not a sensitive index. The response of leukocyte Zn to changes in Zn status is not consistent among laboratories, and the assay is laborious. Hair Zn levels may be depressed in mild Zn-deficiency states, but they may remain normal in severe states when hair growth is arrested. Urinary excretion rates are diminished in severe deficiency states, but this measurement is not sensitive to less dramatic changes and is confounded by many clinical disorders that increase urinary Zn losses.

Functional Indices

Several different in vitro and in vivo tests of physiologic function have been used to evaluate Zn status. Zn is a constituent of over 200 metalloenzymes and other proteins involved in immune function, antioxidant protection, and membrane stabilization. Zn-dependent enzymes proposed as biomarkers of status include serum or erythrocyte alkaline phosphatase (96), serum superoxide dismutase (97), and lymphocyte 5' nucleotidase. The validity of these measurements as markers of Zn status needs further study. Many of the other functional tests are not routine and lack specificity. Dark adaptation requires a high degree of the subject's cooperation and time. Impaired taste acuity, immune function, and glucose tolerance tests lack specificity and must be combined with other biochemical indices of Zn status.

REQUIREMENTS AND RECOMMENDED INTAKES

Human nutrient requirements may be based on one of the following criteria: (a) the lowest intake required to support balance; (b) the amount of absorbed zinc required to replace endogenous losses; or (c) the intake needed to maintain normal function. The amount of absorbed zinc that replaces endogenous losses, or the factorial approach, is generally used. This approach is used because a good functional test for Zn status has not been identified, and balance can be achieved over a wide range of intakes, from 0.05 mmol (3 mg) to above 0.46 mmol (30 mg) (85).

The 1989 RDA (98) and the 1996 World Health Organization (WHO) (7) standards for Zn intake are shown in Table 11.4. The WHO Expert Committee set standards for high-, moderate-, and low-availability diets (7); the standards for high- and moderate-availability diets are shown in Table 11.4. In a highly available diet about 50% of the zinc is assumed to be available. This diet is composed of refined cereal fiber and phytate, with adequate protein principally from nonvegetable sources such as meat and fish. In a moderately available diet about 30% of the zinc is available, and it is supplied either by a mixed diet containing fish or animal protein or a lacto-ovo, ovovegetarian, or vegan diet not based principally on unrefined cereal grains. Only 15% of the zinc is available in a diet of low zinc availability; the diet is high in unrefined, unfermented, and ungerminated cereal grain.

Table 11.4 Recommended Zinc Intakes (mg/day)

Although typical U.S. diets are either of high or moderate availability for zinc, the RDAs are always greater than the WHO standards. In some cases a three-fold difference exists between the two sets of recommendations. The WHO Expert Committee cautioned that their standards should be considered provisional until further experimental or epidemiologic testing is completed.

HIGH-RISK CLINICAL SITUATIONS

Pregnancy

Zn is essential for normal growth and development. The requirement for Zn increases during pregnancy. Adverse effects of Zn deficiency in experimental animals are discussed above in this chapter. Studies of rhesus monkeys provide information about the effect of a marginal Zn deficiency on pregnancy outcome in a primate model (99, 100).

The total incremental Zn need for pregnancy is modest in humans, about 1.5 mmol (100 mg), or an additional daily demand of 9 μmol (0.6 mg) of Zn during late gestation (24). Women may increase their Zn intake a modest amount if total food intake increases. The RDA is 0.23 mmol (15 mg) Zn per day; the WHO Expert Committee recommends 13.3 mg/day from a moderately available diet. The average daily intake is between 0.15 and 23 mmol (10–15 mg). If the increase in Zn intake is small, adequate delivery of Zn to the developing fetus must be achieved by adjustments in Zn use. No significant increase in Zn absorption has been reported in human pregnancies (34). Endogenous fecal Zn loss has not been measured. Urinary Zn loss increases in late pregnancy after a small decline in the first trimester. By late pregnancy, the concentration of circulating Zn in the plasma is about 15 to 35% lower in pregnant women than in nonpregnant women (24). The decline occurs as early as the first gestational month, stabilizes in the second trimester, and then declines further in the third trimester. The fall in plasma Zn may be attributed to expansion of the plasma volume, fetal uptake, and hormonal adjustments in the distribution of Zn from the circulation to other tissues, such as the

liver.

In 1976, Jameson observed that low maternal serum Zn was associated with congenital malformations, fetal dysmaturity, prematurity, and maternal complications in otherwise healthy women (101). That report stimulated further research to examine the relationship between Zn status and pregnancy outcome. Several detailed reviews of this topic are available (24, 61, 66, 81, 102). Human studies indicate that some pregnant women who deliver infants with congenital abnormalities used Zn differently than women who delivered healthy infants. Several groups reported that mothers of infants with congenital anomalies had lower plasma Zn concentrations than other mothers (61). Zn deficiency has been implicated specifically in development of two neural tube defects, anencephaly and spina bifida. Association of plasma Zn concentrations with congenital malformations does not imply causation. Perhaps Zn status simply varies with and reflects the real, but unknown, causal factor(s), or perhaps the association between Zn and congenital abnormalities reflects poor or inefficient Zn use. Double-blind supplementation trials starting prior to conception and continuing through embryogenesis are needed to identify the causal relationship between zinc and congenital anomalies in humans.

Poor maternal Zn status may also cause intrauterine growth retardation. Results are available from 41 studies of the association between infant birth weight and maternal zinc nutriture from various parts of the world (81). Of these 41 studies, 22 claimed maternal zinc nutriture influenced birth weight; 19 did not. Zinc supplementation trials also provide mixed results. Nine supplementation trials have been completed; five provided evidence of a positive relationship. A recent double-blind study of 580 African American women in Alabama provides convincing evidence that maternal zinc nutriture may limit fetal growth and development in some populations. Administration of 25 mg of supplemental zinc from midpregnancy to term increased birth weight by 126 g and head circumference by 0.4 cm above that of infants born to mothers receiving placebo (103). This study is unique in that only mothers with plasma zinc concentrations below the 50th percentile were chosen for study. Possibly, zinc supplementation is only effective among populations with relatively low plasma zinc concentrations early in pregnancy.

Although many investigators have evaluated the relationship between zinc nutriture and infant birth weight, few have studied its association with gestational age at birth. In an epidemiologic study of 818 pregnant women, Scholl et al. found that women with zinc intakes in the lowest quartile (6 mg/day) had about a twofold increase in the risk of preterm delivery after controlling for calories and other confounding variables (104). Adequate zinc nutriture is important for immune function; recent studies suggest that upper genital tract infection is responsible for early-preterm delivery (81).

Poor Zn status also is associated with increased maternal morbidity including preeclampsia or pregnancy-induced hypertension, prolonged labor, and atonic bleeding (81). Results are not consistent, however.

Old Age

The mean intake of Zn by individuals over 65 years of age in the United States is less

than two-thirds of the RDA for Zn (105). Analysis of the Second National Health and Nutrition Examination Survey (NHANES II) showed that white men and women over 65 years of age consumed 72 and 81%, respectively, of the Zn RDA; black men and women consumed 61 and 59%, respectively. The black individuals tended to report diets with lower Zn densities. Approximately two-thirds of the Zn was supplied by animal food sources for all groups.

Several factors may increase the risk of Zn deficiency in the elderly: reduced capacity to absorb Zn (106), increased likelihood of disease states that alter Zn utilization, use of drugs such as diuretics that increase urinary Zn excretion, and consumption of fiber, calcium, or Fe supplements that may alter Zn bioavailability.

Assessment of Zn nutriture in the elderly is confounded by the effects of age itself on both functional and static indicators of status. Elderly subjects tend to have lower plasma Zn levels than younger adults (107). Analysis of the results of the NHANES-II survey showed that serum Zn levels of 65- to 74-year-old individuals were lower than those of young adults, and the difference was more obvious among men than women (7). Generally, the average concentration of Zn in hair samples from elderly subjects is lower than that in hair samples from younger adults and adolescents. Nonetheless, only a few elderly subjects had less than 70 µg of Zn/g hair, a concentration often used to define low hair Zn levels (108).

Several clinical conditions associated with poor Zn status also are problems commonly reported by the elderly, such as slow wound healing, anorexia, dermatitis, depressed taste acuity, and impaired immune function (108). Double-blind or single-blind trials of Zn supplementation failed to improve these functions. Further evaluation of the supplements is warranted. If Zn absorption is compromised in the elderly, administration of a larger Zn supplement together with a Zn-binding ligand such as histidine or methionine may be beneficial.

Diarrhea and Other Malabsorptive Disorders

Diseases of the gastrointestinal tract are frequently complicated by Zn deficiency. Breakdown of the integrity of the gastrointestinal tract reduces normal absorption of dietary Zn and disrupts the enteropancreatic Zn circulation. Recent studies show that supplemental Zn reduces the duration of acute, severe diarrhea in children by 9 to 23%; this rose to 22 to 33% in children with lower initial Zn status (109). Persistent diarrhea is more prevalent than severe diarrhea and causes higher rates of morbidity and mortality. Supplemental Zn reduced the incidence of persistent diarrhea by one-half in children over 1 year of age; there was no effect on younger children (110). Zn supplementation could affect the incidence and duration of diarrheal disorders in children by improving immune status or by correcting pathologic changes in gut integrity.

There is evidence that patients with Crohn's disease, sprue, or short bowel syndrome may develop Zn deficiency. Crohn's disease, or regional enteritis, is a type of inflammatory bowel disease. Many investigators have reported low serum Zn concentrations in patients with Crohn's disease, and it is not unusual to find depressed urinary Zn excretion (83). Other clinical features of Zn deficiency reported in these

patients include growth retardation, abnormal taste acuity, delayed sexual maturation, skin lesions, and retinal dysfunction (111, 112 and 113). Zn absorption is probably impaired in these patients. For example, 3 mmol (200 mg) supplemental Zn/day restored plasma Zn concentrations in patients with Crohn's disease, but 0.9 mmol (60 mg) did not (114). Also, patients with Crohn's disease had a 35% reduction in the area under the serum concentration curve after a large oral dose, compared with healthy controls (112). Large gastrointestinal losses may result from the diarrhea common in these patients (115), and urinary losses may be elevated because of catabolism of skeletal muscle. Plasma Zn concentrations of these patients may be low because of the release of the cytokine interleukin-1.

Decreased plasma Zn levels have been reported in patients with celiac sprue (116). The area under the serum concentration curve for the Zn tolerance test is depressed in untreated sprue patients and improves when a gluten-free diet is fed, indicating that Zn absorption is impaired.

Patients with short bowel syndrome have a double defect in Zn absorption. First, the absorptive surface of the small bowel is decreased and the transit time is increased. Second, intestinal reabsorption of Zn from pancreatic juice is impaired if much of the distal bowel is removed (83). Patients with short bowel syndrome have developed acrodermatitis, abnormal protein metabolism, and impaired immune function, all of which were corrected with Zn supplementation.

Patients who have had intestinal bypass surgery frequently have depressed serum Zn levels (83). The capacity to absorb Zn is probably reduced, as these patients have a two-thirds reduction in the area under the serum Zn concentration curve after an oral load, compared with healthy controls (117). Poor Zn status may contribute to the high incidence of opportunistic infections following jejunioileal bypass surgery.

Alcoholism

Patients with alcoholic cirrhosis often have hyperzincuria, hypozincemia, and lower liver Zn concentrations than controls or patients without cirrhosis (118). Potential mechanisms underlying the hyperzincuria include shifting Zn in plasma to ligands that are easily excreted and that inhibit tubular reabsorption of Zn (118, 119). Although hypozincemia is most prevalent (70%) in alcoholics with liver disease (118), it is also observed in some alcoholics (30–50%), with no evident liver disease. Consistent with human data, long-term alcohol feeding resulted in lower liver Zn concentrations in monkeys, rats, and pigs (118, 120).

Alcoholism-associated changes in Zn metabolism may well be functionally significant. Several studies have linked Zn deficiency and altered vitamin A metabolism in alcoholism (118). As discussed above, Zn deficiency can result in reduced serum retinol concentrations and elevated liver vitamin A stores, presumably because of reduced synthesis of retinol-binding protein in the liver. Zn deficiency can also result in low retinol-alcohol dehydrogenase activity in the retina. Zn administration to alcoholic patients can improve dark adaptation, a retinol dehydrogenase-dependent function (119). Zn supplementation of patients with alcoholic cirrhosis has been reported to

improve their immune responsivity and reduce hepatic lipid peroxidation (119, 121). Zn supplementation of alcoholics with low plasma Zn levels and hypogonadism can result in a return of normal gonadal function (122).

Because the teratogenic expression of Zn deficiency is similar to that of fetal alcohol syndrome (FAS), one hypothesis is that FAS develops by an alcohol-induced embryonic Zn deficiency. Consistent with this suggestion, plasma and umbilical cord blood Zn concentrations are often lower in pregnant women who drink than in controls (123). Although maternal alcohol feeding in rats is associated with reduced placental Zn transfer in the second trimester and with lower than normal fetal liver Zn concentrations, dietary Zn supplementation has not been effective in reducing FAS expression in animal models (124). A direct role for altered Zn metabolism in development of FAS in humans has not been established. Nonetheless, given the negative consequences associated with inadequate Zn delivery to the embryo/fetus, close monitoring of the Zn status of pregnant alcoholic women is prudent.

Diabetes

Altered Zn metabolism occurs in both diabetic humans and experimental animals. Adult rats with genetically or chemically induced diabetes are characterized by Zn accumulation in the liver and kidney and by hyperzincuria (125, 126). Both type 1 and type 2 diabetic patients often exhibit hyperzincuria, which increases with the severity of the diabetes (127). Hyperzincuria may cause a conditioned Zn deficiency in some individuals, but clinical symptoms of Zn depletion are not common among diabetics (128). Hypozincemia, however, is common among diabetics (127). Zn supplementation of diabetic patients has been reported to improve their immune function, but supplementation also caused an increase in hemoglobin A_{1c}, a marker of abnormal glucose tolerance (65, 128, 129). The influence of Zn supplementation on glucose metabolism in diabetic patients needs further study. In the rat, diabetes during pregnancy can result in fetal Zn depletion and poor reproductive performance (126). Whether altered Zn metabolism is a factor underlying the increased risk of birth defects associated with diabetes in humans remains to be established. The mechanisms underlying altered Zn metabolism in the diabetic have not been firmly identified.

Patients with Chronic Infections and/or Trauma

As mentioned above, tissue-specific hormonal induction of metallothionein can occur during periods of acute disease (infection), stress, and inflammation. One consequence of metallothionein induction is a redistribution of body Zn, and plasma Zn concentrations are often markedly reduced (33). The long-term implications of low plasma Zn concentrations secondary to recurring acute-phase reactions have not been well defined, although potentially they could lead to Zn deficiency in select extrahepatic tissues. Although it is tempting to suggest that these individuals should be provided with Zn supplements, at present it is not clear whether the reduction in plasma Zn may actually represent a positive response of the patient to some insults. This issue clearly needs clarification.

AIDS

Because patients with acquired immunodeficiency syndrome (AIDS) often exhibit immunologic abnormalities similar to those associated with Zn deficiency, Zn deficiency has been postulated to underlie the development of some of the disorders associated with AIDS. Although low plasma Zn concentrations have been reported in a number of AIDS patients, individuals with AIDS-related complex (ARC) and asymptomatic human immunodeficiency virus (HIV)-positive subjects have been reported to have normal plasma Zn concentrations (130). Thus, there is no clinical evidence that Zn deficiency is a common contributory factor of HIV infectivity or its clinical expression. In vitro studies show, however, that Zn ions inhibit HIV-1 protease (131). In the late stages of AIDS, excessive Zn loss from diarrhea, as well as from cytokine-directed redistribution of the element, may be expected to further lower plasma Zn concentrations.

ZINC TOXICITY

Acute Toxicity

Although rare, incidences of acute Zn toxicity in humans resulting from high intakes of Zn have been reported. Isolated outbreaks of Zn toxicity have occurred as a result of consumption of foods and beverages contaminated with Zn released from galvanized containers. Typical signs of acute Zn toxicosis include epigastric pain, diarrhea, nausea, and vomiting (106, 107). Doses above 200 mg/day are typically emetic. A fatal outcome occurred in a woman who was inadvertently given 1.5 g of Zn intravenously over a 3-day period (132). Metal fume fever has been reported following inhalation of Zn oxide fumes. Signs develop within 8 hours and include hyperpnea, profuse sweating, and general weakness (133). Signs of toxicity disappear 12 to 24 hours after the individual is removed from the Zn-contaminated environment.

Chronic Toxicity

The major consequence of long-term ingestion of excessive Zn supplements is induction of a secondary Cu deficiency caused by competition between these elements for intestinal absorption. Levels of Zn supplements as low as 50 mg/day have influenced copper status, as indicated by a decline in erythrocyte Cu, Zn-superoxide dismutase (7). Long-term consumption of Zn supplements in excess of 150 mg/day has also been reported to result in low serum HDL levels, gastric erosion, and depressed immune function (134).

The U.S. Environmental Protection Agency has established an oral reference dose (RfD) for Zn of 0.3 mg/kg/day (135). An RfD for a substance represents an estimate of a daily exposure to the human population that is likely to be without appreciable risk of deleterious effects over a lifetime. Increasing the level of intake and frequency of exposure above the RfD increases the probability of seeing adverse effects. Although the RfD for Zn is below the RDA for all age groups below 15 years of age, no health

hazards are known to result from ingesting the RDA for Zn at any age.

HISTORICAL INTRODUCTION

Copper has been used therapeutically since at least 400 BC, when Hippocrates prescribed copper compounds for pulmonary and other diseases (1). The use of copper compounds in the treatment of diseases reached its peak in the 19th century and subsequently declined when the treatments were not successful.

Copper was identified as a normal constituent of blood and its toxicity was described in the late 19th century. By 1900, an anemia that could not be prevented by iron

supplements had been observed in animals kept on a whole-milk diet. In 1928, Hart reported that this anemia in rats responded to iron only when copper supplements were also given (2). Experiments in several animal species produced similar results and suggested that copper-deficiency anemia occurs in all species. Detailed reviews of the early history of copper have been published (1, 3).

Human disease was first linked to copper metabolism shortly after Wilson's disease was described in 1912 and long before the condition was recognized as an inborn error of metabolism in 1953 (1). As early as 1930, a relationship between anemia in humans and copper deficiency was suspected, but copper supplements only improved hemoglobin synthesis in some instances, so the hypothesis was not well accepted. Conclusive evidence of copper deficiency in humans was not reported until 1964 (4). Menkes' disease, another genetic disorder, was described in 1962 and recognized as a disorder of copper absorption in 1972. Since about 1950, an increasing number of diseases that are not specifically disorders of copper metabolism have been associated with altered, usually increased, levels of copper in blood or other tissues.

An official dietary copper recommendation, an estimated safe and adequate daily dietary intake, was first introduced in 1979 and modified in 1989 (3).

CHEMISTRY

Copper, a transition metal with an atomic mass of 63.54 daltons (Da), has two stable isotopes, ^{63}Cu and ^{65}Cu , with natural abundances of 69.2 and 30.8%, respectively. There are seven radioisotopes of copper, most with half-lives of seconds or minutes. The two with the longest half-lives, ^{67}Cu (61.9 h) and ^{64}Cu (12.9 h), and either the stable isotopes ^{65}Cu or ^{63}Cu are used as tracers of copper metabolism.

Copper has two oxidation states, Cu^+ and Cu^{2+} , and may shift back and forth between the two during enzyme action. It may occur rarely as Cu^{3+} (6). Only minute quantities of Cu^+ ions can exist in solution; thus Cu^+ compounds are highly insoluble and strongly complexed (7). Copper is most often found in biologic systems as Cu^{2+} . At least three types of bound Cu^{2+} , each with distinctly different physicochemical properties, are found in copper-containing enzymes. Type 1 is a deep blue protein; many copper-containing oxidases are of this type. Type 2, characteristic of many multicopper oxidases, is not blue but is detectable by electron paramagnetic resonance (EPR). Type 3, neither blue nor detectable by EPR, is also found in a number of enzymes. A single protein may contain one or more types of copper (6, 8).

DIETARY CONSIDERATIONS

Estimates of dietary intake by Americans prior to 1970 were considerably higher than current estimates. This reflects marked improvements in analytical techniques for measuring copper and awareness of the importance of avoiding copper contamination of analytical samples. The usual diet was thought to contain 2 to 5 mg (30 to 80 μmol) of copper, but studies, including one study of 132 diet composites, now show that few diets contain over 2 mg (30 μmol) per day (9, 10). As with all nutrients, copper intake can

vary widely, depending on food choices. Diets in countries where more whole-grain products, legumes, and organ meats are eaten contain more copper.

Food Sources

The richest sources of dietary copper contain from 0.3 to over 2 mg/100 g (50 to >300 nmol/g). These include shellfish, nuts, seeds (including cocoa powder), legumes, the bran and germ portions of grains, liver, and organ meats. Most grain products; most products containing chocolate, fruits and vegetables, such as dried fruits, mushrooms, tomatoes, bananas, grapes, and potatoes; and most meats have intermediate amounts of copper, from 0.1 to 0.3 mg/100 g (20–50 nmol/g). Other fruits and vegetables, chicken, many fish, and dairy products contain relatively low concentrations (<0.1 mg/100 g [20 nmol/g]) of copper (11). Cow's milk is particularly low in copper. The major sources of copper in the US diet are meat, nuts, beans/peas, and main dishes (12).

Because information on the copper content of foods is incomplete and databases often contain missing values, copper intake is underestimated unless missing values are replaced with imputed values (9). A table of the copper content of foods compiled when much of the available data were from the 1930s and 1940s reported consistently higher copper concentrations (13) than tables that exclude pre-1960 data, suggesting that early values are too high. However, a critical evaluation of the reliability of post-1960 published values for the copper content of foods demonstrated that improvement is still needed (11). The copper content of foods can vary because of a combination of factors, including analytical method, sampling procedure, recipe, cooking method, and part of the country from which the foods are collected. Careful analysis of the copper content of high-copper foods from the FDA total diet study varied by an average CV (coefficient of variation) of 24%, which is in the middle of average variation of other minerals in the same foods (9, 12).

Bioavailability

Estimates of the bioavailability of dietary copper to humans are usually based on absorption (14). The amount of copper in the diet appears to influence bioavailability more than the composition of the diet or specific dietary components unless the levels are extremely high or low or diet composition is unusual. Absorption is discussed under "Metabolism."

Interactions

Interactions with Other Nutrients

Nutrients known to affect the bioavailability of copper when included in the diet of humans or animals in extreme amounts are iron, zinc, molybdenum, ascorbic acid, and carbohydrates. In addition, high or low levels of dietary copper may affect metabolism of some of these nutrients. Interactions between dietary copper and other nutrients or

dietary components have been reviewed ([15](#), [16](#)).

Iron. Copper and iron may interact in a number of ways. As discussed under “Copper Deficiency,” copper deficiency alters iron metabolism. Anemia, often accompanied by accumulation of iron in the liver, has been reported in all species studied, including humans. An excess of copper has produced anemia in the pig. Excessive iron in the form of inorganic iron salts decreased copper status and, in time, resulted in clinical signs of copper deficiency in several animal species ([16](#)).

Zinc. When the diet contains excessive zinc over a sufficient period, the copper status of animals and humans is impaired; the effect is reversed by copper supplements. One explanation for this interaction is that high dietary zinc induces intestinal metallothionein (MT). Copper does not play an important role in the induction of MT, but it has a stronger affinity for MT than does zinc. It displaces zinc in intestinal MT and is trapped ([3](#), [17](#)). Copper depletion was observed in humans when supplements of 50 mg (280 μ mol) or more of zinc were given for extended periods. This caused concern that dietary zinc intake slightly above the recommended level might affect copper status, but copper absorption was not affected by 16.5 mg (250 μ mol) of zinc per day. High doses of copper have in some cases reduced the effects of zinc deficiency in animals, but these effects were inconsistent ([18](#)). In one study, a high-copper diet reduced zinc absorption slightly and increased the excretion of zinc in young men but did not impair zinc status ([19](#)).

Molybdenum. Interactions between copper and molybdenum have been observed frequently in ruminants ([3](#)). Slight excesses of molybdenum in the presence of sulfide produce molybdenum toxicity and secondary copper deficiency. A similar response in rats requires much more molybdenum and is independent of sulfur. A single report of a high-molybdenum diet in humans increasing urinary copper excretion suggests that a similar interaction could occur in humans. The toxicity of molybdenum in ruminants is ameliorated when dietary copper is increased.

Ascorbic Acid. Ascorbic acid supplements have produced copper deficiency in laboratory animals and may affect the copper status of humans. Plasma ascorbic acid concentrations in premature infants are negatively correlated with plasma ceruloplasmin concentrations and plasma antioxidant activity ([20](#)). Daily ascorbic acid supplements of 1500 mg (8.5 mmol) given to young men caused ceruloplasmin activity to decline. Copper absorption was not impaired by 600 mg (3.4 mmol) of ascorbic acid, but ceruloplasmin declined, and the results suggested that the oxidase activity of ceruloplasmin may be impaired by excessive ascorbic acid ([15](#)).

Carbohydrates. The type of carbohydrate in the diet affects the rate and severity of copper depletion in rats. They are more resistant to copper deficiency when the carbohydrate source is cornstarch than when it is sucrose or fructose. The interaction between carbohydrate source and copper in humans is not clear. Erythrocyte superoxide dismutase (SOD) levels of humans in one study were lower with a high-fructose diet than with a high-cornstarch diet, but copper retention increased ([21](#)). In addition, research in young pigs, whose cardiovascular and gastrointestinal systems are similar to those in humans, suggests that the interaction observed in rats may not

apply to humans (22, 23).

Interactions with Drugs and Nonnutrient Components of the Diet

Relatively little is known about interactions of copper with drugs. Penicillamine is used to chelate endogenous copper in the treatment of Wilson's disease. Its use results in excretion of up to 5 mg/day (79 $\mu\text{mol/day}$) of copper in the urine (24). Antacids may interfere with copper absorption (15) when used in very high amounts. Fiber and phytate in the diet influence the bioavailability of several minerals, but their effect on copper absorption and metabolism is not clear. Rat studies have demonstrated both inhibition and enhancement of copper absorption by phytate (15). Copper use may be influenced by both phytate and fiber in the diets of humans.

Adequacy of Intake by Various Population Groups

Dietary copper intake in the United States and other countries is usually below the currently recommended 1.5 mg/day (1). The new World Health Organization (WHO) estimated minimum requirements are 0.6 mg/day (9 $\mu\text{mol/day}$) for women and 0.7 mg/day (11 $\mu\text{mol/day}$) for men (10). The estimated usual dietary copper intake in the United States, after correcting for missing values in the USDA database, was 0.96 mg/day (15 $\mu\text{mol/day}$) for women and 1.4 mg/day (22 $\mu\text{mol/day}$) for men. A total diet study estimated intake at 0.92 mg/day (14 $\mu\text{mol/day}$) for women and 1.2 mg/day (19 $\mu\text{mol/day}$) for men (9). Frank copper deficiency in humans is very rare, which suggests that the current dietary intake usually suffices to prevent copper deficiency. It has been suggested that the usual copper intake is marginal and may not support optimal health, but data in this area conflict and do not yet suffice to support that hypothesis.

METABOLISM

Mammalian copper metabolism is depicted schematically in Figure 12.1. Some copper in the diet is absorbed into the body through the intestinal mucosa, transported via the portal blood to the liver, and incorporated into ceruloplasmin. Ceruloplasmin is released into the blood and delivers copper to tissues throughout the body. Albumin-bound copper exchanges with tissue copper and a number of low-molecular-weight moieties also supply copper to the tissues (25). Most endogenous copper is secreted into the gastrointestinal tract, where it combines with unabsorbed dietary copper and is eliminated from the body. A small amount of copper is eliminated through other excretory routes.

Figure 12.1. Schematic representation of the metabolism of copper in mammals. (From Solomons NW. Zinc and copper. In: Shils ME, Young VR, eds. *Modern nutrition in health and disease*. 7th ed. Philadelphia: Lea & Febiger, 1988.)

Absorption

Studies conducted with laboratory animals have begun to provide some basic information on the mechanism of copper absorption (3, 26). Copper is absorbed primarily in the small intestine, with a small amount absorbed in the stomach. Absorption is probably by a saturable, active transport mechanism at lower levels of dietary copper; at high levels of dietary copper, passive diffusion plays a role. Absorption may be regulated by the need for copper, with MT in intestinal cells involved in the regulation.

The recent development of methods for using a stable isotope of copper to investigate copper metabolism in humans has improved the reliability of copper absorption measurement (14). Early estimates of copper absorption in humans ranged from 15 to 97% (1). Estimates of copper absorption varied widely in part because of inadequate methods and because the level of dietary copper was not known or controlled. A series of stable isotope studies of copper absorption have since demonstrated that the level of dietary copper strongly influences absorption (14, 27). As dietary copper increases, the fraction absorbed declines and the amount absorbed increases. Absorption declined from 75% at 0.4 mg (6 μmol) Cu per day to 12% at 7.5 mg (120 μmol) Cu per day. The amount absorbed increased from 0.3 to 0.9 mg (5 to 15 μmol), or only tripled with 20 times the amount of dietary copper. This suggests that copper homeostasis is maintained in part by regulation of absorption.

Storage

The adult human body contains only about 50 to 120 mg (0.79–1.9 mmol) of copper (3), very little compared with other trace elements such as iron and zinc. Animal data suggest that copper is stored in the liver, bound to MT-like proteins. Ruminants and a few other animal species can store much more copper in the liver than can humans or

most other animal species. Copper may also be held, at least temporarily, bound to intestinal MT.

Transport

Following absorption, copper is transported bound primarily to albumin and to transcuprein and low-molecular-weight ligands (26, 28). The newly absorbed copper disappears rapidly from the plasma. Most is taken up by the liver; some is taken up by the kidney. Once in the liver, copper is incorporated into ceruloplasmin within hours. Some is incorporated into MT in the liver of animals, particularly when copper intake is high; a role for MT in cellular detoxification has been proposed (29). A role for copper in the kidney is not known, but copper is probably filtered by the glomerulus and reabsorbed in the tubules (30).

Copper bound to ceruloplasmin is released from the liver into the blood and delivered to cells with specific ceruloplasmin receptors on their surface. Ceruloplasmin binds to these receptors; the copper is reduced, dissociates from ceruloplasmin, and is released into the cells (31).

One suggested sequence leading to excretion of copper in bile is that ceruloplasmin with part of the copper removed may return to the liver, where it is partially degraded (26) and transferred to the bile accompanied by ceruloplasmin fragments. Glutathione, although not a cuproenzyme, may play a role in the rapid transfer of excessive copper to bile (32).

Excretion

The primary route of copper excretion is via bile into the gastrointestinal tract. Little of this copper is reabsorbed. It combines with a small amount of copper from intestinal cells, from pancreatic and intestinal fluids, and unabsorbed dietary copper and is then eliminated in the feces. Other routes of excretion contribute little to total copper losses. Healthy humans excrete only 10 to 30 μg (0.2–0.5 μmol) of copper in the urine (33, 34), but urinary losses can increase markedly in some conditions, such as renal tubular defects (30). Sweat and integumentary losses are usually less than 50 μg (0.8 mmol) per day (33).

Homeostatic Regulation

Absorption of ingested copper is regulated and is much more efficient when dietary copper is low. The importance of an individual's copper status in absorption is not understood. A low-copper diet increases the efficiency of absorption rapidly, but absorption does not become more efficient after several weeks on a low-copper diet (27). This suggests that the dietary content is more important than copper status in regulation of absorption. Another point of regulation in the homeostatic control of total body copper is the excretion of copper into the bile and from there into the gastrointestinal tract. Animals and humans increase endogenous copper excretion when the diet is high in copper and excrete little during copper deficiency or when dietary

copper is low (26, 35, 36). When a stable isotope of copper was administered, tissue copper was conserved in copper-restricted rats. Intravenous doses of a stable isotope of copper were administered to human subjects. When dietary copper was 2.5 mg/day (39 μmol/day), 20% of the dose was excreted and eliminated in the stools in 6 days, while only 7% of the dose was eliminated when the diet contained 0.4 mg/day (6 μmol/day). The homeostatic regulation of copper absorption and excretion protects against copper deficiency and toxicity over a broad range of dietary intakes.

FUNCTIONS

Biochemical

Copper functions in vivo as a part of a number of proteins, including many important enzymes. Detailed descriptions of these proteins and their functions have been published (6, 8, 26). The copper proteins known to be present in humans are listed in Table 12.1 and described briefly below. Many other copper-containing proteins are found in plants, lower organisms, and some animal species. Some of the better known of these include ascorbate oxidase, carboxypeptidase A, hemocyanin, laccase, and uricase.

Copper-containing enzymes	
Amino oxidases	
Amino oxidase (flavin-containing)(monoamine oxidase, tyramine oxidase) (EC 1.4.3.4) ^a	
Amino oxidase (copper-containing)(histamine oxidase, histaminase) (EC 1.4.3.4)	
Lysoyl oxidase (EC 1.4.3.13)	
Peptidylglycine- α -amidating monooxygenase (PAM)	
Ferroxidases	
Ferrioxalase 1 (ceruloplasmin) (EC 1.10.3.1)	
Ferrioxalase II	
Cytochrome c oxidase (cytochrome oxidase)(EC 1.9.3.1)	
Dopamine β -monooxygenase (dopamine β -hydroxylase) (EC 1.14.17.1)	
Superoxide dismutase (hemocuprin, erythrocuprin) (EC 1.15.1.1)	
Extracellular superoxide dismutase	
Copper/zinc superoxide dismutase	
Monophenol monooxygenase (tyrosinase) (EC 1.14.18.1)

Table 12.1 Copper-Containing Proteins in Humans

Copper-Containing Enzymes Found in Humans

Amine Oxidases. Several important amine oxidases are cuproproteins. Relatively small amounts of these enzymes are found circulating in blood plasma, where they inactivate and catabolize physiologically active amines such as histidine, tyramine, and polyamines. They are found in tissues throughout the body. Their activity is elevated in conditions in which connective tissue activation and deposition take place, including liver fibrosis, congestive heart failure, hyperthyroidism, childhood, and senescence (26).

Monoamine Oxidase. Involved in inactivation of catecholamines, monoamine oxidase reacts with substances, such as serotonin, norepinephrine, tyramine, and dopamine, and is inhibited by tricyclic antidepressant drugs.

Diamine Oxidase. A number of copper-dependent diamine oxidase enzymes are found in cells throughout the body. Diamine oxidase inactivates histamine, acting in the small intestine, where histamine stimulates acid secretion, and in allergic reactions throughout the body, where histamine is released in response to exposure to antigens. It also inactivates polyamines involved in cell proliferation, which suggests that diamine oxidase may play a role in limiting excessive growth. Diamine oxidase activity is highest in the small intestine. Activity is also high in the kidney, where diamine oxidase inactivates diamines filtered from the blood, and in maternal placenta, where it may inactivate amines produced by the fetus.

Lysyl Oxidase. Lysyl oxidase, a unique amine oxidase, acts on lysine and hydroxylysine side chains of collagen and elastin. It deaminates the lysine of newly formed, immature elastin and collagen, after which cross-links are formed. The enzyme functions in the formation of connective tissue, including bone, blood vessels, vasculature, skin, lungs, and teeth. The concentrations are highest during development. Long-term estrogen treatment increases the activity of lysyl oxidase, and malignant transformation decreases activity.

Peptidylglycine- α -Amidating Monooxygenase. A newly identified cuproenzyme, peptidylglycine- α -amidating monooxygenase, is involved in the synthesis of many bioactive peptides and may be influenced by copper deficiency (37).

Ferroxidases. *Ceruloplasmin.* Ceruloplasmin, also called ferroxidase I, is an a_2 glycoprotein with a molecular weight of about 150,000. It contains six (possibly seven) atoms of copper per molecule, including Cu^{2+} atoms of all three types described under "Chemistry." Four copper atoms appear to be involved in the oxidation/reduction reactions the enzyme catalyzes. The role of the other atoms is not yet understood. This enzyme catalyzes the oxidation of ferrous iron and plays a role in the transfer of iron from storage to sites of hemoglobin synthesis. Ceruloplasmin also oxidizes aromatic amines and phenols.

Most of the copper in blood plasma is bound to ceruloplasmin. Estimates of the ceruloplasmin fraction range from 60 to 95% (26). The fraction of plasma copper associated with ceruloplasmin appears to be relatively constant within an individual but varies considerably among individuals (33).

Ferroxidase II. Ferroxidase II also catalyzes the oxidation of ferrous iron. It accounts for only about 5% of the ferroxidase activity in human plasma, but plays a more important role in some animal species.

Cytochrome c Oxidase. Cytochrome c oxidase enzyme, present in the mitochondria of cells throughout the body, is the terminal link in the electron transport chain. It reduces

O₂ to form water and permits formation of adenosine triphosphate (ATP) in mitochondrial energy production. Cytochrome c oxidase is considered the single most important enzyme of the mammalian cell, because it is rate limiting in electron transport (28). It contains two or three copper atoms per molecule. The activity of this enzyme is highest in the heart and high in brain, liver, and kidney tissues.

Dopamine b-Hydroxylase. Dopamine b-hydroxylase catalyzes the conversion of dopamine to the neurotransmitter norepinephrine in the brain. Estimates of the copper content of dopamine b-hydroxylase range from two to eight atoms per molecule, with the most recent estimates being the higher amount (38). Dopamine b-hydroxylase concentration is two to three times higher in gray matter of the brain than in white matter, and it is present in the adrenal gland, where it is required for epinephrine production.

Superoxide Dismutase. *Extracellular Superoxide Dismutase (EC-SOD).* EC-SOD, a copper-containing enzyme, is present in high amounts in the lungs, thyroid, and uterus and in small amounts in blood plasma. It functions as a scavenger of superoxide radicals and protects against oxidative damage.

Copper/Zinc Superoxide Dismutase (SOD). Copper/zinc SOD, which contains two copper atoms per molecule, is present within most cells of the body, primarily within the cytosol. It protects intracellular components from oxidative damage, converting the superoxide ion to hydrogen peroxide. It requires both zinc and copper for catalytic function (39). High concentrations are found in brain, thyroid, liver, pituitary, erythrocytes, and kidney of humans. Erythrocyte levels of SOD are high in alcoholics and individuals with Down's syndrome.

Tyrosinase. Tyrosinase catalyzes the conversion of tyrosine to dopamine and the oxidation of dopamine to dopaquinone, steps in the synthesis of melanin. It is present in the melanocytes of the eye and skin and is responsible for the color in hair, skin, and eyes. Deficiency of tyrosinase in skin leads to albinism.

Copper-Binding Proteins

Metallothionein (MT). MTs are small nonenzymatic proteins, rich in cysteine, that are responsible for binding copper. Each molecule can bind 11 or 12 copper atoms as well as zinc and cadmium. They appear to play a role in metal storage and sequester excess metal ions, preventing toxicity. The concentration is highest in the liver, where metals accumulate in MT fractions. MTs are found in many other human tissues, including small amounts in the blood plasma. The presence in blood plasma has prompted the suggestion that MTs also play a role in copper transport, but if so, the role would be minor (26).

Albumin. Albumin, a protein with a molecular weight of 68,000, is the most prevalent protein in blood plasma and interstitial fluids. Albumin binds and transports copper and may also play a role in binding excess copper that would otherwise be toxic. Estimates of the fraction of copper in blood plasma that is bound to albumin range from 5 to 18%

(26).

Transcuprein. Transcuprein, a recently isolated plasma protein with a molecular weight of about 270,000, binds copper and is found in humans. It has not yet been completely characterized and its functions are not clear, but it may play a role in copper transport. Considerably less serum copper is bound to transcuprein than to albumin (26).

Blood-Clotting Factor V. Blood-clotting factor V, a nonenzymatic component of the blood-clotting process, has recently been found to contain one atom of copper per molecule (40). Although this indicates that copper is required for blood clotting, impaired blood clotting is not among the reported manifestations of copper deficiency.

Low-Molecular-Weight Ligands

Amino acids and small peptides also carry a small fraction of the copper in the blood plasma. Estimates range from less than 1% to 4% (26). Histidine, glutamine, threonine, and cystine are examples of amino acids that bind copper in the plasma, and at least one copper peptide complex, glycyl-histidine-lysine, has been isolated from human plasma. The role of these complexes is not known, but the copper carried by low-molecular-weight ligands is thought to exchange with nonceruloplasmin copper in the blood. The ligands may carry copper to cells (25).

Physiologic

Many of the physiologic functions of copper can be deduced from reactions the cuproenzymes catalyze. Others are based on symptoms of copper deficiency. Detailed reviews of the physiologic functions of copper have been published (1, 3).

Connective Tissue Formation. Copper, through the enzyme lysyl oxidase, is essential for cross-linking of collagen and elastin, which are required for formation of strong, flexible connective tissue. Thus, copper plays a role in bone formation, skeletal mineralization, and the integrity of the connective tissue in the heart and vascular system. Lysyl oxidase activity declines during severe copper deficiency in weanling rats, and the resulting defects in connective tissue formation may be responsible for the multiple effects of copper deficiency on cardiac system integrity and bone formation (41). Copper depletion in humans also results in modest changes in lysyl oxidase activity in the skin (42), but the degree of change does not compromise function, as there is a large excess present.

Iron Metabolism. Several mechanisms have been proposed for the role of copper in iron metabolism and erythropoiesis (43). Ceruloplasmin and ferroxidase II oxidize ferrous iron, so it can be transported from the intestinal lumen and storage sites to sites of erythropoiesis. This may explain why anemia develops with copper deficiency, yet iron accumulates in the intestinal lumen and liver. Copper may also be required for formation of normal bone marrow cells, necessary for formation of red blood cells.

Central Nervous System. Copper plays more than one role in the central nervous

system. It is required for formation or maintenance of myelin, a protective layer covering neurons, composed primarily of phospholipids. Phospholipid synthesis depends on cytochrome c oxidase activity, which may explain why copper deficiency leads to poor myelination, necrosis of nerve tissue, and neonatal ataxia in copper-deficient animals. The role of cuproenzymes in catecholamine metabolism (conversion of dopamine to norepinephrine by dopamine b-hydroxylase and the degradation of serotonin, norepinephrine, tyramine, and dopamine by monoamine oxidase) implies a function in normal neurotransmission (37).

Melanin Pigment Formation. The role of copper in the pigmentation of skin, hair, and eyes is related to the requirement for tyrosinase in melanin synthesis. Depigmentation of hair and skin is observed with copper deficiency in several animal species and in Menkes' disease.

Cardiac Function and Cholesterol Metabolism. The role of copper in cardiac function has been explored in a number of laboratory animal experiments (44). Cardiac myopathy and a variety of other conditions appear when weanling, but not older, rats are deprived of copper. Cardiac symptoms have not been reported in the few frankly copper-deficient humans, though links to heart irregularities in humans have been suggested (45). Blood cholesterol levels increase in animals fed copper-deficient diets, but results of studies on the effects of low-copper diets on blood cholesterol in humans are not consistent. Levels have increased in some and declined in others, and copper supplementation increased low-density lipoprotein (LDL) in a study in adult males (46).

Other Functions. Other physiologic functions suggested for copper are not as well understood as those described above. These include roles in thermal regulation and glucose metabolism. A role in blood clotting through factor V is known but has not yet been clearly associated with clinical manifestations of copper deficiency. Copper is known to be both prooxidant and antioxidant. Two key antioxidant enzymes, ceruloplasmin and superoxide dismutase, decrease in copper deficiency and may result in impaired antioxidant status (47). Recent evidence suggests a role for copper in immune function. Both low- and high-copper intake influenced immune function in laboratory animals (48). Some indices of immune function declined with copper depletion of humans, but they were not reversed by a higher copper intake (49). The effect of dietary copper on these functions warrants further investigation.

CAUSES AND MANIFESTATIONS OF DEFICIENCY

Copper Deficiency in Animals

Copper deficiency has been produced experimentally and observed in areas with copper-deficient soil in rats, mice, guinea pigs, rabbits, chicks, pigs, dogs, cattle, goats, and sheep. Detailed descriptions of deficiency symptoms and comparisons among species have been published (1, 3, 50). Animal studies have provided definitive information on the manifestations of copper deficiency. However, the deficiencies produced in animals were more severe than those reported in humans, and species

differences make extrapolation to humans difficult.

Anemia, neutropenia, and osteoporosis are observed with copper deficiency in all species. Other well-established manifestations of copper deficiency observed in animal species are skeletal abnormalities, fractures, and spinal deformities; neonatal ataxia; depigmentation of hair and wool; impaired keratinization of hair, fur, and wool; reproductive failure, including low fertility, fetal death, and resorption; cardiovascular disorders including myocardial degeneration, cardiac hypertrophy and failure, rupture of blood vessels, and electrocardiographic changes; and impaired immune function. Changes in lipid and cholesterol metabolism, increased lipid peroxidation, and impaired glucose metabolism have been observed in some studies. Hypercholesterolemia may be linked to glutathione metabolism (32). Some of the manifestations of copper deficiency are considered controversial because they have only been observed in one or two species or under specific dietary conditions such as unusually high levels of fructose or zinc (3).

Copper Deficiency in Humans

For years following the discovery of copper deficiency in laboratory animals it was considered unlikely that copper deficiency could occur in humans. Although copper deficiency in humans is relatively rare, it has been reported a number of times since 1964 under special circumstances. Reviews of copper deficiency in humans have been published (30, 43).

Copper deficiency has been clearly documented in infants recovering from malnutrition, in premature and low-birth-weight infants fed milk diets, and in patients receiving prolonged total parenteral nutrition. In established cases, blood was sampled for determination of serum copper and ceruloplasmin levels prior to administration of copper supplements, and manifestations of copper deficiency were reversed following copper supplementation.

Frank copper deficiency is accompanied by hypocupremia and low ceruloplasmin levels. Levels fall to 30% of normal and below. Serum copper values as low as 0.5 $\mu\text{mol/L}$ (3 $\mu\text{g/dL}$) and ceruloplasmin values as low as 35 mg/L (3.5 mg/dL) have been reported (50). Usual features of copper deficiency are anemia, leukopenia, and neutropenia. The anemia is most often described as normocytic and hypochromic but is sometimes normochromic and sometimes microcytic. Osteoporosis is often observed when bones are still growing and may be accompanied by metaphyseal flaring and fractures at the margins of the metaphyses.

The possibility of mild copper deficiency because of marginal copper intake over a long period has been suggested. Possible manifestations, in addition to the features of severe deficiency, are conditions such as arthritis, arterial disease, loss of pigmentation, myocardial disease, and neurologic effects (30). Diminished glucose tolerance, increased serum cholesterol, and heart beat irregularities have been linked to marginal copper intake (3). These conditions were not accompanied by the low ceruloplasmin or serum copper levels or other features of severe deficiency, but serum copper levels declined in one individual with these symptoms. Dietary copper intake in these studies

was within the range of intakes consumed by a large segment of the population, 0.8 to 1 mg (13–16 μmol) per day, and these effects were not produced in other studies at this level of dietary copper (33). Further research is required to establish whether these conditions are related to copper status or not, but this is complicated by ethical considerations related to feeding very low copper intakes, the possibility that some individuals may have a higher copper requirement than others, and possible nutrient interactions.

CLINICAL CONDITIONS

Clinical Conditions with Increased Risk of Copper Depletion

Most severe copper deficiency cases reported to date have been associated with other clinical conditions (30). Copper deficiency has been documented during total parenteral nutrition, in premature infants fed milk formulas, in infants recovering from malnutrition (usually associated with chronic diarrhea), in infants undergoing chronic peritoneal dialysis, and in severely handicapped patients (51). Two cases of copper deficiency were observed in full-term infants fed only cow's milk. Increased gastrointestinal losses due to diarrhea or fistulas increase copper losses and the risk of copper depletion. Diseases of malabsorption, such as celiac disease and nontropical sprue, increase the risk of copper depletion because of both malabsorption and increased losses, and it appears that the copper status of cystic fibrosis patients may be compromised (52). Prolonged use of antacids and long-term therapy with very high doses of zinc in treatment of sickle cell anemia have resulted in hypocupremia and some manifestations of copper deficiency.

Parenteral Nutrition. The realization that trace element deficiencies sometimes follow prolonged parenteral nutrition prompted recommendations that several trace elements, including copper, be added to the solutions. Guidelines for their preparation and addition were established in 1979, and these elements are now added routinely in the United States. Copper deficiency usually develops after months of parenteral nutrition without added copper; the risk of deficiency developing is increased substantially in individuals with excessive gastrointestinal losses. Free amino acid solutions increase urinary copper losses, adding to the risk. Adults receiving total parenteral nutrition (TPN) who did not have excessive gastrointestinal fluid losses could maintain balance and normal serum and ceruloplasmin levels on only 0.25 mg (3.9 μmol) Cu per day. These values did not increase after supplementation with copper. In contrast, serum copper and ceruloplasmin values declined steadily in others receiving a TPN solution in which copper was not detectable, and these indices increased when oral feeding was resumed. Stable adult patients receiving TPN need about 0.3 mg (4.7 μmol) Cu daily to maintain balance. The requirements are increased to 0.4 to 0.5 mg (6–8 μmol) daily with excessive gastrointestinal losses and should be reduced in patients with cholestasis and impaired biliary excretion (53).

Clinical Conditions Accompanied by Copper Accumulation

Copper can accumulate in the liver in any disease that causes impaired biliary excretion. Two of these, Wilson's disease and Indian childhood cirrhosis (ICC), are

discussed below. Liver copper level is very high in primary biliary cirrhosis and biliary atresia. Copper chelation rather than dietary copper restriction is recommended to reduce the liver copper stores in these diseases ([54](#)).

Conditions with Increased Serum Copper

Serum copper and ceruloplasmin levels rise progressively during pregnancy, usually reaching twice-normal levels by term. This is partly due to redistribution of copper, and the change is accompanied by increased total body copper ([55](#)). Serum copper and ceruloplasmin levels rise, often to two to three times normal values, in inflammatory conditions, infectious diseases, hematologic diseases, diabetes, coronary and cardiovascular diseases, uremia, and malignant diseases and following surgery ([1](#), [3](#)). Smoking and some drugs also increase serum copper concentrations. Ceruloplasmin is an acute-phase reactant, and the rise in ceruloplasmin is probably responsible for the increase in serum copper in the above conditions, because the increases parallel one another. The mechanism for the increase or the role for ceruloplasmin is not understood but is under investigation in several laboratories ([26](#)).

Genetic Defects in Copper Metabolism

The two best-known defects in copper metabolism in humans are Menkes' disease and Wilson's disease. Several defects in production of cuproenzymes have been identified, including overproduction of SOD in Down's syndrome, absence of tyrosinase in albinism, changes in lysyl oxidase in cutis laxa (Ehlers-Danlos syndrome), and myopathy due to reduction in cytochrome *c* oxidase. Genetic defects in copper metabolism have also been observed in mice and dogs. The reader is referred to reviews of genetic diseases of copper metabolism ([24](#), [56](#)).

Menkes' Disease. Menkes' disease is a fatal X-linked disorder characterized by mental retardation, abnormal hair, and maldistribution of copper ([56](#)). It occurs in 1 in 50,000 to 100,000 live births and is usually fatal by the age of 3 years. Serum copper and ceruloplasmin levels are low, as are levels in liver and brain, but copper accumulates in intestinal mucosa, muscle, spleen, and kidney. Synthesis of ceruloplasmin, SOD, and cytochrome oxidase is impaired. Abnormalities in connective tissue cross-linking because of dysfunction of lysyl oxidase result in defective arteries in the brain and elsewhere, and in osteoporosis. Progressive nerve degeneration in the brain results in intellectual deterioration, hypotonia, and seizures. Hypothermia is common. Skin and hair are poorly pigmented, and hair is characteristically "kinky." The anemia and neutropenia common to nutritional copper deficiency are not found in Menkes' disease, a difference that cannot be explained. Administration of parenteral copper increases serum copper and ceruloplasmin levels but does not improve brain function or slow the progressive deterioration.

Wilson's Disease. Wilson's disease is an autosomal recessive disease of copper storage. The prevalence of the defect is uncertain but has been estimated at approximately 1 in 200,000 in the United States. Copper accumulates in the liver, the brain, and the cornea of the eye (Kayser-Fleischer rings). Urinary copper excretion is abnormally high, but ceruloplasmin values are usually low. There appears to be a defect

in the catabolism and excretion of ceruloplasmin copper into the bile. If the disease goes untreated, copper accumulation in the liver and brain results in neurologic damage and cirrhosis. Hepatitis, hemolytic crisis, and hepatic failure may ensue. (An excellent clinicopathologic exercise of a case of Wilson's disease can be found in reference [57](#).)

Early diagnosis and treatment can prevent the severe consequences of the disease. Dietary copper restriction was advocated for Wilson's disease at one time, but chelation therapy, usually using D-penicillamine, is much more effective in reducing copper stores ([54](#)). Avoidance of large quantities of foods rich in copper may also be recommended, but diets very low in copper are not necessary. D-Penicillamine is an antimetabolite of pyridoxine, so daily pyridoxine supplements of 12.5 to 25 mg (75–150 nmol) are recommended. The treatment induces removal of excess copper and prevents reaccumulation through excretion of 1 to 5 mg (16–79 μ mol) copper daily in the urine. As an alternative to penicillamine, tetrathiomolybdate, 20 mg six times per day, followed by oral zinc supplements of 150 mg/day is sometimes used to eliminate excess copper accumulation ([24](#)).

Childhood Cirrhosis. Indian childhood cirrhosis, a hereditary disease accompanied by rapid copper accumulation in the liver, was fatal but now can be treated with chelators, with improved chances of recovery. A genetic defect is present, but high copper intake is required for symptoms to appear. The incidence of ICC in India has decreased markedly in recent years, but diseases mimicking ICC have appeared in other parts of the world ([58](#)).

EVALUATION OF COPPER STATUS

Biochemical Indices

Currently used indices of copper status easily detect severe copper deficiency. Serum copper and ceruloplasmin concentrations fall to levels far below the normal range and respond quickly to copper supplementation ([30](#)). Ceruloplasmin concentration has generally been considered the most reliable index of copper status ([15](#)), but some consider red cell superoxide dismutase activity equally or more sensitive ([59](#)). SOD values have not yet been reported in cases of severe copper deficiency in humans, and a level that would indicate copper deficiency has not been established. The normal ranges of these indices vary between laboratories but are approximately as follows: 10.0 to 24.6 μ mol/L (64–156 μ g/dL) for serum copper; 180 to 400 mg/L (18–40 mg/dL) for ceruloplasmin; and 0.47 ± 0.067 mg/g for erythrocyte SOD ([15](#)).

Although serum copper and ceruloplasmin levels clearly reflect severe deficiency, they may not be sensitive to marginal copper status. In addition, ceruloplasmin is an acute-phase reactant and, as a result, serum copper and ceruloplasmin levels are elevated in a variety of conditions. Serum copper and ceruloplasmin levels could be within the normal range or even elevated, masking copper deficiency when one of these conditions occurs at the same time.

The search for a reliable index of marginal copper status has been unsuccessful, though

a number of possibilities have been suggested (30). Copper levels in hair, nails, or saliva do not appear to reflect copper status. Urinary copper varies greatly between individuals and declines only when dietary copper is very low (27). Cytochrome C oxidase in red cells, or possibly in platelets or white cells (45), may be sensitive to copper status, but more data are needed. A single index is not sufficient to assess copper nutriture. Other indices may potentially provide information on copper status, such as leukocyte copper content (34) and changes in lysyl oxidase activity (42).

Functional Tests

Most functional tests that might be of value in assessing copper status, such as assessment of immune function or antioxidant status, lack the necessary specificity to diagnose copper deficiency. However, in conjunction with the more established indices of copper status, they may be valuable. Stable isotope measurements of total body copper, the exchangeable copper pool size, or copper turnover may prove useful in evaluating copper status, but research in this area has just begun (60). Compartmental models of copper metabolism should aid in evaluating copper status (61).

REQUIREMENTS AND RECOMMENDED INTAKES

Laboratory Animals

The copper requirements of laboratory animals are influenced by other components of the diet, including those discussed under “Interactions.” They differ between species as well. Approximately 6 µg Cu/g diet appears to be adequate for young animals of most species (3), including pigs, rats, and guinea pigs. This amount can be lower under optimal conditions and higher with confounding factors or for specific functions.

Humans

Copper depletion/repletion studies to establish the minimum requirements of healthy humans were not done until recently with a copper intake low enough to produce systematic reduction in copper status. Recent studies have been conducted under highly controlled and closely monitored conditions. Relatively few cases of frank copper deficiency have been reported, and these were accompanied by confounding factors, such as malnutrition, malabsorption, and excessive gastrointestinal losses, limiting their value in establishing a minimum requirement for healthy individuals.

The most relevant example of a long-term diet containing less than the minimum copper requirement may be the following: An enteral diet containing 15 µg Cu/100 kcal (0.56 pmol/J) produced copper deficiency in six of six severely handicapped patients between the ages of 4 and 24 years after they had consumed the diet for 12 to 66 months. Serum copper values of 1.8 to 7.2 µmol/L (11.7–45.7 µg/dL) and ceruloplasmin values of 30 to 125 mg/L (3–12.5 mg/dL) were discovered, accompanied by other manifestations of copper deficiency. These values increased to within the normal range after 3 months of copper supplementation (62). By extrapolation (though it may not be valid to extrapolate from these growing, severely handicapped individuals to healthy

adults), copper deficiency could be expected to develop eventually if the diet contained 15 µg Cu/100 kcal, or 0.44 mg Cu/2900 kcal for men and 0.29 mg Cu/1900 kcal for women (0.56 pmol/J). The above example, combined with one study in which healthy young men maintained copper balance and status at 0.79 mg/day (12 µmol/day) (14) and another in which young men did not maintain status at 0.37 mg/day (6 µmol/day) (27), suggests that the minimum copper requirement of men is somewhere between 0.4 and 0.8 mg/day (6–12 µmol/day). An adult basal copper requirement within that range, 0.6 mg/day (9 µmol/day) for women and 0.7 mg/day (11 µmol/day) for men, was suggested by WHO (10).

The daily dietary copper intake recommended by the National Research Council of the United States is now 1.5 to 3 mg (24–47 µmol) for adults. Recommended daily ranges for children are 0.4 to 0.6 mg (6–9 µmol) for infants 0 to 6 months of age, increasing to 1.5 to 2.5 mg (24–39 µmol) for children over 11 years of age (5) (see also Appendix Table II-A-2-a-3, Table II-A-2-b-1, Table II-A-2-b-2, Table II-A-2-b-3, Table II-A-2-b-4, Table II-A-2-b-5 and Table II-A-2-b-6). WHO (10) estimated the normative requirement for individuals, which includes a factor of safety to include additional increment for almost all dietary conditions, to be 0.7 mg/day (11 µmol/day) for women and 0.8 mg/day (12.5 µmol/day) for men. After adding margins of safety to the individual requirement to include all dietary conditions, variations in usual intakes, and individual variability, a recommendation of 1.25 mg/day (19 µmol/day) was derived.

CAUSES AND MANIFESTATIONS OF TOXICITY

Copper toxicity can occur in all animal species. It has been observed in sheep, cattle, pigs, rats, and poultry, as well as in humans. The effects of copper poisoning and the levels required for deleterious effects to develop have been reviewed (3).

Copper Toxicity in Animals

Tolerance to high levels of copper differs greatly from one species to another, with sheep being the most susceptible to copper poisoning and rats having high tolerance to excessive copper. Because of species differences and the effects of the levels of zinc, iron, and molybdenum in the diet, the minimum toxic copper level varies. Deleterious effects were observed in pigs at 250 µg Cu/g (4 µmol/g) diet but could be avoided by increasing dietary iron and zinc. Poultry exhibit slowed growth and egg production at 500 µg/g (8 µmol/g), and fatality can occur at 1200 µg/g (19 µmol/g). Sheep have developed copper toxicosis from diets containing 12 µg/g (0.19 µmol/g), and some breeds of sheep are more susceptible to excess copper than others. Copper chloride is more toxic than copper sulfate; lower levels of copper are toxic when the molybdenum content of the diet is low. Single doses of 20 to 100 mg (0.31–1.8 mmol) copper per kilogram body weight have been toxic. Cattle are susceptible to toxicity when diets contain 3 to 12 times the required level of copper. Ruminants can store more copper in their livers than other animals, and symptoms of toxicity appear when the capacity of the liver to sequester copper has been exceeded. Manifestations of copper toxicity include weakness, tremors, anorexia, and jaundice. Tissue copper levels increase, producing liver, kidney, and brain damage, and hemolytic crisis may follow. The immune function of mice was impaired following supplements of 100 ppm of copper in the drinking water

(63).

Copper Toxicity in Humans

Acute copper poisoning has been observed to occur in the following ways: accidental consumption by children, ingestion of several grams in suicide attempts, application of copper salts to burned skin, drinking water from contaminated water supplies, or consumption of acidic food or beverages that had been stored in copper containers. Excessive copper produces epigastric pain, nausea, vomiting, and diarrhea, which usually prevents the more serious manifestations of copper toxicity. Serious manifestations include coma, oliguria, hepatic necrosis, vascular collapse, and death. Chronic copper toxicosis has been observed in dialysis patients following months of hemodialysis when copper tubing was used and in vineyard workers using copper compounds as pesticides. The amount of oral copper required to produce toxic effects is not well established, but liver damage in two infants may have been related to consuming water with 2 to 3 mg Cu/L (31–47 μmol Cu/L) in early infancy (58). An extremely wide range of oral copper, beginning at 0.07 mg/kg (1.1 μmol /kg) per day, has been associated with gastrointestinal effects. Wilson's disease, a genetic disorder described above, and certain liver and biliary diseases are associated with accumulation of toxic levels of copper in the liver and other tissues, without excessive intake. Subtle deleterious effects of high dietary copper have been observed. LDL cholesterol increased when copper supplements were given to men (46). Copper has a critical role in neurologic diseases and there is speculation that copper-induced production of hydroxy radicals may contribute to the neurodegeneration in Alzheimer's disease (64). The WHO recommends intakes below 10 mg/day for women and 12 mg/day for men (10).

HISTORY

Iodine, with an atomic weight of 127 and a molecular weight of 254, is an essential constituent of the thyroid hormones thyroxine, 3,5,3',5'-tetraiodothyronine (T_4), and 3,5,3'-triiodothyronine (T_3). The major role of iodine in nutrition arises from the importance of thyroid hormones to growth and development ([1](#), [2](#), [3](#), [4](#) and [5](#)).

Iodine was discovered by Courtois in 1811 during the course of making gunpowder. Some seaweed ash was being used from which the iodine vaporized as a violet vapor. The element was discovered in the thyroid gland by Baumann in 1895.

The relation of iodine deficiency to enlargement of the thyroid gland, or goiter, was first shown by David Marine, who found that hyperplastic changes occurred regularly in the thyroid when the iodine concentration fell below 0.1% ([3](#)). Subsequently, Marine and Kimball in 1922 demonstrated in school children in Akron, Ohio, U.S.A., that endemic goiter could be both prevented and substantially reduced by administration of small amounts of iodine ([5](#)). Mass prophylaxis of goiter with iodized salt was first introduced in Switzerland and in Michigan, U.S.A. ([5](#)). In Switzerland, the widespread occurrence of a

severe form of mental deficiency and deaf mutism (endemic cretinism) was a heavy charge on public funds. However, following the introduction of iodized salt in 1922, goiter incidence fell rapidly and new cretins were no longer born. Goiter also disappeared from Army recruits (5).

A further major development was administration of injections of iodized oil in Papua New Guinea for people living in inaccessible mountain villages. The successful prevention of goiter and subsequently cretinism was shown in controlled trials over the period 1959 to 1972 (1, 2, 3, 4 and 5).

Major attention is now focused on the effects of iodine deficiency on brain development in the fetus and in infancy. Iodine deficiency is now accepted as the most common cause of preventable mental defect in the world today (6). More details on the historical aspects can be found in the reviews cited (1, 2, 3, 4 and 5).

ECOLOGY OF IODINE DEFICIENCY

There is a cycle of iodine in nature. Most of the iodine resides in the ocean. It was present during the primordial development of the earth, but large amounts were leached from the surface soil by glaciation, snow, or rain and were carried by wind, rivers, and floods into the sea. Iodine occurs in the deeper layers of the soil and is found in oil well and natural gas effluents. Water from such deep wells can provide a major source for iodine. In general, the older an exposed soil surface, the more likely it is to be leached of iodine (1, 5).

The most likely areas to be leached are the mountainous areas of the world. The most severely deficient areas are those of the Himalayas, the Andes, the European Alps, and the vast mountains of China. But iodine deficiency is likely to occur in all elevated regions subject to glaciation and higher rainfall, with runoff into rivers. However, it also occurs in flooded river valleys such as the Ganges in India.

Iodine occurs in soil and the sea as iodide. Iodide ions are oxidized by sunlight to elemental iodine, which is volatile, so that every year some 400,000 tons of iodine escape from the surface of the sea. The concentration of iodide in sea water is about 50 to 60 $\mu\text{g/L}$ and in air is approximately $0.7 \mu\text{g/m}^2$. The iodine in the atmosphere is returned to the soil by rain, which has concentrations in the range 1.8 to $8.5 \mu\text{g/L}$. In this way, the cycle is completed.

However, the return of iodine to the soil is slow and limited in amount compared with the original loss of iodine, and subsequent repeated flooding ensures continuation of iodine deficiency in the soil. Because no "natural correction" can take place, iodine deficiency persists in the soil indefinitely. All crops grown in these soils will be iodine deficient. As a result, human and animal populations that are totally dependent on food grown in such soil become iodine deficient. The iodine content of plants grown in iodine-deficient soils may be as low as $10 \mu\text{g/kg}$ dry weight, compared with 1 mg/kg dry weight in plants grown in an iodine-sufficient soil. This low content of soil iodine accounts for the occurrence of severe iodine deficiency in vast populations in Asia who are living within

systems of subsistence agriculture in flooded river valleys (India, Bangladesh, Burma).

An indication of the iodine content of the soil can be given by the local drinking water concentration. In general, iodine-deficient areas have water iodine levels below 2 µg/L, as in Nepal and India (0.1–1.2 µg/L), compared with levels of 9.0 µg/L in the city of Delhi, which is not iodine deficient.

Iodine deficiency will persist unless a supplement is provided, or alternatively, diversification of the diet occurs, with increased iodine intake derived from food sources outside the iodine-deficient areas. This process has occurred progressively in Europe during the 19th century. However, substantial areas of iodine deficiency remain in some countries (Germany, Italy, and Spain) as well as more localized areas in others (see below).

In developing countries, the World Health Organization (WHO) (6) in 1990 estimated that 1 billion persons were at risk of iodine-deficiency disorders (IDD), of whom 211 million are suffering from goiter and more than 5 million are suffering from mental retardation as gross cretins, while three to five times this number suffer from lesser degrees of mental defect (Table 13.1). In 1993 the WHO increased the estimate of the population at risk to 1.6 billion (7).

	At Risk	Goiter	Overt Cretinism
Africa	227	39	0.5
Latin America	60	30	0.3
Southeast Asia	280	100	4.0
Asia (other countries including China)	400	30	0.9
Eastern Mediterranean	33	12	—
Total	1000	211	5.7

Table 13.1 Prevalence of Iodine Deficiency Disorders in Developing Countries and Numbers of Persons at Risk (in millions)

PHYSIOLOGY OF IODINE DEFICIENCY

The healthy human adult body contains 15 to 20 mg of iodine, of which about 70 to 80% is in the thyroid gland (1, 2). The thyroid gland, which weighs only 15 to 25 g, possesses a remarkable concentrating power for iodine. The amount of iodine in the gland is closely related to the iodine intake. The content may be reduced to 1 mg or less

in the iodine-deficient enlarged thyroid (goiter).

Iodine is rapidly absorbed through the gut. The normal intake and requirement are 100 to 150 μg per day. Excess iodine is excreted by the kidney. The level of excretion correlates well with the level of intake, so it can be used to assess the level of iodine intake (see below).

Iodine exists in the thyroid as inorganic iodine, the iodine-containing amino acids (monoiodothyronine [MIT], diiodothyronine [DIT], triiodothyronine [T_3], and thyroxine [T_4]), polypeptides containing thyroxine, and thyroglobulin. Thyroglobulin, a protein that contains iodinated amino acids in a peptide linkage, is the chief constituent of the colloid that fills the thyroid follicle. It is a glycoprotein (contains glucose) with a molecular weight of 650,000. It is the storage form of the thyroid hormones and contains approximately 90% of the total iodine in the gland.

The thyroid must trap about 60 μg of iodine per day to maintain an adequate supply of thyroxine. This is accomplished by a very active iodide-trapping mechanism, which maintains a gradient of 100:1 between the thyroid cell and the extracellular fluid. In iodine deficiency, this gradient may exceed 400:1 to maintain the output of thyroxine.

This increased trapping of iodine in iodine deficiency can be well demonstrated with radioiodine. In the Argentinean Andes of South America, Stanbury and his colleagues first showed that urinary radioiodine excretion was inversely related to the severity of iodine deficiency (5). Concomitantly, the percentage retention of administered ^{131}I was directly related to the severity of iodine deficiency (5).

Iodide trapping by the thyroid depends on an active transport mechanism (i.e., requires energy) called the *iodine pump*. This mechanism is regulated by the thyroid-stimulating hormone (TSH), which is released from the pituitary to regulate thyroid secretion.

Other ions can compete with iodide, including thiocyanate (SCN^-). Thiocyanate is derived from the metabolism of hydrogen cyanide (HCN), which is found in foods such as cassava. Cassava is a dietary staple in Zaire and in many other countries. The occurrence of goiter and severe hypothyroidism in Zaire (1, 2) is associated with the use of cassava, particularly when it is not well cooked.

Iodide is released by the thyroid cells into the colloid follicle phase between the cells and there is oxidized by hydrogen peroxide from the thyroid peroxidase system (Fig. 13.1). It then combines with tyrosine in the thyroglobulin to form MIT and DIT. The oxidation process then continues with the coupling of MIT and DIT to form the iodotyrosines. This oxidation process can be readily blocked by various drugs, including propylthiouracil and carbimazole, which are widely used for the treatment of hyperthyroidism. There may also be a congenital defect in the formation of iodinated tyrosine; this is a cause of congenital goiter and hypothyroidism that may run in families. Such a defect does not, however, occur in iodine-deficient goiter; the reason why iodine deficiency causes goiter in some people and not in others ingesting the same diet is not

known.

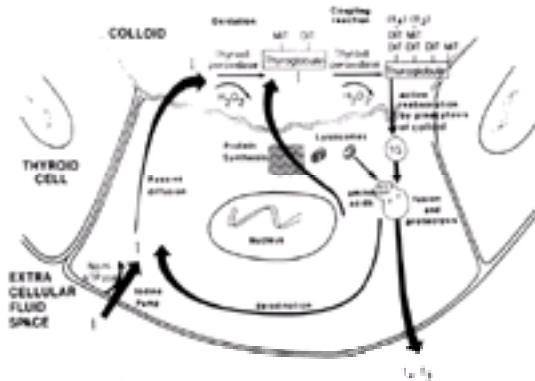

Figure 13.1. Diagram showing pathways of synthesis of thyroid hormones from iodine within the thyroid gland. (From Hetzel BS, Maberly GF. Iodine. In: Mertz W, ed. Trace elements in human and animal nutrition. 5th ed. New York: Academic Press 1986;2: 139–208.)

Finally, the iodinated thyroglobulin, including the iodinated amino acids, is absorbed back into the thyroid cells by pinocytosis. It is then exposed to proteolytic enzymes that break it down to release the T₄ and T₃ into the blood. The unused iodotyrosines are conserved for incorporation into a subsequent cycle of the biosynthetic process. With repeated thyroid stimulation, this reincorporation process may not be able to keep pace with the production of free iodotyrosines, which leak into the circulation but have no biologic effect.

The regulation of thyroid hormones is a complex process involving not only the thyroid, but also the pituitary, the brain, and the peripheral tissues. Secretion of T₃ and T₄ is under the control of the pituitary gland, through TSH. TSH is a glycoprotein with a molecular weight of approximately 28,000. There are two subunits: the X subunit has virtually the same structure as other pituitary hormones; the B subunit is specific for TSH but essentially the same across different species.

TSH secretion is controlled by a feedback mechanism closely related to the level of T₄ in the blood. As the blood T₄ falls, pituitary TSH secretion is increased to increase thyroid activity and the output of T₄ into the circulation, thus maintaining the necessary level of circulating hormone. If this is not possible because of severe iodine deficiency, then the level of T₄ remains lowered and the level of TSH rises. The critical factor in this control is the level of free T₄, the small fraction (less than 1%) not bound to the carrier protein.

The site of thyroid hormone action in regulating metabolic events is the nucleus, where

binding of T_3 to a nuclear receptor (TR) initiates a cascade of changes in gene transcription rates (or messenger RNA stability), which eventuate in the phenotypic expression of thyroid hormone effects. When thyroid hormone enters the cell, it is rapidly bound to proteins in the cytosol but also rapidly enters the nuclear compartment. Within the cell, approximately 10% of the T_3 is in the nuclear compartment, for all tissues except anterior pituitary. In this tissue, the balance between mechanisms leading to nuclear T_3 accumulation and the concentration and affinity of the cytosolic binding proteins are such that roughly equal fractions of T_3 are found in the nuclear and extranuclear compartments.

Both tracer equilibrium and direct radioimmunoassay studies have demonstrated that in most tissues (e.g., the liver, kidney, and heart) receptors are approximately 50% occupied at physiologic plasma T_3 concentrations. There are exceptions; brain and pituitary nuclei have a higher degree of occupancy (80 to 90%) because of the T_3 produced locally from cellular T_4 by the type-2 deiodinase.

These predictions were verified by direct radioimmunoassay of brain cytosol. The free cytosolic T_3 concentrations were approximately 40 pM, three to four times that in the liver, kidney, and heart. That this increment in T_3 over that present in plasma was derived from local T_4 to T_3 conversion was established by showing that the concentration ratio of isotopic T_3 between cytosol and plasma was 1:1. Thus, these results independently verify the significant contribution of locally produced hormone to the nuclear T_3 in the central nervous system. A similar verification has been performed for pituitary tissue using direct radioimmunoassay of nuclear T_3 . More detailed descriptions of the biochemistry of thyroid hormones can be found elsewhere (8).

Blood thyroid hormones and TSH are determined with radioimmunoassay (RIA). In RIA, known amounts of radioactively labeled hormones compete with the unknown amount of hormone in the blood in binding to a specific antibody. The technology for these determinations is still advancing.

Typical normal ranges of values for thyroid-related components of blood are shown in [Table 13.2](#). The values given for TSH were obtained by the enzyme-linked immunoabsorbent (ELISA) assay (8).

Test Factor	Standard Units	SI Units	Conversion
T ₄	5–12 µg/mL	64–154 nmol/L	12.87
T ₃	80–190 ng/dL	1.2–2.9 nmol/L	0.01536
Free T ₄	0.8–2.0 ng/dL	10–26 pmol/L	12.87
Free T ₃	2.6–5.2 pg/mL	4.0–8.0 pmol/L	0.01536
TSH ^a	0.17–2.9 µIU/mL	0.17–2.9 mIU/L	1

Table 13.2 Normal Ranges of Thyroid-Related Components in Plasma and Blood

DEVELOPMENT OF GOITER

The preceding discussion on the production and regulation of thyroid hormones provides the framework for understanding the development of goiter as a result of iodine deficiency. Iodine deficiency is the primary, although not sole, cause of goiter. Goitrogens, such as thiocyanates that can enhance the effect of iodine deficiency, are referred to as secondary factors (1, 2).

Iodine deficiency interferes with the production of thyroid hormones, T₄ and T₃ molecules. Lower hormone output from the thyroid leads to a fall in the blood levels of T₄ but some increase in T₃ (the less iodinated hormone is produced preferentially in iodine deficiency).

The fall in the level of T₄ leads to increased TSH output from the pituitary. TSH increases the uptake of iodide by the thyroid, with increased turnover of iodine associated with hyperplasia of the cells of the thyroid follicles. Because reserves of colloid-containing thyroglobulin are gradually used up, the gland appears more cellular than usual. The size of the gland increases, with formation of a goiter. Enlargement is regarded as significant in the human when the lateral lobes are larger than the terminal phalanx of the thumb of the person examined. More precise measurements can now be made by ultrasound (4).

Extensive reviews of the global geographic prevalence of goiter have been published (1, 2, 3 and 4).

IODINE DEFICIENCY DISORDERS

The effects of iodine deficiency on growth and development are now denoted by the term *iodine deficiency disorders*. These effects are evident at all developmental stages

but are particularly acute in the fetus, neonate, and infant, in the periods of rapid growth. The term *goiter* has been used for many years to describe the effect of iodine deficiency, and goiter is indeed the most obvious and familiar feature of iodine deficiency. Because knowledge has greatly expanded in the last 25 years about the wide spectrum of effects of iodine on growth and development, particularly on brain development ([Table 13.3](#)) ([3](#), [4](#) and [5](#)), it is not surprising that a new term, *IDD*, has been coined.

Fetus	Abortions Stillbirths Congenital anomalies Increased perinatal mortality Increased infant mortality Neurologic cretinism (mental deficiency, deaf mutism, spastic diplegia, rigidity) Hypothyroid cretinism (dwarfism, mental deficiency) Polydactylous defects Increased susceptibility of the thyroid gland to nuclear radiation (after 12 weeks)
Neonate	Neonatal goiter Neonatal hypothyroidism Increased susceptibility of the thyroid gland to nuclear radiation
Child and adolescent	Goiter Acquired hypothyroidism Impaired mental function Retarded physical development Increased susceptibility of the thyroid gland to nuclear radiation
Adult	Goiter with its complications Hypothyroidism Impaired mental function Myxedematous hypothyroidism Increased susceptibility of the thyroid gland to nuclear radiation

Adapted from Hertzell BL, Pomer EI, Kulkarni SR. World Rev Nutr Diet 1982;10:1-10.

Table 13.3 The Spectrum of Iodine Deficiency Disorders (IDD)

The Fetus

Iodine deficiency in the fetus results from iodine deficiency in the mother. The condition is associated with a greater incidence of stillbirths, abortions, and congenital abnormalities, which can be reduced by provision of iodine. Many of the effects are similar to those observed with maternal hypothyroidism and can be reduced by thyroid hormone replacement therapy ([9](#)), which provides both hormone and iodine to mother and fetus.

Another major effect of fetal iodine deficiency is endemic cretinism. This condition occurs when iodine intake is below 25 µg/day (normal intake is 100–150 µg/day) and is still widely prevalent, affecting up to 10% of those living in severely iodine-deficient areas in India, Indonesia, and China as well as elsewhere ([10](#)). In its most common form, it is characterized by mental deficiency, deaf mutism, and spastic diplegia and is referred to as the “nervous” or neurologic-type cretin. The less common “myxedematous” type is characterized as hypothyroidism with dwarfism ([Fig. 13.2](#)).

Figure 13.2. *Left*, A myxoedematous cretin from Sinjiang, China, who is also deaf mute. This condition is completely preventable. *Right*, the barefoot doctor of her village. Both are about 35 years of age. (From Hetzel BS. The story of iodine deficiency—an international challenge in nutrition. Oxford: Oxford University Press, 1989;1–236; with permission of Dr. T Ma of Tianjin, China.)

Cretinism also occurs in Africa and in the Andean region (Ecuador, Peru, and Bolivia) of South America. In all these locations, with the exception of Zaire, neurologic features predominate. In Zaire, the myxedematous form is more common, probably because of the high intake of cassava (manioc or tapioca) (11). Clinically, neurologic cretinism varies considerably, including isolated deaf mutism and mental defects of varying degrees. The common neurologic form of endemic cretinism is not usually associated with severe clinical hypothyroidism, as is myxedematous cretinism, although mixed forms with both neurologic and myxedematous features do occur. Furthermore, the neurologic features are not reversed by administration of thyroid hormones (12).

Although isolated instances of cretinism can still be found, the apparent spontaneous disappearance of classic endemic cretinism in most of southern Europe during the 19th and early 20th centuries raised considerable doubt about the relation of iodine deficiency to the condition (5). To determine whether iodine deficiency and cretinism were related, a controlled trial was conducted in the western highlands of Papua New Guinea to see whether endemic cretinism could be prevented by correcting iodine deficiency with injection of iodized oil, then recently available (13). Injection of iodized oil before pregnancy prevented the occurrence of the neurologic syndrome of endemic cretinism in the infant (Fig. 13.3). The syndrome occurred in infants of women known to be pregnant at the time of oil injection, indicating that the damage probably occurred during the first half of pregnancy (14). This controlled trial also revealed a significant reduction in recorded fetal and neonatal deaths in the treated group (Table 13.4), which is consistent with other evidence indicating that iodine deficiency affects fetal survival (14). In a recent study in China, administration of iodine to iodine-deficient pregnant women up to the end of the second trimester protected the fetal brain from the effects of iodine deficiency. Treatment later in pregnancy or after delivery may improve brain growth and developmental achievement slightly but does not improve neurologic status

(15).

Figure 13.3. Results of a controlled trial of iodized oil injection in the Jimi River district of the highlands of Papua New Guinea. Alternate mothers were given a single injection of iodized oil or saline in September 1966. All newborn children were followed up for the next 5 years. Each dot represents a cretin child. The figure shows that by comparison with their persistence in the untreated group, mothers given iodized oil injections do not have subsequent cretin children, except for those known to be pregnant at the time of injection. (From Pharoah POD, Butfield IH, Hetzel BS. *Lancet* 1971;1:308–10; with permission from Pharoah et al. 1971.)

Location	Characteristic	Untreated	Treated
Papua New Guinea	Total no. of children	406	412
	Normal	380	405
	Stillborn	97	66 ^a
	Cretins	26	7 ^{a,b}
Zaire ^c		2534	2837 ^a
	Perinatal mortality/1000	188	98 ^a
	Infant mortality/1000	250	167 ^a
	Development quotient (g)	104	115 ^a

^cData from Zaire were made on a variable number (86–263) of children in each group.

Table 13.4 Controlled Trials of Iodized Oil in Iodine-Deficient Pregnant Women

A relationship between the level of maternal thyroxine and the outcome of current and recent past pregnancies, including mortality and the occurrence of cretinism was also found in Papua New Guinea. There were proportionally more perinatal (i.e., stillbirths and neonatal) deaths and cretins among the offspring of women with the lowest levels

of serum thyroxine (16).

The demonstrated importance of maternal thyroid function to fetal survival and development is complemented by more recent studies. Studies in experimental animal models and, more recently, in man (17) indicate that maternal thyroxine is transferred to the fetus early in pregnancy. It would seem likely, therefore, that the effects of iodine deficiency on the fetus are mediated by reduced transfer of maternal thyroxine before the onset of fetal thyroid function and are not solely due to fetal deficiency of elemental iodine as originally suggested because of the lack of evidence of transfer of T₄ at that time (14).

The earlier “spontaneous” disappearance of endemic cretinism in Europe is now attributed to increased dietary iodine from dietary diversification and use of iodine supplements associated with economic development (18).

The Neonate

Increased perinatal mortality due to iodine deficiency has been shown in Zaire in a controlled trial of iodized oil injections alternated with a placebo injection given in the latter half of pregnancy (19). Following the iodized oil injection, infant mortality fell substantially, with improved birth weights (Table 13.4). Low birth weight of any cause is generally associated with a higher rate of congenital anomalies and a higher risk through childhood. This has been demonstrated by long-term follow-up of the controlled trial in Papua New Guinea, in children up to the age of 12 years (20).

Apart from mortality, the state of thyroid function in the neonate is important because the brain of the human infant at birth is only about one-half its full size and continues to grow rapidly until the end of the second year (21). Thyroid hormone, which depends on an adequate supply of iodine, is essential for normal brain development, as is confirmed by the animal studies cited above. Severe iodine deficiency that affects neonatal thyroid function and hence poses a threat to early brain development is still found in Europe (22). A series of 1076 urine samples was collected and analyzed in 16 centers from 10 different countries in Europe along with an additional series from Toronto, Canada (22). Because the distribution of urinary iodine is skewed, results were expressed in percentiles rather than as arithmetic means. Some very high values of urinary iodine were seen, which could be attributed to the use of iodinated contrast media for radiologic investigation of the mother during pregnancy. There was a marked difference in the results from the various European cities. The high levels of urinary iodine excretion in Rotterdam, Helsinki, and Stockholm differed from the low levels in Gottingen, Heidelberg, Freiburg, and Jena by a factor of more than 10. Intermediate levels were seen in Catania, Zurich, and Lille.

Data on neonatal thyroid function were analyzed for four European cities where data were available from enough newborns (30,000–102,000) to test the incidence of permanent congenital hypothyroidism (approximately 1/3500 in the absence of iodine deficiency) (22). The incidence of permanent congenital hypothyroidism was very similar in the four cities, but the rate of transient hypothyroidism was much higher in Freiburg (associated with the lowest level of urinary iodine excretion) than in Stockholm, with

intermediate findings from Rome and Brussels. These data confirm the significance of iodine intake for neonatal thyroid function and therefore brain development.

In developing countries with more severe iodine deficiency, observations were made on blood taken from the umbilical vein just after birth. Neonatal chemical hypothyroidism was defined as a T_4 level below 3 $\mu\text{g/dL}$ and a TSH value above 50 mU/L (23). In the most severely iodine deficient environments in northern India, where more than 50% of the population shows urinary iodine levels below 25 $\mu\text{g/g}$ creatinine, the incidence of neonatal hypothyroidism was 75 to 115 per thousand births (23). By contrast, in Delhi, where only mild iodine deficiency is present with low prevalence of goiter and no cretinism, the incidence drops to six per thousand. In control areas without goiter, the level was only one per thousand.

In Zaire, the rate of chemical hypothyroidism among neonates is 10% (24). If the deficiency is not corrected, hypothyroidism persists into infancy and childhood with resultant retardation of physical and mental development (25). These observations indicate that a much greater risk of mental defect exists in severely iodine-deficient populations than is indicated by the presence of cretinism. They provide strong evidence for the need to correct the iodine deficiency in Europe as well as in developing countries.

Another important aspect of iodine deficiency in the neonate and child is an increased susceptibility of the thyroid gland to radioactive fallout. Delange (26) showed that thyroidal uptake of radioiodine reaches its maximum value in the earliest years of life and then declines progressively into adult life. The apparent thyroidal iodine turnover rate was much higher in young infants than in adults and decreased progressively with age. To provide the normal rate of T_4 secretion, Delange estimated that the turnover rate for intrathyroidal iodine must be 25 to 30 times higher in young infants than in adolescents and adults. In iodine deficiency, a further increase in turnover rate is required to maintain normal thyroid hormone levels. This is the reason for the greatly increased susceptibility of the neonate and fetus to iodine deficiency. Iodine deficiency also causes increased uptake of radioiodide resulting from exposure to nuclear radiation, as occurred in the Chernobyl disaster. Protection against this increased uptake can only be provided by correction of iodine deficiency, a further strong indicator for correction of iodine deficiency in Europe as well as in developing countries in view of the possibility of a recurrence of the Chernobyl disaster from other, similar power plants in Eastern Europe and Asia.

The Child

Iodine deficiency in children is characteristically associated with goiter. The classification of goiter, which has been standardized by the WHO, is discussed below. The goiter rate increases with age and reaches a maximum in adolescence. Girls have a higher prevalence than boys. Goiter rates in school children from 8 to 14 years of age provide a convenient indication of the presence of iodine deficiency in a community.

School children living in iodine-deficient areas from a number of countries show lower

school performance and IQs than matched groups from iodine-sufficient areas. These studies are difficult to do because of the problem of the control group. The many possible causes for impaired performance in school and on IQ tests make interpretation of any observed differences difficult. Compared with the iodine-sufficient area, the iodine-deficient area is likely to be more remote and to have poorer school facilities. Its inhabitants usually suffer more social deprivation, have a lower socioeconomic status, and are in a poorer nutritional state. All such factors must be taken into account in evaluating the effects of iodine deficiency in addition to the problem of adapting tests developed in Western countries for use in Third World countries. In a metaanalysis of 18 studies in which comparisons were made between iodine-deficient and normal children, mean scores differed by 13.5 IQ points, which is highly significant ($P < .00001$) (27, 28).

The Adult

Iodine administration in the form of iodized salt, iodized bread, or iodized oil, is effective in the prevention of goiter in adults. Iodine administration may also reduce existing goiter in adults. This is particularly true of iodized oil injections (1, 4, 5), and this obvious effect leads to ready acceptance of the measure by people living in iodine-deficient communities. A rise in circulating thyroxine can be readily demonstrated in adult subjects following iodization by various means.

A more subtle effect in the adult is cerebral hypothyroidism (28) that is manifested by slow responses and by slow reaction times. Because the brain is especially sensitive to hypothyroidism, impaired brain function occurs before the functions of other organs are demonstrably affected. Recent advances in thyroid physiology and biochemistry explain this clinical observation. The major determinant of brain (and pituitary) T_3 is serum T_4 , not serum T_3 (as is true of the liver, kidney, and muscle) (29). Low levels of brain T_3 have been demonstrated in iodine-deficient rats in association with reduced levels of serum T_4 and have been restored to normal with correction of iodine deficiency (30). These findings explain suboptimal brain function in subjects with endemic goiter and lowered serum T_4 levels and its improvement following correction of iodine deficiency.

In northern India, a high degree of apathy has been noted in populations living in iodine-deficient areas. This deficiency may even affect domestic animals such as dogs! This reduced mental function is due to cerebral hypothyroidism. Elimination of the iodine deficiency in these communities reverses the cerebral hypothyroidism and improves the capacity for initiative and decision making. Iodine deficiency is a major block to human and social development in communities in an iodine-deficient environment. Correction of the iodine deficiency makes a major contribution to development and also reduces susceptibility to nuclear radiation.

EFFECTS OF IODINE DEFICIENCY IN ANIMALS

Naturally occurring iodine deficiency in farm animals causes reproductive failure and thyroid insufficiency (31). In iodine-deficient areas, fetal development is retarded or arrested in gestation, resulting in early death or resorption, abortion, stillbirth, or birth of weak, hairless offspring associated with prolonged gestation and parturition and

retention of placental membranes. Subnormal thyroid hormone levels in herds of cattle have been accompanied by a high incidence of aborted, stillborn, and weak calves (31).

In recent experimental work with animal models (3, 21, 31, 32), severe iodine deficiency has been established prior to and during pregnancy. Iodine deficiency in sheep (5–8 μg iodine per day for sheep weighing 40 kg) is associated with increased incidence of abortions and stillbirths. At the end of pregnancy, the fetus shows reduced body weight, complete absence of wool growth, deformation of the skull, and retarded bone development. Retarded brain development is indicated by reduced brain weight and a reduced number of cells (as measured by DNA) (Fig. 13.4). Similar effects have been observed in the marmoset monkey (0.3 μg iodine per day for 340 g body weight).

Figure 13.4. Effect of severe iodine deficiency during pregnancy on lamb development. **A.** A 140-day-old lamb fetus was subjected to severe iodine deficiency by feeding the mother an iodine-deficient diet (5–8 $\mu\text{g}/\text{day}$) for 6 months prior to and during pregnancy (full-term, 150 days). **B.** A control lamb of the same age fed the same diet with addition of an iodine supplement. The iodine-deficient lamb showed absence of wool coat, subluxation of the leg joints, and a domelike head caused by skeletal retardation and a smaller brain. (From Hetzel BS. The story of iodine deficiency—an international challenge in nutrition. Oxford: Oxford University Press, 1989;1–236.)

These data indicate that the effects of severe iodine deficiency on fetal development involve a combination of maternal and fetal hypothyroidism, with the effect of maternal hypothyroidism preceding the onset of fetal thyroid secretion. This implies an effect on neuroblast multiplication, which occurs from 40 to 80 days of gestation in the sheep and 11 to 18 weeks in the human (3, 21, 32, 33). In the rat (a postnatal brain developer in which neuroblast multiplication occurs in the last one-third of fetal life), maternal hypothyroidism early in pregnancy results in reduced weight and number of embryos, reduced brain weight, and reduced transfer of maternal T_4 to the fetus (3, 32). The findings indicate that iodine deficiency has an early effect on neuroblast multiplication; this could be important in the pathogenesis of the neurologic form of endemic cretinism

(3, 32, 33).

ASSESSMENT OF IODINE STATUS

The assessment of iodine status is important for public health programs that carry out iodine supplementation. The problem is therefore one of assessing a population or group living in an area suspected of being iodine deficient. The methods recommended are discussed below.

Goiter Rate

The goiter rate includes the rate of both palpable and visible goiter. A classification of goiter severity has recently been adopted by the WHO (Table 13.5), but there are still minor differences in technique between different observers. In general, visible goiter is more readily verified than palpable goiter. Observations in Tanzania (4) indicate that palpation of the thyroid generally overestimates the size of the gland as determined by ultrasonography, particularly in children. Determination of thyroid size by ultrasonography has now become standardized and, because it is an objective measure, is preferred when this technology is available (34).

Grade 0	No palpable or visible goiter
Grade 1	A mass in the neck that is consistent with an enlarged thyroid that is palpable but not visible when the neck is in the normal position; it moves upward in the neck as the subject swallows; nodular alteration(s) can occur even when the thyroid is not enlarged
Grade 2	A swelling in the neck that is visible when the neck is in a normal position and is consistent with an enlarged thyroid when the neck is palpated

From Joint WHO/UNICEF/ICCIDD Consultation—Indicators for assessing iodine deficiency disorders and their control through salt iodization. Geneva: World Health Organization, 1994.

Table 13.5 Proposed Classification of Goiter

Urinary Iodine Excretion

Urinary iodine determinations can be carried out on casual samples from a group of subjects, with iodine levels expressed as $\mu\text{g/L}$. Because the distribution is skewed, the median level is used for quick reference. Urinary iodine excretion is a good index of the level of iodine nutrition. Recently simplified methods now allow processing of many more samples in a given period (35).

The range of levels include $<20 \mu\text{g/L}$ (severe IDD), $20\text{--}49 \mu\text{g/L}$ (moderate IDD), and

50–99 µg/L (mild IDD). Values between 100 and 200 µg/L are considered satisfactory. Excessive iodine intake can also be most conveniently monitored by determination of urinary iodine excretion. The median level should not exceed 20 µg/dL in an iodine-deficient population following salt iodization programs.

Blood Thyroid-Stimulating Hormone

Particular attention is now focused on levels of TSH in neonatal blood because of the important influence of thyroid function on early brain development. Determination of the TSH level provides an indirect measure of iodine status. The availability of radioimmunoassay and immunometric methods with automated equipment enables large numbers of samples to be processed in a given period, and TSH determinations are now preferred to T₄ because of better stability under tropical conditions and easier methodology. The mean normal levels with the ELISA assay are given in [Table 13.2](#).

In an increasing number of developed countries, mass screening is currently conducted with heel-prick blood samples from neonates (3–4 days after birth), which are spotted onto filter paper, dried, and sent to a regional laboratory. Blood levels of T₄, TSH, or both are measured by immunoassay techniques. As mentioned, the detection rate of neonatal hypothyroidism requiring treatment is about 1 per 3500 babies screened and varies little among developed countries ([36](#)).

In developing countries, severe biochemical hypothyroidism (T₄ concentrations <3 µg/dL) has been reported in up to 10% of neonates ([36](#)) in northern India and in Zaire ([4](#)). These data indicate the massive threat to brain development posed by severe iodine deficiency.

To summarize, iodine status is best determined initially by measuring urinary iodine excretion. Then, thyroid size and blood TSH in the neonate should be measured. The criteria adopted for monitoring progress toward the elimination of IDD as a public health problem are discussed below.

IODINE REQUIREMENTS

In 1989, the Food and Nutrition Board of the U.S. National Academy of Sciences, National Research Council, confirmed the previous 1980 recommendations for a daily iodine intake of 40 µg for children aged 0 to 6 months, 50 µg from 6 to 12 months, 70 to 120 µg from 1 to 10 years, and 120 to 150 µg from 11 years onward. The recommended rates during pregnancy and lactation were, respectively, 175 and 200 µg. The recommendations applied equally to both sexes ([37](#)) (See also Appendix [Table II-A-2-a-2](#)).

Participants in a series of recent WHO/ICCIDD (International Council for the Control of Iodine Deficiency Disorders) meetings suggested that requirements for infants and for pregnant and lactating women be increased. Their counsel has influenced the recent

recommendations of the WHO (1996) ([Table 13.6](#)) ([38](#)).

Age Range or State	Intake ($\mu\text{g/day}$)
0-12 months	50
1-6 years	90
7-12 years	120
12 years to (and through) adulthood	150
Pregnancy	200
Lactation	200

From Trace elements in human nutrition and health. Geneva: World Health Organization, 1996.

Table 13.6 Recommended Intakes of Iodine (Population Requirements)

IODINE TOXICITY

Iodine toxicity has been critically studied in man, laboratory species, poultry, pigs, and cattle. Wolff ([39](#)) has suggested that human intakes of 2000 μg I/day should be regarded as excessive or potentially harmful. Normal diets composed of natural foods are unlikely to supply 2000 μg I/day, and most would supply less than 1000 μg I/day, except those exceptionally high in marine fish or seaweed or containing foods contaminated with iodine from adventitious sources.

Inhabitants of the coastal regions of Hokkaido, the northernmost island of Japan, whose diets contain large amounts of seaweed, have remarkably high intakes of 50,000 to 80,000 μg I/day ([40](#)). Urinary excretion in five patients exhibiting clinical signs of iodide goiter exceeded 20 mg I/day, about 100 times the normal intake.

In Japan ([41](#)) it has been shown that

1. Healthy subjects can maintain normal thyroid function even when they are taking several milligrams/day of dietary iodine
2. High dietary iodine levels markedly decrease the incidence of nontoxic diffuse goiter and toxic nodular goiter
3. High dietary iodine levels do not affect the incidence of Graves' disease and Hashimoto's disease
4. High dietary iodine may induce hypothyroidism in autoimmune thyroid diseases and may inhibit the effects of thionamide drugs

Significant species differences exist in tolerance to high iodine intakes. In all well-nourished species studied, the tolerance is high (i.e., relative to normal dietary

iodine intakes, a wide margin of safety exists for this element). The same tolerance does not apply to iodine-deficient populations.

Iodine-Induced Hyperthyroidism (IIH)

An increased incidence of hyperthyroidism has been described since introduction of iodized salt programs in Europe and South America and following the use of iodized bread in Holland and Tasmania (42, 43). A few cases were noted following administration of iodized oil in South America. The condition is easily overlooked in developing countries because the population is scattered and there are limited opportunities for observation (44). Natural remission occurs. The condition is largely confined to those over 40 years of age, and a smaller proportion of the population in developing countries is affected than in developed countries. Detailed observations are available from the island of Tasmania (43, 45) and, more recently, from Zimbabwe (46).

In Zimbabwe, careful investigation revealed the occurrence of IIH from excessive levels of iodine in the salt that resulted from faulty mixing at the factory. Thus, suitable monitoring procedures for salt iodization and urinary iodine excretion are essential to prevent excessive iodine intake and IIH. Monitoring is also essential to ensure an adequate intake that corrects iodine deficiency, which has been a greater problem than iodine excess in Asia and Latin America.

Joseph et al. (47) reported that daily iodine intakes below 0.10 mg pose no risk for patients with autonomous thyroids due to iodine deficiency but that critical daily intakes are probably between 0.10 and 0.20 mg (47). Iodization of bread in Tasmania resulted in hyperthyroidism for some individuals at iodine intakes of about 0.20 mg/day (43, 45). The use of iodized bread in Holland, which contributed an additional 0.12 to 0.16 mg of iodine per day, increased the incidence of hyperthyroidism. The spring-summer peak of thyrotoxicosis (related to winter milk) in England occurred with average daily iodine intakes of 0.24 mg for women and 0.32 mg for men (48). The lack of iodine deficiency in the Japanese population accounts for the absence of IIH (41).

IIH is accompanied by some morbidity and mortality in older age groups. It is readily controlled with antithyroid drugs or radioiodine. Spontaneous remission also occurs. Risk of hyperthyroidism (1, 2, 4), even with an increase to normal levels of intake, arises because an autonomous thyroid can develop independence from TSH control and continue its high rate of secretion despite increased iodine intake. To minimize IIH, the medium urinary iodine level should not exceed 20 µg/dL. Adequate facilities for diagnosis and treatment are also required.

The occurrence of IIH with consequent morbidity and mortality is not regarded as a contraindication to iodization programs in view of the enormous benefits that correction of iodine deficiency has for the whole population, particularly reduced child mortality, improved child learning, improved health of women, greater economic productivity, and improved quality of life (Table 13.4). Furthermore, correction of iodine deficiency prevents formation of an autonomous thyroid and thereby minimizes IIH. Hence, IIH is included as an "iodine deficiency disorder" (Table 13.3).

CORRECTION OF IODINE DEFICIENCY

Iodized Salt

Iodized salt has been the major method of correcting iodine deficiency since the 1920s, when it was first successfully used in Switzerland (1, 4, 5). Since then, many successful programs have been reported, including those in the U.S., Central and South America (e.g., Guatemala, Colombia), Finland, China, and Taiwan (5).

The difficulties in production, maintenance of quality, and consumption of iodized salt for the millions who are iodine-deficient, especially in Asia, were vividly demonstrated in India, where there was a breakdown in supply. These difficulties led to adoption of a universal salt iodization (USI) policy for India and many other countries. This policy requires access to iodized salt for 80% of the population. It has been promoted by WHO and UNICEF since 1993 to ensure that only iodized salt is available for human and animal consumption. In Asia, iodized salt production and distribution at present costs approximately 3 to 5 cents per person per year (4), which must be considered cheap in relation to the social benefits that accrue, as described above.

However, the problem still exists of ensuring that the salt actually reaches the iodine-deficient subject. There may also be a problem with distribution or with preservation of the iodine content (e.g., it may be left uncovered for long periods or exposed to heat). Salt should be added after cooking, to reduce the loss of iodine. Present recommendations for salt iodine content are in the range of 20 to 40 mg/kg (48a).

Finally, there is the difficulty of ensuring the actual consumption of iodized salt. While addition of iodine makes no difference to the taste of the salt, introduction of a new variety of salt to an area in which brands of noniodized salt are already available and much appreciated as a condiment is likely to be resisted. In the Chinese provinces of Sinjiang and Inner Mongolia, for example, the strong preference of the people for desert salt of very low iodine content led to a program of mass iodized oil injection to prevent cretinism rather than introduction of competing brands of salt (49).

Iodized Oil by Injection

The value of iodized oil injection in the prevention of endemic goiter and endemic cretinism was first established in New Guinea with controlled trials involving the use of saline injection as a control (4, 14). Experience in South America, Zaire, and China has confirmed the value of this measure. Quantitative correction of severe iodine deficiency by a single intramuscular injection can last for more than 4 years (13). Iodized oil is singularly appropriate for isolated mountainous village communities that are commonly endemic goiter areas. The striking regression of goiter following iodized oil injection ensures general acceptance of the measure.

In a high-risk area, until an effective iodized salt program is in place, the oil (1 mL of

poppyseed oil contains 480 mg of iodine) should be administered to all females up to the age of 40 years and all males up to the age of 20 years. A repeat injection is required in 3 to 5 years, depending on the dose given and the age of the subject. Children have a greater need than adults do, and the recommended dose should be repeated in 3 years if severe iodine deficiency persists (4).

Iodized walnut oil and iodized soya bean oil were developed in China since 1980, and Indonesia has now developed iodized peanut oil for oral use (4).

Iodized Oil by Mouth

Because of the hazards associated with injections, there has been a strong recent trend toward oral administration of iodized oil. Recent studies in India and China reveal that oral iodized oil lasts only half as long as a similar dose given by injection (4). A recent study in children indicates that 1 mL (480 mg of iodine) of oral oil provides coverage of iodine deficiency for 1 year (50). Iodized salt and iodized oil are major mass supplementation measures that have been used on a large scale. More than 50 million doses of iodinated oil have been given with evidence of successful prevention of IDD.

INTERNATIONAL ACTION

New knowledge of the causes of IDD and its impact on brain development, as well as the application of this new knowledge in national IDD control programs, particularly in developing countries, led to formation in 1985 of the ICCIDD (4, 5, 51). The inaugural meeting of this multidisciplinary group of epidemiologists, nutritionists, endocrinologists, chemists, public health planners, and economists was held in Kathmandu, Nepal, in March 1986. A series of papers on all aspects of IDD control programs presented in Kathmandu has been published as a monograph (4). The ICCIDD has established a global multidisciplinary network of some 400 professionals from more than 80 different countries with expertise relevant to IDD and IDD control programs. More than half of the members are from developing countries. The ICCIDD works closely with WHO, UNICEF, and national governments within the UN system in the development of national programs (4, 5, 51). Because major concentrations of populations at risk are in Asia, IDD control programs in the last 10 years have escalated in India, Indonesia, Nepal, Bangladesh, and more recently China.

In Latin America, earlier efforts have produced a large measure of control in such countries as Argentina, Brazil, Colombia, and Guatemala. The problem recurred in Colombia and Guatemala, however, largely associated with political and social unrest. Nonetheless, the combination of national government initiatives and support from international agencies through the USI policy has induced remarkable progress in the last 5 years (51).

In Africa, development of IDD control programs has lagged by comparison with the other continents. New initiatives began after a Joint WHO/UNICEF/ICCIDD Regional Seminar held in Yaounde, Cameroon, in March 1987. This seminar set up a joint IDD Task Force that initiated comprehensive planning for prevention and control of IDD in

Africa (5).

In September 1990, the World Summit for Children held at the United Nations in New York was attended by 71 heads of state and 80 other government representatives. The World Summit signed a declaration and approved a plan of action that included the elimination of IDD as a public health problem by the year 2000. The criteria adopted for monitoring progress toward this goal are summarized in [Table 13.7](#).

Indicator	Goal
1. Salt iodization Proportion of households consuming effectively iodized salt	>90%
2. Urinary iodine Proportion below 100 µg/L Proportion below 50 µg/L	<50% <20%
3. Thyroid size In school children 6–12 years of age: Proportion with enlarged thyroid, by palpation or ultrasound	<5%
4. Neonatal TSH Proportion with levels >5 mIU/L, whole blood	<3%

From Joint WHO/UNICEF/ICCIDD Consultation—Indicators for assessing iodine deficiency disorders and their control through salt iodization. Geneva: World Health Organization, 1994.

Table 13.7 Criteria for Monitoring Progress Toward Eliminating IDD as a Public Health Problem

These meetings have led to a new era of political support at the country level. For example, China has made rapid progress since the World Summit for Children. Forty percent of the Chinese population lives in an iodine-deficient environment, either mountainous terrain or flooded river valleys. In 1993, a national advocacy meeting was held in the Great Hall of the People, sponsored by Premier Li Peng. Both the Chinese government and major international agencies made commitments to upgrading the national program with adoption of a USI policy and effective iodization of salt. The Chinese government recognized the major hazard presented by iodine deficiency as a cause of brain damage for the next generation. This concern was accentuated by the government's one-child family policy.

Recent data indicate remarkable progress with USI in developing countries. By mid-1996, WHO estimated that approximately 56% (2.4 billion) of the population in 83 developing countries with a significant IDD public health problem now has access to iodized salt. At the recent (1996) Joint WHO/UNICEF/ICCIDD Meeting in Africa attended by 45 countries, most reported good progress with the USI policy. This remarkable progress encourages confidence that IDD as a public health problem may be largely eliminated by the year 2000, with incalculable benefits to the quality of life of the many millions at risk (51).

Selenium first attracted biologic interest in the 1930s when it was found to cause alkali disease, a chronic poisoning of livestock resulting from the consumption of plants that grow on high-selenium soils (1). In 1957, Schwarz and Foltz reported that traces of selenium prevented liver necrosis in vitamin E–deficient rats, indicating that selenium was an essential nutrient and not only a toxin (2). Soon thereafter, deficiencies of selenium and vitamin E were shown to be involved in several economically important nutritional diseases of cattle, sheep, swine, and poultry (3). The first demonstration of a biochemical function for selenium in animals came in 1973, when it was shown to be a constituent of the enzyme glutathione peroxidase (4).

The importance of selenium in human nutrition was shown in 1979, when Chinese scientists reported that selenium supplementation prevented development of a cardiomyopathy known as Keshan disease in children living in low-selenium areas (5), and New Zealand workers reported a clinical response to selenium in a selenium-depleted patient (6). Information about the role of selenium in human nutrition increased rapidly in the 1980s, and a recommended dietary allowance (RDA) for

selenium was established in 1989 (7). Dietary recommendations from the World Health Organization (WHO) were issued in 1996 (8). Over the last decade, research has provided extensive new information on selenoproteins and the molecular biology of selenium.

CHEMICAL FORMS

Most selenium in biologic systems is present in amino acids as constituents of proteins. The chemistry of selenium is similar to that of sulfur, reflecting its position in the oxygen series of the periodic table of elements. The three amino acids serine, cysteine, and selenocysteine contain, respectively, oxygen, sulfur, and selenium in the same carbon skeleton. Their differences in biochemical activity arise from the chemical reactivity of the element in each of them. Selenocysteine is the most reactive of the three, and its selenol (Fig. 14.1) performs catalytic functions in proteins. Selenomethionine, on the other hand, contains selenium bound to two carbon atoms and is not known to have a biologic function distinct from methionine.

Figure 14.1. Selenium-containing amino acids found in animals. Selenocysteine is the biologically active form of the element found in selenoproteins. Its selenol is largely ionized at physiologic pH and is a stronger nucleophile than the thiol of cysteine. These chemical properties contribute to its catalytic function in selenoenzymes. Selenomethionine contains selenium covalently bound to two carbon atoms. Thus, its selenium is shielded and not as chemically active as the selenium in selenocysteine. Selenomethionine appears to be distributed nonspecifically in the methionine pool.

A selenoprotein is a protein that contains stoichiometric amounts of selenium. Selenocysteine is the form in the primary structure of all the animal selenoproteins identified so far and all but one of the bacterial selenoproteins. Selenium occurs in an unidentified form (not selenocysteine) that is coordinated with molybdenum in nicotinic acid hydroxylase from *Clostridium barkeri* (9), indicating that selenoproteins exist containing forms of the element other than selenocysteine.

Numerous proteins contain selenium in nonstoichiometric amounts and may be referred to as selenium containing proteins. This designation has low utility, because virtually all proteins that contain methionine will contain selenomethionine in proportion to the relative abundance of these two amino acids in the organism (see below).

Selenium enters the food chain through plants that incorporate it into compounds that usually contain sulfur. Thus plant selenium is in the form of selenomethionine and, to a lesser extent, selenocysteine and other analogues of sulfur amino acids. No evidence has been presented that plants require selenium incorporation into a specific molecule necessary for their existence.

Selenophosphate, an important intermediate compound in selenium metabolism, is produced by selenophosphate synthetase and serves as the selenium donor for production of selenium-containing transfer RNAs as well as for selenocysteine destined for incorporation into selenoproteins (10). Methylated forms of selenium are produced as excretory metabolites and rapidly appear in the urine and breath (11). A putative transport form of the element has been detected in blood plasma, but its identity has not been established (12).

DIETARY CONSIDERATIONS

Food Sources

Although SI units (Système International d'Unités, or International System of Units) are increasingly used to express concentrations of nutrients in body fluids and tissues, food composition tables primarily express values in micrograms per gram ($\mu\text{g/g}$). In this regard, 1 μg Se equals 0.0127 μmol Se. The richest food sources of selenium are organ meats and seafood, 0.4 to 1.5 $\mu\text{g/g}$ fresh weight; followed by muscle meats, 0.1 to 0.4; cereals and grains, less than 0.1 to more than 0.8; dairy products, less than 0.1 to 0.3; and fruits and vegetables, less than 0.1 (13). The wide variation in the selenium content of cereals and grains is due to the fact that plants do not appear to require selenium and thus contain variable amounts, depending upon how much soil selenium is available for uptake (phytoavailability). For example, one study showed that the selenium content of corn collected in the People's Republic of China ranged from 0.005 to 8.1 $\mu\text{g/g}$, depending on whether the samples came from areas with soils that were poor or rich in phytoavailable selenium (14). The importance of geographic origin in determining the selenium content of grains was also recently indicated by the reported decline in the selenium content of the British diet from 65 to 31 $\mu\text{g/day}$ after Britain switched its source of wheat from North America to Europe (15). Foods from animal sources vary somewhat in selenium content, but the variation is less because of the tendency toward homeostatic control of selenium under different conditions of exposure. Drinking water generally contributes negligible selenium to the overall intake, except perhaps in some localized highly seleniferous areas (16).

The Total Diet Study conducted by the U.S. Food and Drug Administration showed that a typical diet in the United States provided an average daily selenium intake of 100 and

70 µg for adult men and women, respectively, between 1982 and 1986 (17). Lower daily selenium intakes, 30 µg or less, have been reported in countries with selenium-poor soils, such as New Zealand (18). Because of the increasing evidence that good selenium status may confer human health benefits, the government of Finland decided to start adding selenium to the fertilizers used in that low-selenium country in 1984 as a way of improving the selenium status of the general population (19). Although daily dietary intakes increased from 39 µg in 1984 to 92 µg in 1986, resulting in an increase in plasma selenium concentrations from 0.95 to 1.52 µmol/L after 1.5 years of the intervention, no reduction has been observed in the incidence of cancer or cardiovascular disease to date (20). Extremely low dietary selenium intakes have been reported in Keshan disease-affected areas of China, from 3 to 22 µg/day (14). On the other hand, very high dietary intakes (up to 6690 µg/day) were observed in a region of China with endemic human selenosis (14). Food in this area was grown on soil contaminated with selenium leached from a highly seleniferous coal fly ash.

Bioavailability

Only a limited number of investigations have been carried out to determine the nutritional bioavailability of selenium in foods consumed by humans. Commonly, the experimental procedure to estimate selenium availability follows increases in hepatic glutathione peroxidase activity after feeding various food sources of selenium to rodents previously depleted of selenium (21). On this basis, selenium fed as mushrooms, tuna, and wheat was 5%, 57%, and 83% as available to rats, respectively, as sodium selenite (21, 22). A human bioavailability trial performed in Finland with men of moderately low-selenium status showed significant differences among various forms of selenium tested (e.g., selenate, wheat, yeast), depending on the criterion of availability used (increase in platelet glutathione peroxidase activity, elevation of plasma or red blood cell selenium content, retention of selenium) (23). This study pointed out the need to consider several variables in such trials, including short-term increases in glutathione peroxidase activity, long-term tissue retention of selenium, and metabolic conversion of retained selenium to biologically active forms.

Nutrient-Nutrient Interrelationships

Because of its role in the glutathione peroxidases and thioredoxin reductase, selenium probably interacts with any nutrient that affects the antioxidant/prooxidant balance of the cell. For example, the selenium requirement of chicks is inversely proportional to the dietary vitamin E intake (24). Selenium also protects against the toxicities of mercury, cadmium, and silver (25), and a physiologic role for selenium in counteracting heavy metal pollutants has been proposed (26). The low bioavailability of the selenium in tuna may be due to complex formation with mercury, but this issue needs further investigation (21).

METABOLISM

Selenium enters the body in several forms (Fig. 14.2). The two major ones are selenomethionine, derived ultimately from plants, and selenocysteine in animal selenoproteins. Selenomethionine does not appear to be specifically recognized as a

selenium compound and is metabolized in the methionine pool. It is measured as tissue selenium because it occurs in methionine-containing proteins in tissues. The selenium in selenomethionine is made available for specific use when the amino acid is catabolized (Fig. 14.2). The selenium then enters regulated selenium metabolism and can be incorporated specifically into macromolecules, transported to other organs, or excreted.

Figure 14.2. Relationships of dietary forms of selenium with tissue forms. Dietary forms of the element are shown on the *left* and tissue forms on the *right*. Excretory metabolites and the transport form are also present in tissues but only in relatively small quantities. (From Levander OA, Burk RF. Selenium. In: Ziegler EE, Filer LJ, eds. Present knowledge in nutrition. Washington, DC: ILSI Press, 1996;320–8, with permission.)

Figure 14.3 outlines selenium metabolism in the cell. Selenomethionine catabolism occurs via the transsulfuration pathway and yields selenocysteine. Free selenocysteine, whether derived from selenomethionine or from selenoprotein catabolism, is degraded by selenocysteine b-lyase (28). The resulting selenide can enter the anabolic pathway by conversion to selenophosphate or be methylated for excretion (11, 29). The further metabolism of selenide is the likely point of homeostatic regulation of selenium in the body. The mechanism by which this form of selenium is directed into the anabolic pathway or into the excretory pathway has not been determined.

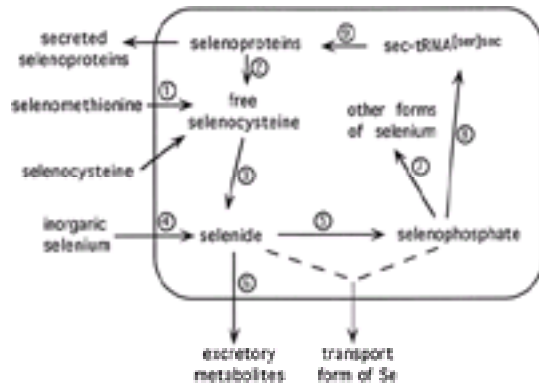

Figure 14.3. Regulated selenium metabolism. An outline of selenium metabolism based on reactions known to take place. The box represents the cell. Circled numbers indicate (1) the transsulfuration pathway, (2) proteolytic breakdown of proteins, (3) selenocysteine b-lyase, (4) reduction by glutathione, (5) selenophosphate synthetase, (6) methylation, (7) replacement of sulfur in tRNA by selenium, (8) replacement of oxygen in serine with selenium to produce selenocysteine, (9) decoding of UGA in mRNA with insertion of selenocysteine into primary structure of protein. The origin and identity of the transport form of selenium is unknown; it might arise from selenide or selenophosphate as indicated by the *broken lines*. (From Levander OA, Burk RF. Selenium. In: Ziegler EE, Filer LJ, eds. Present knowledge in nutrition. Washington, DC: ILSI Press, 1996;320–8, with permission.)

Absorption

Absorption appears to play no role in the homeostatic regulation of selenium. Virtually complete absorption occurs when the element is supplied as selenomethionine (30), and other forms are generally well absorbed. However, absorption of inorganic forms varies widely because it is influenced by luminal factors. Thus, selenium absorption is usually in the range of 50 to 100% and is not affected by selenium nutritional status.

Transport

Little is known about the extracellular transport of selenium. Two selenoproteins, selenoprotein P and extracellular glutathione peroxidase (GSHPx-3), have been identified in plasma, but both contain the element as selenocysteine in their primary structures, making them unlikely candidates for transport forms. Small-molecular-weight forms of the element recognized as minor components of the plasma selenium (12) might serve transport functions. Chemical identification of these forms has not yet been made.

Incorporation into Protein

The animal selenoproteins characterized so far contain selenocysteine in their primary structures. The mechanism by which selenocysteine, the 21st amino acid, is synthesized and then incorporated into selenoproteins is complex. [Figure 14.4](#) outlines selenoprotein synthesis in animals. $\text{tRNA}^{\text{[ser]sec}}$, a unique transfer RNA with the anticodon for UGA, is charged with serine by seryl-tRNA ligase. The serine in the resulting $\text{ser-tRNA}^{\text{[ser]sec}}$ is then converted to selenocysteine by a process requiring selenophosphate synthesized by selenophosphate synthetase ([Fig. 14.3](#)). Two isoforms of selenophosphate synthetase have been identified ([31](#), [32](#)), and one is itself a selenoprotein. In prokaryotes, a pyridoxal phosphate catalyzes the selenophosphate-dependent conversion of serine to selenocysteine ([33](#)). The corresponding enzyme has not yet been characterized in animals.

Figure 14.4. *Panel A.* Outline of selenoprotein synthesis. *Solid lines* indicate reactions that have been characterized and *broken lines* indicate ones that have not yet been characterized. The *circled numbers* indicate (1) seryl-tRNA ligase, (2) selenocysteine synthetase function (enzyme characterized in bacteria but not in animals), (3) selenophosphate synthetase, (4) elongation factor (characterized in bacteria but not in animals), and SECIS motif in selenoprotein mRNA. *Panel B.* Representation of a selenoprotein mRNA. The open reading frame (ORF) contains a UGA codon that is decoded as selenocysteine. The 39 untranslated region (39UTR) contains a stem-loop structure necessary for the decoding of the UGA as selenocysteine. The asterisks on the stem loop indicate the locations of conserved nucleotide sequences. One of these is present on the loop and the other two are present on bulges from the stem. The stem loop with its conserved sequences constitutes the SECIS motif. (From Levander OA, Burk RF. Selenium. In: Ziegler EE, Filer LJ, eds. Present knowledge in nutrition. Washington, DC: ILSI Press, 1996;320–8, with permission.)

[Figure 14.4B](#) represents a typical selenoprotein messenger RNA (mRNA). UGA in the open reading frame codes for insertion of selenocysteine. A stem-loop structure with several conserved features is present in the 3' untranslated region. Absence of the stem loop or modification of its essential features results in the UGA in the open reading

frame functioning as a termination codon instead of designating selenocysteine insertion (34). The stem loop in prokaryotes is adjacent to the UGA codon (33). It binds a complex consisting of a unique elongation factor and sec-tRNA^{[ser]sec} and approximates them to the UGA codon, facilitating selenocysteine insertion into the protein at that point. The precise mechanism by which the animal stem loop facilitates UGA readthrough as selenocysteine has not been determined, but evidence has been presented that an elongation factor is involved (35). It has been proposed that a complex of the putative elongation factor and sec-tRNA^{[ser]sec} binds to the stem loop and that the mRNA then loops back to the ribosome so that the complex can prevent termination at the UGA and effect selenocysteine incorporation into the growing peptide chain (36).

Excretion

Homeostasis of selenium in the body is achieved through regulation of its excretion. As dietary intake increases from the deficient range into the adequate range, urinary excretion of the element increases and accounts for maintenance of homeostasis (37). At very high intakes, volatile forms of selenium are exhaled and the breath becomes a significant route of excretion. There is no evidence that fecal selenium is regulated. Thus, under physiologic conditions, urinary excretion is the primary site of body selenium regulation.

Most excretory metabolites of selenium appear to be methylated. A recent study indicates that a large fraction of urinary selenium is methylselenol (38). A smaller percentage is trimethylselenonium ion (11). Selenium in the breath is largely dimethylselenide (11). How formation of these metabolites is regulated is not known. However, a logical point of regulation would be at the level of selenophosphate synthetase (Fig. 14.3).

BIOCHEMICAL FUNCTIONS

Eleven selenoproteins have been characterized in animals (Table 14.1), and evidence has been presented that additional ones exist. A tRNA that contains selenium has also been described (10). Enzymatic functions have been described for most of the selenoproteins, but the biochemical functions of several have not been discovered.

Protein	Reference
Glutathione peroxidase family	
GSHPx-1 (cytosolic or classical)	(4)
GSHPx-2 (G)	(39)
GSHPx-3 (extracellular or plasma)	(40)
GSHPx-4 (phospholipid hydroperoxide)	(41)
Iodothyronine deiodinase family	
Type I (liver, kidney, thyroid)	(34)
Type II (brain)	(42)
Type III (inactivating)	(43)
Thioredoxin reductase	(44)
Selenophosphate synthetase	(32)
Selenoprotein P	(45)
Selenoprotein W	(46)

Table 14.1 Animal Selenoproteins

Glutathione Peroxidases

The glutathione peroxidases use reducing equivalents from glutathione to catabolize hydroperoxides. Four selenium-containing glutathione peroxidases, all separate gene products, have been characterized (for reviews see [47, 48]). The cellular glutathione peroxidase, GSHPx-1, is the most abundant member of the group and is present in all cells. GSHPx-2, originally designated GSHPx-GI, is also a cellular enzyme but is found predominantly in tissues of the gastrointestinal tract (39). Extracellular glutathione peroxidase, GSHPx-3, is present in plasma and milk (49). Phospholipid hydroperoxide glutathione peroxidase, GSHPx-4, is present inside cells and differs in several respects from other members of the group. It can catalyze reduction of fatty acid hydroperoxides that are esterified in phospholipids (48) and alternative processing can produce a form with a signal that localizes the protein to mitochondria (50).

Selenium deficiency causes a decrease in the activity of all glutathione peroxidases. However, the effect varies according to tissue and enzyme. Brain glutathione peroxidase is relatively well preserved in selenium deficiency as is GSHPx-4 in all tissues. Glutathione peroxidase activities in plasma and liver are very sensitive to selenium supply and are used as indices of selenium nutritional status.

The glutathione peroxidases catabolize hydrogen peroxide and fatty acid–derived hydroperoxides. They have been generally considered to protect cells from these oxidant molecules. However, many oxidant molecules have functions in metabolism and in signaling pathways. Thus, the glutathione peroxidases have regulatory roles in the cell because they affect the concentrations of oxidant molecules. Moreover, the four glutathione peroxidases have different localizations and different substrate specificities that could be part of a regulatory strategy.

Iodothyronine Deiodinases

The iodothyronine deiodinases, types I–III, are all selenoproteins (34, 42, 43). These enzymes catalyze the deiodination of thyroxine, triiodothyronine, and reverse triiodothyronine and thereby regulate the concentration of the active hormone triiodothyronine. Several thiols can serve as the reducing substrate for these enzymes, but glutathione is likely to be the physiologic substrate (34).

Thioredoxin Reductase

Thioredoxin reductase is an NADPH-dependent flavoenzyme that reduces the internal disulfide of thioredoxin (51). The prokaryotic enzyme is highly specific for thioredoxin as a substrate and interacts with it through a redox-active thiol pair. The animal enzyme

has a broader substrate range that includes a number of small molecules, and the animal enzyme is considerably larger than the prokaryotic one. Animal thioredoxin reductase has recently been shown to contain selenocysteine (52), and evidence has been presented that selenium forms part of the active site. It regenerates ascorbic acid from dehydroascorbic acid (52a). The hepatic activity of the enzyme declines in selenium deficiency (53).

Selenoprotein P

Selenoprotein P was identified in plasma about two decades ago but resisted purification and characterization for many years (54). It has now been purified (45) as well as characterized at the nucleic acid level (55). Selenoprotein P is an extracellular glycoprotein that is found in plasma and also associated with endothelial cells (56). Its cDNA indicates that it has a typical signal peptide for secretion from the cell and that its open reading frame contains 10 to 12 UGAs that designate selenocysteine incorporation (55, 57). Thus, it and the type II iodothyronine deiodinase, which apparently has two selenocysteine residues, are the only selenoproteins known to contain more than one selenocysteine residue per polypeptide chain. Isoforms of the protein have been identified in rat plasma. A full-length form and a form that terminates at the second in-frame UGA have been isolated and characterized (58).

Selenoprotein P contains a large fraction of the plasma selenium, about 45% in a typical North American (59). The concentration of selenoprotein P declines in selenium deficiency and can be used as an indicator of selenium status (59).

The function of selenoprotein P is not known but it has been associated with the oxidant defense properties of selenium. Selenium-deficient rats are susceptible to diquat-induced lipid peroxidation and liver necrosis, and protection by selenium correlates with selenoprotein P concentration in plasma (60). It has been speculated that its endothelial cell location indicates that selenoprotein P protects those cells from oxidant molecules generated by inflammation or by xenobiotic metabolism (56).

Selenoprotein W

Selenoprotein W was originally identified in muscle and postulated to play a role in development of white muscle disease, a selenium deficiency condition in sheep. It has now been identified in many other tissues and shown to exist in several forms (46). One form has glutathione bound to it, suggesting that selenoprotein W undergoes redox changes. However, its biochemical function is unknown. Selenoprotein W concentration decreases in selenium deficiency (61).

Selenophosphate Synthetase

Two selenophosphate synthetases have recently been identified in animals. One contains a selenocysteine residue in its primary structure, and the other contains a cysteine residue at the same position (31, 32). Because regulation of selenium homeostasis appears to reside at the level of this activity, work on the function of these

enzymes may reveal the mechanism of selenium regulation.

BIOLOGIC ACTIVITY

Selenium deficiency leads to marked changes in many biochemical systems. A number of drug-metabolizing enzymes, including the cytochrome P-450 system, are affected, some with activities increased and others with activities decreased (62). Glutathione S-transferase activities in rat liver, kidney, and lung rise in selenium deficiency. The underlying causes of these changes have not been established, but they are presumably related to changes in selenoproteins. Glutathione metabolism is affected by selenium deficiency. In the rat, plasma glutathione concentration is increased two to three times above the concentration in selenium-replete animals (63). This has been traced to increased hepatic synthesis of GSH and release of it into the plasma (63).

Changes in thyroid hormone metabolism were characterized many years ago in selenium-deficient animals (64) and are now explained by the discovery that the iodothyronine deiodinases are selenoenzymes. Other metabolic effects, such as changes in glucose metabolism, have not yet been traced to a selenoprotein (65).

Pure selenium deficiency does not usually cause clinical illness in free-living humans or animals. Only when laboratory animals are raised through several generations on a selenium-deficient regimen do they exhibit pathologic changes from selenium deficiency alone. However, first-generation selenium-deficient animals exhibit heightened sensitivity to certain stresses, which is the basis of most naturally occurring conditions of selenium deficiency. One of these stresses is vitamin E deficiency. Simultaneous selenium and vitamin E deficiencies lead to a number of pathologic conditions in animals (3). Selenium-deficient animals are more susceptible to injury by certain chemicals such as the redox cyclers paraquat, diquat, and nitrofurantoin. These injuries are generally oxidative and might be related to decreased levels of the selenoenzymes that defend against oxidative injury.

Selenium can influence the outcome of infections. The increased virulence of coxsackievirus B3 in selenium-deficient mice is described below. Additionally, potential selenocysteine-incorporation codons have been described in a number of viral genomes, including that of HIV (66). This points to a viral strategy of appropriating the selenium of the cell or of disrupting selenium-dependent functions in it. Research in this area is very active.

DEFICIENCY IN HUMANS AND ANIMALS

A combined deficiency of both selenium and vitamin E causes liver necrosis in rats and swine, exudative diathesis in chickens, and white muscle disease in sheep and cattle (3). In animals fed a selenium-deficient diet containing adequate levels of vitamin E, signs attributable to selenium deficiency included hair loss, growth retardation, and reproductive failure in rats fed a deficient diet for two generations (67) and pancreatic degeneration in chicks fed amino acid-based diets severely deficient in selenium (68). This pancreatic atrophy in the chick, however, can be prevented by feeding high levels

of vitamin E or other antioxidants (69). Pancreatic atrophy can be induced in chicks fed practical rations from a selenium-deficient zone of China, but its severity is less than that seen with the amino acid diet, suggesting the presence of partially protective factors in the practical diet (70). In one study, adult squirrel monkeys fed a low-selenium diet for 9 months lost weight and developed alopecia, myopathy, nephrosis, and hepatic degeneration (71). However, in another study, consistent signs of selenium deficiency proved more difficult to produce in rhesus monkeys, even in offspring born to mothers fed a selenium-deficient diet (72). It was hypothesized that elevated glutathione transferase activity in the tissues of rhesus monkeys might account for their relative resistance to selenium deficiency.

Several lines of evidence indicate that selenium is a nutritionally essential trace element for humans. First, selenium is a component of the enzyme glutathione peroxidase isolated from human red blood cells (73). Secondly, favorable responses have been obtained after selenium supplementation of depleted patients undergoing long-term total parenteral nutrition (TPN) (see section below on [high-risk clinical situations](#)). Finally, selenium deficiency has been implicated in certain human diseases.

In 1979, Chinese scientists first described in English the relationship of selenium to Keshan disease, an endemic cardiomyopathy affecting children and young women that occurs in a long belt running from northeastern to southwestern China (5). The acute form is characterized by sudden onset of insufficient heart function, whereas individuals with chronic disease exhibit moderate-to-severe heart enlargement with varying degrees of heart insufficiency (74). The histopathologic features include multifocal necrosis, fibrous replacement of the myocardium, and myocytolysis. Keshan disease is related to a low dietary selenium intake and low blood and hair selenium levels (75). A series of intervention trials encompassing more than a million subjects demonstrated the protective effects of selenium supplements (76). However, selenium cannot reverse the cardiac failure once it occurs. Marginal-to-deficient vitamin E status has also been observed in subjects residing in endemic areas (77), and other complicating nutritional deficiencies (e.g., protein) may exacerbate the condition. Nonetheless, selenium deficiency appears to be the fundamental underlying condition predisposing individuals to development of Keshan disease. With improved living conditions in China, the disease has disappeared from endemic areas.

Because certain features of the disease could not be explained solely on the basis of selenium status (e.g., seasonal variation), it was suggested that a cardiotoxic agent, such as a virus, might also be necessary for the disease to occur (78). Scientists in Beijing provided evidence for a nutrition/infection interaction in the etiology of Keshan disease, since a coxsackievirus B4 isolated from a Keshan disease patient caused more severe cardiopathology when inoculated into selenium-deficient mice than when inoculated into normal mice (79). Beck et al. (80) also found that a myocarditic strain of coxsackievirus B3 (CVB3/20) produced more heart damage in selenium-deficient mice than in normal mice. Likewise, normal mice infected with a benign (amyocarditic) strain of coxsackievirus B3 (CVB3/0) suffered no heart damage, whereas moderate heart damage was observed in infected, selenium-deficient mice (81). Virus isolated from the selenium-deficient mice infected with originally benign CVB3/0 retained its cardiotoxicity when subsequently inoculated into normal mice, thus indicating that the avirulent virus had converted to a virulent strain via a genotypic change. Sequence analysis of the

genome of this newly virulent virus revealed that six of the seven virulence-determining sites had been altered (82). To the authors' knowledge, this was the first report of an effect of host nutritional status on the genetic composition of a pathogen. At the present time, the extent to which these observations can be generalized to other RNA viruses, such as polio, hepatitis C, influenza, or HIV, is unknown.

Another disease that has been associated with poor selenium status in China is Kashin-Beck disease, an endemic osteoarthritis that occurs during preadolescence or adolescence (83). Necrotic degeneration of the chondrocytes is the most striking pathologic feature of this disease. Dwarfism and joint deformation result from these cartilage abnormalities. Aside from selenium deficiency, a number of other etiologic factors have been suggested for this condition (e.g., mycotoxins in grain, mineral imbalance, organic contaminants in drinking water) (84).

Numerous attempts have been made to associate selenium status with various chronic degenerative human diseases, especially cancer. However, the epidemiologic evidence linking low-selenium status and an increased incidence of cancer is conflicting (85) and is often based on small differences in plasma selenium levels between controls and subjects who later developed cancer (86). Some animal experiments show that high levels of dietary selenium can protect against certain chemically or virally induced cancers, but in some cases, selenium itself can stimulate tumorigenesis in rodent models (87).

Nonetheless, recent nutritional intervention studies suggest that selenium supplements may have some beneficial effects against cancer. For example, a study with about 30,000 poorly nourished rural Chinese subjects found that overall cancer mortality could be reduced 13% by giving a supplement containing selenium, vitamin E, and b-carotene (88). However, these results may not be directly applicable to Western populations of better nutritional status. In the United States, Clark et al. (89) recently reported the effect of selenium supplementation on development of basal or squamous cell carcinoma of the skin in subjects with a history of this disease. A total of 1312 patients representing a follow-up of 8271 person-years were enrolled in this multicenter, double-blind, randomized, placebo-controlled cancer prevention trial. The intervention consisted of oral administration of 200 µg of selenium as selenized yeast per day or placebo. Although no effect of selenium was seen on the primary end points for the trial (incidence of basal and squamous cell carcinoma of the skin), significant reductions were observed in several secondary end points, including a 37% reduction in total cancer incidence; 63, 58, and 46% declines in the incidence of prostate, colorectal, and lung cancers, respectively; and a 50% decrease in total cancer mortality. On the other hand, all-cause mortality declined insignificantly by 21%, suggesting that selenium treatment may have increased mortality from diseases other than cancer (90). The study population used in this trial was unusual and consisted largely of male cotton and tobacco farmers with a history of arsenic exposure and skin cancer who were residing in a low-selenium area (20). It was concluded that the data were promising but that it would be "premature to change individual behavior, to market specific selenium supplements, or to modify public health recommendations based on the results of this one randomized trial" (91).

EVALUATION OF NUTRIENT STATUS

Selenium status can be evaluated by dietary and biochemical means.

Analytical Evaluation

Random urine samples are of little use in assessing selenium status because they are affected by dilution and the selenium content of the previous meal (92). Blood selenium levels, which vary widely in different countries, are thought to reflect dietary intakes (13), although a direct relation of dietary selenium to muscle levels or total body selenium content has yet to be established (92). Average blood selenium levels reported in different areas of the United States range between 2.03 and 3.29 $\mu\text{mol/L}$ (93), whereas extreme values of 0.10 and 95.0 $\mu\text{mol/L}$ have been reported in areas of China affected by Keshan disease and endemic selenosis, respectively (10). Plasma selenium levels, which respond to selenium supplementation more rapidly than whole blood levels, are an index of short-term status (92). Average plasma selenium levels observed in areas with marginally adequate (Maryland) or low (Ohio) levels of soil selenium in the United States were 1.70 and 1.51 $\mu\text{mol/L}$, respectively (94, 95). Levels below 0.63 $\mu\text{mol/L}$ are often seen in healthy residents of the south island of New Zealand (18). Serum selenium concentrations fall soon after birth and then gradually increase to adult values (92). Response to selenium supplementation was observed in a New Zealand patient on TPN who had a plasma level of 0.11 $\mu\text{mol/L}$ (6).

Measurement of plasma, serum, or whole blood selenium concentrations became much easier with the recent introduction of graphite furnace atomic absorption spectrometry with Zeeman background correction (96). This procedure lends itself to large-scale epidemiologic surveys because no pretreatment of the samples is required other than dilution (i.e., no wet ashing is needed). This method was used to measure serum selenium concentrations in the Third National Health and Nutrition Examination Survey (NHANES III, 1988–1994) as a way of helping to establish normal selenium ranges in the U.S. population. Determination of total selenium in blood or blood fractions provides no information about the speciation of selenium in blood. Compartmentalization of selenium can influence the interpretation of blood selenium levels (Fig. 14.2). Intake of diets rich in selenomethionine can raise blood selenium concentrations markedly, because this form of selenium is not subject to homeostatic regulation. Also, serum selenium does not reflect the buildup of selenium in the skeletal muscle of animals when high levels of selenomethionine are fed (97). Hair selenium was used in China to evaluate selenium status (76) but may not be valid in Western countries where shampoos containing selenium are used. Toenail selenium has been suggested as a convenient noninvasive index of selenium status (98). However, hair and nail selenium levels, at least in rats, are influenced by the form of selenium fed and the methionine content of the diet (97).

Assessment of selenium status by calculating the dietary intake from food composition tables is a risky procedure because of the wide variation in the selenium content of foods. Unless one is certain that the database used applies to the diet in question, the safest approach is direct chemical analysis of the diet. Nonetheless, it is possible to

obtain reasonable agreement between calculated and analyzed selenium intakes if the appropriate database is available (99).

Biochemical and Clinical Evaluation

A direct relationship exists between blood glutathione peroxidase activity and blood selenium level up to 1.27 μmol selenium/L (100). Beyond that point, the activity of the enzyme plateaus and cannot be used to evaluate selenium nutriture. Moreover, numerous other factors can affect glutathione peroxidase activity (101). Nonetheless, glutathione peroxidase activity remains an extremely useful index of selenium status in the nutritional range of dietary intake, and automated enzyme assays suitable for large-scale surveys have been devised (96). At present, there are no suitable clinical methods for evaluating selenium status.

REQUIREMENTS AND RECOMMENDED INTAKES

In 1980, the National Research Council established an estimated safe and adequate daily dietary selenium intake for adults of 50 to 200 μg (102). This recommendation was the first dietary standard for selenium and was based primarily on extrapolation from animal experiments because few human data were available at that time. A nutritionally generous level of selenium for most animals appears to be about 0.1 $\mu\text{g/g}$ dry diet. If it is assumed that humans consume 500 g of diet (dry basis) daily, then based on the animal results, humans would need 50 $\mu\text{g/day}$ of selenium. Because of uncertainties about the bioavailability of selenium from different diets and possible individual variations in requirements, the dietary recommendation was given as a range.

In the past 15 years, results from a number of human studies have greatly increased our understanding of human selenium requirements. Some of the first attempts to delineate human selenium requirements more precisely involved balance studies, but comparison of international balance data revealed that people could maintain selenium balance over a broad range of intake (86). Thus, the balance method was not especially useful in clarifying human selenium requirements. Another approach was to conduct dietary surveys in areas with and without human selenium deficiency (i.e., with and without Keshan disease). Such surveys showed that Keshan disease was not present in areas where the selenium intake was at least 19 and 13 μg per day for men and women, respectively (78). These values can be considered minimum dietary requirements for selenium.

Human selenium requirements have also been estimated by determining the dietary selenium intake needed to maximize the activity of the selenoenzyme glutathione peroxidase. In these studies, the diets of Chinese men of very low selenium status (residents of an area with Keshan disease) were supplemented with graded doses of selenomethionine (103). Plasma glutathione peroxidase activity tended to be greatest in individuals who received 30 $\mu\text{g/day}$ or more of supplemental selenium over a period of several months. That intake plus their habitual dietary intake (11 $\mu\text{g/day}$) yielded 41 $\mu\text{g/day}$ as the lowest amount tested that resulted in a plateau in enzyme activity.

Maximization of plasma glutathione peroxidase activity was accepted by the U.S. National Research Council as the basis for its RDA for selenium in 1989 (7) (see also Appendix [Table II-A-2-a-2](#)). The Chinese value of 41 µg/day was multiplied by body weight and safety factors to come up with recommendations of 70 and 55 µg/day for adult men and women, respectively. Recommendations for children were extrapolated from the adult values on the basis of body weight. Infant requirements are estimated to be 4 to 7 µg/day, depending on the basis of the estimate (104). The selenium RDA for infants was set at 10 and 15 µg/day for the first and second 6 months of life, respectively, to allow for growth. Increased allowances for women during pregnancy and lactation were 10 and 20 µg/day, respectively, and were based either on fetal demand or lactation losses (see Appendix [Table II-A-2-b-1](#), [Table II-A-2-b-2](#), [Table II-A-2-b-3](#), [Table II-A-2-b-4](#), [Table II-A-2-b-5](#) and [Table II-A-2-b-6](#)).

Although North Americans should easily achieve the selenium RDA through consumption of a typical mixed diet, persons living in countries with selenium-poor soils would have difficulty in attaining such intakes (see above section on [dietary considerations](#)). For that reason, a recent expert consultation of the WHO produced dietary selenium standards that were considerably lower than the RDAs produced in the United States (8) (see also Appendix [Table II-A-2-a-2](#)). Moreover, the WHO advisory group presented the values in their report in the form of safe ranges of population mean intakes, which meant that their recommendations were applicable only to large groups of people and not to individual persons. The purpose of this was to make the WHO document more relevant from the public health point of view (diet planning for large groups and/or diagnostic assessment of dietary intakes of populations). Also, there was a two-tiered system of population mean intake based on two distinct levels of requirement: basal and normative. The basal requirement referred to the “intake needed to prevent pathologically relevant and clinically detectable signs of impaired function attributable to inadequacy of the element,” whereas the normative requirement referred to the “intake that serves to maintain a level of tissue storage or other reserve that is judged ... to be desirable.”

The population minimum mean intake of selenium likely to meet basal requirements was given as 21 and 16 µg/day for adult males and females, respectively, with lower values for children and infants extrapolated on the basis of basal metabolic rate. These figures were calculated from Chinese epidemiologic dietary survey data that showed the selenium consumption necessary to protect against Keshan disease. The population mean intake of selenium that would meet the normative requirements was given as 40 and 30 µg/day for adult males and females, respectively. Again, lower values for children and infants were extrapolated on the basis of basal metabolic rate. These figures were calculated from Chinese experimental data that showed the amount of ingested selenium needed to achieve two-thirds of the maximum attainable activity of plasma glutathione peroxidase. This is in contrast to the RDA approach in the United States, which favored the dietary intake needed to achieve full activity of the enzyme. The decision to use two-thirds of maximal glutathione peroxidase activity was based on the observation that “abnormalities in the ability of blood cells to metabolize hydrogen peroxide became apparent only when the glutathione peroxidase activity in these cells

declines to one-quarter or less of normal.”

TOXICITY IN HUMANS AND ANIMALS

The level of dietary selenium needed to cause chronic selenium toxicity in animals is 4 to 5 µg/g (3). In livestock, chronic selenosis (alkali disease) is characterized by cirrhosis, lameness, hoof malformations, hair loss, and emaciation (3). Laboratory rats chronically poisoned with selenium exhibit growth depression and cirrhosis. The mechanism of selenium toxicity is not known, and the toxic effects of selenium may be modified by adaptation and certain dietary factors (13). No sensitive and specific biochemical test is currently available to indicate overexposure to selenium (105).

Public health surveys carried out in seleniferous areas of the United States failed to establish any symptom specific for selenium poisoning (106, 107 and 108). Field studies conducted in Venezuela showed a higher incidence of dermatitis, loose hair, and diseased nails in children from a seleniferous area than in those from Caracas, a nonseleniferous area, but no differences were seen in the various biochemical tests performed (109). A report from China described an outbreak of endemic selenium poisoning in humans (14); the most common sign of intoxication was loss of hair and nails. In high-incidence areas, lesions of the skin, nervous system, and possibly teeth were observed. Biochemical analyses showed a change in the ratio of plasma selenium to erythrocyte selenium at selenium intakes over 750 µg/day (110). Signs of selenosis (nail changes) were seen in susceptible patients at intakes of 910 µg/day or more, corresponding to a blood selenium level of 13.3 µmol/L or higher. No signs or symptoms of selenium overexposure were observed among residents of seleniferous ranches in South Dakota or Wyoming whose dietary intake was as high as 724 µg/day (108). However, an episode of human selenium poisoning was reported in the United States in 1984 involving 13 persons who consumed a “health food” supplement that contained 182 times the selenium content listed in the label declaration, because of a manufacturing error (111, 112). The total amount of selenium consumed by these subjects was thought to have been between 27 and 2387 mg. Signs and symptoms of poisoning included nausea, diarrhea, irritability, fatigue, peripheral neuropathy, hair loss, and nail changes.

Based on the Chinese data discussed above, the U.S. Environmental Protection Agency formulated a reference dose (RfD) for selenium (113). The RfD is a toxicologic standard defined (114) as “an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime” and is calculated by the following formula:

$$RfD = (NOAEL \text{ or } LOAEL)/(UF \times MF)$$

where *NOAEL* is the no-observed-adverse-effect level, *LOAEL* is the lowest-observed-adverse-effect level, and *UF* and *MF* are various uncertainty factors and modifying factors, respectively (114). For selenium, an *NOAEL* of 0.853 mg/day was used, which for 55-kg persons would yield a value of 0.015 mg/kg/day. The *NOAEL* was calculated from whole-blood selenium concentrations measured in residents of the

high-selenium area who exhibited no clinical signs of selenosis. Then the RfD was calculated using a UF of 3:

$$\text{RfD} = 0.015/3 = 0.005 \text{ mg/kg/day}$$

The UF of 3 was selected to take into account sensitive individuals via intraspecies extrapolation. For the standard 70-kg male, the RfD would be 0.005×70 or 350 $\mu\text{g/day}$. Chinese investigators familiar with the episodes of selenosis in their country suggested 400 $\mu\text{g/day}$ as the maximum safe dietary selenium intake (115). Similarly, the WHO Expert Consultation proposed 400 $\mu\text{g/day}$ as the upper limit of the safe range of adult population mean intake of selenium (8).

HIGH-RISK CLINICAL SITUATIONS

Subjects who are proved selenium deficient by biochemical testing can be considered to be at risk for developing pathologic conditions in response to certain stresses. Unfortunately, the particular stresses concerned are not well characterized. They may be nutritional, chemical, or infectious. Keshan disease is thought to be such a condition that occurs only in selenium-deficient subjects, perhaps triggered by oxidative stress or viral infection. Several patients who were selenium deficient as a result of receiving TPN were reported to have developed a cardiomyopathy similar to Keshan disease (116). Such selenium-deficient individuals might be sensitive to injury by drugs and chemicals, such as nitrofurantoin, in the same way as selenium-deficient animals are.

TPN solutions now contain selenium, so selenium deficiency in patients depending on this type of alimentation is now rare. Semipurified medical diets used to treat conditions such as phenylketonuria are often low in selenium and can produce deficiency of the element. Thus, specialized diets to be fed for protracted periods need to be evaluated for selenium to prevent development of selenium deficiency. Selenium deficiency does not occur in free living healthy individuals in the United States. Because of food distribution patterns, people living in areas with very low soil selenium eat foods that are produced elsewhere and thus escape becoming deficient. Only populations living in selenium-deficient areas and eating local foods can be expected to develop biochemical selenium deficiency. Those populations are found in small countries that are almost entirely low in selenium or in low-selenium areas of large countries that do not distribute food among their regions.

Abbreviations: **RfD**—reference dose; **TPN**—total parenteral nutrition.

HISTORICAL INTRODUCTION

In 1959, chromium was identified as an element that potentiates insulin action and restores normal glucose tolerance in rats (1). Subsequently, infants recovering from malnutrition responded to an oral supplement of 250 μg (4.8 μmol) chromium as chromium chloride with improved glucose removal rates. In a patient receiving total parenteral nutrition (TPN), Jeejeebhoy et al. demonstrated that infusing 250 μg (4.8 μmol) chromium as chromium chloride markedly reduced exogenous insulin requirements as well as lowering circulating glucose and free fatty acid levels (2). Other investigators have confirmed benefits of supplementation with chromium chloride in two additional TPN patients. (For citations to additional references concerning chromium, the reader is referred to several reviews [3, 4, 5, 6 and 7]).

CHEMISTRY AND NOMENCLATURE

Chromium (MW, 52 g/mol) occurs in multiple valence states, and marked differences based on valence characterize absorption, tissue distribution, and potential toxicity of

chromium (5, 8, 9). Most chromium in the food supply is in the trivalent state (8). Any chromium (VI) in food or water as a contaminant should be reduced to chromium (III) by the acidic environment of the stomach (9). Chromium (III) can bind with a number of ligands to form complexes. Chromium is exchanged slowly from these complexes, which makes it unlikely that chromium functions at the active site of a metalloenzyme (8).

Chromium (VI), which usually occurs as chromate or dichromate, is a strong oxidizing agent. Because of their oxidative ability, chromium (VI) compounds are irritating and are potential health hazards.

BIOLOGIC ACTIVITY

Chromium salts differ substantially in solubility (8, 9), and these solubility differences are important in determining the absorption and use of chromium. In addition, chromium (III) can be complexed with many different ligands, which may enhance or hinder both its absorption and tissue retention.

A “glucose tolerance factor” form of chromium was hypothesized originally by Mertz (8) to contain chromium bound to nicotinic acid and the amino acids glycine, cysteine, and glutamic acid. The complex enhanced glucose tolerance and was a low-molecular-weight, dialyzable compound. It has not been possible to purify this particular compound, although some of the low-molecular-weight chromium compounds isolated from biologic fluids do show an ultraviolet-absorbing peak corresponding to nicotinic acid. Furthermore, certain other extracted compounds potentiated insulin activity to a greater extent than chromium chloride alone.

DIETARY CONSIDERATIONS

Food Sources

Chromium is widely distributed, albeit in small quantities, throughout the food supply. Whole grains and cereals contain higher concentrations of chromium than fruits or vegetables (10). Chromium may be added or removed during food processing (11). Refined sugars and flour usually are lower in chromium than less refined products (10); however, acidic foods take up chromium from contact with stainless steel (11). Processed meats are quite high in chromium (10).

Bioavailability

Because of the very low chromium concentrations in biologic tissues, its bioavailability is difficult to assess in humans. However, the solubility of chromium salts varies, and chromium absorption is sensitive to physiochemical reactions within the gastrointestinal tract (8, 9, 12). Several studies in rats examined the tissue distribution of chromium-51 (⁵¹Cr) that was chelated to different ligands. Anderson et al. (13) reported that chromium concentrations in kidney were significantly higher after feeding a complex containing chromium dinicotinic acid, diglycine, cysteine, and glutamic acid for 3 weeks than after

feeding eight other chromium compounds. However, the identified complex did not produce such clear concentration differences in liver, spleen, muscle, lung, and heart (13).

High-fiber intakes raise concerns about the bioavailability of dietary trace minerals. One study in rats indicated that phytate impaired, and oxalate enhanced, absorption of ^{51}Cr . Two other studies in rats found no reduction in ^{51}Cr absorption with lower concentrations of phytate in the diet.

The bioavailability of chromium from human milk is important because breast-fed infants have chromium intakes well below (14) the current estimated safe and adequate daily dietary intake (ESADDI) recommendations. No studies in humans have compared the bioavailability of chromium from human milk and formulas. The extremely low chromium concentrations in biologic fluids and tissues would make chromium bioavailability studies in human infants very difficult.

Nutrient-Nutrient Interrelationships

Chromium uptake is enhanced by simultaneous administration with ascorbate in both human beings and experimental animals. Offenbacher (15) administered 1 mg (19.2 μmol) chromium as chromium chloride with and without 100 mg (0.56 mmol) ascorbate and monitored plasma chromium concentrations for 8 hours. The plasma chromium concentration was consistently enhanced by the presence of ascorbate. In rats dosed with $^{51}\text{CrCl}_3$, oral supplementation with ascorbate increased [^{51}Cr] in urine without reducing tissue concentrations, which also suggests that ascorbate enhanced ^{51}Cr absorption (16).

Absorption of ^{51}Cr from $^{51}\text{CrCl}_3$ was enhanced in zinc-deficient rats, and oral administration of zinc decreased ^{51}Cr absorption in zinc-deficient rats (reviewed in [6]). Chromium absorption was higher in iron-deficient mice than in iron-replete mice (reviewed in [6]). These observations raise the issue of mineral-mineral competition for absorption.

Tissue chromium concentrations generally were higher in mice fed starch as a carbohydrate source than in those fed sucrose, fructose, or glucose (17). Some 19 men and 18 women consumed a diet containing either 35% of total calories from complex carbohydrates and 15% from simple sugars (reference diet) or a diet containing 35% of total calories from simple sugars and 15% from complex carbohydrates (high-sugar diet). The high-sugar diet enhanced urinary chromium losses in 27 of 37 subjects, for a significantly increased mean excretion (18).

Nutrient-Drug Interrelationships

Some commonly used medications affect absorption of ^{51}Cr from $^{51}\text{CrCl}_3$ in rats. Administration by gavage of large doses of antacids composed of calcium carbonate or magnesium hydroxide significantly reduced [^{51}Cr] in blood, tissues, and urine 6 to 12

hours after oral dosing with $^{51}\text{CrCl}_3$ (16, 19). Aspirin and indomethacin, which block the synthesis of prostaglandins, increased ^{51}Cr absorption (19, 20), while oral dosing with 16,16-dimethyl prostaglandin E_2 decreased ^{51}Cr absorption (20). Total chromium administration was low (<180 ng [<3.5 nmol] per rat) in these studies but was consistent with the low intakes required to demonstrate signs of chromium depletion in rodents. However, in another study, rats were dosed with less than 1000 ng (19.2 nmol) of chromium, and several prostaglandins did not affect chromium retention (21). These relationships need to be clarified.

Adequacy of Intakes

Lack of an appropriate indicator of status makes assessment of adequacy of chromium intake problematic. Chromium balance was monitored for 12 days in a metabolic unit in two normal males consuming a mean of 36.9 and 36.7 μg (0.71 μmol) chromium per day from the diet. Apparent net retention was 0.6 and 0.2 μg (12 and 4 nmol)/day, respectively, indicating that the subjects were in equilibrium (22). Bunker et al. (23) conducted a 5-day balance study with 22 apparently healthy elderly people between 69 and 86 years of age. Mean daily intake was 24.5 μg (471 nmol), with a mean retention of 0.2 μg (4 nmol), again indicating apparent adequacy of less than 25 μg (<480 nmol) chromium intake per day. In another study, subjects with serum glucose concentrations below 100 mg/dL (<5.56 mmol/L) 90 minutes after an oral glucose load were fed diets containing less than 20 μg /day chromium for a total of 9 weeks without apparent change in their glucose tolerance (24). Their glucose, insulin, and glucagon values also did not change in response to 4 weeks of chromium supplementation. On the other hand, upon feeding the same diet to subjects who initially presented with glucose values between 100 and 200 mg/dL (5.57–11.1 mmol/L) 90 minutes after a glucose load, glucose, insulin, and glucagon sums (over a glucose tolerance test) showed significant reductions after 4 weeks of supplementation with 200 μg chromium as chromium chloride (24).

These three carefully conducted studies suggest that the actual need for chromium in many healthy adults is substantially less than current recommendations (50–200 μg /day). Unfortunately, long-term studies in which diets have been supplemented with doses such as 25 or 50 μg (0.48–0.96 μmol) chromium, which would double or triple usual dietary intakes (~15 μg /1000 kcal) (10), have not yet been conducted. Such studies would allow fine-tuning of dietary recommendations.

Another indication that the requirement for chromium may be quite low is that the mean breast milk chromium concentration is approximately 0.18 ng/mL (3.43 nmol/L) (14). Thus, exclusively breast-fed infants would receive approximately 130 ng/day (2.5 nmol) chromium (14) or less than 1.3% of the current lower limit of the ESADDI for infants (10–40 μg). No studies of the bioavailability of chromium from breast milk have been conducted in human infants.

METABOLISM

Digestion

Solubility of any mineral in food is affected by reduction potential, pH, and processing techniques as well as by complex formation. Transition-series minerals, including chromium, can form hydrates that may become hydroxides as gastrointestinal pH is increased. The hydroxides may precipitate or form large aggregates with reduced solubility (8, 12).

Absorption

Dowling and colleagues (reviewed in 6) used an in situ double-perfusion technique in which both the intestinal vasculature and the intestinal lumen were perfused to investigate absorption mechanisms. Amino acids in the test meal and the presence of either albumin or transferrin in the vascular perfusate enhanced chromium absorption. On the basis of studies in rats perfused with 3.8 μg (73 nmol) chromium plus 3 μCi of ^{51}Cr as $^{51}\text{CrCl}_3$, the authors concluded that absorption was a nonmediated process of passive diffusion (6). However, they noted that other mechanisms might also operate under specific conditions.

Chromium-depleted guinea pigs dosed with less than 200 ng (<3.8 nmol) ^{51}Cr as $^{51}\text{CrCl}_3$ absorbed a higher percentage of ^{51}Cr than did controls fed adequate chromium diets (25). In humans, Anderson and Kozlovsky (26) similarly reported that a higher percentage of dietary chromium intake was absorbed when dietary intakes were low, which also indicates some homeostatic control of absorption.

Transport

Chromium is transported primarily by transferrin (27). Incubation of serum with iron reduced the amount of ^{51}Cr bound by transferrin (27).

Storage

Chromium is a bone-seeking element (28), and its uptake in bone appears to be rapid. Several investigators have noted that chromium accumulates in bone, spleen, liver, and kidney. O'Flaherty emphasized the need for physiologically based kinetic modeling to understand the behavior of bone-seeking minerals (28). Early modeling work using rats indicated three pools for chromium with half-lives of less than 1 day, approximately 1 week, and 7 to 12 weeks. A recent model in humans suggested four compartments, with different half-lives for diabetic and normal subjects in at least some of the compartments (29). The half-life of chromium in the compartment that turned over most slowly was 346 days. This compartment presumably is related to long-term tissue deposition (29).

Homeostatic Regulation

Studies in guinea pigs (25) and humans (26) indicate that chromium absorption is higher

when chromium intakes are low. Specifically, in humans, Anderson and Kozlovsky (26) noted that when dietary chromium intakes reached 40 µg (0.77 µmol)/day, apparent absorption (measured by urinary excretion) dropped to 0.5% per day.

Excretion

Most ingested chromium is excreted in the feces. In balance studies, Offenbacher et al. recovered a mean of 98.1% of the dietary chromium in stools (22). Excretion via the bile does not appear to be a major contributor to fecal chromium (7). Urinary excretion increased fourfold following a supplemental dose of 200 µg (3.8 µmol) chromium as CrCl₃ (30). Also, tannery workers who were occupationally exposed to trivalent chromium had significantly higher urinary chromium excretion than controls, and their urinary chromium declined significantly during a weekend without exposure to chromium (31).

Increased chromium excretion induced by stress may be an important factor exacerbating chromium deficiency (32). Ascorbate-depleted guinea pigs had high circulating cortisol concentrations (33) and excreted more ⁵¹Cr from an oral dose of ⁵¹CrCl₃ than controls (33). Patients who had experienced physical trauma excreted more chromium than normally in urine (34). Furthermore, the urinary chromium excretion of distance runners was approximately doubled on the day of a 6-mile run, compared with a rest day (35).

FUNCTIONS

Chromium potentiates the action of insulin in vitro and in vivo. Mertz (4) recently summarized the results of 15 controlled studies in which subjects with impaired glucose tolerance were supplemented with defined chromium (III) compounds. In 12 of these studies, chromium supplementation improved the efficiency of insulin or had beneficial effects on the blood lipid profiles. The reasons for lack of response to chromium in the remaining three studies are uncertain; however, chromium depletion is not the only cause of impaired glucose tolerance. Furthermore, chromium status of subjects in supplementation trials still cannot be adequately assessed; a nonpharmacologic response to chromium supplementation would be expected only if the subjects were chromium depleted. Recent preliminary reports suggest that chromium supplementation may benefit diabetics, but these studies have not yet been published in their entirety.

A number of beneficial effects of chromium on lipid profiles have been reported. Responses are not consistent from study to study, but total cholesterol, low-density-lipoprotein (LDL)-cholesterol, and triglyceride levels have decreased, while HDL-cholesterol and apolipoprotein A levels have increased. These studies have been reviewed recently (4, 5, 6 and 7).

Intense public interest has emerged in using chromium as an ergogenic (muscle-building) aid. Chromium is second only to calcium in mineral supplement sales at the present time (5). This enthusiasm is surprising, given the equivocal effects on body composition seen to date in human studies. Evans (36) first reported an effect of

chromium on body composition: young men undergoing resistance training and taking chromium picolinate supplements (200 µg [3.8 µmol] Cr daily) increased lean body mass and decreased fat mass. Skinfold thickness measurements were used to estimate changes in lean body mass. Several additional studies with both positive and negative results have been reviewed ([5](#), [6](#) and [7](#)).

Two recent studies have used very sensitive techniques to estimate body composition. Lukaski et al. ([37](#)) supplemented 36 young men with placebo, chromium chloride, or chromium picolinate as they participated in an 8-week weight-training program. Fat-free mass, mineral-free mass, and body fat were estimated by dual x-ray absorptiometry. While resistive exercise increased lean body mass, no effects of chromium supplementation on either fat-free mass or body fat were found. Hallmark et al. ([38](#)) likewise supplemented 16 untrained healthy males undergoing a 12-week resistive-exercise program with 200 µg (3.8 µmol)/day chromium as picolinate or with placebo. Based on food records, these men were consuming approximately 36 µg (0.7 µmol) chromium from their diets. The authors assessed body composition with hydrodensitometry and found no significant differences in lean body mass, percentage body fat, or strength measurements as a result of chromium supplementation.

Chromium supplementation trials have also been conducted in rapidly growing food animals. Barrows were fed a fortified, corn-soybean meal basal diet supplemented with 0 or 200 µg (3.8 µmol)/kg diet of chromium as chromium picolinate. In this study, addition of chromium picolinate to the diet increased the accretion of muscle tissue and decreased the total gain of fat ([39](#)). In a study using gilts of a similar size, basal diets were supplemented with 300 µg (5.8 µmol) chromium/kg diet as chromium picolinate and recombinant porcine somatotropin (rPST) was administered to half of the pigs in a 2 × 2 factorial design. All rPST-treated gilts demonstrated better growth than controls. Diets supplemented with chromium picolinate, however, produced no differences in growth performance ([40](#)).

Effects of chromium on morbidity in livestock stressed by shipping or disease exposure have received a great deal of recent attention. Chromium significantly decreased serum cortisol ([41](#), [42](#)) and increased serum immunoglobulin M and total immunoglobulins in stressed and growing calves ([42](#)). Supplemental chromium also lowered serum cortisol after a disease challenge ([41](#), [42](#)).

KEY CAUSES OF DEFICIENCY AND THEIR MANIFESTATIONS

Chromium deficiency has been reported in three patients who did not receive supplemental chromium in their TPN solutions. The first, a female who had received TPN for more than 3.5 years, developed unexplained weight loss and peripheral neuropathy. Glucose removal from the plasma was impaired and her respiratory quotient was low, indicating preferential use of fat for fuel. Addition of 250 µg (4.8 µmol) chromium to the daily TPN infusate for 2 weeks restored the glucose removal rate and increased her respiratory quotient ([2](#)). Another patient developed severe hyperglycemia and rapid weight loss after 5 months of TPN therapy without added chromium (see reviews). The third patient developed weight loss, glycosuria, and hyperglycemia after 7 months of TPN. This patient was receiving 6 µg (0.12 µmol)/day of chromium, but the

situation was perhaps complicated by jejunostomy losses. The American Medical Association has recommended supplementing TPN solutions with chromium (43). However, a number of different TPN solutions contain a fairly high basal level of chromium (34, 44), and a recent report suggests that some TPN patients may be exposed to excessive amounts of trivalent chromium, primarily as a contaminant from amino acids in the solutions (44).

The hypothesis has been advanced by Nielsen (32) that alterations in metabolism secondary to malnutrition, disease, injury, or stress may be responsible for deficiencies of the ultratrace elements. A number of studies in animals and humans lend support to his hypothesis. Trauma patients excreted more urinary chromium than normal controls (34). Strenuous exercise causes “dumping” of chromium in the urine (35). Guinea pigs excreted more ^{51}Cr from $^{51}\text{CrCl}_3$ when they were stressed by ascorbate depletion (25). Many of the studies in farm animals that report beneficial effects of chromium supplementation also involved some type of stress: shipping, infectious agents, crowding, hot temperatures.

Finally, some commonly used medications may interfere with chromium absorption. Chronic effects of these medications have not been investigated in relation to chromium; however, studies have indicated a negative effect of antacids on iron and copper status.

EVALUATION OF NUTRIENT STATUS

Currently, there is no reliable indicator of chromium status. Chromium in blood is very difficult to measure because the extremely low concentrations approach the detection limits of even sensitive instruments. Further more, serum or plasma chromium may not be in equilibrium with other body pools. No enzyme has been identified for which chromium is specific. Thus, both nutritional and clinical assessments are difficult. In the absence of reliable indicators of chromium status, considerable diversity must exist in the chromium status of patients in supplementation trials.

REQUIREMENTS AND RECOMMENDED INTAKES

Humans

The current ESADDI for adults of 50 to 200 μg (0.96–3.8 μmol)/day for chromium, established in 1980, was not changed in the 10th edition of the recommended dietary allowances (RDAs), published in 1989 (45) (see also Appendix Table II-A-2-a-2). Until the late 1970s, techniques and instrumentation for measuring the very low concentrations of chromium in biologic materials were very limited, and many laboratories reported mean daily urinary chromium excretion substantially above 2 μg /day. There is consensus that chromium absorption is between 0.5 and 2%. Thus, the ESADDI for adults was established in line with the data available at that time, and values for infants (10–40 μg) and children were extrapolated.

Anderson and Kozlovsky (26) determined the chromium content of self-selected diets of 10 males and 22 females for 7 consecutive days. The 7-day average intake for males

was 33 μg (0.63 μmol)/day (range, 22–48 μg) and for females was 25 μg (0.48 μmol)/day (range, 13–36 μg). Mean chromium intake per 1000 kcal was approximately 15 μg (0.29 μmol). They observed that when dietary chromium intake was 10 μg (0.19 μmol), urinary excretion (representing absorption) was approximately 2%. With increasing intake to 40 μg (0.77 μmol), however, chromium absorption decreased to 0.5% (26).

Today, average urinary chromium excretion is considered to be approximately 0.20 ng/mL or approximately 0.4 μg /day for the average person. If absorption of 0.5 to 2% is assumed, the current ESADDI would be lowered substantially.

Experimental Animals

In experimental animals, dietary concentrations below 50 μg (0.96 μmol) chromium/kg diet are necessary to produce symptoms associated with chromium deficiency. The American Institute of Nutrition (AIN)-93 diet includes addition of chromium at the level of 1 mg (19.2 μmol) chromium/kg diet as chromium potassium sulfate and defines it as a “potentially beneficial mineral element” (46). Many experimental animals get enough chromium in their unsupplemented feed, however, to prevent well-recognized symptoms of deficiency.

TOXICOLOGY

Risk assessment for chromium is affected by its oxidation state. Trivalent chromium, which is the predominant form in the food supply, has low oral toxicity, at least partially because it is very poorly absorbed (8).

A recent report has generated some controversy about the safety of chromium (III) supplements (47). Relatively high concentrations of chromium picolinate, chromium chloride, or chromium nicotinate were added to Chinese hamster ovary cells in culture. Chromium picolinate and picolinic acid tested positive in an assay used to predict mutagenicity, while chromium nicotinate and chromium chloride did not (47). There have been many supplementation trials in humans with chromium chloride and with chelated chromium compounds without reports of toxicity. However, because of the current widespread use of chromium supplements, more research would be appropriate to evaluate the risk and cost/benefit ratios of trivalent chromium supplements.

On the other hand, chromium (VI), a product of manufacturing, is included in health risk assessments at Environmental Protection Agency superfund sites (9). Fortunately, certain foods and substances in our gastrointestinal tract have substantial capacity for reduction of chromium (VI) to chromium (III). For example, Kuykendall et al. (48) gave volunteers 5 mg (96 μmol) of chromium (VI), alone or fully reduced to chromium (III) with orange juice (prior to ingestion). They demonstrated no DNA-protein cross-links in leukocytes due to acute ingestion of either chromium (III) or (VI) and suggested that all of the chromium (VI) was reduced to chromium (III) intragastrically prior to absorption (48).

To evaluate further the in vivo genotoxicity of chromium (VI), Mirsalis et al. (49) administered chromium (VI) to mice at concentrations of 1, 5, or 20 mg (19.2, 96, or 384 µmol)/L in drinking water. These levels represent the range from a relevant human exposure level to the upper limit of palatability in rodents. They concluded that animals either had sufficient reductive capacity in their gastrointestinal tracts to prevent uptake of chromium (VI) or that even these high doses were insufficient to exert a genotoxic effect via oral administration (49).

Route of exposure has an impact on toxicity. Chromium (VI) is known to be a human pulmonary carcinogen. Stainless steel welding may be the most common source of occupational exposure to chromium. Various research groups have suggested that products formed during intracellular reduction of chromium (VI) to chromium (III) may be responsible for the DNA damage ascribed to chromium (VI) (50).

Ultratrace minerals are those elements with estimated dietary requirements usually less than 1 µg/g and often less than 50 ng/g of diet for laboratory animals (1). For humans, the term often is used for mineral elements with established, estimated, or suspected requirements below 1 mg/day, often expressed in micrograms per day. At least 18 elements could be considered ultratrace minerals: aluminum, arsenic, boron, bromine, cadmium, chromium, fluoride, germanium, iodine, lead, lithium, molybdenum, nickel, rubidium, selenium, silicon, tin, and vanadium. Two additional elements, cobalt and manganese, perhaps belong in the ultratrace category also. Although cobalt is required

in ultratrace amounts, it has to be in the form of vitamin B₁₂; thus, it is usually discussed as a vitamin and is not considered here. An estimated safe and adequate daily dietary intake (ESADDI) for manganese of 2.5 to 5.0 mg/day has been established for adults (2); however, recent studies with humans suggest that the actual requirement may be near 1.0 mg/day. Even if it is above 1.0 mg/day, knowledge about the practical importance or beneficial actions of manganese is in a state similar to that for most of the ultratrace minerals; therefore it belongs in the discussion of the ultratrace minerals.

The quality of the experimental evidence for nutritional essentiality varies widely for the ultratrace elements. Evidence for the essentiality of the four elements iodine, manganese, molybdenum, and selenium is substantial and noncontroversial; specific biochemical functions have been defined for these elements. The nutritional importance of iodine and selenium are such that separate chapters have been devoted to them in this treatise. Manganese and molybdenum, however, are given less nutritional attention, apparently because deficiencies of these elements have only been unequivocally identified in a few individuals nourished by total parenteral nutrition (TPN) or with genetic defects causing metabolic disturbances involving these elements. Specific biochemical functions have not been defined for the other 15 elements; thus, their essentiality is based on circumstantial evidence, which most often is that dietary deprivation in some animal model results in a suboptimal biologic function that is prevented or reversed by an intake of physiologic amounts of the element in question. Often the circumstantial evidence includes biochemical actions suggesting a biologic role or beneficial actions in humans. The circumstantial evidence for essentiality is substantial for arsenic, boron, chromium, nickel, silicon, and vanadium; thus, except for chromium (discussed in [Chapter 15](#)), they are discussed in detail here. The evidence for essentiality of the other elements is generally limited to a few gross observations in one or two species by one or two research groups. Because it was judged premature to discuss these elements in detail here, they are only briefly mentioned at the end of the chapter. However, fluoride, which has a well-known beneficial pharmacologic property (anticariogenic), is discussed in detail.

ARSENIC

Historical Overview

For about 1100 years, through the 19th century, arsenic reigned as the king of poisons because some arsenic compounds were found to be convenient, scentless, and tasteless instruments for homicide. Although arsenic was considered synonymous with poison, by 1937, the pharmacologic actions of 8000 arsenicals had been recorded. Arsenicals were used at various times for the treatment of anorexia and other nutritional disturbances, syphilis, neuralgia, rheumatism, asthma, chorea, malaria, tuberculosis, diabetes, various skin diseases, and numerous hematologic abnormalities (3). The use of arsenicals for these disorders has either fallen into disrepute or been replaced by more effective alternatives. Although attempts to produce a nutritional arsenic deficiency first occurred in the 1930s, the first substantial evidence for arsenic essentiality appeared in 1975 and 1976 (4).

Chemistry

Both trivalent and pentavalent arsenic exists in biologic material. The most biochemically important organic arsenic compounds are those that contain methyl groups. Methylation of inorganic oxyarsenic anions occurs in organisms ranging from microbial to mammalian. The methylated end-products include arsenocholine, arsenobetaine, dimethylarsinic acid, and methylarsonic acid.

Other arsenic compounds of interest may be biologic molecules in which phosphate is replaced by arsenate. The relatively unstable nature of arsenyl esters is apparently why there is no direct evidence for the existence of compounds such as glucose-6-arsenate and adenosine diphosphate-arsenate. Nonetheless, an arsenate ester might be the form of arsenic that performs an essential function.

A comprehensive review of arsenic chemistry and biochemistry has been published (5).

Metabolism

Absorption of inorganic arsenic from the gastrointestinal tract correlates well with the solubility of the compound ingested (6). In humans and most laboratory animals, more than 90% of inorganic arsenate and arsenite fed in a water solution is absorbed (6). About 60 to 75% of inorganic arsenic ingested with food is absorbed (7). On the other hand, only 20 to 30% of arsenic in arsenic trioxide or lead arsenate, which are only slightly soluble in water, is absorbed by hamsters, rats, and rabbits.

The form of organic arsenic also determines how well it is absorbed. For example, when orally dosed, more than 90% of arsenobetaine was recovered in the urine of hamsters (8); 70 to 80% of arsenocholine was recovered in the urine of mice, rats, and rabbits (9); and 45% of dimethylarsinic acid was recovered in the urine of hamsters (10). In contrast, arsenosugars as found in seaweed are poorly absorbed from the gastrointestinal tract (10). They must be metabolized to another form before the arsenic can be absorbed.

Contrary to what once was believed, arsenate and phosphate, despite structural similarities, do not share a common transport pathway in the duodenum (12). The absorption of arsenate can be separated into two components. First, arsenate becomes sequestered primarily in or on the mucosal tissue. Eventually, the sites of sequestration become filled, with concomitant movement of arsenate into the body. The absorption of arsenate apparently involves a simple movement down a concentration gradient. In rats, some forms of organic arsenic are absorbed at rates directly proportional to their intestinal concentration over a 100-fold range. This finding suggests that organic arsenicals are absorbed mainly by simple diffusion through lipid regions of the intestinal boundary.

Once absorbed, inorganic arsenic is transferred to the liver, where it is methylated with S-adenosylmethionine as the methyl donor (13). Before arsenate is methylated, it is

reduced to arsenite in a reduction facilitated by glutathione (13). Arsenite methyltransferase is the enzyme that methylates arsenite. Methylation of the monomethylarsenic acid by monomethylarsenic acid methyltransferase, yields dimethylarsinic acid, the major form of arsenic in urine (14). The methylation of arsenic can be modified by changing the glutathione, methionine, and choline status of the animal (13).

The fate of absorbed organic arsenic depends on its form. For example, arsenobetaine passes through the body into the urine without biotransformation. Some orally ingested arsenocholine appears in the urine, and some is incorporated into body phospholipids in a manner similar to choline; however, most is transformed to arsenobetaine before being excreted in the urine.

Excretion of ingested arsenic is rapid, principally in urine. In some species, significant amounts of arsenic are excreted in the bile in association with glutathione (13). The usual proportions of the forms of arsenic in human urine is about 25% inorganic arsenic, 20% monomethylarsenic acid, and 55% dimethylarsinic acid (7). The proportions are quite different, however, with the consumption of organic arsenic. For example, an analysis of urine from 102 Japanese students who consumed luxuriant amounts of organic arsenic in seafood revealed 9.4% inorganic arsenic, 3.0% monomethylarsenic acid, 28.9% dimethylarsinic acid, and 58.2% trimethylated arsenic compound (15).

Functions and Mode of Action

The metabolic function of arsenic is not clearly defined. Recent findings suggest that arsenic has a biochemical role that affects the metabolism of the amino acid methionine or is involved in labile methyl-group metabolism. For example, arsenic deprivation has been found to slightly increase liver S-adenosylhomocysteine (SAH) and decrease liver S-adenosylmethionine (SAM) concentrations, thus resulting in a decreased SAM:SAH ratio (16); SAM and SAH are involved in methyl transfer. Also, arsenic deprivation depressed the concentration of the methionine metabolite taurine in plasma of hamsters and rats (17).

Arsenic possibly has a role in some enzymatic reaction. However, although arsenic has been found to activate some enzymes, this probably occurs because arsenate can act as a substitute for phosphate. Arsenic as arsenite inhibits many enzymes by reacting with key sulfhydryl groups.

Another possible role for arsenic is in the regulation of gene expression. Arsenite can induce the isolated cell production of certain proteins known as heat shock or stress proteins. Arsenite apparently has an effect at the transcriptional level, which may involve changes in the methylation of core histones (18). Recently, it has been shown that arsenic increases the methylation of the *p53* promoter, or DNA, in human lung cells (19). Also, arsenic enhances DNA synthesis in unsensitized human lymphocytes and in those stimulated by phytohemagglutinin (20).

Deficiency Signs

Arsenic deprivation has been induced in chickens, hamsters, goats, miniature pigs, and rats (4, 16, 17, 21). In the goat, miniature pig, and rat, the most consistent signs of arsenic deprivation were depressed growth and abnormal reproduction characterized by impaired fertility and increased perinatal mortality. Other notable signs of deprivation in goats were depressed serum triglyceride concentrations and death during lactation. Myocardial damage also occurred in lactating goats. The organelle of the myocardium most markedly affected was the mitochondrion at the membrane level. In advanced stages of deficiency, the membrane actually ruptured. Other reported signs of arsenic deprivation include changes in mineral concentrations in various organs. However, listing all signs may be misleading because the nature and severity of the signs of arsenic deprivation are affected by other factors. For example, female rats fed a diet conducive to kidney calcification have more severe calcification when dietary arsenic is low; kidney iron was also elevated (16). Male rats fed the same diet do not show these changes. Other factors that can affect the response to arsenic deprivation include variations in the dietary concentrations of zinc, arginine, choline, methionine, taurine, and guanidoacetic acid. Generally, the signs of arsenic deprivation can be changed and enhanced by nutritional stressors that affect sulfur amino acid or labile methyl-group metabolism.

Toxicology

Because mechanisms exist for homeostatic regulation of arsenic, its toxicity through oral intake is relatively low; it is actually less toxic than selenium, an ultratrace element with well-established nutritional value. Toxic quantities of inorganic arsenic generally are reported in milligrams. For example, reported estimated fatal acute doses of arsenic for humans range from 0.9 to 1.50 mmol (70–300 mg) or about 13 to 53 μmol (1.0–4.0 mg) As/kg body weight (22). These doses suggest that the human is more sensitive to the acute lethal effects of arsenic than are experimental animals. The ratio of the toxic to nutritional dose for rats apparently is near 1250. Some forms of organic arsenic are virtually nontoxic; a 56 mmol (10 g)/kg body weight dose of arsenobetaine depressed spontaneous motility and respiration in male mice, but these symptoms disappeared within 1 hour (23).

Briefly, the signs of subacute and chronic high exposure of arsenic in humans include the development of dermatoses of various types (hyperpigmentation, hyperkeratosis, desquamation, and hair loss); hematopoietic depression; liver damage characterized by jaundice, portal cirrhosis, and ascites; sensory disturbances; peripheral neuritis; anorexia; and loss of weight (24). A reference dose (RfD, lifetime exposure that is unlikely to cause adverse health effects) of 4.0 nmol (0.3 μg)/kg body weight/day has been suggested for arsenic (25).

Results of numerous epidemiologic studies suggest an association between chronic arsenic overexposure and the incidence of some forms of cancer, particularly skin cancer; however, the role of arsenic in carcinogenesis remains controversial. Arsenic does not seem to act as a primary carcinogen and is either an inactive or extremely

weak mitogen.

Dietary Considerations

Only data from animal studies are available for estimating the possible arsenic requirement of humans. An arsenic requirement between 83 and 167 nmol (6.25 and 12.5 µg)/4.18 MJ (1000 kcal) was suggested for growing chicks and rats (26). Thus, a possible arsenic requirement for humans eating 8.37 MJ (2000 kcal) would be about 160 to 200 nmol (12–25 µg) daily. Reports from various parts of the world indicate that the average daily intake of arsenic is in the range of 160 to 800 nmol (12–60 µg) (26, 27). In the United States, the individual mean total arsenic intake from all food, excluding shellfish, has been estimated to be 400 nmol (30 µg)/day (27). Fish, grain, and cereal products contribute the most arsenic to the diet. Clarification of the need for arsenic for optimal health and performance is needed so that a safe and adequate intake of the element can be established.

Clinical Considerations

Until more is known about the biochemical and physiologic functions of arsenic, it is inappropriate to associate specific disorders with deficient arsenic nutriture. However, it has been suggested that arsenic could play an essential role in humans because injuries of the central nervous system, vascular diseases, and cancer were correlated with markedly decreased serum arsenic concentrations (28). Perhaps the most important consideration at present is recognizing the likelihood that arsenic is essential for humans. The belief that any form or amount of arsenic is unnecessary, toxic, or carcinogenic is unrealistic, if not potentially harmful.

BORON

Historical Overview

In the 1870s it was discovered that borax (sodium borate) and boric acid could be used to preserve foods. For about the next 50 years, borates were considered among the best of preservatives for extending the palatability of foods such as fish, meat, cream, and butter. In 1904, however, it was reported that human volunteers consuming over 500 mg of boric acid per day for 50 days displayed disturbed appetite, digestion, and health. After this report, the opinion that boron posed a risk to health gained momentum; by the middle 1950s, boron was essentially banned throughout the world as a food preservative.

In 1923 boron was shown to be essential for plants. About 15 years later, attempts to demonstrate boron essentiality for higher animals began; these attempts were unsuccessful. Thus, before 1980 students of biochemistry and nutrition were taught that boron was a unique element because it was essential for plants but not for higher animals. In 1981, it was reported that boron stimulated growth and partially prevented leg abnormalities present in marginally cholecalciferol-deficient chicks. Since then, evidence has been accumulating indicating that boron has an essential function in

higher animals, including humans.

Chemistry

Boron biochemistry is essentially that of boric acid, which exists as $B(OH)_3$ and $B(OH)_4^-$ in dilute solutions at the pH of blood (7.4); because the pK_a of boric acid is 9.2, the abundance of these two species in blood should be 98.4 and 1.6%, respectively.

Boric acid forms ester complexes with hydroxyl groups of organic compounds; this occurs preferentially when the hydroxyl groups are adjacent and *cis*. Boron complexes with many substances of biologic interest, including sugars and polysaccharides, adenosine-5-phosphate, pyridoxine, riboflavin, dehydroascorbic acid, and pyridine nucleotides. To date, five naturally occurring biologic boron esters synthesized by various bacteria have been characterized, the latest being tartrolon B isolated from the myxobacterium *Sorangium cellulosum* (30). All of these boron esters are antibiotics. One of them, boromycin, reportedly can encapsulate alkali metal cations and increase the permeability of the cytoplasmic membrane to potassium ions (31).

Metabolism

Food boron, sodium borate, and boric acid are rapidly absorbed and excreted mostly in the urine. Based on urinary recovery findings, more than 90% of ingested boron is usually absorbed (32, 33). Most ingested boron probably is converted into, and transported through the body as, $B(OH)_3$, the normal hydrolysis end product of most boron compounds and the dominant inorganic species at the pH of the gastrointestinal tract.

Boron is distributed throughout the tissues and organs of animals and humans at concentrations mostly between 4.6 and 55.5 nmol (0.05 and 0.6 μ g)/g fresh weight (29, 34). Bone, fingernails, and teeth usually contain several times these concentrations (34).

Evidence that boron is homeostatically controlled includes the rapid urinary excretion of absorbed boron, the lack of accumulation of boron in tissues, and the relatively narrow range of boron concentrations in blood of apparently healthy individuals. For example, mean plasma boron concentrations ranged from 1.85 to 6.2 nmol (20–67 ng)/mL in 44 perimenopausal women; upon supplementation with 3.0 mg of boron a day, this range increased to 2.8 to 6.9 nmol (28–75 ng)/mL (35). In some parts of the world where the daily intake of boron is very high because of environmental exposure (1.6 to 2.5 mmol [17–27 mg]/day), blood boron concentrations have been found to be much higher (41.7–65.9 nmol [450–659 ng]/mL) (36). As with other mineral elements, overcoming homeostatic mechanisms by high boron intakes elevates tissue boron concentrations.

Functions and Mode of Action

A biochemical function for boron has not been elucidated, even for plants for which boron has been known to be essential for 70 years. Its deficiency in plants, as in

humans, has multiple effects. Two hypotheses, which accommodate a large and varied response to boron deprivation and the known biochemistry of boron, have recently been advanced for the biochemical function of boron in higher animals. One hypothesis is that boron acts as a metabolic regulator by complexing with a variety of substrate or reactant compounds that have hydroxyl groups in favorable positions (37). Because this complexing usually results in competitive inhibition of enzymes in vitro, the regulation is hypothesized to be mainly negative. The second hypothesis is that boron has a role in cell membrane function or stability such that it influences the response to hormone action, transmembrane signaling, or transmembrane movement of regulatory cations or anions (38). This hypothesis is supported by the findings that boron influences the transport of extracellular calcium and the release of intracellular calcium in rat platelets activated by thrombin (39) and that boron influences redox actions involved in cellular membrane transport in plants (40).

Deficiency Signs

Listing the signs of boron deficiency for animals is difficult because most studies used stressors such as magnesium or cholecalciferol deficiency to enhance the response to deprivation. However, although the nature and severity of the signs varied with the stressor used, many of the findings indicated that boron deprivation impairs calcium metabolism, brain function, and energy metabolism (37, 39). Recent studies also suggest that boron deprivation impairs immune function and exacerbates adjuvant-induced arthritis in rats (41).

Findings involving boron deprivation of humans come mainly from two studies in which men over the age of 45, postmenopausal women, and postmenopausal women on estrogen therapy were fed a low-boron diet (23 $\mu\text{mol}/8.37 \text{ MJ}$ [0.25 mg/2000 kcal]) for 63 days and then fed the same diet supplemented with 278 μmol (3.0 mg) of boron/day for 49 days (39). The major differences between the two experiments were the intakes of copper and magnesium: in one experiment they were marginal or inadequate; in the other they were adequate. Some effects of boron supplementation after 63 days of boron depletion found in these experiments are summarized in Table 16.1. Boron supplementation after depletion also enhanced the elevation in serum 17 β -estradiol and plasma copper caused by estrogen ingestion (42), altered encephalograms to suggest improved behavioral activation (e.g., less drowsiness) and mental alertness, and improved psychomotor skills and the cognitive processes of attention and memory (43).

Metabolism Affected	Evidence for Effect
Macromineral and electrolyte	Increased serum 25-hydroxycholecalciferol Decreased serum calcitonin ^b
Energy	Decreased serum glucose ^a Increased serum triglycerides ^a
Nitrogen	Decreased blood urea nitrogen Decreased serum creatinine Decreased urinary hydroxyproline excretion
Oxidative	Increased erythrocyte superoxide dismutase Increased serum ceruloplasmin
Erythropoiesis/ hematopoiesis	Increased blood hemoglobin ^c Increased mean corpuscular hemoglobin ^c Decreased hematocrit ^c Decreased platelet number ^c Decreased red cell number ^c

^aSee review (39) for references to original articles.

^bFound when dietary copper was marginal and magnesium was inadequate.

^cFound when dietary copper and magnesium were adequate.

Table 16.1 Responses of Boron-Deprived (23 $\mu\text{mol}/8.37$ MJ [0.25 mg/2000 kcal] for 63 days) Men over Age 45, Postmenopausal Women and Postmenopausal Women on Estrogen Therapy to a 278 μmol (3 mg) Boron per Day Supplement for 49 Days^a

Toxicology

In a recent symposium (44), boron was described as having low toxicity when administered orally. Toxicity signs in animals generally occur only after dietary boron exceeds 9.25 μmol (100 μg)/g diet. In humans, the signs of acute toxicity include nausea, vomiting, diarrhea, dermatitis, and lethargy (45). In addition, high-boron intake induces riboflavinuria (46). The signs of chronic boron toxicity have been described as including poor appetite, nausea, weight loss, and decreased sexual activity, seminal volume, and sperm count and motility. Two infants who had their pacifiers dipped into a preparation of borax and honey for a period of several weeks exhibited scanty hair, patchy dry erythema, anemia, and seizures (47). The seizures stopped and the other abnormalities were alleviated when use of the borax and honey preparation was discontinued. Recently, it was suggested that an acceptable safe intake of boron could well be 13 mg/day (48).

Dietary Considerations

In the human studies just described, the subjects responded to a boron supplement after consuming a diet supplying boron at only about 23 $\mu\text{mol}/8.37$ MJ (0.25 mg/2000 kcal) for 63 days. Thus, humans apparently have a dietary requirement above this. On the bases of both human and animal data, an acceptable safe range of daily mean intakes of boron for adults could well be 0.09 to 1.2 mmol/day (1.0–13 mg/day) (48).

Foods of plant origin, especially noncitrus fruits, leafy vegetables, nuts, pulses, and legumes are rich sources of boron. Wine, cider, and beer are also high in boron. Meat, fish, and dairy products are poor sources of boron (49). Using food analyses included in the U.S. Food and Drug Administration total diet studies, the mean adult male daily intake has been determined to be 141 μmol (1.52 mg)/day (50) or 112 μmol (1.21 mg)/day (49).

Clinical Considerations

Knowledge about boron nutrition, biochemistry, and metabolism is growing, but more is needed before clinical disorders can be attributed to subnormal boron nutrition. Thus, reports such as those suggesting that low boron status may enhance the susceptibility or exacerbate some forms of arthritis (51) must be viewed with caution. Nonetheless, boron clearly is a biologically dynamic ultratrace element in higher animals, including humans. Thus, boron deprivation may have a role in some disorders of uncertain cause

(e.g., osteoporosis, arthritis).

FLUORINE (FLUORIDE)

Historical Overview

Fluorine first attracted nutritional attention when its ion form, fluoride, was identified in the 1930s as causing mottled enamel of teeth known as “Colorado brown stain” or other such descriptive terms. It was also noted at this time that fewer dental caries occurred in areas with mottled enamel and subsequently that fluoride intakes could be achieved that resulted in caries reduction without mottling of teeth (52). In 1945, water fluoridation began as a public health measure. In the 1960s, an association was made between high fluoride intakes and reduced incidence of osteoporosis (53). Although the use of pharmacologic amounts of fluoride to prevent bone loss is still being investigated, its usefulness in this regard seems limited. In the early 1970s, scientists suggested that fluoride is necessary for hematopoiesis, fertility, and growth in mice and rats (53), but this suggestion was based on experiments in which animals were not fed optimal diets. It was later concluded that fluoride affected hematopoiesis, fertility, and growth through pharmacologic mechanisms (53), and thus no substantive evidence exists to support essentiality.

Chemistry

The biochemistry of fluoride has been briefly reviewed (53). Fluorine exists as the fluoride ion or as hydrofluoric acid (HF) in body fluids. However, approximately 99% of total body fluorine is found in mineralized tissues as fluorapatite. Fluoride is incorporated into apatite, a basic calcium phosphate mineral with a theoretical formula of $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, by substituting for the OH^- moiety. This substitution occurs because F^- and OH^- have similar ionic radii and share the same charge and primary hydration number.

Metabolism

Several reviews of fluoride metabolism (52, 53, 54 and 55) indicate that about 75 to 90% of ingested fluoride is absorbed from the gastrointestinal tract. Generally, less than 20% of ingested fluoride is excreted in the feces. Absorption of fluoride is rapid; about 50% of a moderate dose of soluble fluoride is absorbed in 30 minutes, and complete absorption occurs in 90 minutes. The rapidity of absorption verifies that a significant portion of ingested fluoride is absorbed from the stomach; absorption also occurs throughout the small intestine.

Fluoride absorption is generally considered to occur by passive diffusion and to be inversely related to pH; thus, factors that promote gastric acid secretion increase the rate of absorption. The pH dependence of absorption is consistent with the generally accepted view that HF ($\text{pK}_a = 3.4$), and not ionic fluoride, is the form that is absorbed from the stomach. Diffusion as HF in the small intestine because of its high pH is less

likely. In the small intestine, the HF concentration would be very low and the gradient small. In contrast, the concentration and gradient of F^- would be high.

Soluble fluorides, such as sodium fluoride, are almost completely absorbed. Less soluble sources, such as bone meal, are relatively poorly absorbed (less than 50%). Aluminum hydroxide, widely used as an antacid, markedly inhibits fluoride absorption.

The rapid absorption of fluoride following oral ingestion leads to a prompt rise in its plasma concentration. Fluoride in plasma exists in ionic form; it is not bound by plasma proteins or by any other constituent of plasma. However, HF, not ionic fluoride, apparently is the form that is in diffusion equilibrium across cell membranes.

Removal of fluoride from the circulation occurs principally through two mechanisms: renal excretion and calcified tissue deposition. Approximately 50% of fluoride absorbed each day is deposited in the calcified tissues (bone and developing teeth) within 24 hours, which results in about 99% of the body burden of fluoride being associated with these tissues. The rate of uptake by bone is affected by the stage of skeletal development. Renal excretion is the major route for removal of fluoride from the body; about 50% of the daily intake is cleared by the kidney. Urinary excretion of fluoride is directly related to urinary pH; thus, factors that affect urinary pH, such as diet, drugs, metabolic or respiratory disorders, and altitude of residence, can affect how much absorbed fluoride is excreted.

Functions and Mode of Action

The major known function of fluoride is its role in protecting against pathologic demineralization of calcified tissues. This is not an essential function in the true sense, but a beneficial action, described elsewhere in this treatise ([Chapter 66](#) and [Chapter 85](#)). An essential function has not been described for fluoride.

Deficiency Signs

In the early 1970s, it was reported that mice fed low fluoride diets (as low as 0.26 nmol [5 ng]/g) exhibited anemia and infertility, compared with mice supplemented with 2.6 μ mol (50 μ g) F/mL of drinking water ([53](#)). These findings were obtained with diets that were iron deficient, however, and high dietary fluoride (similar to that fed to the supplemented controls) was shown to improve iron absorption or use. Thus, mice fed low-fluoride diets containing sufficient iron exhibited neither anemia nor infertility. Relatively high fluoride supplementation (130–395 nmol [2.5–7.5 μ g]/g) to a diet containing 2.1 to 24.2 nmol [0.04–0.46 μ g]/g slightly improved the growth of suboptimally growing rats ([56](#)) and (1.3 μ mol [25 μ g]/g diet) enhanced growth in chicks ([57](#)). These growth-promoting effects were probably pharmacologic. High or pharmacologic amounts of fluoride have also been found to depress lipid absorption ([53](#)) and to alleviate nephrocalcinosis induced by phosphorus feeding ([58](#)). Recently, it was reported that a fluoride deficiency in goats decreased life expectancy and caused pathologic histology in the kidney and endocrine organs ([59](#), [60](#)). These findings need to be confirmed in a nonruminant species before being accepted as evidence for essentiality in higher animals. In summary, unequivocal or specific signs of fluoride

deficiency have not been described for higher animals including humans. However, fluoride still must be recognized as a trace element with beneficial properties.

Toxicology

The toxicity of fluoride has received much attention since it was discovered to cause mottled teeth. Reviews of fluoride toxicity (52, 53, 55) indicate that chronic toxicity through excessive intake, mainly through water supplies and industrial exposure, has been reported in many parts of the world. Ingestion of water and food containing in excess of 0.1 mmol (2 mg) F/kg results in dental fluorosis or mottled enamel, ranging from barely discernible to stained and pitted enamel. Crippling skeletal fluorosis apparently occurs in people who ingest 0.53 to 1.32 mmol F (10–25 mg) per day for 7 to 20 years (55). The asymptomatic preclinical stage of skeletal fluorosis is characterized by slight increases in bone mass that are detectable radiographically. As skeletal fluorosis progresses, symptoms range from occasional stiffness or pain in the joints to chronic joint pain and osteoporosis of long bones. In severe cases of chronic fluorosis, muscle wasting and neurologic defects occur.

The signs and symptoms of acute fluoride toxicity are nausea, vomiting, diarrhea, abdominal pain, excessive salivation and lacrimation, pulmonary disturbances, cardiac insufficiency and weakness, convulsions, sensory disturbances, paralysis, and coma (55). The probably acute toxic dose or the minimum dose of fluoride that could cause toxic signs and symptoms, including death, is 0.26 mmol (5 mg) per kg body weight (52).

Dietary Considerations

Although fluoride is not generally considered an essential element for humans, it is still considered a beneficial element. The Food and Nutrition Board (2) has established the following ESADDIs for fluoride: infants aged 0 to 0.5 years, 5.3 to 26.3 μmol or 0.1 to 0.5 mg; infants aged 0.5 to 1 years, 10.5 to 52.6 μmol or 0.2 to 1.0 mg; children and adolescents aged 1 to 3 years, 26.3 to 78.9 μmol or 0.5 to 1.5 mg, aged 4 to 6 years, 52.6 to 131.6 μmol or 1.0 to 2.5 mg, aged 7 years and older, 78.9 to 131.6 μmol or 1.5 to 2.5 mg; adults, 78.9 to 210.5 μmol or 1.5 to 4.0 mg. These ESADDIs are based on amounts that protect against dental caries and generally do not result in any mottling of teeth.

The major source of dietary fluoride in the United States is drinking water; about 52% of the population uses water with a fluoride concentration adjusted between 36.8 to 63.2 μmol (0.7–1.2 mg)/L (55). The richest dietary sources of fluoride are tea and marine fish that are consumed with their bones. Fluoride is ubiquitous in foodstuffs, but similar products can vary greatly with source. Thus, estimating fluoride intakes is difficult. For an adult male residing in a community with fluoridated water, estimates of daily fluoride intake range from 52.8 to 157.9 μmol (1–3 mg) per day. This range is reduced to less than 52.8 μmol (1.0 mg) per day in nonfluoridated areas (55). Foods marketed in different parts of the United States contribute only 15.8 to 31.6 μmol (0.3–0.6 mg) to the daily intake of fluoride (2).

Clinical Considerations

At present, the clinical importance of fluoride is not through its nutritional effects but through its beneficial pharmacologic (anticariogenic and possibly antiosteoporotic) or toxicologic (dental and skeletal fluorosis) actions. However, the possibility that fluoride is an essential nutrient should not be dismissed. It seems possible that fluoride could have a role in biologic mineralization.

MANGANESE

Historical Overview

Although manganese was known to be a constituent of animal tissues as early as 1913, it was not until 1931 that manganese deficiency signs were described for experimental animals. Manganese deficiency has since been induced in numerous species of animals. A few cases of possible manganese deficiency in humans have recently been reported. The importance of manganese in health and disease is the focus of a recent book (61).

Chemistry

A brief review of manganese biochemistry (62) indicated that the characteristic oxidative state of manganese in solution, in metal-enzyme complexes, and in metalloenzymes is Mn^{2+} . Mn^{3+} also is important in vivo; it is the oxidative state in the enzyme manganese superoxide dismutase, the form that binds to transferrin, and probably the form that interacts with Fe^{3+} . Ingested Mn^{2+} is thought to be converted into Mn^{3+} in the duodenum. In manganese-activated biologic reactions, the enzymemanganese interaction involves either chelation of the metal ion with a phosphate-containing substrate (particularly adenosine triphosphate [ATP]) or a direct interaction with the protein. The chemistry of Mn^{2+} is similar to that of Mg^{2+} . Therefore, for most enzymatic reactions activated by Mn^{2+} , the activation is nonspecific; Mg^{2+} can also act as the activator.

Metabolism

For the adult human, absorption of manganese from the diet has long been assumed to be near 5%. This estimate is complicated, however, by the fact that endogenous manganese is almost totally excreted through biliary, pancreatic, and intestinal secretions into the gut. If manganese status is adequate, endogenous excretion of absorbed manganese into the gut is so rapid that it is difficult to determine the portion of fecal manganese not absorbed from the diet and the portion endogenously excreted. Thus, the true absorption of manganese by humans probably remains to be determined. Absorption efficiency apparently declines as dietary intake of manganese increases (63) and increases with low manganese status (64). On the other hand, endogenous excretion of manganese does not seem to be markedly influenced by dietary intake or status (64). Thus, the often cited hypothesis that manganese homeostasis is regulated

mainly by variable excretion through the digestive tract probably needs to be replaced with one that has the control of absorption in the gut as a major factor.

Absorption of manganese, through an unestablished mechanism, apparently occurs equally well throughout the small intestine. Some findings indicate that manganese is absorbed through an active transport mechanism that is a rapidly saturable process involving a high-affinity, low-capacity, active-transport system (65). On the other hand, diffusion has been implicated because studies with brush border membrane vesicles indicated that mucosal transport of manganese occurs through a nonsaturable, simple diffusion process (66). Perhaps both processes are involved in manganese movement across the gut; studies using CACO-2 cells, which mimic many of the actions of enterocytes, showed that apical to basolateral manganese uptake and transport were strictly concentration dependent, but basolateral to apical uptake and transport were saturable (67). Manganese might well be absorbed by a two-step mechanism: initial uptake from the lumen followed by transfer across the mucosal cells. The two kinetic processes operate simultaneously, with manganese competing with iron and cobalt for common binding sites in both processes. Thus, one of these metals, if present in a high amount, can exert an inhibitory effect on absorption of the others.

The form of manganese entering the portal blood from the gastrointestinal tract is also controversial. In addition to hydrated manganese complexes, Mn^{2+} bound both to plasma α_2 -macroglobulin (68) and to albumin (64) have been suggested to be the form. Regardless of the form, manganese is removed rapidly from the blood by the liver. A fraction is oxidized to Mn^{3+} and is bound to the plasma transport protein transferrin or possibly to a specific transmanganin protein. Transferrin-bound manganese is taken up by extrahepatic tissue.

Within cells, manganese is found predominantly in mitochondria, and thus organs rich in mitochondria, such as liver, kidney, and pancreas, have relatively high manganese concentrations; in contrast, plasma manganese in humans is extremely low (68).

As indicated above, manganese is almost totally excreted in feces; only trace amounts are found in urine. Excretion of absorbed manganese into the gut is rapid and apparently occurs in two waves. The first wave results from the clearance of initially absorbed manganese; the second represents a combination of initially absorbed manganese and that arising from the enterohepatic circulation.

Functions and Mode of Action

Manganese is known to function in enzyme activation and be a constituent of several metalloenzymes (69). The numerous enzymes that can be activated by manganese include oxidoreductases, lyases, ligases, hydrolases, kinases, decarboxylases, and transferases. Most enzymes activated by manganese can also be activated by other metals, especially magnesium; exceptions are the manganese-specific activation of glycosyltransferases and possibly of xylosyltransferase (62). There are only a few manganese metalloenzymes; these include arginase, pyruvate carboxylase, glutamine

synthetase, and manganese superoxide dismutase (62, 69).

Deficiency Signs

Manganese deficiency (reviewed in refs. 70, 71) has been induced in many species of animals. Signs of deficiency include impaired growth, skeletal abnormalities, disturbed or depressed reproductive function, ataxia of the newborn, and defects in lipid and carbohydrate metabolism.

A review of studies reportedly describing manganese deficiency in humans finds that most are not conclusive. One frequently cited case concerns a man who, after consuming a semipurified formula diet for an extended period, developed weight loss, depressed growth of hair and nails, dermatitis, and hypocholesterolemia. Also, his black hair developed a reddish tinge, and his clotting-protein response to vitamin K supplementation was abnormal. After these symptoms appeared, it was realized that manganese had been left out of his diet. The subject responded to a mixed hospital diet containing manganese (72). Unfortunately, supplementation with manganese alone was not tried. In another study (73), men were fed a purified diet containing only 2.0 μmol (0.11 mg) manganese per day for 39 days. They exhibited decreased serum cholesterol concentrations and a fleeting dermatitis. Calcium, phosphorus, and alkaline phosphatase activity increased in blood. Short-term manganese supplementation (10 days), however, did not reverse these changes. More recently, 14 young women consumed a conventional diet providing 18.2 μmol (1.0 mg) or 101.8 μmol (5.6 mg) manganese per day each for 39 days (74). Low dietary manganese slightly increased plasma glucose concentration during an intravenous glucose tolerance test (IVGTT) and increased menstrual losses of manganese, calcium, iron, and total hemoglobin. These intriguing findings need to be confirmed before they are accepted as signs of manganese deprivation because the subjects did not exhibit negative manganese balance during manganese deprivation, nor were the changes highly significant. Probably the most convincing case of manganese deficiency is that of a child on long-term parenteral nutrition who exhibited diffuse bone demineralization and poor growth that were corrected by manganese supplementation (75).

Manganese deprivation may contribute to disease processes. Low dietary manganese or low blood and tissue manganese has been associated with osteoporosis, diabetes, epilepsy, atherosclerosis, and impaired wound healing (61).

Toxicology

Manganese is often considered to be among the least toxic of the trace elements through oral intake. However, manganese may be of more toxicologic concern than believed in the past, especially for people with compromised homeostatic mechanisms or infants whose homeostatic control of manganese is not fully developed. In the past, the most common form of manganese toxicity identified in humans resulted from chronic inhalation of large amounts of airborne manganese as found in mines, steel mills, and some chemical industries. In these cases of toxicity, the principal organ affected was the brain. In miners intoxicated by manganese, the initial signs of toxicity were severe psychiatric abnormalities including hyperirritability, violent acts, and hallucinations,

which were referred to as “manganic madness.” As toxicity progressed, a permanent crippling neurologic disorder of the extrapyramidal system resulted that displayed morphologic lesions similar to those associated with Parkinson's disease (76). Although there is no conclusive report of oral toxicity of manganese in humans, many suggestive findings have recently appeared. High brain manganese concentrations have been associated with neurologic dysfunction (77). High manganese concentrations in hair have been associated with violent behavior (78). An RfD (safe daily intake over a lifetime) of 2.6 μmol (0.14 mg) per kg of body weight per day has been determined (79); for a 70-kg man this is a daily intake of 0.18 mmol (9.8 mg).

Dietary Considerations

The current United States ESADDIs for manganese (2) (see [Tables of RDI \[RDA\]](#) in the Appendix) are the following: infants aged 0 to 0.5 years, 5.5 to 10.9 μmol or 0.3 to 0.6 mg, and aged 0.5 to 1 years, 5.5 to 18.2 μmol or 0.6 to 1.0 mg; children and adolescents aged 1 to 3 years, 18.2 to 27.3 μmol or 1.0 to 1.5 mg, aged 4 to 6 years, 27.3 to 36.4 μmol or 1.5 to 2.0 mg, aged 7 to 10 years, 36.4 to 54.6 μmol or 2.0 to 3.0 mg, and aged 11 years and older, 36.4 to 91.0 μmol or 2.0 to 5.0 mg; adults, 36.4 to 91.0 μmol or 2.0 to 5.0 mg. Few data are available to support these estimates.

The above-cited values apparently were set mainly through the reasoning that most dietary intakes fall in this range and do not result in deficiency or toxicity signs. Other evidence used was balance data of questionable value. Thus, the ESADDIs of manganese may need modification as additional data become available. One recent study indicated a minimal requirement for manganese of 13.5 μmol (0.74 mg) per day for young men, based on obligatory losses while consuming a semipurified, manganese-deficient formula diet (73). However, this amount probably did not allow for storage of manganese for use at times of enhanced need nor for the possible inhibition of manganese absorption by dietary substances such as fiber. A requirement near 18 μmol (1.0 mg) per day was indicated in another study in which 14 young women were fed that amount for 39 days without negative manganese balance occurring (74). Five men who received varying amounts of manganese in a diet of conventional foods for 105 days exhibited negative retention of manganese with daily dietary intakes of 22.0, 37.5, and 52.6 μmol (1.21, 2.06, and 2.89 mg), but positive retention was found at daily dietary intakes of 48.2 and 69.0 μmol (2.65 and 3.79 mg). Regression analysis of intake versus balance yielded a recommended daily intake of 63.7 μmol (3.5 mg) (79). This value is difficult to reconcile with the fact that most diets contain less manganese, and no evidence that manganese deficiency is a problem has appeared. Also, attempts to produce manganese deficiency by feeding diets containing as little as 13.5 to 18.2 μmol (0.74 or 1.0 mg) per day resulted in no conclusive or significant effects on the health of adults. These studies show that no firm data are available to establish the lower value of the ESADDI of manganese.

The upper level of acceptable intake probably should be the amount encountered in a diet high in manganese-rich foods that allows positive balance if the diet contains large quantities of substances that inhibit manganese absorption. Thus, increasing the upper value to 182 μmol (10 mg) per day needs to be considered, especially since an RfD has

been set at that level.

Unrefined cereals, nuts, leafy vegetables, and tea are rich in manganese; refined grains, meats, and dairy products contain small amounts (80). Most reported daily mean intakes of manganese throughout the world fall between 9.5 and 196 μmol (0.52 and 10.8 mg) (79).

Clinical Considerations

Determination of the importance of manganese in human nutrition is urgently needed. Key issues are whether or not low manganese status is an important clinical consideration for osteoporosis, atherosclerosis, epilepsy, diabetes, and wound healing and whether or not manganese toxicity is a significant factor in abnormal brain function.

MOLYBDENUM

Historical Overview

Reviews of molybdenum (81, 82) state that evidence for the essentiality of this element first appeared in 1953, when xanthine oxidase was identified as a molybdenum metalloenzyme. However, molybdenum deficiency signs appeared in rats and chickens only when the diet contained massive amounts of tungsten, an antagonist of molybdenum metabolism. These studies showed that the dietary requirement to maintain normal growth of animals was less than 10.4 nmol (1 μg) molybdenum/g diet, an amount substantially lower than requirements for other trace elements recognized essential at the time. Thus, molybdenum was not considered of much practical importance in animal and human nutrition. Consequently, over the past 35 years, relatively little effort has been devoted to studying the metabolic and pathologic consequences of molybdenum deficiency in monogastric animals or humans.

Chemistry

Molybdenum is a transition element that readily changes its oxidation state and can thus act as an electron transfer agent in oxidation-reduction reactions. In the oxidized form of molybdoenzymes, molybdenum is probably present in the 6+ state. Although the enzymes during electron transfer are probably first reduced to the 5+ state, other oxidation states have been found in reduced enzymes. Molybdenum is present at the active site of enzymes as a small nonprotein cofactor containing a pterin nucleus (82). Almost all molybdenum in liver exists as this cofactor, with about 60% of the total amount in sulfite oxidase and xanthine oxidase. In addition to the molybdenum cofactor and "enzymatic" molybdenum, the other important form of molybdenum is the molybdate ion (MoO_4^{2-}) (83), which is the main form in blood and urine.

Metabolism

Molybdenum (except as MoS_2) in foods and in the form of soluble complexes is readily

absorbed. Humans absorbed 88 to 93% of the molybdenum fed as ammonium molybdate in a liquid formula component of a diet (84). In another study, about 57% of intrinsically labeled molybdenum in soy and 88% in kale were absorbed (85). Molybdenum absorption occurs rapidly in the stomach and throughout the small intestine, with the rate of absorption being higher in the proximal than in the distal parts (83). Whether an active or a passive mechanism is more important in the absorption of molybdenum is uncertain. One study indicated that at low concentrations, molybdenum absorption is carrier mediated and active (86). Another study showed that in vivo absorption rates were essentially the same over a 10-fold range of molybdenum concentrations, which suggests that molybdate was absorbed by diffusion only (87). Molybdate possibly is moved both by diffusion and by active transport, but at high concentrations, the relative contribution of active transport to molybdenum flux is small.

Molybdate is absorbed and transported loosely attached to erythrocytes in the blood; it tends to bind specifically to α_2 -macroglobulin (88). Organs that retain the highest amounts of molybdenum are liver and kidney (81, 83, 88).

After absorption, most molybdenum is turned over rapidly and eliminated as molybdate through the kidney (84); this elimination is increased as dietary intake is increased. Thus, excretion rather than regulated absorption is the major homeostatic mechanism for molybdenum. Nonetheless, significant amounts of this element are excreted in the bile (88).

Functions and Mode of Action

Molybdenum functions as an enzyme cofactor (81, 82). Molybdoenzymes catalyze the hydroxylation of various substrates (89). Aldehyde oxidase oxidizes and detoxifies various pyrimidines, purines, pteridines, and related compounds. Xanthine oxidase/dehydrogenase catalyzes the transformation of hypoxanthine to xanthine and of xanthine to uric acid. Sulfite oxidase catalyzes the transformation of sulfite to sulfate.

Molybdate might also be involved in stabilizing the steroid-binding ability of unoccupied steroid receptors (90, 91). During isolation procedures, molybdate protects steroid hormone receptors, such as the glucocorticoid receptor, against inactivation. It is hypothesized, however, that molybdate affects the glucocorticoid receptor because it mimics an endogenous compound called “modulator.”

Deficiency Signs

The signs of molybdenum deficiency in animals have been reviewed (81). Deficiency signs in goats and minipigs are depressed feed consumption and growth, impaired reproduction characterized by increased mortality in both mothers and offspring, and elevated copper concentrations in liver and brain. A molybdenum-responsive syndrome found in hatching chicks is characterized by a high incidence of late embryonic mortality, mandibular distortion, anophthalmia, and defects in leg bone development and feathering. Skeletal lesions, subsequently detected in older birds, include separation of the proximal epiphysis of the femur, osteolytic changes in the femoral shaft, and lesions

in the overlying skin that ultimately were attributed to intense irritation in these areas. The incidence of this syndrome was particularly high in commercial flocks reared on diets containing high concentrations of copper (a molybdenum antagonist) as a growth stimulant. These apparently dissimilar pathologic changes could possibly be explained by a defect in sulfur metabolism.

Recognition that molybdenum is a component of sulfite oxidase whose deficiency disrupts cysteine metabolism has resulted in identification of human disorders caused by a lack of functioning molybdenum. A lethal inborn error in metabolism resulting from a sulfite oxidase deficiency is characterized by severe brain damage; mental retardation; dislocation of ocular lenses; increased urinary output of sulfite, S-sulfocysteine, and thiosulfate; and decreased urinary output of sulfate (82). A patient receiving prolonged TPN therapy acquired a syndrome described as “acquired molybdenum deficiency.” This syndrome, exacerbated by methionine administration, was characterized by hypermethioninemia, hypouricemia, hyperoxypurinemia, hypouricosuria, and low urinary sulfate excretion. In addition, the patient suffered mental disturbances that progressed to coma. Supplementation with ammonium molybdate improved the clinical condition, reversed the sulfurhandling defect, and normalized uric acid production (92).

Toxicology

Large oral doses are necessary to overcome the homeostatic control of molybdenum (81, 83). Thus, molybdenum is a relatively nontoxic element; in nonruminants, an intake of 1.04 to 52.1 mmol (100–5000 mg)/kg of food or water is required to produce clinical symptoms. Ruminants are more susceptible to elevated amounts of dietary molybdenum. The mechanism of molybdenum toxicity is uncertain. Most toxicity signs are similar or identical to those of copper deficiency (i.e., growth depression and anemia). In humans, both occupational and high dietary exposures to molybdenum have been linked by epidemiologic methods to elevated uric acid concentrations in blood and an increased incidence of gout.

Dietary Considerations

The current United States ESADDIs for molybdenum (2) (see [Tables of RDI \[RDA\]](#) in the Appendix) are the following: infants aged 0 to 0.5 years, 0.16 to 0.31 μmol or 15 to 30 μg , and aged 0.5 to 1.0 years, 0.21 to 0.42 μmol or 20 to 40 μg ; children and adolescents aged 1 to 3 years, 0.26 to 0.52 μmol or 25 to 50 μg , aged 4 to 6 years, 0.31 to 0.78 μmol or 30 to 75 μg , aged 7 to 10 years, 0.52 to 1.76 μmol or 50 to 150 μg , and aged 11 years or older, 0.78 to 2.08 μmol or 75 to 200 μg ; adults, 0.78 to 2.61 μmol or 75 to 250 μg . Data to support these estimates are scant. These values apparently were set by using balance data (which may be questionable) and the reasoning that usual dietary intakes are within this range without apparent signs of deficiency or toxicity. Recent studies indicate that the requirement for molybdenum in adults is actually close to 0.26 μmol (25 μg) per day (93).

The daily intake of molybdenum ranges between 0.52 and 3.65 μmol (50 and 350 μg) (94, 95 and 96). Most diets, however, apparently supply about 0.52 to 1.04 μmol

(50–100 µg) molybdenum per day. The richest food sources of molybdenum include milk and milk products, dried legumes or pulses, organ meats (liver and kidney), cereals, and baked goods. The poorest sources of molybdenum include nonleguminous vegetables, fruits, sugars, oils, fats, and fish ([95](#), [96](#)).

Clinical Considerations

Except for the molybdenum-responsive patient with “acquired molybdenum deficiency” resulting from long-term use of TPN, there is no indication that molybdenum deficiency is of clinical importance. Nonetheless, the search for possible molybdenum-responsive syndromes in humans is still warranted because situations may be occurring where molybdenum nutriture is important. For example, low dietary molybdenum might be detrimental to human health and well-being through an effect on the detoxification of xenobiotic compounds. The molybdenum hydroxylases apparently are as important as the microsomal monooxygenase system in the metabolism of drugs and foreign compounds ([89](#)). This may be why molybdenum has an inhibitory effect on some forms of cancer in animal models ([97](#)).

NICKEL

Historical Overview

An earlier review of nickel ([98](#)) stated that although nickel was first suggested to be nutritionally essential in 1936, strong evidence for essentiality did not appear until 1970. Studies between 1970 and 1975, however, gave inconsistent signs of nickel deprivation, probably because of suboptimal experimental conditions. Since 1975, diets and environments that allow optimal growth and survival of laboratory animals have been used in studies of nickel nutrition and metabolism. Thus, most of the significant biochemical, nutritional, and physiologic studies of nickel appeared after 1975.

Chemistry

Books devoted to nickel have extensive reviews of the biochemistry of this element ([99](#), [100](#)). These reviews indicate that monovalent, divalent, and trivalent forms of nickel apparently are important in biochemistry. Like other ions of the first transition series, Ni²⁺ can complex, chelate, or bind with many substances of biologic interest. This binding, particularly by amino acids (especially histidine and cysteine), proteins (especially albumin), and by a macroglobulin called nickeloplasmin, probably is important in the extracellular transport, intracellular binding, and urinary and biliary excretion of nickel. Ni²⁺ in a tightly bound form is required for the activity of urease, an enzyme found in plants and microorganisms. In the microbial enzyme, methyl coenzyme M reductase, nickel is present in a chromophore called factor F430, which is a tetrapyrrole similar in structure to that in vitamin B₁₂. Ni³⁺ apparently is essential for enzymatic hydrogenation, desulfurization, and carboxylation reactions in mostly anaerobic microorganisms. In some of these reactions, the redox action of nickel may involve the 1+ oxidation state, especially in that of methyl coenzyme M reductase.

Nickel is also a structural component of some enzymes.

Metabolism

When nickel in water is ingested after an overnight fast or in low quantities, as much as 50%, but usually closer to 20 to 25%, of the dose is absorbed (101, 102). Certain foodstuffs and simple substances, including milk, coffee, tea, orange juice, and ascorbic acid, however, depress this high absorption (101). Foods such as those found in a typical Guatemalan meal or in a North American breakfast suppress absorption of nickel to less than 1%. Thus, nickel is often poorly absorbed (less than 10%) when ingested with typical diets. Nickel absorption is enhanced by iron deficiency, pregnancy, and lactation (103, 104).

The mechanisms involved in transport of nickel through the gut are not conclusively established. Persuasive evidence indicates that no specific nickel carrier mechanism exists at the brush border membrane (104); this means that absorption probably depends on the efficiency of mucosal trapping via charge neutralization on the membrane. In other words, nickel crosses the basolateral membrane via passive leakage or diffusion, perhaps as an amino acid complex or some other low-molecular-weight complex. Passage as a lipophilic complex is a possibility, because these types of complexes markedly increase the nickel concentrations in tissues of experimental animals (106). However, there is also some evidence for energy-driven transport of nickel across the mucosal epithelium (104, 107).

Nickel transported in blood is principally bound to serum albumin (108). Small amounts of nickel in serum are associated with the amino acid L-histidine and with α_2 -macroglobulin (108, 109). No tissue or organ significantly accumulates orally administered physiologic doses of nickel. In humans, the thyroid and adrenal glands apparently have relatively high nickel concentrations, with reported values of 2.40 and 2.25 μmol (141 and 132 μg)/kg dry weight, respectively (110). Most organs contain less than 0.85 μmol (50 μg) nickel/kg dry weight.

Although fecal nickel excretion (mostly unabsorbed nickel) is 10 to 100 times as great as urinary excretion, most of the small fraction of nickel absorbed is rapidly and efficiently excreted through the kidney as urinary low-molecular-weight complexes. Measurable amounts of nickel are also lost in sweat and bile. The nickel content in sweat is high (about 1.19 μmol or 70 $\mu\text{g/L}$), which points to active nickel secretion by the sweat glands (111). Biliary loss of nickel has been estimated at 34 to 85 nmol (2–5 μg) per day (110).

Functions and Mode of Action

No biochemical function for nickel has been clearly defined for higher animals or humans. Nickel may, however, function as a cofactor or structural component in specific metalloenzymes in higher organisms, because such enzymes have been identified in bacteria, fungi, plants, and invertebrates. These nickel-containing enzymes include urease, hydrogenase, methyl coenzyme M reductase, and carbon monoxide

dehydrogenase (99, 100). Nickel may have a function in higher animals that involves a pathway using vitamin B₁₂ and/or folic acid. Both these vitamins affect signs of nickel deprivation in rats (112, 114). The interaction between nickel and folic acid affects the vitamin B₁₂- and folic acid-dependent pathway of methionine synthesis from homocysteine (114). Nickel might also have a very basic function, because nickel in vitro is a calcium channel blocker (115) and can activate the Ca²⁺ “receptor” on the osteoclast to elicit cytosolic Ca²⁺ signals (116).

Deficiency Signs

Signs of nickel deficiency have not been described for humans. The reported signs of nickel deprivation for six animal species—chick, cow, goat, pig, rat, and sheep—are extensive and have been listed in several reviews (98, 103, 117). Unfortunately, many of the reported signs may have been misinterpreted manifestations of pharmacologic actions of nickel (118). High dietary nickel, used in some experiments, may have alleviated an abnormality caused by something other than a nutritional deficiency of nickel (many diets were apparently low in iron). However, recent studies with rats and goats indicate that nickel deprivation depresses growth, reproductive performance, and plasma glucose and alters the distribution of other elements in the body, including calcium, iron, and zinc. As with other ultratrace elements, the nature and severity of signs of nickel deprivation are affected by diet composition. For example, both vitamin B₁₂ and folic acid affect the response to nickel deprivation (112, 113 and 114).

Toxicology

Life-threatening toxicity of nickel through oral intake is unlikely. Because of excellent homeostatic regulation, nickel salts exert their toxic action mainly by gastrointestinal irritation and not by inherent toxicity (117). Generally, concentrations of Ni above 4.26 μmol (250 μg)/g of diet are required to produce signs of nickel toxicity (such as depressed growth and anemia) in animals; by weight extrapolation, a daily oral dose of 4.26 mmol (250 mg) of soluble nickel should produce toxic symptoms in humans. However, more moderate doses of nickel may have adverse effects in humans. An oral dose in water as low as 10.2 μmol (0.6 mg) nickel as nickel sulfate, which is well absorbed, given to fasting subjects produced a positive skin reaction in some individuals with nickel allergy (119). That dose is only a few times higher than the human daily requirement postulated on the basis of results from animal studies.

Dietary Considerations

Because of the strong circumstantial evidence indicating that nickel is essential for several animals, a reasonable hypothesis is that nickel is required by humans also. Moreover, knowledge about the nickel requirements of animals is helpful in estimating the amount of nickel possibly required by humans. Most monogastric animals have an apparent nickel requirement of less than 3.41 μmol (200 μg)/kg diet. On the basis that adult humans usually consume 500 g of a mixed diet daily (dry basis), a dietary requirement for humans of 426 to 596 nmol (25–35 μg) per day has been suggested (120). Total dietary nickel intakes of humans vary greatly with the amounts and

proportions of foods of animal (nickel-low) and plant (nickel-high) origin consumed. Rich sources of nickel include chocolate, nuts, dried beans, peas, and grains (95, 120, 121); diets high in these foods could supply more than 15.33 μmol (900 μg) nickel per day. Conventional diets, however, often provide less than 2.55 μmol (150 μg) daily (some much less than 1.70 μmol [100 μg] daily). Examples of reported intakes are 1.18 to 2.76 μmol (69–162 μg) per day in the United States (95) and 2.21 μmol (130 μg) per day (range of 1.02–4.43 μmol or 60–260 μg) in Denmark (121).

Clinical Considerations

Until more is known about the physiologic function of nickel and its dietary requirement, it is inappropriate to suggest specific disorders other than nickel dermatitis as wholly or partially attributable to abnormal nickel nutrition. However, be aware that nickel status affects the functions of vitamin B₁₂ and folic acid, two nutrients receiving increasing clinical attention.

SILICON

Historical Overview

As early as 1911, researchers (122) suggested that silicon might have an antiatheroma action. A review of silicon in nutrition (123) indicated that until 1972, silicon was generally considered nonessential, except for some lower classes of organisms (diatoms, radiolarians, and sponges), in which silica serves a structural role. Most of the limited studies on the biochemical, nutritional, and physiologic roles of silicon have been published since 1974.

Chemistry

The chemistry of silicon is similar to that of carbon, its sister element (124). Silicon forms silicon-silicon, silicon-hydrogen, silicon-oxygen, silicon-nitrogen, and silicon-carbon bonds. Thus, organosilicon compounds are analogues of organocarbon compounds. However, substitution of silicon for carbon, or vice versa, in organocompounds results in molecules with different properties, because silicon is larger and less electronegative than carbon.

In animals, silicon is found both free and bound. Silicic acid probably is the free form. The bound form has never been rigorously identified. Silicon might be present in biologic material as a silanolate, an ether (or esterlike) derivative of silicic acid. Bridges of R₁-O-Si-O-R₂ or R₁-O-Si-O-Si-O-R₂ possibly play a role in the structural organization of some mucopolysaccharides or collagen.

Metabolism

Little is known about the metabolism of silicon. Increasing silicon intake increases urinary silicon output up to fairly well defined limits in humans, rats, and guinea pigs.

The upper limits of urinary silicon excretion, however, apparently are not set by the excretory ability of the kidney, because urinary excretion can be elevated above these upper limits by peritoneal injection of silicon (125). Thus, the upper limits apparently are set by the rate and extent of silicon absorption from the gastrointestinal tract. The form of dietary silicon determines whether it is well absorbed. In one study, humans absorbed only about 1% of a large single dose of an aluminosilicate compound but absorbed more than 70% of a single dose of methylsilanetriol salicylate, a drug used in the treatment of circulatory ischemias and osteoporosis (126). Some dietary forms of silicon must be well absorbed, because daily urinary silicon excretion in humans can be a high percentage (close to 50%) of daily silicon intake (127). The mechanisms involved in intestinal absorption and blood transport of silicon are unknown.

Silicon is not protein bound in plasma, where it is believed to exist almost entirely in the undissociated monomeric silicic acid form, Si(OH)_4 (123, 124, 125, 126, 127 and 128). Connective tissues, including aorta, trachea, tendon, bone, and skin and its appendages contain much of the silicon that is retained in the body (123). Absorbed silicon is mainly eliminated via the urine, where it probably exists as magnesium orthosilicate (123, 128).

Functions and Mode of Action

The distribution of silicon in the body and the biochemical changes in bone caused by silicon deficiency indicate that silicon influences bone formation by affecting cartilage composition and ultimately cartilage calcification. In bone (123, 129, 130), silicon is localized in the active growth areas or osteoid layer and within the osteoblasts. In bone of silicon-deficient animals, hexosamine (glycosaminoglycans) and collagen concentrations are depressed, but macromineral composition is not markedly affected. Silicon apparently affects collagen formation, because it is required for maximal bone polyhydroxylase activity (130), and silicon deficiency decreases ornithine aminotransferase (131); both enzymes are involved in collagen formation. Silicon also apparently is involved with phosphorus in the organic phase in the series of events leading to calcification (129). Thus, silicon possibly has a function that facilitates association between phosphoprotein-mucopolysaccharide macromolecules and collagen, which plays a role in the initiation of calcification and the regulation of crystal growth. The finding that silicon affects gene expression in some diatoms suggests that a similar role might also exist in higher animals (132).

Deficiency Signs

Silicon deficiency signs have not been defined for humans. Most of the signs of silicon deficiency in chickens and rats indicate aberrant metabolism of connective tissue and bone (123, 129, 130, 133). Chicks fed a semisynthetic, silicon-deficient diet exhibit structural abnormalities of the skull and long-bone abnormalities characterized by small, poorly formed joints, defective endochondral growth and depressed contents of articular cartilage, water, hexosamine, and collagen. Silicon deprivation can affect the response to other dietary manipulations. Rats fed a diet low in calcium and silicon and high in aluminum accumulated high amounts of aluminum in the brain; silicon supplements prevented the accumulation (134). Also, high dietary aluminum intakes depressed brain zinc concentrations in thyroidectomized rats fed low dietary silicon; silicon supplements

prevented the depression (135). The effects of silicon and aluminum were not seen in nonthyroidectomized rats.

Toxicology

Silicon is essentially nontoxic when taken orally. Magnesium trisilicate, an over-the-counter antacid, has been used by humans for more than 40 years without obvious deleterious effects. Other silicates are food additives used as anticaking or antifoaming agents. However, ruminants consuming plants with a high silicon content may develop siliceous renal calculi. Renal calculi in humans may also contain silicates (123).

Dietary Considerations

Postulating a silicon requirement is difficult because only limited data are available. Rats fed about 0.16 mmol (4.5 mg) silicon/kg diet, mostly as the very available sodium metasilicate, do not differ from rats fed about 1.25 mmol (35 mg) silicon/kg diet; both prevent, equally well, silicon deficiency signs exhibited by rats fed about 36 μ mol (1.0 mg) silicon/kg diet (133). Thus, if dietary silicon is highly available, as animal data suggest, the human requirement for silicon is quite small, perhaps in the range of 0.07 to 0.18 mmol (2–5 mg) per day. However, much of the silicon found in most diets probably is not absorbable or as available as sodium metasilicate; significant amounts probably occur as aluminosilicates and silica, from which silicon is not readily available. Thus, the recommended intake of silicon probably should be higher than the estimated requirement. On the basis of balance data, a silicon intake of 1.07 to 1.25 mmol (30–35 mg) per day was suggested for athletes, which was 0.18 to 0.36 mmol (5–10 mg) higher than that for nonathletes (136).

Total dietary silicon intake of humans varies greatly with the amount and proportions of foods of animal (silicon-low) and plant (silicon-high) origin consumed and with the amounts of refined and processed foods in the diet (137, 138). Normally, refining reduces the silicon content of foods. However, in recent years, silicate additives have been used increasingly as anticaking or antifoaming agents in prepared foods and confections. Although this increases total dietary silicon, most of it is not bioavailable. The silicon content of drinking water and beverages made thereof shows geographic variation; silicon is high in hard-water and low in soft-water areas. The richest sources of silicon are unrefined grains of high fiber content and cereal products (137, 138).

Average daily intakes of silicon apparently range from about 0.71 to 1.79 mmol (20–50 mg) per day. The calculated silicon content of the FDA total diet was 0.68 mmol (19 mg) per day for women and 1.42 mmol (40 mg) for men (138). A human balance study indicated that oral intake of silicon could be about 0.75 to 1.64 mmol (21–46 mg) per day (127). The average British diet has been estimated to supply 1.10 mmol (31 mg) silicon per day (137).

Clinical Considerations

Ample circumstantial evidence indicates that silicon is an essential nutrient for higher animals, including humans. However, more work is needed to clarify the consequences of silicon deprivation in humans. A severe lack of dietary silicon could have detrimental effects on brain and bone function and composition.

VANADIUM

Historical Overview

Findings reported between 1971 and 1974 by four different research groups led many to conclude that vanadium is an essential nutrient. However, many of these findings may have been the consequence of high vanadium supplements (10 to 100 times the amount normally found in natural diets) that induced pharmacologic changes in animals fed imbalanced diets ([118](#), [139](#), [140](#)). A surge of interest in vanadium started in 1977 when it was rediscovered that vanadate inhibits ATPases ([141](#)) and has been maintained by the finding that vanadium is an insulin-mimetic agent ([142](#)). The first vanadium-containing enzyme, a bromoperoxidase from a marine alga, was isolated in 1984 ([143](#)). These findings have stimulated speculation about the nutritional importance of vanadium, for which the most substantive evidence has appeared only since 1987.

Chemistry

The chemistry of vanadium is complex because the element can exist in at least six oxidation states and can form polymers. In higher animals, the tetravalent and pentavalent states apparently are the most important forms of vanadium ([144](#)). The tetravalent vanadyl cation, VO^{2+} , behaves like a simple divalent aquo ion and competes well with Ca^{2+} , Mn^{2+} , Fe^{2+} , etc., for ligand-binding sites. Thus, VO^{2+} easily forms complexes with proteins, especially those associated with iron, such as transferrin and hemoglobin, which stabilize the vanadyl ion against oxidation. The pentavalent form of vanadium is known as vanadate (H_2VO_4^- or more simply VO_3^-). Vanadate forms complexes, including those that result in its being a phosphate transition-state analogue, and thus competes with or replaces phosphate in many biochemical processes. Vanadate is easily reduced nonenzymatically by relatively small molecules such as ascorbate and glutathione.

Another form of vanadium, the peroxy form, might be responsible for many biologic actions of vanadium, including its insulin-mimetic action and haloperoxidase role ([145](#)). Vanadate can interact with O^- formed by NADPH oxidase to generate the peroxovanadyl (V-OO) radical. Peroxovanadyl can in turn remove a hydrogen atom from NADPH to yield vanadyl hydroperoxide (V-OOH). Peroxy (heteroligand) vanadate adducts represent a useful model for the active-site vanadium involved in bromide oxidation in haloperoxidases ([145](#)).

Metabolism

Recent reviews of vanadium metabolism ([140](#), [146](#)) found that most ingested vanadium is unabsorbed and is excreted in the feces. Based on the very low concentrations of vanadium normally found in urine compared with the estimated daily intake and fecal content of vanadium, less than 5% of vanadium ingested is absorbed. Animal studies generally support the concept that vanadium is poorly absorbed. However, two studies with rats indicated that vanadium absorption can exceed 10% under some conditions, which suggests caution in assuming that ingested vanadium always is poorly absorbed from the gastrointestinal tract.

Most ingested vanadium is probably transformed in the stomach to VO^{2+} and remains in this form as it passes into the duodenum ([147](#)). However, in vitro studies suggest that vanadate can enter cells through phosphate- or other anion-transport systems. This may explain why VO_3^- is absorbed 3 to 5 times more effectively than VO^{2+} . Thus, apparently the different absorbability rates, the effect of other dietary components on the forms of vanadium in the stomach, and the rate at which it is transformed into VO^{2+} markedly affect the percentage of ingested vanadium absorbed ([147](#)). Supporting this concept are the reviewed findings showing that a number of substances can ameliorate vanadium toxicity, including EDTA, chromium, protein, ferrous ion, chloride, and aluminum hydroxide ([140](#)).

If vanadate appears in the blood, it is quickly converted into the vanadyl cation, most likely in erythrocytes. The vanadyl cation, either absorbed as such or formed in vivo, complexes with transferrin and ferritin in plasma and body fluids ([148](#)). It remains to be determined whether vanadyl-transferrin can transfer vanadium into cells through the transferrin receptor or whether ferritin is a storage vehicle for vanadium. Vanadium is rapidly removed from the blood plasma and is retained in highest amounts in the kidney, liver, testes, bone, and spleen. However, little of the absorbed vanadium is retained under normal conditions in the body; most tissues contain less than 196 pmol (10 ng) V/g fresh weight ([140](#)). Bone apparently is a major sink for excessive retained vanadium.

Excretion patterns after parenteral administration indicate that urine is the major excretory route for absorbed vanadium ([148](#), [149](#)). However, a significant portion of absorbed vanadium may be excreted through the bile. Human bile contains measurable vanadium (about 20 pmol [1.0 ng]/g) ([150](#)), and about 10% of an injected dose of ^{48}V was found in the feces of rats ([149](#)).

Both high- and low-molecular-weight complexes of vanadium have been found in urine ([148](#), [149](#)); one of these may be the vanadyl-transferrin complex. The form of vanadium in bile has not been determined.

Functions and Mode of Action

A defined biochemical function for vanadium in higher animals and thus for humans has not been described. Numerous biochemical and physiologic functions for vanadium have been suggested on the basis of its in vitro and pharmacologic actions; these have

been reviewed ([144](#), [151](#), [152](#)) and are too extensive to discuss in detail here. Briefly, in vitro studies with cells and pharmacologic studies with animals have shown that vanadium has insulin-mimetic properties; numerous stimulatory effects on cell proliferation and differentiation; effects on cell phosphorylation-dephosphorylation; inhibitory effects on the motility of sperm, cilia, and chromosomes; effects on glucose and ion transport across plasma membranes; interfering effects on intracellular ionized calcium movement; and effects on oxidation-reduction processes. Vanadium inhibits numerous ATPases, phosphatases, and phosphoryl transfer enzymes in in vitro cell-free systems. The pharmacologic action of vanadium receiving the most attention recently is its ability to mimic insulin ([142](#)).

Enzymatic roles for vanadium have been defined for some algae, lichens, fungi, and bacteria ([143](#), [145](#), [153](#)). Vanadium enzymes include nitrogenase in bacteria, which reduces nitrogen gas to ammonia, and bromoperoxidase, iodoperoxidase and chloroperoxidase in algae, lichens, and fungi, respectively. The haloperoxidases catalyze the oxidation of halide ions by hydrogen peroxide, thus facilitating the formation of a carbon-halogen bond. The best known haloperoxidase in animals is thyroid peroxidase. Vanadium deprivation in rats affects the response of thyroid peroxidase to changing dietary iodine concentrations ([154](#)).

Deficiency Signs

Most of the early reported deficiency signs for vanadium are questionable. The diets used in early vanadium deprivation studies had widely varying contents of protein, sulfur amino acids, ascorbic acid, iron, copper, and perhaps other nutrients that affect, or can be affected by, vanadium ([139](#)). Also, vanadium supplementation in these experiments was relatively high compared with apparent need. As a result, it is difficult to determine whether the deficiency signs in early experiments were true deficiency signs, indirect changes caused by an enhanced need for vanadium in some metabolic function, or manifestations of a pharmacologic action of vanadium. Vanadium deficiency signs for humans have not been described.

The uncertainty about vanadium deficiency signs prompted new efforts to characterize a consistent set for animals. In these studies, goats fed diets apparently containing adequate and balanced amounts of all known nutrients exhibited an elevated abortion rate and depressed milk production when deprived of vanadium. About 40% of kids from vanadium-deprived goats died between days 7 and 91 of life, with some deaths preceded by convulsions; only 8% of kids from vanadium-supplemented goats died during the same time. Also, skeletal deformations were seen in the forelegs, and forefoot tarsal joints were thickened ([155](#)). In a rat study, vanadium deprivation increased thyroid weight and the thyroid weight:body weight ratio and decreased growth ([154](#)). Stressors that change thyroid status or iodine metabolism enhanced the response of rats to vanadium deprivation.

Toxicology

Vanadium is a relatively toxic element. Acute toxicity studies indicate that vanadium is a neurotoxic and hemorrhagic-endotheliotoxic poison with nephrotoxic, hepatotoxic, and

probably leukocytotoxic and hematotoxic components (156). Apparently, this breadth of toxic effects is the reason for the large number of signs of vanadium toxicity described for animals that vary among species and with dosage (157). Some of the more consistent signs include depressed growth, elevated organ vanadium, diarrhea, depressed food intake, and death. Animal data indicate that long-term daily intake above 196 μmol (10 mg) vanadium might lead to toxicologic consequences. Limited studies with humans support this contention. When 12 subjects were given 265 μmol (13.5 mg) vanadium daily for 2 weeks and then 442 μmol (22.5 mg) vanadium daily for 5 months, five patients exhibited gastrointestinal disturbances and five patients exhibited green tongue (158). In another study, six subjects were fed 88 to 353 μmol (4.5–18 mg) vanadium daily for 6 to 10 weeks; green tongue, cramps, and diarrhea were observed at the higher doses (159).

Dietary Considerations

If vanadium is essential for humans, its requirement most likely is small. The diets used in animal deprivation studies contained only 39 to 491 pmol (2–25 ng) V/g diet; these amounts often did not markedly affect the animals. Vanadium deficiency has not been identified in humans, yet diets generally supply less than 589 nmol (30 μg) vanadium daily and most supply only 294 nmol (15 μg) daily (95, 96, 150). Thus, a daily dietary intake of 196 nmol (10 μg) vanadium probably will meet any postulated requirement. Foods rich in vanadium include shellfish, mushrooms, parsley, dill seed, black pepper, and some prepared foods (150, 161, 162). Beverages, fats and oils, and fresh fruits and vegetables contain the least vanadium (less than 20 to 98 pmol [1–5 ng]/g).

Clinical Considerations

The clinical importance of vanadium is uncertain. It will be necessary to disentangle pharmacologic from nutritional observations to assess the nutritional importance of vanadium and to determine its safe and adequate intakes. Because vanadium is so pharmacologically active, a beneficial clinical role for this element may be found.

OTHER ULTRATRACE ELEMENTS

As indicated above, the evidence for essentiality of aluminum, bromine, cadmium, germanium, lead, lithium, rubidium, and tin is quite limited. Nonetheless, because beneficial claims for the elements are sometimes made in health magazines, newsletters, books, special publications, announcements, and advertisements, they should be considered here. Most likely none of these mineral elements are of nutritional or toxicologic concern if intakes are near those in a typical well-balanced diet.

Aluminum

A dietary deficiency of aluminum in goats reportedly results in increased abortions, depressed growth, incoordination and weakness in hind legs, and decreased life expectancy (163). Aluminum deficiency has been reported to depress growth in chicks (164). Aluminum toxicity is not a concern for healthy individuals. Cooking foods in

aluminum cookware does not lead to toxic intakes of aluminum. Ingestion of high dietary amounts of aluminum is no longer believed to cause Alzheimer's disease. However, high intakes of aluminum from such sources as buffered analgesics and antacids by susceptible individuals (e.g., those with impaired kidney function, including the elderly and low-birth-weight infants) may lead to pathologic consequences and thus should be avoided. Aluminum toxicity is of most concern when contaminated solutions are used for parenteral feeding or for kidney dialysis (165). Aluminum toxicity caused in this manner results in neurotoxicity and adverse skeletal changes. Severe neurotoxicity, called dialysis dementia, is characterized by speech disturbances, disorientation, seizures, and hallucinations. Aluminum skeletal toxicity is characterized by bone pain and fractures. The typical daily dietary intake of aluminum is 74 to 371 μmol (2–10 mg). Rich sources of aluminum include baked goods prepared with chemical leavening agents (e.g., baking powder), processed cheese, grains, vegetables, herbs, and tea (166).

Bromine (Bromide)

It has been reported that a dietary deficiency of the bromide anion results in depressed growth, fertility, hematocrit, hemoglobin, and life expectancy, and in increased milk fat and abortions in goats (167). Also, insomnia exhibited by some hemodialysis patients has been associated with bromide deficiency (168). The bromide anion has a low order of toxicity; thus, it is not of toxicologic concern in nutrition. The typical daily intake of bromide ion is 25 to 100 μmol (2–8 mg). Rich sources of bromide are grains, nuts, and fish (169).

Cadmium

Cadmium deficiency reportedly depresses growth of rats (170) and goats (171). Although cadmium might be an essential element at very low intakes, it is of more concern because of its toxicologic properties (172). Cadmium is a potent antagonist of several essential minerals, including zinc, copper, iron, and calcium. Cadmium has a long half-life in the body and thus high intakes can lead to accumulation resulting in damage to some organs, especially the kidney. The typical daily dietary intake of cadmium is 89 to 178 nmol (10–20 μg). Rich sources of cadmium include shellfish, grains (especially those grown on high-cadmium soils), and leafy vegetables (172).

Germanium

A low germanium intake alters the mineral composition of bone and liver and decreases tibial DNA in the rat (173). Germanium is also touted as having anticancer properties because some organic complexes of this element inhibit tumor formation in animal models (174). High intakes of inorganic germanium, which is more toxic than organic forms of germanium, causes kidney damage (174). Some individuals consuming high amounts of organic germanium supplements contaminated with inorganic germanium have died from kidney failure. The typical daily dietary intake of germanium is 5.5 to 20.7 μmol (0.4–1.5 mg). Rich sources of germanium include wheat bran, vegetables, and leguminous seeds (169).

Lead

A large number of findings from one research group ([175](#), [176](#)) suggest that low dietary intake of lead has adverse effects in pigs and rats. Apparent deficiency signs found include depressed growth; anemia; elevated serum cholesterol, phospholipids, and bile acids; disturbed iron metabolism; decreased liver glucose, triglycerides, LDL-cholesterol and phospholipid concentrations; increased liver cholesterol; and altered blood and liver enzymes. Although lead might have beneficial effects at low intakes, lead toxicity is of more concern than lead deficiency. Lead is considered a major environmental pollutant because of past use of lead-based paints and the combustion of fuels containing lead additives. Lead toxicity ([177](#)) results in anemia, kidney damage, and central nervous system abnormalities ranging from ataxia and stupor to coma and convulsions. Ingestion of high amounts of lead from the environment by children has been associated with reduced intelligence and impaired motor function. The typical daily dietary intake of lead is 72 to 483 nmol (15–100 µg). Rich sources of lead include seafood and plant foodstuffs grown under high lead conditions ([178](#)).

Lithium

Lithium deficiency reportedly results in depressed fertility, birth weight, and life span and in altered activity of several liver and blood enzymes in goats ([179](#)). In rats, lithium deficiency apparently depresses fertility, birth weight, litter size, and weaning weight ([180](#), [181](#)). Lithium is best known for its pharmacologic antimanic properties ([182](#)). Its ability to affect mental function perhaps explains the report that incidence of violent crimes is higher in areas with low-lithium drinking water ([183](#)). The principal disadvantage in the use of lithium for psychiatric disorders is the narrow safety margin between therapeutic and toxic doses. Mild lithium toxicity results in gastrointestinal disturbances, muscular weakness, tremor, drowsiness, and a dazed feeling ([182](#)). Severe toxicity results in coma, muscle tremor, convulsions, and even death ([182](#)). The typical daily dietary intake of lithium is 28.8 to 86.5 µmol (200–600 µg). Rich sources of lithium include eggs, processed meat, fish, milk, milk products, potatoes, and vegetables ([179](#)).

Rubidium

Rubidium deficiency in goats reportedly results in depressed food intake, growth, and life expectancy and increased spontaneous abortion ([184](#)). Rubidium is relatively nontoxic and thus not of toxicologic concern. The typical daily dietary intake of rubidium is 12 to 59 µmol (1–5 mg). Rich sources of rubidium include coffee, black tea, fruits, vegetables (especially asparagus), and poultry ([185](#)).

Tin

A dietary deficiency of tin has been reported to depress growth, response to sound, and feed efficiency; to alter the mineral composition of several organs; and to cause hair loss in rats ([186](#), [187](#)). Inorganic tin is relatively nontoxic. However, routine consumption

of foods packed in unlacquered tin-plated cans may result in excessive exposure to tin, which could adversely affect the metabolism of other essential trace elements including zinc and copper (188). The typical daily dietary intake of tin is 8 to 337 μmol (1–40 mg). A rich source of tin is canned foods (188).

HISTORICAL OVERVIEW

Historical research provides evidence that Egyptian and Greek physicians in ancient times may have understood the curative value of liver, a rich source of vitamin A, for night blindness, an early ocular manifestation of vitamin A deficiency (1). The first scientific reports of an essential dietary component with vitamin A activity were published in 1913 by E. V. McCollum and M. Davis and by T. B. Osborne and L. V. Mendel. These investigators noted that certain “lipins” extracted from butter, eggs, or cod liver oil were essential for the growth of young rats fed diets with lard or olive oil as the only fat. McCollum and Davis first referred to this then-unknown growth factor as “fat-soluble A,” and later as “vitamin A.” Steenbock and others soon recognized that a factor present in yellow vegetables had similar activity. Moore drew the prescient

inference that the latter yellow substance, now recognized as carotene, might be a precursor of the nearly colorless vitamin A.

During the 1920s, several investigators made several fundamental discoveries regarding the relationship of vitamin A deficiency to growth, xerophthalmia, normal tissue differentiation, and resistance to infection. In the 1920s to 1930s, Karrer and his colleagues in Switzerland elucidated the chemical structure of vitamin A as all-*trans*-retinol, and in the late 1940s, Arens and van Dorp (2) reported the synthesis of vitamin A acid, now known as retinoic acid (RA). These investigators and others showed that RA restores growth in vitamin A-deficient animals. During the 1950s, the role of vitamin A in vision was elucidated by the work of Wald, Hubbard, and others, which showed that “retinene” (now retinal) is the essential visual pigment of the photoreceptor cells (3).

Other milestones in vitamin A research include a series of discoveries of proteins essential for transport and metabolism of retinoids. The plasma transport protein for retinol, retinol-binding protein (RBP), was isolated from human plasma in the late 1960s (4). A number of cellular retinoid-binding proteins were first identified in the 1970s and have been extensively characterized since then (5). Simultaneously, it became clear that RA is the most potent metabolite of vitamin A, possessing most, if not all, of vitamin A's biologic activities apart from the activity of retinal in vision.

The first members of a new family of nuclear retinoid receptors were described in 1987 and shown to be highly homologous in structure and mechanism of action to the previously described superfamily of steroid/thyroid hormone receptors. This area of retinoid receptor research has expanded extremely rapidly with the recognition of two main subfamilies of nuclear retinoid receptors (RAR and RXR) (6, 7). Through the use of molecular biologic techniques much has been learned about the nuclear retinoid receptors with respect to their physical characteristics, ligand specificities and interactions, patterns of expression in tissues and cells, and interactions with coregulatory molecules and the DNA of retinoid-responsive genes. The stage is now set for understanding molecular regulation of gene expression by retinoids under nutritionally relevant conditions and the therapeutic action of retinoids used as pharmacologic agents.

CHEMISTRY

Vitamin A is a nutritional term that describes a family of essential, fat-soluble dietary compounds that are structurally related to the lipid alcohol retinol and share its biologic activity. Vitamin A in its various forms is required for vision, growth, reproduction, cell proliferation, cell differentiation, and the integrity of the immune system. Formally, the term *vitamin A* includes those provitamin A carotenoids that serve as dietary precursors of retinol (see Chapter 33). The term *retinoids* refers both to retinol and its natural metabolites as well as to a large number of synthetic analogues that have structural similarities to retinol but may subserve only some (or none) of the functions of natural vitamin A.

Properties

Retinol ([Fig. 17.1A](#)) is a pale yellow crystalline solid of molecular mass 286.46. The molecule comprises a substituted cyclohexenyl (b-ionone) ring, a tetraene side chain, and a primary hydroxyl group at C-15. Retinol and its metabolites exist in nature as several geometric isomers including all-*trans*, 9-*cis*, 11-*cis*, and 13-*cis* retinoids ([8](#)). The system of five conjugated double bonds in retinol confers characteristic spectral properties (ultraviolet (UV) absorption and fluorescence absorption and emission) that are used in the detection, identification, and quantification of retinoids ([9](#), [10](#)).

All-*trans*-retinol (vitamin A₁) has a characteristic UV spectrum with a maximum near 325 nm ($E^{1\%}_{1\text{cm}}$ in alcohol of 1835 [[10](#)]). The UV maximum of vitamin A₂ (all-*trans*-3,4-didehydroretinol), which has a second double bond within the b-ionone ring, is red-shifted to 351 nm.

Figure 17.1. Structures of common biologic (A–F) and representative synthetic (G, H) retinoids.

Retinol's hydroxyl group may be esterified with a fatty acid. In nature, retinol is esterified with long-chain fatty acids (mainly palmitate and stearate), whereas pharmaceutical preparations may include short-chain esters. Long-chain esters are yellow viscous oils at room and body temperatures. Esterification confers greater stability on retinol, but the UV absorption maxima and molar extinction coefficients of unesterified and esterified retinol are nearly identical.

The hydroxyl group of retinol undergoes successive oxidation to produce, first, an aldehyde (retinaldehyde, or retinal) which may be further oxidized to a carboxylic acid, RA. In the retina, 11-*cis*-retinal ([Fig. 17.1B](#)) plays a specific role through binding to proteins (opsins) to form the visual pigments rhodopsin (in rod cells) and iodopsins (in cone cells). (See “[Vision](#)” below.) Unbound 11-*cis*-retinal absorbs light maximally at 365 nm. RA (molecular mass, 300.4) exists as all-*trans*-RA ([Fig. 17.1C](#)), 9-*cis*-RA ([Fig.](#)

[17.1D](#)), and 13-*cis*-RA ([Fig. 17.1E](#)), as well as some di-*cis* isomers. All-*trans*-RA has a UV absorption maximum (in alcohol) of about 351 nm ([10](#)).

As analytical methods have improved, additional retinoids have been isolated and characterized. These include a number of more polar metabolites with keto, hydroxyl, or epoxide functional groups. Several water-soluble retinoids such as the glucuronide conjugates of retinol and RA ([Fig. 17.1F](#)) have been isolated from plasma, bile, and other tissues or have been synthesized. Water solubility is accompanied by marked reduction in most indices of toxicity, as well as differences in transport and metabolism, compared with lipophilic retinoids ([11](#)).

A large number of retinoid analogues have been synthesized ([8](#)). Naturally occurring retinoids are of limited use as pharmaceutical products because of their potential toxicity. Therefore, a principal goal of retinoid synthesis has been creation of new molecules with a higher therapeutic ratio, e.g., greater beneficial potency and/or less toxicity. Some synthetic retinoids have greater stability (conformationally restricted forms [[12](#)]) than the natural retinoids and/or bind selectively to certain retinoid receptors as agonists or antagonists. [Figure 17.1G](#) illustrates a synthetic retinoid, acitretin, an analogue of RA that is used in dermatology. [Figure 17.1H](#) illustrates a retinobenzoic acid, Am80, which binds selectively to the nuclear receptor RAR- α ([13](#)). Some retinoids (e.g., all-*trans*- and 13-*cis*-RA) belong to both the biologic and pharmaceutical categories of retinoids. A discussion of retinoid properties and routes of synthesis can be found in ([8](#)).

Most natural retinoids are soluble in body fat, oils, and most organic solvents but not in water. They are sensitive to isomerization, oxidation, and polymerization; therefore, they must be protected from light, oxygen, and high temperature. However, retinoids are usually quite stable when stored in crystalline form, oil, or some organic solvents, in the absence of light and oxygen, and at low temperature. In tissue specimens that have been kept sealed and deep-frozen (preferably at -70°C), retinol and its esters have been stable for several years ([9](#)).

Methods of Analysis

Most modern methods of retinoid analysis are based on solvent extraction of samples followed by chromatographic separation of molecular species, usually by high-performance liquid chromatography (HPLC), with detection by UV absorption at a single or multiple wavelengths ([14](#)). Some metabolic and biochemical studies have used forms labeled with deuterium or carbon-13. The proteins involved in retinoid transport and function have been analyzed spectrophotometrically, immunologically, and by the use of molecular biologic methods ([5](#), [15](#)).

NUTRITIONAL SOURCES

Plants and some lower organisms (e.g., algae) synthesize the carotenoids that serve as precursors of vitamin A (see [Chapter 33](#)), but they do not synthesize retinoids directly (the halobacteria, however, provide an interesting exception). Humans and other

animals convert carotenoids to retinol and its metabolites, or they obtain preformed vitamin A in foods of animal origin or in nutritional supplements. It is possible to obtain an adequate intake of vitamin A from diets of diverse types, ranging from strictly vegetarian (see [Chapter 106](#)) to strictly carnivorous. Preformed vitamin A comprises over two-thirds of dietary vitamin A in the United States and Europe ([16](#)), whereas provitamin A predominates in many other parts of the world.

Vitamin A in the U.S. diet comes mainly from liver, yellow and green leafy vegetables, eggs, and whole-milk products ([16](#)). Liver and fish liver oils constitute the most concentrated sources of preformed vitamin A. Nutritional supplements contain vitamin A as retinol, esterified retinol, and/or β -carotene in doses that generally equal and sometimes exceed the recommended dietary allowances (RDAs). 3,4-Didehydroretinol, found in freshwater fish, has about 40% of the bioactivity of crystalline vitamin A₁. Foodstuffs contain very little retinal or RA.

The commonly used nutritional unit for vitamin A is the μg *retinol equivalent* (μg RE), equal to 1 μg of all-*trans* retinol. The USP unit or International Unit (IU) is still sometimes used to quantify vitamin A activity in pharmaceutical preparations. One USP unit or IU equals 0.30 μg of retinol, 0.344 μg of retinyl acetate, and 0.55 μg of retinyl palmitate, all as their all-*trans* isomers. Because preformed and provitamin A differ in biologic activity, it has been necessary to develop factors to equate the biologic activity of carotenoids and retinol in foods ([9](#), [16](#)). Generally, it is assumed that 6 μg of all-*trans*- β -carotene or 12 μg of other all-*trans* provitamin A carotenoids are equivalent nutritionally to one RE (μg) of all-*trans*-retinol (see refs. [16](#) and [17](#) and [Chapter 33](#) for discussion). Système International d'Unités (SI) units are preferred for expressing vitamin A concentrations in tissues (see Appendix [Table I-A-1-a](#) and [Table I-A-1-b](#)). Conversion factors are 1 μmol retinol/L equals 286.46 μg retinol/L of fluid or per g of tissue. One μmol /L of retinyl palmitate equals 524.86 μg /L of retinyl palmitate or 286.46 μg /L of retinol.

Recommended Dietary Allowance

The RDA for vitamin A ([16](#)), expressed in RE/day, ranges from 375 μg RE/day for infants to 1000 μg RE/day for male adults. A complete table of U.S. RDAs is found in Appendix [Table II-A-2-b](#). The Appendix also contain tables of nutrient recommendations issued by Canada, the United Kingdom, Japan, Korea, and the World Health Organization (WHO).

RETINOID-BINDING PROTEINS AND RECEPTORS

Retinoid-binding proteins provide solubility to retinoids and serve as specific chaperones during their transport and metabolism. Three principal classes of transport or receptor proteins have been identified. In plasma, RBP functions to solubilize retinol and deliver it to cells. Within cells, cytosolic (cellular) retinoid-binding proteins limit the concentration of "free," unbound retinoid and channel retinoids to specific enzymes responsible for metabolic transformations. In the nuclei of cells, specific retinoid-receptor proteins bind RA and regulate the activity of retinoid-responsive genes ([Table 17.1](#)).

Name	Abbreviation	See 10/6	Molar Weight	Location	Physiology/Role	Mechanism of Regulation
Retinol-binding protein	RBP	21.2	All-trans-retinol	Plasma (complexed with TTR)	Plasma transport	Secretion of total-RBP-retinol complex
Cellular retinol-binding	CRBP-I	14.8	All-trans-retinol	Cytoplasm of many cell types	Delivers retinol to enzymes, controls free retinol concentration	Induced transcriptional regulation
Cellular retinol-binding-II	CRBP-II	14.8	All-trans-retinol, retinoic	Cytoplasm, mainly of intestinal absorptive cells	Delivers retinol to enzymes involved in vitamin A absorption	Possible regulation through RXR and by fatty acids
Cellular retinoic acid-binding protein-I	CRABP-I	14.8	All-trans-retinoic	Cytoplasm of many cells, in the brain	Controls RA concentration, facilitates oxidation	Unknown
Cellular retinoic acid-binding protein-II	CRABP-II	14.8	All-trans-retinoic	Cytoplasm, mainly in skin	Controls RA concentration, related to RA oxidation?	Transcription-induced by binding RA
Retinoic acid receptors	RAR- α , RAR- β , RAR- γ	-50	All-trans-retinoic (9-cis-RA)	Sensitivity and temporally varied expression patterns, nuclear location	Binds with RXR to RXR β	Developmentally regulated, binding required by RA
Retinoic X receptors	RXR- α , RXR- β , RXR- γ	-50	9-cis-RA	Sensitivity and temporally varied expression patterns, nuclear location	Binds with RXR α to RXR β , or homodimers to RXR α , and as the heterodimer partner of other receptors	Developmentally regulated

Table 17.1 Properties of Major Retinoid-Binding Proteins

Retinol-Binding Protein (RBP)

Plasma RBP is the principal carrier of all-*trans*-retinol, which typically constitutes more than 90% of plasma vitamin A. RBP is a single polypeptide chain of molecular mass 21.2 kDa in humans, which circulates in association with a cotransport protein, transthyretin (TTR, also called prealbumin, molecular mass approximately 55 kDa). RBP and TTR have been well conserved during evolution, and homologous forms of these proteins exist in the plasma of all vertebrate species that have been examined (15). RBP binds retinol with high affinity ($K_a = \sim 1.5 \times 10^{-6} \text{ M} \times \text{L}^{-1}$); furthermore, the binding affinity of retinol to RBP is approximately doubled by association of RBP with TTR (18).

Protein Structure and Genomic Characteristics. RBP is a member of a family of relatively low-molecular-weight proteins that bind small hydrophobic ligands (15). The tertiary structure of RBP is described as a “b-barrel.” The barrel is formed from eight antiparallel b-sheets positioned in two orthogonal arrays. The interior of the RBP barrel provides a binding cavity into which one molecule of retinol fits with its hydroxyl group oriented toward the surface of RBP (15).

The gene for RBP has been cloned and partially characterized. The RBP gene exists as a single copy per haploid genome, is located on human chromosome 10q23-24, and comprises 10 kb of genomic DNA having six exons and five introns. Based on a comparison of the genomic and protein crystalline structures, each exon encodes a defined unit of protein structure. The human RBP cDNA is approximately 1000 bp long with a 600-bp open reading frame that encodes a 199-amino acid protein, including a 16-amino acid signal peptide and a 183-amino acid mature protein. The relative abundance of RBP mRNA is highest in liver (defined as 100%), less than 10 to more than 35% in various adipose beds, about 5 to 10% in kidney, and lower in a number of other tissues (15). RBP mRNA is also expressed at high relative abundance in the embryonic visceral yolk sac (~50%) and fetal liver (~25%). RBP protein is expressed by liver parenchymal cells, the eye, and visceral yolk sac, and perhaps by other RBP

mRNA-containing organs (15). An RBP-like protein has been isolated from uterine/allantoic fluid (19).

RBP is present in plasma at a concentration of approximately 2 to 3 $\mu\text{mol/L}$ (0.42–0.64 mg/mL). Regulation of RBP synthesis, secretion, plasma concentration, and turnover is discussed below.

Cellular Retinoid-Binding Proteins

The first cellular retinoid-binding protein was identified in 1973 (5) when a 14.6-kDa cytosolic protein that specifically binds all-*trans*-retinol, but otherwise is distinct from RBP, was identified in the cytoplasm of several tissues (e.g., testis, liver). Four main cellular retinoid-binding proteins are now known that bind either retinol or RA: cellular retinol-binding protein (designated CRBP or CRBP-I), CRBP-type II (CRBP-II), and two forms of cellular RA-binding protein designated CRABP-I and CRABP-II. Each of these proteins is a member of a gene family whose basic structural motif is a “b-clam” composed of a clamshell-like arrangement of two nearly orthogonal arrays of antiparallel β strands that enclose an interior pocket that binds a single molecule of ligand. In contrast to RBP, the retinoid ligand of the CRBP or CRABPs is oriented with its functional (hydroxyl or carboxylic acid) group innermost within the protein's binding cavity (5, 20). Each form of CRBP and CRABP is a unique gene product with distinct tissue and cellular distribution (5, 21); nearly all cells and organs contain one or more of these proteins. Each of the CRBP and CRABP genes is similarly arranged in four exons and three introns (5).

Cellular Retinol-Binding Proteins (CRBP-I and CRBP-II)

The principal endogenous ligand of CRBP-I is all-*trans*-retinol (5); however, some other ligands may also bind (20). CRBP-I is widely distributed, with greatest expression in liver, kidney, and the male reproductive tract. In liver, CRBP-I mRNA is expressed by gestational day 16, increases during the suckling and weaning periods, and then declines gradually to adult levels (22). In adult rat liver, CRBP-I is expressed in both parenchymal cells (hepatocytes) and stellate (vitamin A–storing) cells but is found in highest concentration in stellate cells, especially in animals fed vitamin A–enriched diets (23). CRBP-I expression is modestly regulated by retinoid status. Liver CRBP-I protein and mRNA levels were reduced somewhat in vitamin A–depleted rats, but they did not rise significantly in rats fed elevated levels of retinol or RA (24). The gene for CRBP-I does, however, contain an RA response element (RARE, below), and induction of CRBP-I mRNA by RA has been demonstrated in the lung (25).

CRBP-II was first isolated from neonatal rats and subsequently shown to be abundant (~1% of soluble mucosal protein) in the small intestine of young and adult rats and humans (5). Although CRBP-I and CRBP-II are nearly identical in size and structure, only 56% of their amino acids are identical. And, although all-*trans*-retinol is an endogenous ligand of both CRBP-I and CRBP-II, CRBP-II also binds all-*trans*-retinal (26). These differences in protein composition and ligand binding may be related to the proposed function of CRBP-II in vitamin A absorption (see below).

CRBP-II is expressed mainly in villus-associated enterocytes (5). During development, mRNA for CRBP-II is first detectable in the rat intestine between 16 and 19 days of gestation, a time corresponding to appearance of the absorptive epithelial cells (27). In adult rat jejunum, fatty acids modestly regulate CRBP-II expression (28). During the perinatal period, CRBP-II is also expressed transiently in the liver. The mouse CRBP-II gene was shown to be closely linked to the gene for CRBP-I on chromosome 9; both the CRBP-I and CRBP-II genes are located on human chromosome 3 (5).

Cellular Retenoic Acid–Binding Proteins (CRABP-I and CRABP-II)

The principal endogenous ligand for CRABP-I and CRABP-II is all-*trans*-RA. The tissue distributions of the CRABPs differ somewhat, and both are different from, and more restricted than, those of CRBP. Most organs of the adult rat express CRABP-I at very low levels, whereas neonatal rats and some adult organs (e.g., eye, some reproductive organs) express CRABP-I at a level similar to that of CRBP-I (5). Vitamin A status has little effect on expression of CRABP-I. CRABP-I is expressed in the skin of neonatal and adult mice (29), but not in human skin (30).

CRABP-II is expressed strongly in a number of tissues during embryogenesis but is largely restricted to skin (mouse and human [31]). The expression of CRABP-II, but not CRABP-I, mRNA was markedly induced by all-*trans*-RA in adult human skin, but not in lung fibroblasts (30). In developing mouse embryos and cultured embryonal stem cells, increased expression of CRABP was associated with a lower differentiation response to RA (32). Consistent with these data and as noted below, one function of CRABP-I may be to sequester all-*trans*-RA, thereby limiting its distribution to the nucleus and controlling RA's biologic effects. CRABP-I-associated RA also is a substrate for metabolism (33) (see “[Metabolism](#)” below).

The genes for CRABP-I and CRABP-II have been cloned (34), and their regulation studied. The promoter region of the mouse CRABP-I gene contains several positive and inhibitory elements that respond in a cell type–specific fashion. These elements may be responsible for the specificity of CRABP-I expression during development (35).

Other Retinoid-Binding Proteins. Variant forms of RBP, CRBP, and CRABP have been identified and characterized from certain tissues, particularly reproductive organs (5, 19). Additionally, at least two distinctly different types of retinoid-binding proteins are restricted almost entirely to the eye (which also has CRBP and CRABP). A binding protein of 45 kDa, known as cellular retinal-binding protein (CRALBP), is located in the retina; this protein can bind one molecule of either retinol or retinal (36). The primary structure of CRALBP (37) and its cDNA have been described (36). A larger protein (~145 kDa, 1264 amino acids) is located in the interphotoreceptor space between the photoreceptor cells and the retinal pigment epithelium (RPE). This interphotoreceptor (interstitial) retinoid-binding protein (IRBP) is a lipoglycoprotein with two binding sites for various isomers of retinol and retinal, but it can also bind other small lipid ligands (36, 38). IRBP is synthesized by photoreceptor cells and the pineal gland (38). The functions of CRALBP and IRBP in retinoid transport within and between cells of the visual system

(36) are discussed in the section on [vision](#).

Nuclear Retinoid Receptors

The fundamental mechanism of action of RA in cell differentiation was clarified with the discovery of the first retinoic acid receptor, RAR (now RAR- α 1), a nuclear transcription factor shown to be activated by all-*trans*-RA. The six retinoid receptors of the RAR and RXR gene subfamilies are each a unique gene product; these receptors belong to the larger superfamily of steroid/thyroid hormone nuclear transcription factors. Numerous reviews of the RAR/RXR provide detailed information on the structure, expression, and function of these receptors (6, 7, 39). Each of the retinoid receptors is a protein of approximately 48 kDa, located in the nucleus, and organized similarly into four major functional domains: a DNA-binding domain (DBD) and a ligand-binding domain (LBD) separated by a hinge region; a heterodimerization domain; and one or more ligand-dependent transcription-activation domains (activation functions, AF). The mechanism of action of each receptor is thought to involve its interaction with a receptor partner (dimer formation); binding of a specific ligand; binding to specific DNA nucleotide sequences (response elements, RARE or RXRE); and interacting through one or more AF regions with other nuclear proteins that collectively regulate gene transcription, either positively or negatively. Although RAR and RXR are present in the nuclei of all retinoid-responsive cells, each receptor is regulated independently and has a unique spatial and temporal pattern of expression. Nearly all cells express at least one member of the RAR and RXR subfamilies.

Several other proteins of the steroid/thyroid/retinoid-receptor superfamily bear considerable homology to the RAR-RXR and are termed *orphan receptors* because their ligands, if they exist, are unknown. Examples are the ROR, LXR, and LOR. These receptors may function through interaction with the RXR to regulate retinoid-mediated signaling indirectly (40).

RARs

The RAR subfamily includes RAR- α , RAR- β , and RAR- γ (6, 7, 39). Each of these receptors exists in two or more isoforms (caused by differential usage of each gene's promoter region, which results in different amino-terminal [DNA-binding] ends). RAR- α is expressed nearly ubiquitously. As noted below (see "[Cancer Chemoprevention and Treatment](#)"), a chromosomal translocation affecting the gene for RAR- α is related to a specific disease, acute promyelocytic leukemia (APL). RAR- β is unusual in having an RARE in its promoter region. This RARE permits "autoregulation" of the expression of RAR- β by RA. RAR- γ is expressed mainly in connective tissue, skin, and the embryo at critical stages of development. Structurally, the three RARs are highly homologous within their DBD (zinc-finger) regions. The amino acid sequences of the DBDs of RAR- β and RAR- γ ; are 97% identical to the DBD of RAR- α ; implying very similar abilities to bind to RAREs. In contrast, the LBDs of human RAR- β and RAR- γ ; are only 90 and 84%, respectively, identical to the LBD of RAR- α ; (41). Recently, a form of human holo-RAR- γ containing the LBD has been crystallized with all-*trans*-RA in the binding pocket, and its structure, analyzed by x-ray crystallography, has been compared with crystals of human apo-RXR- α (7). From this structural analysis it can be inferred

that an α -helical portion of the RAR and RXR between their DBD and LBD domains serves as a molecular hinge that allows a significant change in receptor conformation. The conformational change induced by retinoid binding is thought to create one or more new “interaction surfaces” that are necessary for RAR-RXR to interact with cognate DNA response elements (see below) and with a complex of coactivator or repressor molecules and basal transcription factors (7).

RXRs

Shortly after discovery of the first RAR, another distinct yet homologous gene subfamily was identified and named the RXR. All-*trans*-RA was subsequently recognized to be a specific ligand only for the RAR, whereas 9-*cis*-RA can activate through binding to both the RAR and RXR (42). Although two RXRs may bind to one another as homodimers, they appear to function most often as the heterodimeric partner of RAR. Equally important, the RXRs bind as heterodimers with several other nuclear transcription factors, including the receptors for vitamin D (see Chapter 18) and thyroid hormone, the peroxisome proliferator-activated receptors (PPARs), and others (43). Through these “promiscuous” interactions with multiple partners, the RXRs mediate “cross-talk” among different signaling pathways that collectively may affect expression of a large number of genes (6). The RARs and RXRs also differ in that the RARs appear to be active only in the presence of RA (or an active analogue), whereas heterodimers of RXR need not bind RA as long as their partners are activated by their respective ligands (e.g., they may function as “silent,” yet biologically active, partners).

The three RXRs are highly homologous to one another within their LBDs and DBDs. However, homology between RARs and RXRs is much lower, especially in their LBDs, consistent with their ligand specificity for all-*trans*-RA only (the RARs) and for all-*trans*-RA or 9-*cis*-RA (the RXRs). Indeed, the LBD of the RARs is more homologous to that of the thyroid hormone receptors than to the LBD of RXRs (41).

Levels of Expression

Information is still relatively scarce regarding the natural regulation of the retinoid receptor genes under most physiologic conditions. Receptor expression has been studied by in situ hybridization and analysis of extracted mRNA. In embryos (see “Development”), the expression of the RARs and RXRs follows unique temporal and spatial patterns. In most tissues of the adult rat, RAR- α predominates, especially in the intestinal tract, although many tissues express two or even three forms of RAR at different levels (44). RAR- γ is highest in reproductive and epidermal tissues (44). During vitamin A deficiency, expression of RAR- β mRNA is low (45, 46) but increases following administration of retinol or RA, especially in lung and skin (45). Further studies are needed to elucidate the regulation of the RARs and RXRs in vivo and to define new retinoid-responsive genes.

Chromosomal Abnormalities. Given the regulatory roles of retinoid receptors, it was to be expected that mutations would be associated with disorders of cell proliferation and differentiation (cancer) or development. Mutations in the receptors RAR- α and RAR- β have been found in cell lines that have become resistant to the action of RA and in

certain human cancers. These are discussed below in the section "[Cancer Chemoprevention and Treatment](#)."

RAR and RXR Response Elements

Retinoid response elements—RAREs and RXREs—have been identified in the promoter regions of numerous genes that encode proteins with diverse functions. This is consistent with retinoids being pleiotropic regulators that affect development, cell proliferation, and differentiation. The strongest RAREs are direct repeats (DRs) of the consensus sequence *AGGTCA*, or slight variants thereof, which are spaced apart by either five or two nucleotides, denoted *N* (e.g., *AGGTCANNNNNAGGTCA* is a response element of the DR-5 type) (6). Response-element spacing is critical for receptor-DNA recognition and/or the appropriate alignment and intercalation of the receptor-protein complex into the major groove of DNA. The context (flanking regions) around the RARE or RXRE also affects the strength of receptor interaction (6, 47). Some of the retinoid-binding proteins and receptors discussed above have RARE or RXRE sequences within their own promoters, a feature that provides a mechanism for their autoregulation by retinoids. The gene promoters for RAR-b, CRBP-I, and CRABP-II have been shown to contain RAREs. The promoters for CRBP-II and CRABP-II-2 contain RXREs (6); however, their physiologic significance is not yet clear (7).

METABOLISM

Dietary vitamin A is first processed in the intestine. The overall absorptive efficiency for physiologic amounts of preformed vitamin A is high (70–90%) and remains high (60–80%) as intake increases. Over 90% of retinol enters the body as retinyl esters in the lipid core of chylomicra. The liver acts as a central clearinghouse and bank: it clears chylomicron vitamin A, is the principal organ of vitamin A storage, is a major site of retinoid oxidation and catabolism, and is responsible for regulated secretion of retinol bound to RBP. The target tissues for retinol and/or RA include nearly all organ systems of the body, and most can further metabolize these retinoids. The retinoid form present in greatest concentration in most tissues, esterified retinol, serves as a concentrated storage pool that can be readily hydrolyzed. As noted above, most cells contain one or more cellular retinoid-binding proteins and two or more RARs or RXRs. [Figure 17.2](#) provides a schematic overview of some of these processes and their interrelationships. Retinol, RA, and a large number of more polar metabolites (e.g., with hydroxyl groups at carbons 4, 14, or 18; keto groups; or epoxide groups) have been isolated from various tissues. A schema of the metabolic relationships among some of the major retinoids is shown in [Figure 17.3](#). Retinoid metabolism occurs in many organs (liver, intestine, kidney, skin, etc.) in a manner specific to the tissue or cell type.

Figure 17.2. Schematic overview of intraorgan transport and cellular metabolism. PL, phospholipid; BB, brush border; RE, retinyl ester; LPL, lipoprotein lipase; Chylo, Chylomicron; LRAT, lecithin retinol acetyltransferase.

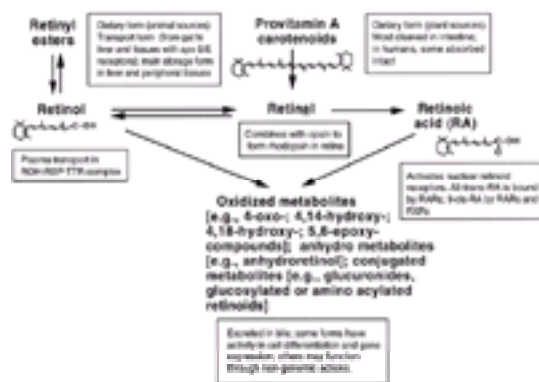

Figure 17.3. Simplified schematic of retinoid conversion reactions.

Digestion and Absorption

Vitamin A assimilation involves, first, processing of dietary retinyl esters, retinol, or carotenoids (see [Chapter 33](#)) in the lumen of the small intestine, followed by uptake of these molecules or their products into intestinal absorptive cells ([48](#)). Vitamin A is packaged along with newly absorbed lipids into chylomicra for transport through lymph and plasma to the liver. Numerous cycles of hydrolysis and reesterification are characteristic of the metabolism of vitamin A in the intestine, liver, and other tissues.

Luminal Processing. Dietary retinol must be released from foodstuffs by digestion and then emulsified with bile salts and lipids before being absorbed. Retinyl esters must be hydrolyzed. Several retinyl ester hydrolases (REHs) have been described (see [[49](#)] for

review). The importance of luminal pancreatic cholesteryl ester hydrolase (also called carboxyl ester lipase, which is capable of retinyl ester hydrolysis in vitro [49]), has been challenged by new information that the small intestine contains microvillus-associated enzymes capable of hydrolyzing retinyl esters. Two REH activities are located in brush border membranes of rat small intestine (50): one of these preferentially hydrolyzes short-chain retinyl esters and apparently is derived from the pancreas; the other preferentially hydrolyzes long-chain retinyl esters and is an intrinsic component of the brush border (50). The hydrolytic activity of the latter enzyme, calculated for the rat small intestinal mucosa, is more than sufficient to process the daily requirement for vitamin A (50).

Factors that interfere with lipolysis or emulsification reduce intestinal absorption of vitamin A (51). Uptake of retinol is reduced by a lack of bile salts or too little dietary fat and significantly enhanced by micellar solubilization. It is thought that at physiologic concentrations retinol absorption is saturable, carrier mediated, and passive, whereas at high (pharmacologic) concentrations retinol absorption is nonsaturable (52). The latter feature is likely to contribute to the toxicity of preformed vitamin A.

Intracellular Retinol Metabolism and Chylomicron Formation. Regardless of whether *b*-carotene or retinol is ingested, the predominant form of vitamin A present in rat or human lymph is esterified retinol (53, 54). Vitamin A absorption is rapid, reaching a maximum by 2 to 6 hours. Cleavage of *b*-carotene (see Chapter 33) within the enterocytes yields retinal, which CRBP-II also binds. An enzyme in rat intestinal membranes, retinal reductase, can reduce retinal to retinol (55). Thus, retinol is a common intracellular product of the hydrolysis of preformed vitamin A and cleavage of provitamin A. Furthermore, CRBP-II is a common carrier for retinol and retinal. Analysis of the composition of chylomicron retinyl esters has shown a strong predominance of long-chain saturated fatty acids (palmitate and stearate), regardless of the fatty acid composition of the fat fed with the vitamin A. Years ago, palmitate and stearate were noted to also predominate at the *sn*-1 position of lymph lecithin (phosphatidyl choline) (56).

Esterification. Two different enzymatic activities present in the microsomal fraction (endoplasmic reticulum) can esterify retinol. Acyl-CoA-retinol acyltransferase (ARAT) has been assayed in rat and human intestinal microsomes (53). This activity does not recognize retinol bound to CRBP-II but does esterify unbound retinol. ARAT derives its fatty acid from fatty acyl-CoA (57). The reaction characteristics of ARAT suggest its involvement in esterifying retinol when retinol is present at relatively high concentrations. A second microsomal enzyme, lecithin:retinol acyltransferase (LRAT), esterifies retinol at physiologic concentrations. As substrates, LRAT uses retinol bound to CRBP-II and the *sn*-1 fatty acid of phosphatidyl choline, present in the same membranes. The newly formed retinyl esters are deposited in the endoplasmic reticulum where they are assembled with triglycerides, cholesteryl esters, and other neutral lipids into the chylomicron's lipid core. Thus, the quantity of retinyl ester in each chylomicron particle is directly related to recently absorbed vitamin A. CRBP-II apparently has two roles: to *solubilize* and sequester retinoids (either retinal or retinol) and to *direct* them to specific enzymes (e.g., retinal reductase and LRAT). As discussed below, a similar model applies to the role of CRBP in hepatic retinol esterification and oxidation and to the role of CRABP in further metabolism of RA (58). These models imply that the

surfaces of the binding proteins must be recognized by the specific enzymes with which they interact (5).

Under physiologic circumstances, nearly all vitamin A is absorbed in chylomicra in the lymphatics and rapidly transported to the circulation (see [Chapter 4](#)). However, alternate absorptive pathways apparently may be used by patients with abetalipoproteinemia (absent or low levels of apolipoprotein B, which is essential for chylomicron assembly) because their plasma vitamin A is low without vitamin A treatment but normal after oral vitamin A supplementation (59).

Hepatic Metabolism of Vitamin A

Initial Processing of Chylomicron Vitamin A. As discussed in [Chapter 4](#), chylomicron triglycerides are first metabolized in the periphery through the action of lipoprotein lipase, forming chylomicron remnants that are taken into hepatocytes by receptor-mediated endocytosis. Chylomicron retinyl esters remain in the chylomicron core during lipolysis and are rapidly cleared with chylomicron remnants into the liver (54). In kinetic studies, the half-life of vitamin A in lipoproteins with densities below 1.006 g/mL (containing chylomicron remnants) was less than 20 minutes in normal human subjects (60). Some factors that delay remnant clearance include familial dysbetalipoproteinemia (see [Chapter 75](#)) and low lipoprotein lipase activity (e.g., caused genetically or suppressed during inflammation). When remnant circulation is prolonged, retinyl esters may transfer to other lipoproteins such as low- and high-density lipoproteins, presumably through the action of the plasma cholesteryl ester-transfer protein (61). Thus, retinyl esters are associated with longer-lived lipoproteins that enter cells through their own receptor-mediated pathways.

Although most chylomicron vitamin A is rapidly taken up into liver parenchymal cells, other tissues may also assimilate some retinyl esters from chylomicra. The ability of human macrophage-like cells to take up chylomicron retinyl esters in vitro has been demonstrated (62), and uptake into bone marrow has been reported (63); however, the quantitative importance of these processes in humans is unknown.

In rats, the efficiency of uptake of vitamin A-labeled chylomicra into liver is very high (85–90%). Parenchymal cells are the initial site of processing of chylomicron vitamin A ([Fig. 17.2](#)). When vitamin A-labeled chylomicra were injected intravenously into recipient rats, retinyl esters of intestinal origin underwent rapid hydrolysis, followed by synthesis of new retinyl esters (54). Chylomicron remnant vitamin A apparently is not directed to lysosomes for processing (64). An REH associated with the plasma membrane (49) may function, either at the surface of the hepatocyte and/or within endocytic vesicles, to hydrolyze newly absorbed retinyl esters. This hydrolysis and reesterification resulted in even greater proportions of retinyl palmitate and stearate in liver, compared with those in chylomicra.

Blomhoff et al. (53) first showed that within a few hours of chylomicron uptake by parenchymal cells, chylomicron-derived vitamin A is transferred to hepatic stellate cells, the principal site of retinyl ester storage. Transfer was specific for vitamin A, as cholesteryl esters in the same chylomicra remained within hepatocytes. The mechanism

of intercellular movement of vitamin A as well as the form of the retinoid at time of transfer is still uncertain. It has been suggested that retinol is transferred by RBP because injection of anti-RBP serum inhibited vitamin A transfer (65). It is also possible that some vitamin A transfers as retinyl ester or as a water-soluble retinoid (9). Collectively, these initial steps result in remodeling of dietary retinyl esters and intercellular transfer of vitamin A from hepatocytes to stellate cells for storage.

Hepatic Vitamin A Storage. When vitamin A status is adequate, approximately 50 to 85% of total body retinol is stored in the liver, more than 90% as retinyl esters (66, 67). Electron microscopy reveals that the perisinusoidal stellate cells contain numerous lipid droplets (68). The size and number of these droplets appear to increase with liver vitamin A content (69). In normally nourished rats, liver stellate cells contain approximately 30 times more total retinol per cell than parenchymal cells; neither liver endothelial nor Kupffer cells contain appreciable vitamin A (70). Taking the number of rat liver parenchymal and stellate cells into account, it was estimated that 80 to 90% of vitamin A is contained within stellate cells (71).

Comparable figures for humans are not available. Species differences in stellate cells may be considerable, as the very high level of vitamin A in polar bear liver (sufficient to produce vitamin A toxicity in arctic explorers who consumed it) has been linked to an abundance of vitamin A-enriched hepatic stellate cells in this species (72).

Both hepatic stellate cells and parenchymal cells contain the plasma transport proteins RBP and TTR, as well as CRBP, a low level of CRABP, and several enzymes thought to be important in retinol esterification and retinyl ester hydrolysis. In isolated rat liver cells, the plasma retinoid-transport proteins were highly enriched in the parenchymal cell-enriched fraction. In contrast, CRBP, CRABP, and retinyl palmitate hydrolase were more nearly evenly distributed on a per cell basis (73, 74). When expressed per total liver, nearly 98% of RBP, 91% of CRBP, and 90% of the REH activity were associated with parenchymal cells (74).

As in the intestine, LRAT in liver is thought to be the principal enzyme involved in retinol esterification (54). Hepatic LRAT uses retinol bound to CRBP. LRAT activity is enriched in the stellate cell-rich fraction of liver (75, 76) in proportion to stored retinyl esters; in contrast, REHs are nearly equally distributed between parenchymal and stellate cells (76). Two mechanisms are likely to regulate the overall balance between retinol esterification (storage) and retinyl ester hydrolysis (mobilization). First, the activity of hepatic (not intestinal) LRAT is under very sensitive nutritional regulation; LRAT activity is reduced markedly in rats undergoing vitamin A depletion (77). However, hepatic LRAT activity is rapidly induced by dietary retinol or administration of RA (78). A reduction in hepatic LRAT activity may serve to reduce the esterification and storage of retinol, presumably sparing it for oxidation and/or other processes that take priority. Second, apo-CRBP, which increases in concentration as retinol falls, can stimulate hydrolysis of retinyl esters by a microsomal REH (79). When dietary vitamin A does not meet requirements, liver vitamin A stores can be almost totally mobilized. Kinetic studies have shown that both parenchymal and stellate cells lose their vitamin A nearly in proportion to their initial vitamin A contents (67).

Acute and chronic liver inflammation induces stellate cells to proliferate and to change their appearance into myofibroblast-like cells (71, 80). A gradual loss of vitamin A has been reported to accompany this morphologic change (81, 82) and to be partly reversed by supplementation with retinoids (80). In alcoholic liver disease, liver vitamin A is markedly reduced even though serum retinol, RBP, and TTR levels are still normal (6, and below).

Plasma Transport

Plasma Retinol and RBP Concentrations. The concentration of plasma (or serum) vitamin A may be determined as *total* retinol (measured after hydrolysis, i.e., saponification) or as *unesterified* retinol (measured without saponification). The difference is considered a valid estimate of *esterified retinol*. In fasting plasma samples, unesterified and total retinol values usually are nearly identical because more than 95% of plasma total retinol is unesterified. However, in postprandial plasma, the concentration of total vitamin A (or of retinyl esters measured separately) may be elevated. As noted above, these retinyl esters are associated with chylomicra or their remnants, and their concentration in plasma depends on the rates of vitamin A absorption and chylomicron clearance.

In healthy humans, plasma retinol concentrations are quite constant both within and between individuals, usually in the range of about 1.5 to 3 $\mu\text{mol/L}$ (43-86 $\mu\text{g/dL}$). Plasma vitamin A levels in the U.S. population were measured in several national surveys (NHANES I, II, III, and Hispanic HANES, spanning 1976 to 1984 [83, 84]). Mean vitamin A levels were lowest in young children, increased in adolescence, and continued to increase throughout adulthood. Male adolescents and adults had higher mean serum retinol levels than premenopausal females, whereas values were similar after menopause (84). For all age groups, black Americans had slightly lower mean levels than white Americans. Retinyl esters were present at 2 to 20% of the serum retinol concentration (84). In NHANES I (conducted from 1976 to 1980), data for males and females between the ages of 3 and 74 years were used to form a reference sample that excluded individuals with factors known to alter plasma retinol (vitamin/mineral supplement users, women using oral contraceptives, and pregnant women). The 50th percentiles for male and female children were similar, near 35 $\mu\text{g/dL}$ (1.23 $\mu\text{mol/L}$). For adult men and women (18 to 44 years), the 50th percentiles equaled 57 and 45 $\mu\text{g/dL}$ (2.00 and 1.58 $\mu\text{mol/L}$), respectively (83). Significantly lower levels of plasma RBP and retinol have been observed in premature infants (<36 weeks gestation) than in term neonates (85).

Plasma levels of vitamin A and RBP may (86) or may not (87, 88) be depressed in chronic alcoholics. In chronic liver disease, regardless of cause, plasma concentrations of retinol and RBP are usually reduced in proportion to disease severity (89, 90). In a study of liver transplantation, the diseased liver was directly implicated in these low concentrations (91).

Nonlinear Relationship between Liver Vitamin A Storage and Plasma Vitamin A.

Whereas hepatic vitamin A concentrations may vary widely within and between

individuals, most plasma retinol concentrations fall within a narrow, regulated range, decreasing only when liver vitamin A stores are nearly exhausted. Thus, in the absence of inflammation, a low serum retinol level usually indicates that hepatic vitamin A stores are depleted. A useful theoretical curve (Fig. 17.4) (92) illustrates the relationship between plasma and liver vitamin A. Low hepatic stores (less than ~20 µg total retinol/g) are associated with low plasma retinol concentration. From about 20 to 300 µg total retinol/g liver, plasma retinol is maintained at a relatively constant value. Above approximately 300 µg total retinol/g liver, circulating retinyl esters are likely to increase and be detectable by HPLC. Although total retinol concentration rises, unesterified retinol and RBP concentrations are still normal (92). If delayed chylomicron clearance is ruled out as a possible cause of the circulating retinyl esters, then this elevation in esterified retinol may indicate a state of hypervitaminosis A (see below).

Figure 17.4. Relationship of plasma retinol to liver vitamin A stores. (Modified from Olson JA. *J Natl Cancer Inst* 1984;73:1439–44, with permission.)

Synthesis, Secretion, and Turnover of Holo-RBP-TTR

RBP

RBP is synthesized as a 24-kDa preprotein on ribosomes in the rough endoplasmic reticulum of hepatocytes. The amino-terminal signal sequence is cleaved cotranslationally, and the mature 21-kDa protein then progresses through the secretory pathway to the Golgi apparatus (15), where some of the newly synthesized RBP apparently combines, in a manner not yet fully understood, with retinol. Several hepatic REHs have been identified (49), but it still is unclear exactly how retinyl esters in stellate cells yield the retinol that, following combination with RBP in hepatocytes, is released into the circulation. Apparently not all newly synthesized RBP is secreted, and the RBP that does not complex with retinol undergoes proteolytic degradation (93). Hepatocytes also synthesize TTR. The synthesis and plasma concentrations of RBP and TTR depend on an adequate supply of amino acids and energy, and both are reduced during protein-energy malnutrition (94, 95). The level of mRNA for RBP and its translation are

normal in vitamin A deficiency (96); however, secretion is markedly reduced, and apo-RBP builds up in liver. When retinol is provided, retinol combines with RBP and the holo-RBP complex is rapidly secreted (97). This retinol-regulated secretion of holo-RBP forms the basis for the relative dose-response tests described below (see “[Assessment of Vitamin A Status](#)”). In inflammation reduces the biosynthesis of RBP and TTR, which behave as negative acute-phase proteins (98, 99).

Transport and Kinetics. Holo-RBP (~21 kDa) and TTR (~55 kDa) interact strongly to form a 1:1 molar complex. Association of TTR with RBP stabilizes the binding of retinol to RBP, and the complex is too large for free filtration through the renal glomeruli. Plasma concentrations of retinol and RBP are highly correlated (4) and are nearly equal when expressed on a molar basis. Besides being reduced in vitamin A deficiency (4), RBP and TTR have been reported to be low during infections and inflammation (acute-phase response) (100) and trauma (101). A significant reduction in plasma retinol concentration (but still within the normal range) was reported to accompany successful reduction of hypercholesterolemia (102). Vitamin A and RBP concentrations (usually 1.9–2.4 $\mu\text{mol/L}$ [40–50 $\mu\text{g/dL}$] [9]) are significantly increased (15–35%) in women using oral contraceptives (83, 103). Due to the relatively short plasma half-life of RBP and TTR (~0.5 day and 2–3 days, respectively [4]), a comparatively high rate of protein synthesis is necessary to maintain their concentrations. For this reason, RBP and TTR are used as indicators in clinical assessment of protein status (reflecting recent protein synthesis). Plasma also contains a small amount of apo-RBP, calculated to be 3.8% of total RBP (4). “Free” RBP is readily filtered in the kidneys, and its plasma half-life is only about 4 hours (4).

Kinetic studies have shown that the plasma half-life of retinol is longer than that of RBP. Kinetic modeling of turnover data has led to the understanding that retinol undergoes extensive recycling between the liver, plasma, and peripheral tissues before it is catabolized (4, 104). In contrast, RBP apparently is not reused after retinol dissociates (4). The relationship of whole-body retinol turnover to vitamin A status has been studied in rats with varying vitamin A reserves. In animals whose liver vitamin A contents differed more than 400-fold, the rate of irreversible vitamin A disposal differed by less than 10-fold (105). Therefore, although the body's capacity for vitamin A storage is high, its ability to degrade and eliminate vitamin A is quite limited. The low rate of catabolism together with efficient absorption seems to explain the propensity for vitamin A to accumulate in tissues. Plasma retinol and retinol kinetics are altered by drugs, including RA and synthetic retinoids (106, 107 and 108; also see “[Cancer Chemoprevention and Treatment](#)”), and certain environmental toxins (109).

Most literature concerning retinoid transport and metabolism is based on studies conducted in humans or in rats, which have generally proved to be a good animal model. However, dogs and other carnivores differ significantly in transporting a large proportion of preprandial vitamin A as esterified retinol and in excreting significant quantities of vitamin A in urine (110).

Vitamin A Uptake by Tissues. Retinol from holo-RBP is taken into many tissues of the body, but the uptake mechanism is still uncertain. Two mechanisms have been proposed: (a) RBP may be bound by a plasma membrane receptor on target cells that

facilitates retinol uptake, although not necessarily that of RBP (23, 111), or (b) retinol may dissociate from RBP in the aqueous environment, producing free retinol that then diffuses and partitions into cells. A third possibility, that the holo-RBP complex is taken up by cells, is unlikely, based on double-labeling experiments. By binding retinol, CRBP within cells may provide the driving gradient for continued uptake (112). Similarly, retinoid metabolism may function to keep the concentration of retinol low and to regenerate apo-CRBP.

More-polar retinoids such as RA and the retinoid glucuronides are presumed to enter cells by diffusion. Lipoprotein-associated retinyl esters may be assimilated as the result of lipoprotein internalization through cell-surface receptors (apo E, low-density lipoprotein, low-density lipoprotein-related protein (LRP), or scavenger receptors) (113).

Retinoic Acid in Plasma and Tissues

Several more-polar retinoids, including all-*trans*-RA, 13-*cis*-RA, and 13-*cis*-4-oxo-RA, are present in plasma at much lower concentrations than retinol. The acidic retinoids are transported in association with serum albumin, not RBP (114). Mean plasma concentrations of 4 to 14 nmol/L for all-*trans*-RA, 4 to 5 nmol/L for 13-*cis*-RA, and 11 to 12 nmol/L for 13-*cis*-4-oxo-RA have been reported for healthy males (115, 116). Concentrations of 13-*cis*-RA and 13-*cis*-4-oxo-RA increased two- to four-fold after daily doses of retinyl palmitate well in excess of dietary levels (116) or after consumption of liver (117). Other acidic metabolites, including 9-*cis*-RA and 9,13-di-*cis*-RA, have been reported (117) but not yet studied systematically.

The *in vivo* half-life of RA is quite short. In pharmacokinetic studies conducted in nonhuman primates, the initial decline in plasma all-*trans*-RA concentration following a large intravenous dose was described by a first-order (terminal) half-life averaging 19 minutes (118). However, a dose-dependent plateau in plasma concentration suggested that the clearance of all-*trans*-RA is capacity limited; no such plateau was observed after dosing with 9-*cis*-RA (119). All-*trans*-RA can induce its own catabolism (120; and see below). Thus, following RA administration, the rate of clearance increases as dosing is repeated (120). There is rapid interconversion between the all-*trans* and 9-*cis* isomers, and of all-*trans*-RA to 13-*cis*-RA in cultured cells and *in vivo* (121), but mechanisms have not been established.

Relatively few data are available on tissue concentrations of endogenous RA, but they appear to be greater than plasma levels (~40–580 pmol/g for kidney, liver, lung, and pancreas of normal rats vs. ~8–16 pmol/mL of plasma [122]). In liver and kidney, 9-*cis*-RA was present at concentrations of 13 and 100 pmol/g of tissue, respectively (123). In rats given oral ¹⁴C-all-*trans*-RA for 8 days, less than 10% of the label remained in the body, and of this, the highest concentrations were present in the liver, kidney, and intestine. In liver, 58% of ¹⁴C behaved as acidic lipid, presumably unchanged RA, and 23% was more polar than RA (114). RA metabolism in various tissues includes conversion between the all-*trans*, 9-*cis*, and 13-*cis* isomers (124, 125 and 126), which may be concentration dependent (126); however, no enzymatic mechanism has yet been characterized except in the retina (see “[Vision](#)”). The relative contributions of

plasma uptake of RA and synthesis of RA vary considerably among organs (127).

Glucuronide conjugates of retinol and RA also are present in human serum at low nanomolar concentrations (128). Retinoyl-b-glucuronide (11) has been described as a major metabolite of all-*trans*-RA administered at high dosage (126).

Mechanisms of Oxidative Metabolism

All-*trans*-RA is the most potent of the biologic retinoids in assays of cell differentiation and gene expression. The concentration of RA is closely regulated through both synthesis and degradation. Numerous enzymes have been implicated in RA formation and oxidation, but it is still uncertain which ones are most important in physiologic settings. Oxidation of retinol to RA is a two-step process involving a retinol dehydrogenase (RDH) and a retinal dehydrogenase. Several distinct enzymes in the membranous or soluble tissue fractions can oxidize retinol to retinal (129, 130 and 131). It is proposed that CRBP acts as a “cassette” to direct retinol to one or more RDHs in the membrane fraction of liver and other tissues (129). Similarly, numerous aldehyde dehydrogenases use retinal as a substrate (129, 132, 133, 134 and 135). Once RA is formed, CRABP can facilitate its further metabolism to more-polar products (129). Several isoforms of the cytochrome P450 enzyme family hydroxylate various isomers of retinal (31, 136) or RA (132). Microsomes of several tissues catalyze b-glucuronidation of several isomers of RA (124, 136a). Side-chain-shortened metabolites have been found in excreta (137). In all, a large number of oxidative metabolites with varied structures are formed by metabolism of retinol and RA.

Renal Metabolism and Excretion

The kidneys are the principal organ of RBP loss and catabolism. Glomerular filtration and renal catabolism are estimated to account for metabolic clearance of RBP equivalent to about 7/8 L of plasma per day in a 70-kg human (4). Chronic renal disease is typically associated with abnormal elevations of plasma retinol and RBP (4). In 26 patients with chronic renal disease of various etiologies, plasma RBP averaged 116 µg/mL (5.5 µmol/L), versus 46.2 µg/mL (2.2 µmol/L) in 109 controls (138). The molar ratios of RBP to vitamin A and of RBP to TTR were both elevated. In a rat model of acute renal failure, serum retinol increased up to 70% within 2 hours of nephrectomy (139), whereas injection of apo-RBP caused a rapid and significant increase in plasma retinol (140). The latter result suggests that free apo-RBP, which is readily filtered, may provide a feedback signal to liver that stimulates output of holo-RBP. Urinary retinol excretion may be detected in some infections causing diarrhea (141) or proteinuria (142). Fex et al. (143) have proposed that an “acute vitamin A deficiency” may exist during inflammation and may contribute to the excess mortality associated with certain infectious diseases.

FUNCTIONS

Vision

Vitamin A is required in the eye in two distinct forms for two distinct processes: (a) as 11-*cis*-retinal, vitamin A functions in the retina in transduction of light into the neural signals necessary for vision and (b) as RA, vitamin A maintains normal differentiation of the cells of the conjunctival membranes, cornea, and other ocular structures, preventing xerophthalmia. Detailed reviews are available on phototransduction (36) and xerophthalmia (144).

The photoreceptor cells of the retina include the rods, which are specialized for motion detection and vision in dim light, and the red-, green-, and blue-sensitive cones, specialized for color vision in bright light. The essential light-absorbing unit consists of 11-*cis*-retinal bound to a protein (an opsin). Each cell type possesses specialized plasma membrane structures (outer segment disks) that contain a high concentration of a “visual pigment” (e.g., rhodopsin in rods and iodopsins in cones). Whereas unbound retinal maximally absorbs light of 365 nm, the absorption spectrum is shifted to longer wavelengths (the “opsin shift”) by formation of a protonated Schiff base between the aldehyde of retinal and a lysine amino group in opsin and by additional conformational changes. As noted by Saari (36), “opsin is tailor-made to shift the absorption spectrum of the retinoid into the visible range, increase its quantum efficiency of photoisomerization, and trigger further biochemical responses.” Thus, human rods absorb maximally at 509 nm, blue-sensitive cones at 420 nm, green-sensitive cones at 530 nm, and red-sensitive cones at 565 nm (36). As shown schematically in Figure 17.5, absorption of a photon of light catalyzes photoisomerization of a molecule of 11-*cis*-retinal to all-*trans*-retinal, followed by its release from opsin. This isomerization triggers a reaction cascade that involves G proteins, phosphorylation, and decreased sodium conductance across the photoreceptor cell's plasma membrane; the latter event initiates signaling to neuronal cells that communicate to the brain's visual cortex. Although this process is described for a single retinal molecule, in reality, signals from thousands of rods, each containing millions of molecules of rhodopsin (which reaches a concentration of 2.5 mmol/L in rod outer-segment membranes) are triggered simultaneously, and their signals integrated.

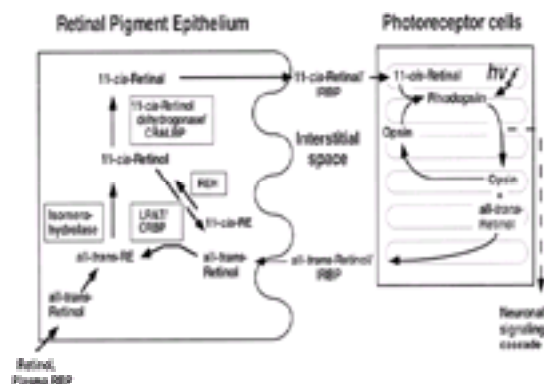

Figure 17.5. Retinoid metabolism in vision. CRALBP, cellular retinol-binding protein; RE, retinyl ester; LRAT, lecithin:retinyl acyltransferase; IRBP, interstitial retinoid-binding

protein; hr, light.

For vision to continue, 11-*cis*-retinal must be regenerated. In vertebrates this occurs through thermal—not light-catalyzed—processes (“dark reactions”) in the supporting RPE cells that are adjacent to the rods and cones but separated by an interphotoreceptor space. The time constant for regeneration of rhodopsin is on the order of minutes (36). This process requires, first, reduction of all-*trans*-retinal to retinol and its movement across the photoreceptor space to the RPE cells by IRBP (38), a protein present in the photoreceptor space (36). In the RPE cells, all-*trans*-retinol is esterified through an LRAT-mediated reaction, providing a local storage pool of retinyl esters that, when needed, are hydrolyzed and isomerized to form 11-*cis*-retinol. This unusual reaction is coordinately catalyzed by isomerohydrolase, an enzyme unique to the retina. 11-*cis*-Retinol may then be esterified by LRAT or oxidized by a specific dehydrogenase (145) to form 11-*cis*-retinal. This retinoid is then shuttled by IRBP back across the interstitial space to the photoreceptor cells for recombination with opsin, thus beginning another photo cycle. Although the pool of retinyl esters in the RPE is small in comparison to total body reserves, this pool provides a highly concentrated source of vitamin A for immediate re-formation of 11-*cis*-retinal after bleaching. Thus, in a “conveyor belt”-like fashion, as molecules of 11-*cis*-retinal are bleached, other molecules are released from storage for rapid regeneration of the visual pigments. The phenomenon of poor dark adaptation after exposure to bright light (night blindness) results from light-stimulated depletion of rhodopsin, a normal event, *together with* a failure to resynthesize 11-*cis*-retinal rapidly; this latter failure is due to depletion of the RPE cells' retinyl ester storage pool. In a recent report, night blindness in Sorsby's fundus dystrophy, an autosomal dominant retinal degeneration, disappeared within a week after provision of 50,000 IU (~15,000 µg RE) of vitamin A to patients in early stages of disease (146).

The various cell types in the retina, cornea, and conjunctival epithelium contain several cellular retinoid binding proteins and nuclear retinoid receptors whose presence implies that these structures depend on RA in the same manner as the epithelia of other tissues. The structural integrity of the cornea, an avascular tissue, depends on vitamin A delivered via tear fluid. The lacrimal gland can synthesize and secrete RBP, which is proposed to be important in solubilizing the retinol in tears (147).

The corneal pathology observed in vitamin A deficiency (see [color plate in Chapter 30](#)) appears to result from a lack of RA. Vitamin A deficiency appears as dryness of the conjunctival membranes and cornea (xerosis) (144) and the presence of Bitô's spots (foamy-appearing deposits of cells and bacteria in the outer quadrant of the eye). These changes are reversible by vitamin A. If, however, vitamin A deficiency continues and the cornea softens (keratomalacia) and ulcerates, blindness is irreversible (144).

Cellular Differentiation

The first evidence that vitamin A is required for the integrity of epithelial tissues was

reported in the mid-1920s by Wolbach and Howe (148). While examining the tissues of vitamin A–deficient rats under the light microscope, these investigators observed that epithelia normally composed of columnar or cuboidal mucus-secreting cells were, instead, flat (squamous), dry, and keratinized. Later studies with cultured cells showed that RA may induce undifferentiated stem cells to cease proliferation and to assume a differentiated, mature phenotype (149). It is now appreciated that all-*trans*- and 9-*cis*-RA, through activation of RAR and RXR, regulate expression of a large number of genes. Because the various forms of RAR and RXR, like other transcriptional regulators, are expressed in time and location-specific patterns, gene regulation can be finely tuned. Examples of genes with RARE include those encoding structural proteins (skin keratins), extracellular matrix (laminin), enzymes (alcohol dehydrogenases, transglutaminases), and retinoid-binding proteins and receptors (CRBP-I, CRABP-II, and RAR-b) (see [39] and [150] for reviews).

Retinoid-induced cell differentiation is often accompanied by an inhibition of cell proliferation. Retinoid receptors may form inhibitory complexes with nuclear factors known to promote proliferation, such as the AP-1 complex (151). Retinoid ligands with selective anti-AP-1 activity have been described (151). Retinoids may also stimulate apoptosis (programed cell death) (152). Induction of differentiation, inhibition of proliferation, and induction of apoptosis are either known or hypothesized to be related to the actions of retinoids as anticancer agents and in normal embryonic development.

Development

Both a deficiency and an excess of vitamin A cause fetal malformations. Association of vitamin A deficiency with failure of embryonic development and congenital abnormalities was well established during the 1940s to 1950s by the work of Wilson and others (153). Offspring of vitamin A–deficient mice and rats show a variety of abnormalities including microphthalmia, craniofacial abnormalities, umbilical hernia, edema, and spongy tissue structures of the thymus, liver, and heart (154). The teratogenic effects of vitamin A, especially of acidic retinoids, are well demonstrated in several models of vertebrate development (amphibian, avian, rodent, primate). Retinoids have been implicated in the development of the central nervous system, limbs, cardiovascular system, and eyes (see [154] for review).

RA does not appear to be involved in vertebrate embryogenesis prior to the stage of gastrulation (155). Following gastrulation, specific genes of the *Hox* family (homologues of the *Drosophila melanogaster* *HOM-C* genes that regulate body segmentation) are expressed in a wave, beginning about 7.5 days postcoitus in the mouse embryo, from the hindbrain posteriorly (154, 156). The *Hox* family consists of 38 genes arranged in four chromosomal clusters, *Hox A*, *B*, *C*, and *D*, which code for transcription factors that regulate development along the posterior axis. Some *Hox* genes (e.g., *Hoxa1*, *Hoxb1*, *Hoxd4*) possess a functional RARE and are subject to direct regulation by RA (155, 157). Therefore, it is proposed that RA functions as a posterior transformation signal that alters the identity of trunk mesoderm through regulation of 3' members of the *Hox* gene family and perhaps additional genes (155, 157). Studies using RA-sensitive reporter genes have shown that RA, as well as RAR and RXR, CRBP, CRABP-I, and CRABP-II, is present in embryonic regions known to have organizing activity for

development of structures posterior to the hindbrain (e.g., the spinal cord and vertebrae) (154). The presence of retinoids together with their binding proteins and receptors in a temporally precise manner provides strong circumstantial evidence that RA-activated RARs regulate *Hox* gene expression. Loss-of-function mutations of *Hox* and RAR result in similar phenotypic abnormalities affecting the anterior (cervical) vertebral region and, conversely, overexpression of *Hox* genes and provision of excess RA produce similar abnormalities in the posterior vertebral region, which are reciprocal to those above (155). Not all *Hox* genes are regulated by RA, and other mechanisms may well refine the boundaries established by *Hox* genes and RA (155). The concepts that RARs are involved in normal development at certain critical periods and that RA plays a role as a posteriorizing hormone are supported by recent work on the effect of RAR-b and RA on neural tube closure in the *curly tail* mouse, a genetic model of neural tube defects (154).

RA also functions in limb development and formation of the heart, eyes, and ears. Although the concept that RA itself is an endogenous morphogen in vertebrate limb development (158) has been challenged (155), substantial evidence indicates that RA can respecify undifferentiated regions of the limb buds (154, 157). RA is needed for normal development of the heart (159, 160). In the regions that form the eyes, specific isoforms of retinal dehydrogenase, which mediates RA biosynthesis, are expressed at appropriate times during development in tissue that will differentiate into the ventral and dorsal portions of the eye (161). Development of the otic vesicle (ear) is also sensitive to a deficiency or excess of vitamin A (154).

Using the technique of homologous recombination to delete specific genes (see Chapter 36), mice lacking one or more of the retinoid receptors or binding proteins have been created. The need for retinol transport in the fetus is inferred from the lethal effect of suppressing expression of RBP in the fetal yolk sac (162). However, mice lacking CRBP, which is expressed in many embryonic tissues, unexpectedly appeared normal at birth, and even double mutants lacking CRABP-I and CRABP-II showed only mild limb abnormalities. Similarly, the embryos of mice lacking RAR-a1 (the RAR-a1 homozygous null mutation, denoted RAR-a1^{-/-}) survived in utero and appeared normal at birth (154), and even embryos lacking all of the isoforms of RAR-a or RAR-b (total RAR-a or RAR-b knockouts) survived in utero and showed nearly normal development. Of the single RAR null mutations, only RAR-g^{-/-} mice were born with obvious congenital malformations of the type expected if RAR-g is involved in *Hox* gene expression in the cervical spinal region (154). Mice lacking RXR-a showed abnormalities of the eye and heart, while mice lacking RXR-b appeared normal (although males were sterile). In general, single null mutations of RAR or RXR have resulted in abnormalities of differentiation that resemble those seen in vitamin A deficiency, rather than in the severe morphologic abnormalities that might have been expected. Most of these results are difficult to reconcile with the precise expression of retinoid-binding proteins and receptors during embryogenesis and the evidence for RA-induced gene expression. Functional redundancy among homologous receptors or binding proteins has been offered as a possible explanation. Mice bearing compound mutations show more severe abnormalities; e.g., mice lacking both RAR-a and RAR-g (RAR-a^{-/-}, RAR-g^{-/-}) displayed multiple abnormalities of cranio facial, ocular, and limb structures, resembling those seen in wild-type embryos with severe vitamin A deficiency (163).

Requirement for Retinol. Most work has focused on understanding the functions and teratogenicity of RA during early development in the mouse or chick. However, studies conducted in pregnant, retinoid-depleted rats provide evidence that provision of RA alone is not sufficient for fetal development beyond day 15. To prevent later fetal resorption, it was necessary to provide a small quantity of retinol to pregnant dams by day 10 (164). These data imply that there are different retinoid signals—RA, retinol, or another metabolite (164)—with separate and necessary roles at different stages of gestation.

In summary, recent studies have clarified that vitamin A in the form of retinol must be transported within the embryo and that RA produced locally is necessary for normal postgastrulation development. Retinoid receptors interact with *Hox* and other regulatory genes to control morphogenesis. This regulatory system apparently has many built-in safeguards, as evidenced by the lack of severe defects in null mutants lacking a single type of retinoid receptor.

Immunity

Researchers in the 1920s to 1930s first recognized that vitamin A deficiency is associated with decreased resistance to infection. In the late 1960s, Scrimshaw et al. (165) reviewed over 50 clinical, experimental, and observational studies concerning vitamin A as part of an extensive review for the WHO and concluded that no nutritional deficiency is as likely to be associated with infection as a lack of vitamin A. Nevertheless, they also emphasized that not all infections appear to be exacerbated by vitamin A deficiency. It is now appreciated that immunity to pathogens is exquisitely specific; thus, it is not surprising that depending on the pathogen and type of host immune response that it elicits, vitamin A may or may not be a critical determinant in the host's response. In randomized, controlled community studies and hospital-based studies, interventions with vitamin A reduced the severity of some infections, especially measles and diarrhea (see [166, 167 and 168] and Chapter 97 for discussions of the impact of vitamin A in reducing child morbidity and mortality). In contrast, however, the severity of respiratory infections has not been reduced by vitamin A supplementation (169, 170 and 171).

In experimental vitamin A deficiency, both cell-mediated immunity and antibody-mediated responses are generally reduced (see Chapter 45). Responses are generally poor to immune stimuli that depend on T cells for the host's response. Alterations are evident in the numbers of lymphocytes and their subset distribution (172) and in cytokine production (173). Nonspecific immunity, assessed by the microbicidal or cytotoxic functions of neutrophils, macrophages, and natural killer cells, has also been reported to be reduced or abnormal (174). In nearly all studies in which vitamin A has been provided to vitamin A-deficient hosts, immune functions have been restored, often quite rapidly. These observations and other evidence (175) suggest that the cellular “machinery” for an adequate response is intact but that the signaling pathways necessary for normal immune responses are impaired during retinoid deficiency and rapidly reestablished when vitamin A is provided.

PHARMACOLOGIC USE OF RETINOIDS

Dermatology

Nowhere has the clinical impact of retinoids been greater than in the treatment of diseases of the skin. Natural and synthetic retinoids influence epithelial cell proliferation and epidermal differentiation and have been used increasingly as systemic or topical agents in the treatment of hyperkeratotic disorders (e.g., etretinate and acitretin for psoriatic disease), acne and acne-related disorders (13-*cis*-RA, and retinoyl-b-glucuronide), and certain skin cancers ([11](#), [176](#), [177](#)). Acitretin ([Fig. 17.1G](#)) normalizes hyperproliferative states and induces differentiation of basal cells in the dermis toward a less keratinized, more epithelial phenotype. 13-*cis*-RA is a potent suppressor of sebocyte proliferation and sebum production. Retinoids most likely induce and modulate expression of dermal growth factors and their receptors ([176](#), [177](#)). Recent reviews provide detailed information on the indications for therapeutic use of retinoids in dermatology ([176](#)), characteristics of their metabolism ([176](#)), adverse reactions and tolerability ([176](#)), and retinoid metabolism and molecular biology of the skin ([31](#), [177](#)). The profile of adverse effects of oral retinoids is dose dependent and closely related to hypervitaminosis A (see below).

Other Treatments. In the near future, retinoids may prove beneficial for treatment of other diseases. A recent study reported significant improvement in the lungs of rats with experimentally induced emphysema after treatment for 25 days with RA ([178](#)). This result is consistent with a critical role of RA in lung development ([25](#)) and suggests that differentiation can be modulated by RA in the alveoli of adults.

Cancer Chemoprevention and Treatment

Epidemiologic ([179](#), [180](#)) and experimental data ([180](#), [181](#)) support a role for vitamin A and retinoids in decreasing the risk of certain cancers, especially those of epithelial origin. Some epidemiologic studies, many of the case-control design, have implicated total vitamin A as a beneficial dietary factor in reducing cancer risk ([179](#), [182](#)). Few studies, however, have shown a significant beneficial association between intake of preformed vitamin A and cancer risk ([179](#), [180](#)). In comparison, studies conducted in numerous rodent and other animal models have documented the ability of natural and synthetic retinoids to reduce carcinogenesis significantly in the skin, breast, liver, colon, prostate, lung, and other sites ([181](#)). The toxicity of natural retinoids precludes their long-term use in chemoprevention of human cancers, but some synthetic retinoids are better tolerated ([180](#), [181](#)), and some of these may prevent or delay cancer recurrence ([180](#)). Possible mechanisms of retinoid action in cancer chemoprevention are likely to include induction of cell differentiation, inhibition of proliferation, and/or induction of apoptosis ([152](#), [183](#)). The outcomes of clinical trials testing retinoids for cancer chemoprevention or therapy have been reviewed ([11](#), [180](#), [184](#), [185](#)).

Cancer Treatment: Acute Promyelocytic Leukemia

Experiments first conducted with the human promyelocytic cell line HL-60 implicated retinoids in myeloid differentiation (186). The chromosomal translocations observed in leukemias may contribute to carcinogenesis through enhanced expression of an oncogene or formation of chimeric fusion proteins with new functional properties (187). Also, cytologic analysis has shown that virtually all patients with a specific form of acute myeloid leukemia, acute promyelocytic leukemia (APL), bear a specific chromosomal abnormality characterized as a balanced reciprocal translocation between the long arms of chromosomes 15 and 17 (t15,17). In 1987, the gene for RAR- α was mapped to the long arm of chromosome 17 (17q21). In 1988, Chinese scientists reported that APL patients treated with high-dosage all-*trans*-RA (generally 45 mg/m²/day) showed remarkable clinical improvement, with complete remission in about 90% of patients (188). At the same time, molecular genetic analysis revealed that in virtually all APL patients, the gene for RAR- α is severed in intron 2 and fused with a previously unknown gene now named *PML* (for promyelocytic leukemia) on chromosome 15 (187). This reciprocal chromosomal exchange results in two abnormal genes that are expressed in APL patients as the chimeric fusion proteins PML-RAR- α (always present) and RAR- α -PML (present in about two-thirds of cases) (187).

Although the effectiveness of all-*trans*-RA in inducing remission was rapidly confirmed, the reasons for the success of this “differentiation therapy” are still not fully understood. To date, APL is the only example of differentiation therapy of human cancer, and all-*trans*-RA is the only anticancer drug targeted to a defined genetic location (187). The abnormal fusion protein PML-RAR- α , which is expressed at higher abundance than RAR- α in APL cells, contains all of the putative or known functional domains of PML and the DBD and LBD of RAR- α (187). It therefore is possible that this chimeric receptor functions as a dominant negative competitor of the normal RAR- α allele. PML-RAR- α can bind to RXR. Thus, it is possible that this abnormal complex blocks normal hematopoietic differentiation at the promyelocytic stage, enabling leukemogenic transformation to occur. Treatment with all-*trans*-RA rapidly induces expression of the remaining normal RAR- α allele (188), which may rebalance the receptor system toward normal differentiation. Because all-*trans*-RA alone cannot eliminate the leukemogenic clone, standard chemotherapy is used with, or following, treatment with RA, as consolidation therapy.

In treating APL patients with high doses of RA, it rapidly became clear that this treatment is associated with a high-risk syndrome, the “retinoic acid syndrome” (188, 189), a combination of fever, respiratory distress, hypotension, and renal failure, which has led to death of a significant percentage of patients. Consequently, therapy has been modified so that high-dose all-*trans*-RA is strictly administered for only a short period, followed by conventional chemotherapy for consolidation (188, 190). Furthermore, APL patients treated with all-*trans*-RA become refractory to its differentiating activity, so patients who relapse after its withdrawal are resistant to further treatment with all-*trans*-RA (120, 188). Resistance appears to be due at least in part to an increase in the rate of RA catabolism (see “Metabolism”).

DEFICIENCY AND TOXICITY

Vitamin A Deficiency

Nutritional vitamin A deficiency still exists in parts of the developing world, especially in young children (191). Deficiency leads to dedifferentiation (metaplasia), epithelial keratinization (e.g., trachea, skin), appetite changes that contribute to poor growth, and xerophthalmia. Animal and human studies have shown that the liver vitamin A content is low at birth because of limited placental transfer of fat-soluble vitamins, even in the offspring of well-nourished mothers (9, 192, 193). Hepatic vitamin A storage can increase significantly during the nursing period if milk vitamin A (related to maternal dietary vitamin A) is adequate (193). The liver vitamin A stores of children and young animals also depend on the adequacy of their postweaning diets (194). Provision of vitamin A to breast-feeding Indonesian women early in lactation increased their breast-milk vitamin A significantly and reduced the frequency of low serum retinol concentrations among their infants (195). Once liver vitamin A reserves are established, they can supply retinol to other tissues for several months or even longer. Vitamin A deficiency in children occurs most often in the postweaning period and thus is likely to reflect inadequate vitamin A both during the suckling period and in the postweaning diet.

The WHO criteria for a vitamin A public health problem now include not only the prevalence of traditional eye signs of severe deficiency (e.g., corneal xerosis, Bitô's spots [see Fig 10.1]) but also population-based cutoff levels for subclinical indicators (e.g., low serum retinol, low breast-milk retinol [196]). It is estimated that each year, some 3 to 10 million children, most living in developing countries, become xerophthalmic, and between 250,000 and 500,000 go blind (144, 196). International public health programs to eradicate vitamin A deficiency and xerophthalmia continue to have high priority. Providing vitamin A supplements of 50,000 to 200,000 IU (15,000–60,000 µg RE, depending on age) to young children at risk of vitamin A deficiency is considered to protect for 4 to 6 months (196). Improved dietary intakes are clearly required for long-term solution to vitamin A deficiency (196).

Retinoid Toxicity and Teratogenicity

Hypervitaminosis A. The condition hypervitaminosis A results from acute or chronic overconsumption of preformed vitamin A (not carotenoids). The presence of esterified retinol in *fasting* plasma (in association with plasma lipoproteins) is an early indicator of hypervitaminosis A. However, the plasma concentration of holo-RBP remains near normal (197). Generally, signs of toxicity are associated with chronic consumption of doses in excess of 10 times the RDA resulting from food faddism (e.g., excessive consumption of liver [198]) or self-medication with high-dose vitamin A preparations (199). (See [198] and [197] for typical case reports of nutritionally induced vitamin A toxicity.) Even among healthy users of vitamin/mineral supplements (in quantities approximately one to two times the RDA for vitamin A), significant increases in fasting plasma retinyl esters were observed (200). In elderly men and women, an elevation of plasma retinyl esters was associated with long-term vitamin A supplement use (>5 years) and, in some, with biochemical evidence of liver damage (elevated serum transaminases) (200). These data raise the possibility that even moderate, chronic vitamin A supplementation may cause mild hypervitaminosis A in some individuals

(199).

Dose-dependent manifestations of retinoid toxicity include headache, vomiting, diplopia, alopecia, dryness of the mucous membranes, desquamation, bone and joint pain, liver damage, hemorrhage, and coma (9, 16, 201, 202). Mechanisms that plausibly explain the etiology of hypervitaminosis A and vitamin A toxicity (203) include first, that retinoids may insert into, expand, and destabilize membranes (204). Symptoms such as joint and bone pain may be explained by rupture of membranes of cells and intracellular organelles such as lysosomes. Second, as intracellular retinoids accumulate, RA may induce inappropriate expression of genes. Several reviews (201, 203, 205, 206) provide information on structure-activity relationships associated with the clinical pharmacology, toxicology, and teratogenicity of retinoids.

Teratogenic Effects. A high incidence (>20%) of spontaneous abortions and birth defects has been observed in the fetuses of women ingesting therapeutic doses of 13-*cis*-RA (as prescribed for skin disorders, see above) during the first trimester of pregnancy (16), and similar retinoid-induced birth defects are well documented in several animal models (see [206] for review). Three retinoids are currently approved for oral use in the United States and many other countries (13-*cis*-RA [isotretinoin, Accutane]; etretinate [Tegison, Tigason] and acitretin [Neotigason]). Because 13-*cis*-RA is known to be teratogenic in humans, it is marketed in the United States as contraindicated during pregnancy (206). Tegison is currently approved for treatment of psoriasis. However, the risk for fetal dysmorphogenesis by these retinoids may persist for many months after use ceases (206). The dysmorphogenic effects caused by retinoids depend on dosage (exposure), the form of retinoid, its rate of metabolism, the species studied, and the stage of fetal development at the time of retinoid intake. Retinoids are teratogenic during the period of fetal organogenesis (first trimester). Human and other primate embryos are considerably more sensitive to retinoid-induced congenital malformations than are those of rabbits, rats, and mice, although the types of congenital malformations (exencephaly, craniofacial malformations, eye defects, and cardiac abnormalities [206]) are similar across species (201). Each of the main isomers of RA (9-*cis*, 13-*cis*, and all-*trans*-RA) is teratogenic in animals. Structure-activity analysis indicates that retinoids with stabilized structures, an acidic group at C-15 or the ability to form one in vivo, and a high rate of transplacental transfer are more teratogenic (206). In this regard, retinoyl- β -glucuronide, which lacks a free carboxyl group, shows little, if any, teratogenicity when given orally (11). The greater teratogenicity of 13-*cis*-RA in humans (1 mg/kg/day) versus rodents (75 mg/kg/day in rats and mice) is likely to be explained by a higher rate of placental transfer, a longer plasma half-life (10–20 h in humans vs. 1 h in rodents), and differences in metabolite formation, with more 4-oxo-all-*trans*-RA and 4-oxo-13-*cis*-RA produced in humans (206).

A recent epidemiologic study by Rothman et al. (207) investigated the relationship of dietary vitamin A intake to birth defects. Birth records and dietary interviews for 22,748 pregnant American women were reviewed. Of 339 babies with birth defects, 121 were in sites that originated from the embryonic cranial neural crest. From logistic-regression analysis these authors concluded that the risk of birth defects was significantly greater in women who consumed more than 10,000 IU/day of vitamin A from supplements (1.4% of the group studied) and was related to vitamin A consumption in the periconceptual period. Rosa (207a) has reviewed published case reports and reports to

the U.S. Food and Drug Administration of birth defects associated with maternal vitamin A exposures in excess of 20,000 IU/day during early pregnancy. Concerns have also been raised about the frequent consumption by pregnant or potentially pregnant women of very high vitamin A foods such as liver (>100,000 IU [33,000 mg RE]/100 g) ([117](#), [208](#)).

Safe Upper Limit of Intake. A generally recognized safe upper limit of intake for vitamin A is 8,000 to 10,000 IU (~3,000 mg RE)/day ([201](#), [209](#)).

ASSESSMENT OF VITAMIN A STATUS

Vitamin A status comprises a continuum from overt, clinically evident deficiency to overt, clinically evident toxicity ([Table 17.2](#)). In between, the range of marginal, adequate, and excessive vitamin A covers a broad range of body vitamin A reserves. This range is not associated with clinical signs, and plasma retinol is quite constant ([Fig. 17.4](#)). The lack of sensitivity of plasma retinol to changes in body reserves has led to the quest for other indicators of status, particularly of marginal vitamin A status, which may be useful in clinical and population-based studies. In the 8th edition of *Modern Nutrition in Health and Disease*, Olson ([9](#)) dealt with several tests of vitamin A status in detail. This chapter focuses on recent results and on those tests most often used.

Category	Severe Deficit	Severe Deficit/Deficient in the Feeding State	Lower States	Clinical Signs	Substrate Grouped Most Common Situations
Deficient	Generally <0.05 μmol/L*	Very low if at all detectable	Severely depleted (0-0.2 μmol/L)	Night blindness, other ocular manifestations (see "Signs"), dryness of skin	Preschool-age children and pregnant or lactating women with low RA; women, chronic alcoholics, chronic liver diseases
Marginal	Generally 0.05-0.1 μmol/L	Low (0-2%)	Severely depleted (0-0.2 μmol/L)	None (However, response to provision of vitamin A†)	Large proportions of children and women living in poverty with low diets; populations with high rates of infectious diseases‡
Adequate	Generally 0.2-1.2 μmol/L	2-20%†	~0.2-0.5 μmol/L	None	Typical of a well-nourished general population
Excessive	High (normal is <0.2 μmol/L*)	Significantly greater, often in fasting plasma; correlated on appropriate	High (0.500 μmol/L)†	None apparent or very mild, decreased liver enzymes in plasma	Chronic supplement use; Reports make of foods (e.g., liver) high in preformed RA
Toxic	Higher than the above certain values	May exceed upper limit in certain states	Very high in liver and increased in plasma	Headache, conjunctivitis, elevated liver enzymes in plasma and clinical signs of liver disease	Fresh tuberos and diets of high-dose RA supplements; patients treated with retinoid§

*Based on WHO (10) RA data for U.S. population (10).
†Normal and high normal (top normal) values for other states.
‡Based on data from low and high altitude in Kenya (10) (normal values being 0.2-0.5 μmol/L and 0.1-0.2).
§Retinoid responses (usually retinoids, not retinoids, plasma retinoid (RA) and urinary retinoid excretion are not observed), however, then clinical signs of vitamin A toxicity (see text for a detailed review of vitamin A).

Table 17.2 Vitamin A Status: Typical Findings

Clinical Assessment

Eye Signs. Conjunctival xerosis with Bitôt's spots in young children (WHO classification X1B) is strongly associated with vitamin A deficiency ([9](#), [144](#)). A prevalence above 0.5% X1B in young children is one of the criteria used by the WHO to identify vitamin A deficiency as a public health problem (see below). Questioning children and their parents on the child's ability to see in dim light (i.e., probing about night blindness) may be useful in revealing subclinical manifestations of vitamin A deficiency for which further

tests may be indicated. Night blindness has also been reported during pregnancy in regions of low vitamin A intake.

Public Health Assessment. Although the serum retinol level is not considered a strong indicator of the vitamin A status of an individual, low values in populations have greater significance. In 1987, WHO identified 37 countries, most in Africa, whose populations had vitamin A deficiency of varying degrees of severity, based largely on the prevalence of xerophthalmia (210). In 1994, criteria were updated for determining whether vitamin A deficiency is a public health problem in children 6 to 71 months old (196). These criteria combine ocular, biochemical (including serum retinol), and nutritional indicators. Even when the prevalence of xerophthalmia is very low, the presence of other indicators—low serum retinol, low breast-milk retinol, abnormal cytology (see below)—still warns that mild, moderate, or severe vitamin A deficiency may be significant (Table 17.2). One impetus for this change is the growing awareness of an association between marginal vitamin A deficiency and increased child morbidity and mortality (see Chapter 97).

Biochemical

Vitamin A concentration in serum (plasma), breast milk, or tear fluid may indicate vitamin A deficiency. Of these, only serum retinol has generally accepted cutoff values for classification of vitamin A status. Liver vitamin A concentrations (which seldom are obtainable) below 5 µg total retinol/g have been associated with deficiency, and from 5 to 20 µg/g with marginal status (9).

Response assays have been developed to assess indirectly the adequacy of liver vitamin A stores. Based on the findings that RBP accumulates in the livers of vitamin A-deficient animals and is rapidly released when vitamin A is provided, the relative dose response (RDR) and the modified relative dose response (MRDR) were developed to assess the adequacy of liver stores in children and other vulnerable groups. In the RDR (9, 211), plasma is sampled for a baseline retinol concentration, and a small dose of retinol (1.6–3.5 µmol [450 to 1000 µg RE]) is given orally in oil. The larger dose (3.5 µmol) gives more reproducible results. Plasma is collected again about 5 hours later. An increase in retinol in excess of 20% of baseline is generally considered a positive result (although other values have been used [212]), which indicates that hepatic vitamin A reserves are not adequate to maximize secretion of holo-RBP. To reduce the blood requirement to a single sample, the MRDR test takes advantage of the low level of vitamin A₂ (3,4-didehydroretinol) normally present in plasma and the similarity of vitamin A₂ to retinol during absorption and in formation of holo-RBP in liver. A dose of 0.35 µmol vitamin A₂/kg body weight, recently revised to a 5.3 µmol dose for preschool children (213), is administered orally, and a single blood sample is collected 5 hours later (9, 214). A serum ratio of 3,4-didehydroretinol:retinol of 0.060 or above is generally considered to indicate inadequate status, and a value below 0.030, adequate status. For both the RDR and the MRDR, intermediate values suggest marginal deficiency but are harder to interpret. When the MRDR was used in a study of 57 pregnant low-income women of low socioeconomic status, 26% had values between 0.030 and 0.060, interpreted as indicating marginal vitamin A deficiency, and 9% had values of 0.060 or above (214). Recent validation and comparison studies provide comparisons to other measures of

status and references to earlier studies ([212](#), [215](#)).

Histologic. Evaluation of conjunctival histology (conjunctival impression cytology, CIC) has been proposed as a field-operative test. CIC is based on the lack of normal goblet cells and the presence of enlarged epithelial cells in the conjunctiva of vitamin A-deficient children or adults. Cells are transferred from the conjunctiva to filter paper with gentle pressure, stained, examined microscopically, and scored by a trained observer. The test requires patient cooperation. Recently, CIC has been compared with the RDR, serum retinol, and RBP measurements in a group of 2- to 8-year-old children in Belize, Central America ([212](#)). Some 49% of children in this population had an abnormal CIC test, compared with 24% with low serum retinol (<0.87 $\mu\text{mol/L}$) and 17% with a positive RDR test. The response of the corneal epithelium to vitamin A supplementation is typically slow, and several months may be required for the eye to appear normal ([144](#), [215a](#)).

Dietary Assessment

Because vitamin A is concentrated in relatively few foods and is well conserved in the body, short-term dietary recall (e.g., for 24 h) is not useful for individuals, but it may be useful in population studies. Food-frequency questionnaires have been used in numerous case-control clinical or epidemiologic studies, both with and without assessment of food portion size. As noted previously ([9](#)), dietary data are of greatest value in assessing the food habits of populations at risk of vitamin A deficiency.

Assessment Tools Now Limited to Research. Methods to assess body vitamin A reserves have been developed using stable isotopes that equilibrate with tissue retinoids. A test of the retinol isotope-dilution method in rats showed that liver stores could be predicted well over a wide range of vitamin A nutriture (mean liver vitamin A from 0.17 to 1885 nmol/g [[216](#)]). In human volunteers consuming different levels of vitamin A, a deuterated-retinol dilution test was both useful in estimating total body reserves of vitamin A and was responsive to differences in daily retinol consumption ([217](#)).

Ocular tests requiring specialized equipment have been used to assess visual acuity in relationship to vitamin A status. Pupillary response and visual threshold were tested in assessment of vitamin A status in young children and correlated with serum retinol and results of the RDR test ([218](#)). Children with abnormal pupillary thresholds had significantly higher RDRs and lower serum retinol concentrations than normal children.

SUMMARY

Vitamin A is essential for growth and life, taking part not only in vision but in developmental processes that begin early in embryogenesis. Vitamin A continues to be necessary to maintain normal cellular differentiation throughout life. The basic mechanism of action of vitamin A, in the form of RA and as a potent modulator of gene expression, is now well understood. However, much less is known of the physiologic and pharmacologic situations in which specific genes are regulated in vivo. This

understanding will be necessary if vitamin A–like molecules are to be used over an extended time for cancer prevention and control. The value of synthetic retinoids or natural compounds used pharmacologically has been demonstrated dramatically in the treatment of dermatologic diseases and in the specific leukemia APL. At the same time, the inherent potential of most retinoids to be toxic or teratogenic has been observed anew or under new circumstances. Vitamin A thus remains an essential nutrient with an unusually broad range of activities, and it is likely that much more remains to be revealed.

ACKNOWLEDGMENTS

The author wishes to acknowledge research support from NIH grants DK-46869 and DK-41479 and the generous support of Dorothy Foehr Huck to the Pennsylvania State University.

Abbreviations: **APL**—acute promyelocytic leukemia; **CRBP**—cellular retinol-binding protein; **CRABP**—cellular retinoic acid-binding protein; **RA**—retinoic acid; **RAR**—retinoic acid receptor; **REH**—retinyl ester hydrolase; **RXR**—retinoid X receptor; **RBP**—retinol-binding protein; **RARE**—RAR response element; **RPE**—retinal pigment epithelium; **RXRE**—RXR response element; **TTR**—transthyretin; **UV**—ultraviolet.

[Recommended Dietary Allowance of Vitamin D for Humans](#)

[Chapter References](#)

Vitamin D has existed on Earth for at least 500 million years. It was first produced in ocean-dwelling phytoplankton while they were exposed to sunlight for photosynthesis. Although the physiologic function of vitamin D in these lower life forms is unknown, vitamin D and its precursors may have acted either as a natural sunscreen to absorb high-energy ultraviolet radiation, thus protecting ultraviolet-sensitive organelles and macromolecules, or as a photochemical signal (1). For reasons that are not understood, terrestrial vertebrates during evolution became dependent on vitamin D for the development and maintenance of their ossified skeletons. The principal physiologic function of vitamin D in all vertebrates including humans is to maintain serum calcium and phosphorus concentrations in a range that supports cellular processes, neuromuscular function, and bone ossification. Vitamin D accomplishes this goal by enhancing the efficiency of the small intestine to absorb dietary calcium and phosphorus and by mobilizing calcium and phosphorus stores from bone.

Vitamin D is inherently biologically inactive and requires successive hydroxylations in the liver and kidney to form 1,25-dihydroxyvitamin D (1,25(OH)₂D), the biologically active form of vitamin D (2, 3 and 4). 1,25(OH)₂D interacts with a specific nuclear receptor in its target tissues that results in a biologic response. Recent evidence

suggests that $1,25(\text{OH})_2\text{D}$ may also have rapid actions on intracellular calcium, phosphatidylinositol metabolism, and cyclic guanosine triphosphate (GTP) metabolism (2, 3 and 4).

The identification of vitamin D metabolites led to development of assays for them. These assays have become valuable diagnostic tools for evaluating patients with hypocalcemic, hypercalcemic, and metabolic bone disorders.

The major target tissues for $1,25(\text{OH})_2\text{D}$ are the intestine and bone; however, nuclear receptors for $1,25(\text{OH})_2\text{D}$ have been identified in several other tissues and in cultured tumor cells. $1,25(\text{OH})_2\text{D}$ inhibits the proliferation and induces terminal differentiation of many tumor and normal cultured cells that possess its receptor (2, 3 and 4). These observations have been the impetus for a reevaluation of the physiologic and pharmacologic actions of $1,25(\text{OH})_2\text{D}$.

HISTORY OF RICKETS

Although historians state that rickets occurred in humans as early as the 2nd century AD, the disease was not considered a significant health problem until the industrialization of northern Europe. In the 17th century, Whistler, DeBoot, and Glissen independently recognized that many of the children who lived in the crowded and polluted cities in northern Europe (Fig. 18.1) developed a severe bone-deforming disease characterized by enlargement of the epiphyses of the long bones and rib cage, bowing of the legs, bending of the spine, and weak and toneless muscles (Fig. 18.2) (5). The incidence of this debilitating bone disease increased dramatically in northern Europe and North America during the industrial revolution, and by the latter part of the 19th century, autopsy studies done in Leiden, the Netherlands, showed evidence that about 90% of the children had rickets (6). This disease was especially devastating for young women of childbearing age who often had a deformed pelvis, resulting in a high incidence of infant and maternal morbidity and mortality. This high incidence led to the development and widespread use of cesarean sections in Great Britain.

Figure 18.1. A typical scene in Glasgow in the mid-1800s is captured by this photograph taken by Thomas Annan. (From Thomas Annan. Photographs of the old

closes and streets of Glasgow 1868/1877. New York: Dover, 1977, with permission.)

Figure 18.2. Child with rickets showing rachitic rosary of the rib cage, bowed legs, deformity of the long bones, and muscle weakness. (From Fraser D, Scriver CR. Hereditary disorders associated with vitamin-D resistance or defective phosphate metabolism. In: DeGroot L, ed. Endocrinology, vol 2. New York: Grune & Stratton, 1979, with permission.)

From the earliest recognition of rickets in 1650, scientists and physicians throughout Europe began what would be a 270-year search for the cause and cure of this unfortunate childhood malady. In 1822, Sniadecki observed that children living in Warsaw had a high incidence of rickets, whereas children living in rural areas outside Warsaw did not (7). Based on this observation, he advocated exposure to sunlight as a means of curing this disease. Little attention was focused, however, on the environment as the cause of this disorder. In 1889 (8), the British Medical Society conducted an epidemiologic survey and confirmed previous observations that the incidence of rickets was extremely high in the industrialized cities in Great Britain and was less frequent in rural districts of the British highlands. This differed from the incidence of rheumatism and malignant disease, which were common in all districts in the British Isles (9). Unfortunately, they were unable to relate the lack of exposure to sunlight with their observations. One year later, however, Palm published an extensive epidemiologic survey and came to the same conclusion as Sniadecki (10). Observations he collected from a number of physicians throughout the British Empire and the Orient revealed that rickets was rare in children living in impoverished cities in China, Japan, and India where people received poor nutrition and lived in squalor, whereas the children of middle class and poor who lived in industrialized cities in the British Isles had a high incidence of rickets. Based on this survey, he urged systematic sunbathing as a preventive and therapeutic measure in rickets and other diseases. He also advocated educating the public to appreciate sunshine as a means of health.

Unfortunately, little attention was paid to the insightful observations of Sniadecki and Palm, and another 30 years passed before Huldshinski demonstrated that exposure of rachitic children to radiation from a mercury vapor arc lamp was effective in curing this bone disease (11). When he exposed one arm of a rachitic child to the ultraviolet radiation, he demonstrated that rickets in the other arm was cured to the same degree as in the exposed arm. He concluded that phototherapy was not a local effect and speculated that something made in the skin could be transported to distal sites to carry out its antirachitic activity. Two years later, Hess and Unger exposed seven rachitic children on a roof of New York City Hospital to varying periods of sunshine and reported that radiographic examinations showed improvement of rickets in each child as evidenced by calcification of the epiphyses (12).

THE ANTIRACHITIC FACTOR: VITAMIN D

During the 18th and 19th centuries, cod liver oil was used as a common folklore medicine for the prevention and cure of rickets. As early as 1827, Bretonneau treated acute rickets in a 15-month-old child with cod liver oil and noted the incredible speed with which the patient was cured. His student Trousseau advocated the use of oils from fish and sea mammals accompanied by exposure to sunlight for a rapid cure of rickets (13). This knowledge prompted intense investigation to determine what nutritional factor in cod liver oil was responsible for preventing rickets. In 1918, Mellanby reported that he could produce rickets in dogs by feeding them oatmeal and could cure the disease by adding cod liver oil to their diet (14). Two years later, McCollum et al. examined whether the antirachitic factor in cod liver oil was identical to or distinct from vitamin A (15). Cod liver oil was heated and oxidized to destroy all vitamin A activity. When the oil was administered to rachitic rats, it maintained its antirachitic properties. Thus, the antirachitic factor present in cod liver oil clearly was not vitamin A but a new fat-soluble vitamin that was called vitamin D.

Powers et al. showed that exposure to radiation from a mercury arc lamp had the same antirachitic potency as cod liver oil (16). At the same time, Hess and Weinstock (17) and Steenbock and Black (18) found that exposure of food and a variety of other substances such as rat liver; human serum; cotton, olive, and linseed oils; lettuce; growing wheat; and rat chow to ultraviolet radiation resulted in their having antirachitic properties. This led Steenbock to patent use of the addition of provitamin D to foods followed by ultraviolet irradiation to impart antirachitic activity. Addition of provitamin D₂ to milk followed by ultraviolet irradiation became widely practiced in the United States and Europe in the 1930s. This vitamin D–fortification process eradicated rickets as a significant health problem in countries that used it. Today, fortification of milk and infant formula with 400 IU (10 µg) of vitamin D₂ or vitamin D₃ has eliminated rickets as a health problem in the United States and Canada. In Europe, vitamin D fortification of milk is prohibited because of severe vitamin D intoxication that resulted from the indiscriminate addition of excessive amounts of vitamin D to infant formulas in the 1940s and 1950s. Today, some foods, including cereals and margarine, are fortified with vitamin D in many European countries.

PHOTOBIOLOGY

History

The first vitamin D isolated was a photoproduct from irradiation of the fungal sterol ergosterol. This vitamin D was known as vitamin D₁ until it was realized that it was a combination of substances. Further purification of the irradiation mixture yielded a single compound, which was called ergocalciferol, or vitamin D₂ (19) (Fig. 18.3). At the time of its identification, it was assumed that the vitamin D made in human skin during exposure to sunlight was vitamin D₂ (20). In the 1930s, however, it was reported that vitamin D obtained from irradiation of ergosterol had little antirachitic activity in chickens, whereas vitamin D isolated from irradiation of cholesterol-like sterol yielded a potent antirachitic substance (21, 22 and 24). The confusion about whether vitamin D₂ was identical to the substance produced in human skin was resolved when Windaus and Bock reported the synthesis of a new provitamin D analogue that was similar to ergosterol except that the side chain was cholesterol (Fig. 18.3) (25). This provitamin D was called provitamin D₃, or 7-dehydrocholesterol, and on irradiation, it gave rise to vitamin D₃ (cholecalciferol) (Fig. 18.3). Vitamin D₃, unlike vitamin D₂, had equal antirachitic activity in chicks and rats and was identical to the vitamin D found in fish liver oils and mammalian skin. Therefore, it was concluded that 7-dehydrocholesterol rather than ergosterol was the parent compound in the skin and its resulting photoproduct was vitamin D₃.

Figure 18.3. Structure of vitamins D₃ and D₂ and their respective precursors, 7-dehydrocholesterol and ergosterol. The only structural difference between vitamins D₃ and D₂ is their side chains; the side chain for vitamin D₂ contains a double bond between C₂₂ and C₂₃ and methyl group on C₂₄. (From MacLaughlin JA, Holick MF. Mediation of cutaneous vitamin D₃ synthesis by UV radiation. In: Goldsmith LA. Biochemistry and physiology of the skin. New York: Oxford University Press. 1983, with permission.)

Because of the availability of large quantities of ergosterol, vitamin D₂ was the vitamin D used for fortification of milk in the United States and Canada and for pharmaceutical preparations. During the past two decades, vitamin D₃ has also been used to fortify milk and other food substances worldwide.

Originally, it was believed that during exposure to sunlight, provitamin D₃ was directly converted to vitamin D₃. This concept was challenged by Velluz et al., who reported that exposure of provitamin D₃ in an organic solvent to ultraviolet radiation at 0°C did not yield any vitamin D₃ (26). They reported the isolation of a new photoproduct, which they called previtamin D₃ (27), that was thermally labile and underwent rearrangement of its double bonds to form vitamin D₃ in a temperature-dependent process.

Photosynthesis of Previtamin D₃ in Human Skin

The sun emits a broad spectrum of electromagnetic radiation. The high-energy photons that are most damaging to life on Earth (below 290 nm) are absorbed by the thin layer of ozone that envelops the planet. The small band of radiation between 290 and 315 nm (UV-B radiation) is responsible for the photolysis of provitamin D₃ in the epidermis and dermis. During exposure to sunlight, the 5,7-diene of provitamin D₃ absorbs radiation with energies between 290 and 315 nm (28), causing the cleavage of ring B between carbons 9 and 10 (Fig. 18.3) and the formation of a 6,7-*cis* conjugated triene to form a 9,10-seco (seco from the Greek word for split) sterol known as previtamin D₃ (Fig. 18.4). In adult skin, approximately 60% of the cutaneous stores of provitamin D₃ are found in the epidermis; the other 40% resides in the dermis (29). When white and black adults are exposed to sunlight, approximately 70 to 80% and 95 to 98% of the UV-B photons are absorbed by the epidermis, respectively (30). Therefore, approximately 80 to 90% of the previtamin D₃ that is formed in the skin occurs in the actively growing layers of the epidermis, including the stratum basale and stratum spinosum, and less than 20% occurs in the dermis (31). In neonates, approximately 50% of the provitamin D₃ stores are found in both the epidermis and dermis. Because the thin neonatal epidermis transmits more UV-B photons into the dermis, the dermis is also a major site for previtamin D₃ synthesis.

Figure 18.4. Photochemical events that lead to the production and regulation of cholecalciferol (vitamin D₃) in the skin. (From Holick MF. Am J Clin Nutr 1994;60:619–30, with permission.)

Once previtamin D₃ is made in the skin, it immediately begins to isomerize to vitamin D₂ in a temperature-dependent process (Fig. 18.4). This thermal equilibration would take approximately 1 to 2 days to reach completion at body temperature (37°C) in humans. However, because previtamin D₃ is made in the plasma membrane of skin cells, it is trapped in an *s-cis, s-cis* conformation. Once it isomerizes to vitamin D₃, its conformation is altered, resulting in vitamin D₃ being jettisoned from the plasma membrane into the extracellular space. The vitamin D-binding protein in the circulation in turn attracts vitamin D₃ into the dermal capillary bed (32).

Regulation of Previtamin D₃ Synthesis in Human Skin

Photochemical Regulation

Loomis speculated that melanin pigmentation evolved in humans who lived near the equator as a mechanism for preventing sunlight-induced vitamin D intoxication (33). Although melanin is an excellent natural sunscreen that competes with provitamin D₃ for UV-B photons, thereby limiting the cutaneous production of previtamin D₃ (29, 34), firm evidence exists that sunlight itself is responsible for regulating the total production of vitamin D₃ in human skin (29). Loomis based his theory on the concept that exposure to prolonged intense sunlight would result in a time-dependent increase in production of vitamin D₃ in the skin. Once previtamin D₃ is photosynthesized in the skin, however, it can either thermally isomerize to vitamin D₃ or, during exposure to sunlight, absorb ultraviolet radiation and isomerize to the biologically inert isomers lumisterol and tachysterol (Fig 18.4). Thus, if a white individual is exposed to sunlight at the equator, provitamin D₃ is rapidly converted to previtamin D₃ during the initial few minutes of exposure. Prolonged exposure to sunlight, however, does not increase previtamin D₃

production; rather, previtamin D₃ is photodegraded to biologically inert isomers (Fig. 18.4) (29, 35).

Vitamin D₃ is exquisitely sensitive to photodegradation when exposed to sunlight (Fig. 18.4). The principal photoisomers that are formed are 5,6-*trans*-vitamin D₃ and supersterols I and II (Fig. 18.4). Thus, once vitamin D₃ is made from previtamin D₃, it must exit the epidermis into the dermal capillary bed; otherwise, it is rapidly photodegraded during exposure to sunlight (36).

Effect of Age

Photoproduction of previtamin D₃ in any layer of skin depends on the concentration of provitamin D₃, the presence of chromophors that compete with provitamin D₃ for UV-B photons, and the quanta of UV-B photons that can penetrate the skin and be absorbed by provitamin D₃. The average concentration of provitamin D₃ in 1 cm² of young adult skin is approximately 0.8 μg for the epidermis and 0.15 to 0.5 μg for the dermis (31). The concentrations of provitamin D₃ in the epidermis are inversely related to age (Fig. 18.5) (37). The net effect of this age-related decrease is demonstrated in Figure 18.6. Circulating concentrations of vitamin D were measured in healthy young and elderly subjects exposed to the same amount of whole body ultraviolet radiation. Peak circulating concentrations of vitamin D in the elderly were about 30% of those in young adults (38).

Figure 18.5. Effect of aging on 7-dehydrocholesterol concentrations in human epidermis and dermis. Concentrations of 7-dehydrocholesterol (provitamin D₃) per unit area of human epidermis (*open circles*) were obtained from surgical specimens from donors of various ages. Linear regression analysis gave slopes of -0.05 , -0.06 , and -0.0005 for epidermis ($r = -0.89$), stratum basale ($r = 2.92$), and dermis ($r = -0.04$), respectively. The slopes for epidermis and stratum basale differ significantly from the slope for dermis ($P < .001$). (From MacLaughlin JA, Holick MF. J Clin Invest 1985;76:1536–8, with permission.)

Figure 18.6. Circulating concentrations of vitamin D in healthy young and elderly volunteers exposed to ultraviolet radiation. To convert nanograms per milliliter to nanomoles per liter, multiply by 2.60. (From Holick MF, Matsuoka LY, Wortsman J. *Lancet* 1989;2:1104–5, with permission.)

Sunscreens

Awareness that the alarming increase in the incidence of skin cancer is related to chronic exposure to sunlight has led to the recommendation that people apply sunscreen before going outdoors (39). The solar radiation responsible for causing wrinkles and skin cancer, however, is the same radiation responsible for producing previtamin D₃ in the skin. Thus, application of a sunscreen with a sun protection factor of only 8 can markedly reduce (~ 95%) cutaneous production of previtamin D₃ (Fig. 18.7) (40). The use of sunscreens by children and young adults should not affect their vitamin D status, because it is unlikely that they will always apply a sunscreen before going outdoors. The elderly, however, are often more conscious of their health and apply a sunscreen before going outdoors. Evidence exists that chronic use of sunscreens by the elderly can decrease circulating concentrations of 25-hydroxyvitamin D (25-OH-D), which is a hallmark for determining vitamin D deficiency. As shown in Figure 18.8, almost one-half of subjects in Springfield, Illinois, who always wore a sunscreen before going outdoors had overt vitamin D deficiency as determined by low circulating concentrations of 25-OH-D (41).

Figure 18.7. Mean (\pm SEM) serum vitamin D₃ concentrations in eight normal subjects. Four subjects (*open circles*) applied p-aminobenzoic acid and four applied vehicle (*closed circles*) to the entire skin before exposure to ultraviolet B (UV-B). On day 0, all subjects underwent total body exposure to 1 MED of UV radiation. To convert nanograms of vitamin D per milliliter to nanomoles per liter, multiply by 2.60. (From Matsuoka LY, Ide L, Wortsman J, et al. *J Clin Endocrinol Metab* 1987;64:1165–8, with permission.)

Figure 18.8. Serum concentration of 25-hydroxyvitamin D in long-term sunscreen users and in age- and sex-matched controls simultaneously. The mean serum 25-hydroxyvitamin D level was significantly lower in long-term sunscreen users ($P < .001$). Two long-term sunscreen users had absolute vitamin D–deficiency 25-hydroxyvitamin D levels below 20 nmol/L. PABA, p-aminobenzoic acid; *open circles*, subjects from Philadelphia; *closed circles*, subjects from Springfield, IL. (From Matsuoka LY, Wortsman J, Hanifan N, et al. *Arch Dermatol* 1988;124:1802–4, with permission.)

Season, Latitude, and Time of Day

At the turn of the century, a seasonal incidence of rickets was recognized in the industrialized cities of the United States and Europe. Rickets was seen less frequently in children at the end of summer and more frequently at the end of winter and in early spring (9). As winter approaches, the solar zenith angle of the sun becomes more oblique. This configuration causes the UV-B photons to be absorbed more efficiently by the stratospheric ozone layer, thereby decreasing the total number of photons that reach the Earth's surface. As a result, cutaneous synthesis of previtamin D₃ is affected by the time of day, season of the year, and latitude. As shown in Figure 18.9, exposure to sunlight in Boston (42° N) promoted cutaneous photosynthesis of previtamin D₃ in human skin from March through October. By November, however, the number of 290- to 315-nm photons that penetrated the stratospheric layer into Boston was insufficient for significant conversion of provitamin D₃ to previtamin D₃. Just 10° north, in Edmonton (Alberta), Canada, this period ran from mid-October through mid-March. Farther south, in Los Angeles (34° N) and Puerto Rico (18° N), production of previtamin D₃ occurred throughout the year (Fig. 18.9) (42).

Figure 18.9. Photosynthesis of previtamin D₃ after exposure of 7-dehydrocholesterol (7-DHC) to sunlight in Boston (42° N) for 1 h (open circles) and 3 h (closed circles) and in Edmonton, Canada (52° N) after 1 h (open triangles) each month for 1 year, Los Angeles (34° N) (closed triangle) and Puerto Rico (18°) in January (inverted triangle). (From Webb AR, Kline L, Holick MF. J Clin Endocrinol Metab 1988;67:373–8, with permission.)

In Boston in summer, exposure to sunlight from 5:30 Eastern Standard Time (EST) to 18:30 EST resulted in cutaneous production of previtamin D₃. By October, however, most of the UV-B photons were absorbed by the ozone layer, and as a result, exposure to sunlight before 10:00 EST and after 15:00 EST was ineffective in producing previtamin D₃ in the skin (43) (Fig. 18.10). These observations are beginning to provide guidelines for recommendations regarding the use of sunlight as a means of providing people with their vitamin D requirement. For example, it is reasonable to advise people,

especially elderly individuals, that exposure to morning or late afternoon sunlight in the summer is a good source for their vitamin D requirement. At these times, sunlight exposure is less damaging to the skin.

Figure 18.10. Photosynthesis of previtamin D₃ at various times on cloudless days in Boston in October (*closed circles*) and July (*open circles*). (From Lu Z, Chen T, Holick MF. Influences of season and time of day on the synthesis of vitamin D₃. In: Holick MF, Kligman A, eds. Proceedings, Biologic Effects of Light Symposium. Berlin: Walter De Gruyter, 1992;53–6, with permission.)

INTESTINAL ABSORPTION

In nature, only a few foods contain vitamin D: fish liver oils and fatty fish. Several countries fortify some foods with vitamin D. In the United States, milk is the principal dietary component subject to fortification with either vitamin D₂ or vitamin D₃. Some cereals, breads, and infant formulas are also fortified with vitamin D. However, the amount of vitamin D in milk can vary. Studies have found that up to 80% of milk samples tested did not contain 80 to 120% of the vitamin D, and about 14% had no detectable vitamin D ([44](#), [45](#) and [46](#)). In other countries, some cereals, margarine, and breads have small quantities of vitamin D added to them.

When vitamin D is ingested, this fat-soluble compound is incorporated into the chylomicron fraction, and about 80% is absorbed into the lymphatic system ([4](#)). After ingestion of a single dose of 50,000 IU of vitamin D₂, circulating concentrations of vitamin D begin to increase within hours, peak at 12 hours, and gradually decline to near baseline by 72 hours ([Fig. 18.11](#)) ([47](#)). This provocative vitamin D absorption test has been useful in determining whether a patient with an intestinal malabsorption syndrome can absorb this fat-soluble vitamin. A blood sample is drawn just before and 12 to 24 hours after a single oral dose of 50,000 IU of vitamin D₂ ([Fig. 18.11](#)). If no elevation in the circulating concentration of vitamin D is observed, complete malabsorption of vitamin D should be suspected; however, any increase in the

circulating concentration of vitamin D reflects vitamin D absorption. The dose of vitamin D can, therefore, be tailored accordingly.

Figure 18.11. Serum vitamin D concentrations in seven patients with intestinal fat malabsorption syndromes after a single oral dose of 50,000 IU (1–25 mg) of vitamin D₂. The means and standard errors of vitamin D concentrations measured in seven normal control subjects after a similar dose are indicated by the *closed circles and dotted line*. Note that two patients, one with Crohn's ileocolitis (patient F) and one with ulcerative colitis (patient G), had essentially normal absorption curves. Five patients showed a dramatic lack of response, with no values above 25–2 nmol/L (10 ng/mL). (From Lo CW, et al. *Am J Clin Nutr* 1985;42:644–9.)

Patients who suffer from chronic intestinal malabsorption syndromes caused by chronic liver disease, cystic fibrosis, Crohn's disease, Whipple's disease, and sprue are more likely to develop vitamin D deficiency because the small intestine cannot absorb this fat-soluble vitamin. Diseases that affect the more distal small intestine and large intestine, such as ileocolitis caused by Crohn's disease and ulcerative colitis, have little effect on absorption of vitamin D ([Fig. 18.11](#)).

METABOLISM

Vitamin D to 25-Hydroxyvitamin D

Once vitamin D (the term *vitamin D* without a subscript relates to either vitamin D₂, vitamin D₃, or both and their metabolites) enters the circulation, it is bound to the group-specific protein (Gc) commonly known as the vitamin D-binding protein. Vitamin D is transported to the liver, where it undergoes its first hydroxylation on carbon 25, resulting in formation of the major circulating form of vitamin D, 25-hydroxyvitamin D (25-OH-D) ([Fig. 18.12](#)) ([2](#), [3](#) and [4](#), [21](#), [48](#)). Production of 25-OH-D by the liver is regulated by a negative feedback mechanism controlled by vitamin D, 25-OH-D, and 1,25(OH)₂D ([49](#)). This negative feedback control is not regulated tightly, inasmuch as an

increase in exposure to sunlight or dietary intake of vitamin D results in increased circulating concentrations of 25-OH-D (Fig. 18.13) (50, 51). Although the liver is the major site of 25-OH-D production, some extrahepatic sites are capable of this hydroxylation. It is likely that cholesterol-25-hydroxylase can recognize vitamin D and hydroxylate the side chain on carbon 25 to produce 25-OH-D (4).

Figure 18.12. Metabolism of vitamin D and the biologic actions of 1,25-dihydroxyvitamin D (1,25(OH)₂D). (From Holick MF. Am J Clin Nutr 1994;60:619–30, with permission.)

Figure 18.13. Serum levels of 25-OH-D₃ observed in response to various oral doses of vitamin D₃ given to vitamin D–deficient rats. A clear linear correlation extends well into the pharmacologic range for both parameters. To convert nanograms per milliliter to nanomoles per liter, multiply by 2.50. (From Holick MF. Vitamin D: relevance for clinical medicine. Los Angeles: Nichols Institute, 1981.)

Circulating concentrations of 25-OH-D often are low in patients with severe parenchymal and cholestatic liver disease (52), in part because of the associated

intestinal malabsorption of vitamin D as well as the decrease in the reservoir of the vitamin D-25-hydroxylase in the liver. Although low circulating concentrations of 25-OH-D can cause vitamin D-deficiency bone disease, it is unlikely that these low levels are responsible for the debilitating osteoporosis-like bone disease associated with severe liver failure. Little correlation exists between the severity of osteopenia and fractures in patients with primary biliary cirrhosis and other chronic liver disorders with circulating levels of 25-OH-D. Furthermore, treatment of these patients with 25-OH-D or its metabolites does not provide any significant benefit (53). Because these patients are more prone to developing vitamin D deficiency as a result of associated fat malabsorption, however, it is prudent to increase their vitamin D intake and monitor circulating concentrations of 25-OH-D.

25-Hydroxyvitamin D to 1,25-Dihydroxyvitamin D

Although 25-OH-D is the major circulating form of vitamin D, it is biologically inert at physiologic concentrations. For it to become active, it must be hydroxylated on carbon 1 by a specific 25-OH-D-1 α -hydroxylase, present in the kidney (see Fig. 18.12) (1, 2, 3 and 4, 21). Although the kidney is the principal site for the production of 1,25(OH)₂D under most circumstances, the placenta also appears to play a role in producing 1,25(OH)₂D at a time of increased requirement for calcium by the fetus (54, 55 and 56). A variety of authors report extrarenal sites for production of 1,25(OH)₂D. Most of these studies were conducted in vitro. Certain cultured cells, such as placental cells, human bone cells, keratinocytes, and stimulated monocytes, also produce 1,25(OH)₂D (3, 4, 57, 58 and 59). Some people speculate that 1,25(OH)₂D may be produced locally in cells to act in an autocrine or paracrine manner. In patients who have had bilateral nephrectomy or have chronic renal failure, the concentrations of 1,25(OH)₂D in the circulation usually are low or undetectable. Thus, the kidney is the principal organ responsible for activating vitamin D for the regulation of calcium metabolism.

Alternative Metabolism of 25-Hydroxyvitamin D

25-OH-D and its biologically active metabolite 1,25(OH)₂D are substrates for a variety of hydroxylases. The principal site of metabolism is the side chain, where carbons 23, 24, and 26 undergo hydroxylation and oxidation to yield a plethora of metabolites of 25-OH-D and 1,25(OH)₂D (2, 3 and 4, 21). Although the metabolic importance of these side-chain modifications is uncertain, most likely they are related to the deactivation and rapid clearance of 1,25(OH)₂D. This is particularly true for the C-23 and C-24 oxidations, which ultimately yield a biologically inactive, water-soluble metabolite 1 α -OH-24,25,26,27-tetranor-23-COOH-vitamin D₃ (calcitric acid) (2, 50). In addition to the multiple hydroxylations in the side chain, 25-OH-D₃ can have its A ring oxidized, whereby a keto group replaces C-19. This reaction occurs in vivo in ruminants and in vitro in chick kidney homogenates, resulting in conversion of 25-OH-D₃ to the *cis* and *trans* isomers of 10-keto-19-nor-25-hydroxyvitamin D₃ (2, 4, 60). Although this keto metabolite is biologically inactive, it is of interest because it comigrates on many chromatographic systems with 1,25(OH)₂D₃ and can be mistaken for 1,25(OH)₂D₃.

Additional chromatography with methylene chloride as one of the solvents separates these metabolites (4, 61).

To date, more than 40 metabolites of vitamin D have been structurally identified (62). On a weight basis, all of these metabolites are biologically less active than 1,25(OH)₂D. At present, many people believe that most of the side-chain and A-ring metabolites exist only in intoxicated states and are not relevant to the physiologic actions of vitamin D.

Regulation of Vitamin D Metabolism

Synthesis of vitamin D in the skin and its metabolism to 1,25(OH)₂D₃ are regulated carefully in the body. Sunlight regulates the total production of previtamin D₃ and vitamin D₃ in the skin. Once vitamin D enters the circulation, it can be stored in the fat for later use or metabolized in the liver to 25-OH-D. This hydroxylation step is feedback regulated. The most critical step in vitamin D metabolism is the production of 1,25(OH)₂D by the kidney. During periods of calcium deprivation, circulating ionized calcium concentrations decline. The parathyroid glands immediately detect this decrease and increase production and secretion of parathyroid hormone (63). The principal role of parathyroid hormone in calcium metabolism is to increase tubular reabsorption of calcium and renal production of 1,25(OH)₂D. 1,25(OH)₂D travels to the small intestine where it increases the efficiency of intestinal calcium absorption. 1,25(OH)₂D, along with parathyroid hormone, acts synergistically on osteoclasts, which in turn mobilize calcium stores from bone (Fig. 18.12).

It is generally believed that parathyroid hormone does not directly regulate the renal 25-OH-D-1α-hydroxylase. Evidence suggests that the hypophosphatemic effect of parathyroid hormone is ultimately responsible for enhancing the renal 1α-hydroxylase activity (64). In healthy men, phosphorus restriction caused an increase in circulating concentrations of 1,25(OH)₂D to 80% above control values; this increase was related to an increase in the production rate without any change in the metabolic clearance of this hormone (Fig. 18.13). With phosphorus supplementation, serum concentrations of 1,25(OH)₂D decreased abruptly, reaching a nadir within 2 to 4 days. After 10 days of supplementation, the mean concentration of 1,25(OH)₂D was 29% lower than the value measured when phosphorus intake was normal (Fig. 18.13).

Under certain physiologic circumstances, factors other than calcium, phosphorus, and parathyroid hormone may also modulate the activity of 25-OH-D-1-hydroxylase (4). The efficiency of intestinal calcium transport is enhanced when calcium demands are increased during pregnancy, lactation, and skeletal growth. Because 1,25(OH)₂D is the principal hormone responsible for regulation of calcium absorption in the small intestine, it is not surprising that growth hormone, estrogen, and prolactin can directly or indirectly enhance renal production of 1,25(OH)₂D in various in vitro and in vivo animal models (65, 66, 67, 68 and 69). Although estrogen appears to play a significant role in regulating production of 1,25(OH)₂D (70, 71, 72 and 73) in laying hens, it does not have that same effect in women. This statement is based on the observation that circulating

free concentrations of $1,25(\text{OH})_2\text{D}$ do not change in women before, during, and after menopause. Furthermore, circulating concentrations of $1,25(\text{OH})_2\text{D}$ are not altered in young women with estrogen deficiency caused by anorexia nervosa (71). A few authors have suggested that circulating concentrations of $1,25(\text{OH})_2\text{D}$ are slightly lower in osteoporotic women than in age-matched control subjects. Estrogen replacement in postmenopausal women increased circulating concentrations of $1,25(\text{OH})_2\text{D}$ (71).

The responsiveness of the renal 25-OH-D-1 α -hydroxylase to parathyroid hormone may be affected by either age or osteoporosis (74, 75 and 76). When osteoporotic women were infused with a synthetic fragment of parathyroid hormone, circulating concentrations of $1,25(\text{OH})_2\text{D}$ doubled within 24 hours in healthy young control subjects; no significant increase was observed in older osteoporotic patients (Fig. 18.14). Whether the moment-to-moment regulation of renal 25-OH-D-1 α -hydroxylase by parathyroid hormone is altered by aging or osteoporosis, and its role in the disease process, remain to be determined.

Figure 18.14. Effect of synthetic parathyroid hormone [hPTH-[1–34]] on levels of $1,25(\text{OH})_2\text{D}$ in normal subjects (*closed circles*) and patients with untreated osteoporosis (*open squares*). **A.** All values are expressed as the mean \pm SEM; * denotes significant differences at $P < .01$, and ** at $P < .05$, between the level in the patients and that in the controls at corresponding time points. Asterisks also refer to significant differences between the preinfusion baseline levels on ionized calcium (Ca^{2+}) (**B**), and inorganic phosphate (P_i) (**C**) in normal subjects (*closed circles*) and patients with osteoporosis (*open squares*). All values are expressed as means \pm SEM. There was no significant difference between the levels in the two groups. (Modified from Slovik DM, Adams JS, Neer RM, et al. N Engl J Med 1981;305:372–4, with permission.)

One study has suggested that the number of vitamin D receptors (VDRs) in the small intestine decreases in the elderly (77). This may help explain why the efficiency of

intestinal calcium absorption is decreased in elderly persons.

BIOLOGIC FUNCTIONS

Role in Calcium and Phosphorus Metabolism

The principal physiologic function of vitamin D in vertebrates, including humans, is to maintain intracellular and extracellular calcium concentrations within a physiologically acceptable range. Vitamin D accomplishes this goal through the action of $1,25(\text{OH})_2\text{D}$ on regulating calcium and phosphorus metabolism in the intestine and bone.

$1,25(\text{OH})_2\text{D}$ interacts with a specific high-affinity receptor in its respective target tissue (2, 3 and 4). This rare intracellular protein has been cloned and belongs to the superfamily of the steroid-hormone zinc-finger receptors (78). It selectively binds $1,25(\text{OH})_2\text{D}$ and retinoic acid X receptor (RXR) to form a heterodimeric complex that interacts with specific DNA sequences, known as vitamin D–responsive elements (62, 76, 79).

This nuclear binding activity results in transcription of hormone-specific mRNA, which in turn governs the translation of several proteins, including the calcium-binding protein (Fig. 18.15) (80). This protein is thought to be important in the transcellular transport of calcium in the intestine. The net result is increased absorption of calcium and phosphorus from intestinal contents into the circulation (Fig. 18.12).

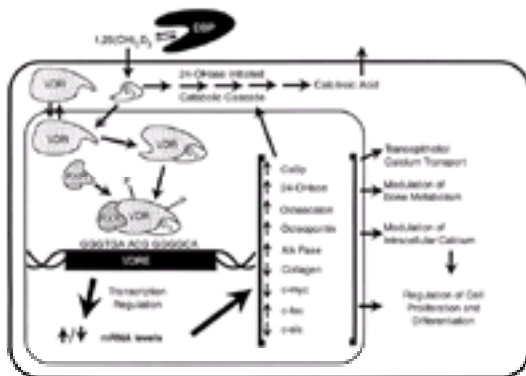

Figure 18.15. Proposed mechanism of action of $1,25(\text{OH})_2\text{D}_3$ in target cells, resulting in a variety of biologic responses. The free form of $1,25(\text{OH})_2\text{D}_3$ (D_3) enters the target cell and interacts with its nuclear vitamin D receptor (VDR), which is phosphorylated (P). The $1,25(\text{OH})_2\text{D}_3$ -VDR complex combines with the retinoic acid X receptor (RXR) to form a heterodimer, which in turn interacts with the vitamin D–responsive element (VDRE) to enhance or inhibit transcription of vitamin D–responsive genes such as $25(\text{OH})\text{D}$ -24-hydroxylase (24-OHase).

1,25(OH)₂D has a variety of effects on bone cells. In keeping with its principal physiologic function in maintaining serum calcium levels within an acceptable physiologic range for cellular activity, it enhances mobilization of calcium and phosphorus stores from bone at times of calcium deprivation. 1,25(OH)₂D induces stem cell monocytes to become mature osteoclasts (81). Once mature, osteoclasts lose their nuclear receptors for 1,25(OH)₂D and, therefore, are no longer responsive to this hormone (82).

Osteoblasts have nuclear receptors for 1,25(OH)₂D (1, 2, 3 and 4). In vitro studies have suggested that 1,25(OH)₂D increases alkaline phosphatase activity and gene expression of osteocalcin and osteopontin (83, 84). Although vitamin D is regarded as essential for the development and maintenance of a healthy skeleton, evidence is minimal to suggest an active role for 1,25(OH)₂D in bone mineralization. Studies in vitamin D-deficient rats either maintained on a high-calcium, high-phosphorus, vitamin D-deficient diet or infused with calcium and phosphorus to maintain serum calcium and phosphorus concentrations within the normal range showed that they could mineralize their bones in a fashion similar to that of rats maintained on a normal-calcium, normal-phosphorus, vitamin D-sufficient diet (85, 86). Thus, vitamin-D and its metabolites are not absolutely required for the bone ossification process. Instead, vitamin D is responsible for maintaining extracellular calcium and phosphorus concentrations in a supersaturated state that results in the mineralization of bone (87).

Other Biologic Actions of 1,25(OH)₂D

Much effort has been directed toward identifying actions of 1,25(OH)₂D that are not directly related to maintenance of calcium and phosphorus homeostasis because a variety of tissues that are not related to calcium metabolism possess nuclear receptors for 1,25(OH)₂D (Table 18.1) (2, 3 and 4, 88). Careful analysis has shown that these tissues as well as activated B and T lymphocytes (89, 90) and several cultured normal and tumor cell lines possess high-affinity, low-capacity 1,25(OH)₂D receptor-like proteins that are quantitatively similar to the intestinal receptor (2, 3 and 4).

Table 18.1 1,25(OH)₂D₃ Receptor Distribution in Mammalian Tissues

The first insight into a noncalcemic action of 1,25(OH)₂D₃ came when promyeloid leukemic cells (line M-1) that had nuclear receptors for 1,25(OH)₂D₃ responded to this hormone by differentiating into macrophages (91). 1,25(OH)₂D₃ induced time- and dose-dependent phagocytic activity and expression of cell surface antigens, including Fc and C3 receptors and lysozyme activity. Similar studies were done in a human promyelocytic leukemic cell line (HL-60). Cell growth was inhibited by as little as 10⁻⁹ M 1,25(OH)₂D₃ (92). 1,25(OH)₂D₃ was also found to be an effective antiproliferative agent for cultured tumor cells, such as tumor breast cells and melanoma cells, that possessed its nuclear receptor (93). The effect of 1,25(OH)₂D₃ on leukemia cells is reversible. When clones of HL-60 cells that possessed less than 10% of nuclear binding activity for 1,25(OH)₂D₃ were incubated with 1,25(OH)₂D₃, little difference in their proliferative activity was noted (94).

The effect of pharmacologic doses of 1,25(OH)₂D₃ on the immune system has been dramatically demonstrated in animal models for autoimmune diseases. 1,25(OH)₂D₃ markedly decreased the incidence of type I diabetes in NOD mice (Fig. 18.16) (95, 96). This calciotropic hormone also reduces development of thyroiditis and encephalomyelitis and prolongs the survival of transplanted skin allografts in mice (97, 98 and 99).

Figure 18.16. The effect of 1,25(OH)₂D₃ on reducing the incidence of diabetes mellitus type I in NOD mice. (From Mathieu C, Waer M, Laureys J, et al. *Endocrinology* 1994;136:866, 872, with permission.)

Human epidermal cells have nuclear receptors for $1,25(\text{OH})_2\text{D}_3$, which inhibited the proliferation and induced terminal differentiation of cultured murine and human keratinocytes in a dose-dependent manner ([100](#), [101](#)). These laboratory observations were put to practical use by development of $1,25(\text{OH})_2\text{D}_3$ and its analogues as safe and effective treatment for the hyperproliferative epidermal disorder psoriasis ([102](#), [103](#), [104](#), [105](#), [106](#) and [107](#)).

USE AND INTERPRETATION OF ASSAYS FOR VITAMIN D AND ITS METABOLITES

Vitamin D and 25-OH-D Assays

The first assays for vitamin D were chick and rat bioassays ([108](#), [109](#)). The rat bioassay, commonly known as the line-test, was used widely to determine the concentration of vitamin D in fortified foods such as milk ([109](#)). Development of specific assays for vitamin D and its biologically important metabolites made these bioassays obsolete.

A specific assay that measures circulating concentrations of vitamin D_2 and vitamin D_3 ([110](#), [111](#)) has been of great value in evaluating circulating concentrations of vitamin D after exposure to quantitative doses of UV-B radiation ([50](#)). It has also been useful as a provocative test for determining which patients with intestinal malabsorption syndromes are at risk for developing vitamin D deficiency ([47](#)). In this assay, the half-life of circulating vitamin D is approximately 24 hours. The serum concentration of vitamin D at any time depends on both the most recent ingestion of vitamin D and the last exposure to sunlight. The normal range of serum vitamin D is 0 to 310 nmol/L (0–120 ng/mL). Consequently, serum vitamin D_2 and vitamin D_3 concentrations are of little value in determining the vitamin D status of a patient.

Circulating concentrations of 25-OH-D are measured by a specific competitive protein-binding assay using the vitamin D-binding protein ([112](#), [113](#), [114](#) and [115](#)). Because the half-life of circulating 25-OH-D is approximately 3 weeks, the steady-state concentration of 25-OH-D in the circulation sums the concentrations of vitamin D derived from diet and photoproduction over several weeks to several months ([108](#)). 25-OH- D_2 and 25-OH- D_3 can be measured separately ([115](#), [116](#)). Originally, it was thought that 25-OH- D_2 reflected the dietary component of vitamin D and 25-OH- D_3 reflected exposure to sunlight. Because milk is fortified with either vitamin D_2 or vitamin D_3 , however, the separate measurement of these metabolites is of little value.

Measurement of the circulating concentration of 25-OH-D is most valuable for determining the vitamin D status of an individual. The normal circulating concentration of 25-OH-D is usually reported to be between 20 and 150 nmol/L (8–60 ng/mL). Serum values below 25 nmol/L (10 ng/mL) are considered to indicate impending or overt vitamin D deficiency. Although most diagnostic laboratories report the upper limit of the

normal range for 25-OH-D to 150 nmol/L (60 ng/mL), a circulating concentration of 250 nmol/L (100 ng/mL) in lifeguards after a full summer of exposure to sunlight is not surprising and is considered normal. Vitamin D intoxication is usually associated with 25-OH-D concentrations above 375 nmol/L (150 ng/mL) with attendant hypercalcemia and hyperphosphatemia (63, 108).

The assay for serum 25-OH-D is clinically useful for determining vitamin D deficiency in patients with intestinal malabsorption syndromes, severe hepatic failure, and the nephrotic syndrome. It is the hallmark assay for determining vitamin D deficiency in very young and elderly individuals.

1,25-Dihydroxyvitamin D Assays

1,25(OH)₂D levels in serum and plasma can be specifically measured with a competitive receptor-binding assay using a nuclear/cytosolic receptor for 1,25(OH)₂D. The assay involves use of a bovine thymus 1,25(OH)₂D receptor that recognizes 1,25(OH)₂D₂ and 1,25(OH)₂D₃ equally well (76, 108, 117, 118 and 119). A bioassay was developed that uses cultured calvaria (120). This assay, which is tedious to conduct, measures directly the biologic activity of 1,25(OH)₂D in serum.

The half-life of circulating 1,25(OH)₂D has been estimated to be between 4 and 6 hours. Normal serum values range between 38 and 144 pmol/L (16–60 pg/mL). As vitamin D deficiency develops, the body responds by increasing production and secretion of parathyroid hormone (Fig. 18.12). Parathyroid hormone in turn enhances the 1-hydroxylation of 25-OH-D. Thus, secondary hyperparathyroidism associated with vitamin D deficiency accelerates the conversion of 25-OH-D to 1,25(OH)₂D. Because the circulating concentration of 25-OH-D is about three orders of magnitude higher than that of 1,25(OH)₂D, even low levels of 25-OH-D in the blood can provide enough substrate for the formation of 1,25(OH)₂D. Thus, a patient who is becoming vitamin D deficient will still have enough 25-OH-D substrate for the renal 25-OH-D-1α-hydroxylase. As a result, a patient who has low stores of vitamin D and is becoming vitamin D deficient can have low, normal, or even high circulating concentrations of 1,25(OH)₂D (63). For example, if a patient who is vitamin D deficient is taken from his or her dwelling and exposed to sunlight on the way to the hospital or obtains vitamin D from dietary sources in the hospital, the vitamin D is rapidly metabolized to 25-OH-D and then to 1,25(OH)₂D. As a result, circulating levels of 1,25(OH)₂D can be elevated to twice normal levels for several months (50). Thus, serum 1,25(OH)₂D concentrations are of little value in evaluating vitamin D deficiency. In an absolute vitamin D deficiency state, no circulating 1,25(OH)₂D is detected.

Measurement of circulating 1,25(OH)₂D levels has been of great value to clinicians for evaluating patients with inherited and acquired disorders of 25-OH-D metabolism. Patients with chronic renal failure, hyperphosphatemia, hypoparathyroidism, pseudohypoparathyroidism, tumor-induced osteomalacia, hypercalcemia of malignancy (in most cases), or vitamin D-dependent rickets type I (an inborn error reducing the

conversion of 25-OH-D to 1,25(OH)₂D) often have low circulating concentrations of 1,25(OH)₂D ([2](#), [3](#) and [4](#), [35](#), [63](#), [108](#)). Serum concentrations of 1,25(OH)₂D are above normal in some patients with primary hyperparathyroidism; vitamin D–dependent rickets type II (an inborn error in which the recognition of 1,25(OH)₂D by target tissue receptors is defective); chronic granulomatous disorders such as sarcoidosis, tuberculosis, and silicosis; and lymphoma. Patients with chronic granulomatous disorders and some lymphomas that activate macrophages and lymphoma cells, respectively, can 1α-hydroxylate 25-OH-D, a process that is inhibited by glucocorticoids and ketoconazole ([2](#), [3](#) and [4](#), [63](#), [76](#), [108](#)).

RECOMMENDATIONS

Exposure to Sunlight

It is not often appreciated that casual exposure to sunlight during everyday activities provides most humans with their vitamin D requirement ([121](#)). Increased awareness from scientific and lay press reports about the causal relationship between long-term exposure to sunlight and skin cancer and skin wrinkling has made sunscreen use more prevalent ([10](#)). Children and young active adults are often outdoors for short periods of time at least two or three times per week, and this casual exposure to sunlight will provide their vitamin D requirement.

Elderly persons, on the other hand, have a decreased capacity to produce vitamin D in their skin. In addition, they are likely to heed the warnings about the damaging effects of sunlight and use a sunscreen and wear more clothing, thus preventing cutaneous synthesis of vitamin D₃. Because many elderly individuals do not drink milk because of a lactase deficiency or because they believe that they no longer need milk (it is only for growing children), their only source of vitamin D is from either a multivitamin pill containing vitamin D or exposure to sunlight. If elderly persons do not take advantage of the beneficial effect of sunlight, they can develop vitamin D deficiency, which can result in secondary hyperparathyroidism. This condition accelerates osteoporosis and can cause a mineralization defect in bones, resulting in adult rickets or osteomalacia. The net effect of this process is to weaken bones and increase the risk of fracture ([121](#), [122](#), [123](#), [124](#), [125](#) and [126](#)), and several studies indicate that vitamin D deficiency does put elderly individuals at risk of developing hip fractures. An epidemiologic survey in a controlled nursing-home environment revealed that of both free-living and institutionalized elderly persons who took a vitamin supplement or drank two to three glasses of milk per day, approximately 80% were overtly to borderline vitamin D deficient by the end of the winter ([Fig. 18.17](#)) ([127](#)). Thus, especially for elderly people, exposure to sunlight in the morning or afternoon in the spring, summer, and fall (depending on skin sensitivity to sunlight) will provide the recommended vitamin D requirement and will permit them to store any excess vitamin D in fat for use during the winter months. Elderly individuals need not be exposed to prolonged periods of sunlight, because the amount they can produce in this period of time should satisfy their body's requirement.

Figure 18.17. Seasonal averages of the percentage of volunteers with circulating concentrations of 25(OH)D > 37.5 nmol/L (*unshaded areas*) and 25(OH)D > 25.0 nmol (*shaded areas*). Volunteers include those with (+D) and without (-D) vitamin D supplements and free-living subjects (F), who were without supplements. (From Webb AR, Pilbeam C, Hanafin N, et al. *J Clin Nutr* 1990;51:1075–81.)

Therefore, I recommend 5 to 30 minutes of exposure of hands, forearms, and face two or three times a week to a suberythemal amount of sunlight for elderly persons in Boston (depending on their sensitivity to sunlight). This is based on our observation that a healthy individual whose whole body is exposed to one minimal erythemal dose of simulated sunlight will have circulating vitamin D concentrations comparable to those from ingestion of 10,000 to 25,000 IU of vitamin D. After exposure to sunlight for a short period, elderly individuals should apply a sunscreen with a protection factor of at least SPF-8; this will protect them from the chronic damaging effects of excessive exposure to sunlight (10).

Vitamin D Supplements

A variety of pharmaceutical preparations are available by prescription, including a capsule that contains 50,000 IU of vitamin D₂ and an oil preparation that contains 100,000 IU/mL. Pharmaceutical preparations containing 50,000 IU of vitamin D₂ have been of value in treating vitamin D deficiency in elderly patients and in patients with intestinal malabsorption syndromes, hepatic failure, and nephrotic syndrome. The dose is generally 50,000 IU once per week for 8 weeks. Circulating concentrations of 25-OH-D usually increase into the midnormal range (~ 100 nmol/L, 40 ng/mL). For those unable to ingest a capsule containing vitamin D, an alternative source is an oil-based preparation. I usually recommend that patients take 800 IU each day until circulating concentrations of 25-OH-D are in the midnormal range. Once these concentrations have returned to normal, I recommend an over-the-counter multivitamin containing 400 IU of vitamin D. Because most pharmaceutical companies put in 1.5 to 2 times the amount of vitamin D stated on the label, patients often receive up to 800 IU of vitamin D per day. This amount usually suffices to maintain adequate circulating

concentrations of 25-OH-D ([Fig. 18.18](#)).

Figure 18.18. Distribution of circulating concentrations of 25(OH)D for residents with (*closed circles*) and without (*x*) vitamin D supplements in September (**A**) and February (**B**). Each data point represents $n - 10$ to n ; e.g., 75 represents all samples between 65 and 75.0 nmol/L. (From Webb AR, Pilbeam C, Hanafin N, et al. *J Clin Nutr* 1990;51:1075–81, with permission.)

Recommended Dietary Allowance of Vitamin D for Humans

Beginning in the 1930s, milk was fortified with 400 IU (10 μg of vitamin D_2 per quart). This fortification eliminated rickets as a significant health problem in the United States and other countries that used it. During the 1940s and early 1950s, milk in Great Britain was supplemented with up to 2000 IU of vitamin D to compensate for wartime nutritional deprivation that British children had undergone. Manufacturers often put 1.5 to 2 times as much vitamin D in the food preparations to compensate for anticipated vitamin D breakdown during shelf storage. As a result, an epidemic of hypercalcemia in neonates appeared ([128](#)). Although the hypercalcemia was easily reversible, some of the infants were thought to have suffered from hypercalcemia-induced brain damage. As a result, even though there was little scientific documentation, laws were passed in many European countries preventing fortification of milk and infant formulas with vitamin D. In August 1997, the Institute of Medicine in conjunction with the National Academy of Sciences recommended that the recommended requirement for vitamin D should be as an adequate intake (AI) rather than an RDA ([129](#)) (see Appendix [Table II-A-2-b-4](#)).

In the United States, infant formula is fortified with 400 IU of vitamin D per quart. It has been estimated that a minimum of 100 IU of vitamin D daily is required to prevent rickets in infants. To provide a margin of safety, the recommended AI was set at 5 μg (200 IU) for infants from birth to 6 months of age, which is approximately the amount consumed by formula-fed normal infants. Because human milk contains little vitamin D, it has been recommended that breast-fed infants be exposed to sunlight or ingest formula supplemented with vitamin D. The recommended allowance for children older than 6

months has been set at 5 µg (200 IU) to satisfy their requirement during rapid periods of bone growth and mineralization.

In the mid-1960s, studies in infants fed either 300 IU, 350 to 550 IU, or 1380 to 2170 IU daily demonstrated no differences in growth in length or weight or in serum calcium concentrations. Earlier studies, however, suggested that daily ingestion of 2000 to 5000 IU of vitamin D in the diet caused hypercalcemia and all of its clinical features (128).

Vitamin D–deficiency osteomalacia is associated with intakes below 100 IU of vitamin D per day. The recommended AI of 5 µg (200 IU) for adults is reasonable as long as there is adequate sun exposure. Otherwise, 400 to 800 IU/day may be needed to prevent vitamin D deficiency (35).

Aging does not alter vitamin D absorption (121). Most studies, however, have been conducted in otherwise healthy older individuals who received some exposure to sunlight. Thus, the combination of exposure to sunlight and 200 IU of vitamin D will suffice for adults under 50 years of age. However, the vitamin D requirement for older adults appears from the available literature to be higher. The newly recommended AIs for ages 51 to 70 and 71+ years are 10 µg (400 IU) and 15 µg (600 IU), respectively. The exact amount of vitamin D required by adults who are not exposed to sunlight is less well understood.

Since there was no supporting literature that there is an increased vitamin D requirement during pregnancy and lactation, the recommended AI for both was 5 µg (200 IU). However, in the absence of adequate exposure to sunlight, an intake of 400 IU is prudent.

The Institute of Medicine also provided guidelines for tolerable upper intake levels. For infants and neonates 0 to 12 months, the limit was set at 25 µg/day. For those older than 1 year and for pregnancy and lactation, the upper intake level was set at 50 µg/day.

[Selected Readings](#)

Vitamin E is unique in human nutrition because for decades it was “a vitamin looking for a disease” (1). Most water-soluble vitamins are enzyme cofactors; fat-soluble vitamins, such as vitamins A, D, and K, have specific roles in vision, bone formation, and blood clotting, respectively. Thus, it was anticipated that vitamin E would have a specific role in some metabolic function. But in 75 years of study, this has not proven to be the case. The literature is replete with studies describing a variety of vitamin E–deficiency

symptoms in various species, leading to confusion about its function in humans. But, this range of symptoms is not surprising given that its major function is as an antioxidant. Consequently, vitamin E–deficiency symptoms in target tissues depend not only upon vitamin E content, uptake, and turnover, but also on the degree of oxidative stress and polyunsaturated fatty acid (PUFA) content. Furthermore, vitamin E activity depends upon an “antioxidant network” involving a wide variety of antioxidants and antioxidant enzymes, which maintains vitamin E in its unoxidized state, ready to intercept and scavenge radicals (2). In addition, vitamin E being fat-soluble is transported in plasma lipoproteins and partitions into membranes and fat-storage sites, where it has the unique role of protecting PUFAs from oxidation.

The antioxidant function of vitamin E cannot be fulfilled by just any antioxidant. Plasma vitamin E is apparently regulated by the liver α -tocopherol transfer protein (α -TTP) (3), and in humans, a genetic defect in α -TTP results in severe vitamin E deficiency (4). α -TTP is necessary for hepatic intracellular α -tocopherol transfer and likely is necessary for α -tocopherol incorporation into nascent very low density lipoproteins (VLDLs) (5).

This chapter describes the structure-function relationships of vitamin E, its antioxidant properties, its lipoprotein transport and delivery to tissues, and its role in human health and disease.

HISTORICAL PERSPECTIVE

The first two decades of vitamin E history were reviewed by Mason (6), a pioneer in studies of vitamin E. Vitamin E deficiency was first described by Evans and Bishop (7) at the University of California in Berkeley in 1922 during their investigations of infertility in rats fed rancid lard. In 1936, Evans et al. (8) isolated a factor from wheat germ with the biologic activity of vitamin E. They named this factor, “ α -tocopherol” a name derived from the Greek *tokos* (offspring) and *pherein* (to bear) with an “ol” to indicate that it was an alcohol. Two other tocopherols, b- and g-, were isolated from vegetable oils in the subsequent year, with lower biologic activities than α -tocopherol (9). This was the first description of different naturally occurring forms of vitamin E and demonstration that α -tocopherol is the most effective form in preventing vitamin E–deficiency symptoms.

These early observations formed the basis for determining the “biologic activity” of vitamin E. As defined by Machlin (10), the biologic activity of vitamin E is based on its ability to prevent or reverse specific vitamin E–deficiency symptoms (e.g., fetal resorption, muscular dystrophy, and encephalomalacia). The most popular, though most tedious and time-consuming, assay for the biologic activity of vitamin E is the fetal resorption assay (10). Here, vitamin E–depleted virgin female rats are mated with normal males. After successful mating, various levels of single vitamin E forms are fed in several divided doses to the females, which are killed 20 to 21 days after mating. The number of living, dead, and resorbed fetuses are counted, and the percentage of live young determined. Thus, vitamin E biologic activity depends on the amount necessary to maintain the maximum number of live fetuses.

Vitamin E–deficiency symptoms in various animal species were described by Machlin (10) in his comprehensive chapter on vitamin E. Necrotizing myopathy has been

observed in vitamin E–deficient monkeys, pigs, rats, dogs, rabbits, goats, guinea pigs, horses, cows and calves, sheep and lambs, mink, chicken, ducks, turkeys, salmon, catfish, antelope, and elephants. Fetal death and resorption was a symptom of vitamin E deficiency in rats, mice, guinea pigs, cows, pigs, sheep, and chickens. Anemia has been observed in rats, pigs, monkeys, salmon, catfish, and chickens. Lipofuscin (a fluorescent pigment of “aging”) frequently accumulates in tissues of vitamin E–deficient animals. Based on the symptoms observed in animals, attempts were made to treat humans with muscular dystrophy or anemia by supplementation with vitamin E. Except for anemia of prematurity (11), infants fed formulas high in PUFAs and iron (12), or children with anemia associated with protein-calorie malnutrition (13), these vitamin E trials were largely unsuccessful. These negative findings gave credence to the viewpoint, which we now know is incorrect, that vitamin E deficiency does not occur in humans.

Horwitt (14, 15) attempted to induce vitamin E deficiency in men by feeding a diet low in vitamin E for 6 years to volunteers at the Elgin State Hospital in Illinois. After about 2 years, their serum vitamin E levels decreased into the deficient range. Although their erythrocytes were more sensitive to peroxide-induced hemolysis, anemia did not develop. In 1968, the Food and Nutrition Board of the U.S. National Academy of Sciences (16) set for the first time a recommended daily allowance (RDA) for vitamin E: 30 mg for adult males and 25 mg for adult females. Subsequently, the RDA was reduced on the basis of observations that vitamin E intakes for most of the U.S. population were below these amounts and that PUFA intakes were not as high as in these experimental diets (10).

Not until the mid-1960s was vitamin E deficiency described in children with fat malabsorption syndromes, principally abetalipoproteinemia and cholestatic liver disease, as reviewed by Sokol (17). By the mid-1980s, it was clear that the major vitamin E–deficiency symptom in humans was a peripheral neuropathy characterized by degeneration of the large caliber axons in the sensory neurons (17). Subsequently, vitamin E–deficient patients with peripheral neuropathies without fat malabsorption were described (18). Studies in such patients opened new avenues in vitamin E investigations because they were found to have a genetic defect in hepatic α -TTP (4).

STRUCTURES AND NOMENCLATURE

Vitamin E is the collective name for molecules that exhibit the biologic activity of α -tocopherol, including all tocol and tocotrienol derivatives, as reviewed by Sheppard et al. (19). Vitamin E occurs naturally in eight different forms: four tocopherols and four tocotrienols, which have similar chromanol structures: trimethyl (α -), dimethyl (β - or γ -), and monomethyl (δ -) (Fig. 19.1). Tocotrienols differ from tocopherols in having an unsaturated side chain.

Figure 19.1. Structures of tocopherols and tocotrienols. There are 8 naturally occurring forms of vitamin E, the 4 tocopherols are shown in **A** and the 4 tocotrienols in **B**. Shown is the natural *RRR*- α -tocopherol stereochemistry; the three chiral centers give rise to 8 different stereoisomers in synthetic vitamin E (*all rac*- α -tocopherol): *RRR*-, *RRS*-, *RSR*-, *RSS*-, *SRR*-, *SSR*-, *SRS*-, *SSS*-.

Unlike most other vitamins, chemically synthesized α -tocopherol is not identical to the naturally occurring form. α -Tocopherol synthesized by condensation of trimethyl hydroquinone with racemic isophytol (20) contains eight stereoisomers, arising from the three chiral centers (Fig. 19.1: 2,4', and 8') and is designated *all-rac*- α -tocopherol (incorrectly called *d*, *l*- α -tocopherol). The naturally occurring and most biologically active form, *RRR*- α -tocopherol (formerly called *d*- α -tocopherol) constitutes only one of the eight stereoisomers present in *all rac*- α -tocopherol. The other stereoisomers have lower biologic activity than *RRR*- α -tocopherol, with the 2*S*-forms generally having lower activity than the 2*R*-forms (21, 22).

Vitamin E supplements often contain esters of α -tocopherol, such as α -tocopheryl acetate, succinate, or nicotinate. The ester form prevents oxidation of vitamin E and prolongs its shelf life. Except in individuals with malabsorption syndromes, these esters are readily hydrolyzed in the gut and are absorbed in the unesterified form (23).

BIOLOGIC FUNCTION

Vitamin E functions *in vivo* as a chain-breaking antioxidant that prevents propagation of free radical damage in biologic membranes (24, 25, 26 and 27). In vitamin E deficiency, anemia occurs as a result of free radical damage (28). Similarly, peripheral neuropathy likely occurs because of free radical damage to the nerves (29).

Vitamin E is a potent peroxy radical scavenger and especially protects PUFAs within phospholipids of biologic membranes and in plasma lipoproteins (26). When lipid hydroperoxides are oxidized to peroxy radicals (ROO^\bullet), these react 1000 times faster with vitamin E (Vit E-OH) than with PUFA (RH) (2). The phenolic hydroxyl group of

tocopherol reacts with an organic peroxy radical to form the corresponding organic hydroperoxide and the tocopheroxyl radical (Vit E-O[•]) (30):

In the presence of vitamin E: $\text{ROO}^\bullet + \text{Vit E-OH} \rightarrow \text{ROOH} + \text{Vit E-O}^\bullet$

In the absence of vitamin E: $\text{ROO}^\bullet + \text{RH} \rightarrow \text{ROOH} + \text{R}^\bullet$
 $\text{R}^\bullet + \text{O}_2 \rightarrow \text{ROO}^\bullet$

In this way vitamin E acts as a chain-breaking antioxidant, preventing the further autooxidation of lipids. Further information concerning the reactions of tocopherols and tocotrienols in vivo and in vitro can be found in the extensive review by Kamal-Eldin and Appelqvist (31).

Antioxidant Network

The tocopheroxyl radical (Vit E-O[•]) formed in membranes emerges from the lipid bilayer into the aqueous domain. Here the tocopheroxyl radical reacts with vitamin C (or other reductants serving as hydrogen donors, AH), thereby oxidizing the latter and returning vitamin E to its reduced state.

$\text{Vit E-O}^\bullet + \text{AH} \rightarrow \text{Vit E-OH} + \text{A}^\bullet$

Biologically important hydrogen donors, which have been demonstrated in vitro to regenerate tocopherol from the tocopheroxyl radical, include ascorbate (vitamin C) and thiols (32), especially glutathione (33, 34, 35 and 36). Subsequently, the vitamin C and thiol radicals can be reduced via metabolic processes. This phenomenon has led to the idea of "vitamin E recycling," in which the antioxidant function of oxidized vitamin E is continuously restored by other antioxidants (2). This antioxidant network depends upon the supply of aqueous antioxidants and the metabolic activity of cells.

Structure-Function Relationships of Vitamin E Forms

The biologic activities of the various vitamin E forms correlate roughly with their antioxidant activities; the order of relative peroxy radical scavenging reactivities of α -, β -, γ -, and δ -tocopherols (100, 60, 25, 27, respectively) (37) is similar to the relative order of their biologic activities (1.5, 0.75, 0.15, 0.05 mg/IU, respectively), as determined by the classical fetal resorption assay in rats (38). However, biologic activities are unlikely to depend solely on antioxidant activity; indeed, some forms of vitamin E show high antioxidant activities but rather poor biologic activities. For example, α -tocotrienol has only one-third the biologic activity of α -tocopherol (38, 39), yet it has higher (40) or equivalent (41) antioxidant activity. A vitamin E analogue (2,4,6,7-tetramethyl-2-(4',8',12'-trimethyltridecyl)-5-hydroxy-3,4-dihydrobenzofuran), while showing equivalent biologic activity to *RRR*- α -tocopherol, has 1.5 times the antioxidant activity (43). Furthermore, the eight different stereoisomers of synthetic vitamin E (*all rac*- α -tocopherol) have equivalent antioxidant activity but different biologic

activities (21).

Overall, the highest biologic activity is found in molecules with three methyl groups and a free hydroxyl group on the chromanol ring in which the phytyl tail meets the ring in the *R*-orientation (Fig. 19.1). This specific requirement for biologic, but not chemical, activity can best be rationalized by the preferential interactions of *RRR*- α -tocopherol with some stereospecific ligands in cells. One such ligand clearly is the hepatic protein α -TTP.

Hosomi et al. (43a) have demonstrated that the relative affinities of α -TTP towards the various forms of vitamin E (calculated from the degree of competition with *RRR*- α -tocopherol) were *RRR*- α -tocopherol = 100%; *b*-tocopherol = 38%; *g*-tocopherol = 9%; *d*-tocopherol = 2%; *a*-tocopheryl acetate = 2%; *a*-tocopheryl quinone = 2%; *SRR*- α -tocopherol = 11%; *a*-tocotrienol = 12%; and Trolox = 9%. They concluded that the affinity of vitamin E analogs for α -TTP is one of the critical determinants for the biological activity of vitamin E.

In addition to its antioxidant function, *a*-tocopherol shows structure-specific effects on several enzyme activities and membrane properties (44). The most convincing work in this respect is on the regulation of vascular smooth muscle cell proliferation and protein kinase C activity (45, 46 and 47) and on the suppression of arachidonic acid metabolism via phospholipase A_2 inhibition (48).

Thus, Clement et al. (48a) report that *a*-tocopherol, but not *b*-tocopherol, prevents the phosphorylation of protein kinase Ca (PKCa) and suggest that *a*-tocopherol decreases PKCa-activity by this mechanism.

g-, *b*- or *d*-Tocopherols, unlike *a*-tocopherol, can be nitrated (48b, 48c and 48d) in vitro, a potentially important reaction with nitric oxide (48d). The physiologic significance of the nitration of tocopherols, however, remains to be demonstrated.

Only one of the vitamin E forms, *g*-tocotrienol, enhances the degradation of the enzyme 3-hydroxy-3-methyl glutaryl coenzyme A (HMGCoA) reductase, which is the rate-controlling step in cholesterol biosynthesis (48e, 48f and 48g). Furthermore, the addition of *g*-tocotrienol and lovastatin (a drug that competitively inhibits HMGCoA reductase) to the incubation medium of HepG2 cells decreased both the amount and the activity of HMGCoA reductase (48f). In this regard, *g*-tocotrienol shows potent hypocholesterolemic effects in hypercholesterotemic humans in some studies (48h) but not in others (48i, 48j and 48k). Because the presence of *a*-tocopherol reduces the inhibitory effect of *g*-tocotrienol on HMGCoA reductase (48j, 48l), a possible explanation of these disparate findings may be the higher *a*-tocopherol/*g*-tocotrienol ratio of the preparations used in the latter studies (48i, 48j and 48k). On the other hand, when mixed tocopherols and tocotrienols (16 mg *a*-tocopherol, 40 mg *g*- and *a*-tocotrienols) were given to patients with hyperlipemia and carotid stenosis, carotid atherosclerotic plaques significantly regressed in the treated group relative to matched controls (48m).

Thus, various forms of vitamin E show specific physiologic effects not directly related to

their antioxidant activities.

DIETARY CONSIDERATIONS

The richest dietary sources of vitamin E are edible vegetable oils ([19](#)). These oils contain all four homologues: α -, β -, γ -, and δ -tocopherols in varying proportions. *RRR*- α -tocopherol is especially high in wheat germ oil, safflower oil, and sunflower oil. Soybean and corn oils contain predominantly γ -tocopherol, as well as some tocotrienols. Cottonseed oil and palm oil contain both α - and γ -tocopherols in equal proportion. In addition, palm oil contains large amounts of α - and γ -tocotrienols ([49](#)). Unprocessed cereal grains and nuts are also good sources of vitamin E; fruits and vegetables contain smaller amounts. Meats, especially animal fat, also contain vitamin E.

An important source of vitamin E in the American diet is the supplement pill. Many Americans believe that supplemental antioxidants, especially vitamin E, are beneficial. Vitamin E supplements are sold as esters (acetate, succinate, nicotinate, etc.) of either natural (*RRR*-) or synthetic forms (all *rac*-) of α -tocopherol. The vitamin E pills containing natural vitamin E (*RRR*- α -tocopherol) are labeled “ δ α -tocopherol,” while those containing synthetic vitamin E (all *rac*- α -tocopherol), which consist of 8 different stereoisomers, are labeled “*dl* α -tocopherol.” Because the relative bioactivities of *RRR*- α -tocopheryl acetate and all-*rac*- α -tocopheryl acetate by the resorption-gestation assay in rats is 1.36:1 (see Appendix [Table IV-A-23-b](#)), pills made with “natural” vitamin E need contain only 74% by weight of those made with synthetic vitamin E.

The biopotency of *RRR*- α -tocopherol relative to all-*rac*- α -tocopherol may well be considerably higher. When acetate esters of *RRR*- α -tocopherol labeled with 3 deuterium atoms and all-*rac*- α -tocopherol labeled with 6 were administered orally to human subjects, the relative bioavailability of the d_3/d_6 labeled compounds was 2.0 ± 0.06 , determined by comparing the areas-under-the-curves of the plasma response with time ([49a](#)).

Kiyose et al. ([48b](#), [49c](#)) demonstrated that 2*R*-isomers, but only small amounts of 2*S*-isomers, were detectable in the serum of human subjects administered all-*rac*- α -tocopheryl acetate. Furthermore, the increase in the plasma concentration of *RRR*- α -tocopherol after daily doses of 100 mg *RRR*- α -tocopheryl acetate for 28 days was similar to the increase in plasma α -tocopherol after daily doses of 300 mg of all-*rac*- α -tocopheryl acetate for the same period. They suggest that the ratio of bioavailabilities is closer to 3 ([49b](#)).

Therefore, in view of the current availability of isotopically labeled tocopherol compounds and chiral HPLC columns, the relative bioavailabilities of various tocopherol species in humans clearly warrant reinvestigation.

INTESTINAL ABSORPTION

Vitamin E Absorption Requires Bile and Pancreatic Secretions

Absorption of vitamin E from the intestinal lumen depends upon processes necessary for fat digestion and uptake into enterocytes. Pancreatic esterases are required for release of free fatty acids from dietary triglycerides. Bile acids, monoglycerides, and free fatty acids are important components of mixed micelles (50).

Esterases are also required for the hydrolytic cleavage of tocopheryl esters (51), a common form of vitamin E in dietary supplements. Generally, these esterases are quite effective; the apparent absorption of deuterated *RRR*- α -tocopherol was similar whether administered as α -tocopherol, α -tocopheryl acetate, or α -tocopheryl succinate (23).

Bile acids, which are needed for the formation of mixed micelles, are essential for vitamin E absorption (52, 53). In the absence of either pancreatic or biliary secretions, vitamin E absorption and secretion into the lymphatic system is poor. In the absence of both, only negligible amounts of vitamin E are absorbed (52, 53, 54 and 55). Thus, vitamin E deficiency occurs as a result of malabsorption in patients with biliary obstruction, cholestatic liver disease, pancreatitis, or cystic fibrosis (18).

Vitamin E Absorption Requires Chylomicron Synthesis and Secretion

Movement of vitamin E through the absorptive cells is not well understood; no intestinal tocopherol-transfer proteins have been described. In the intestinal mucosa, chylomicrons containing triglycerides, free and esterified cholesterol, phospholipids, and apolipoproteins (especially apolipoprotein (apo) B-48) are synthesized. In addition, fat-soluble vitamins, carotenoids, and other fat-soluble dietary components are incorporated into chylomicrons. Subsequently, chylomicrons containing these fats are secreted by the intestine into the lymph (56). Even in healthy individuals, the efficiency of vitamin E absorption is low (~15–45%), estimated by using radioactively labeled α -tocopherol (57). The relative uptake decreases as the amount of vitamin E ingested increases, as shown in thoracic-duct-cannulated rats (58).

Differences in plasma concentrations of various forms of vitamin E are often assumed to result from differences in intestinal absorption, but this is not the case. Studies using deuterated tocopherols have shown that discrimination between forms of vitamin E does not occur during their absorption by the intestine and their secretion in chylomicrons (59, 60). Various forms of vitamin E, such as α - and γ -tocopherols (61, 62), or *RRR*- and *SRR*- α -tocopherols (59, 60), showed similar apparent efficiencies of intestinal absorption and secretion in chylomicrons. As shown in Fig. 19.2, all dietary forms of vitamin E are absorbed and secreted into chylomicrons.

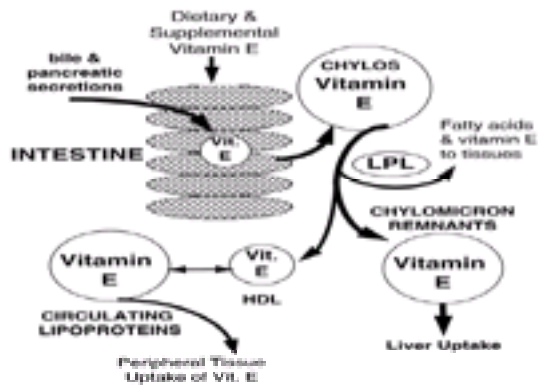

Figure 19.2. Pathways for absorption of vitamin E and its delivery to tissues during chylomicron catabolism. Vitamin E absorption requires bile acids (secreted from the liver) and fatty acids and monoglycerides (released from dietary fat by pancreatic enzymes) for micelle formation. Following uptake into enterocytes of the intestine, all forms of dietary vitamin E are incorporated into chylomicrons (chylos). These triglyceride-rich lipoproteins are secreted into the circulation where lipolysis by lipoprotein lipase (*LPL*) bound to the endothelial lining of capillary walls takes place. The resultant chylomicron remnants are mainly taken up by the liver. During lipolysis, various forms of vitamin E can be transferred to tissues or to high-density lipoproteins (*HDL*). Vitamin E can exchange between *HDL* and other circulating lipoproteins, which can also deliver vitamin E to peripheral tissues.

PLASMA TRANSPORT

Distribution of Vitamin E to Tissues During Triglyceride-Rich Lipoprotein Lipolysis

During chylomicron catabolism in the circulation, some of the newly absorbed vitamin E is transferred to circulating lipoproteins and some remains with the chylomicron remnants. Chylomicron catabolism is quite rapid—when rats were injected with [³H]-tocopherol-labeled chylomicrons, the radioactivity disappeared from the circulation in about 5 minutes (63, 64). During delipidation of chylomicrons by lipoprotein lipase, the size of the chylomicron triglyceride core is reduced, and excess surface is created. This excess surface is transferred to high-density lipoproteins (*HDLs*) (65). During this process, vitamin E is also transferred to *HDLs*. Because *HDLs* readily transfer vitamin E to other lipoproteins (66, 67, 68, 69 and 70), vitamin E is distributed to all circulating lipoproteins (Fig. 19.2). Previously, this was thought to be a spontaneous process. However, Kostner et al. (71) demonstrated that the phospholipid transfer protein (*PLTP*) isolated from human plasma catalyzed vitamin E exchange between lipoproteins. The transfer activity was 2.45 ± 0.88 nmol/mL/h, a rate that represents transfer of approximately 10% of the plasma vitamin E per hour.

Requirement for VLDL Synthesis in the Preferential Secretion of α -Tocopherol

from the Liver

Following partial delipidation by lipoprotein lipase and acquisition of apo-E, chylomicron remnants are taken up by the liver parenchymal cells. The precise mechanisms for chylomicron remnant uptake remain under intense investigation; several pathways involving lipoprotein lipase, apo-E, LDL-receptor-related protein (LRP), as well as the LDL receptor have been proposed (72, 73). The remnants taken up by the liver likely contain a major portion of absorbed vitamin E.

Once chylomicron remnants reach the liver, the dietary fats are repackaged and secreted into the plasma in VLDLs (65). Like chylomicrons, VLDLs have a triglyceride-rich core, but they have apolipoprotein B-100 (apo-B-100) as a major apolipoprotein instead of apo-B-48 (65). Vitamin E is secreted from hepatocytes in VLDL, as demonstrated in rats and in isolated rat hepatocytes (74, 75). In the circulation, VLDLs are delipidated to form LDLs, which retain apo-B-100. LDLs then interact with receptors for apo-B-100 in peripheral tissues as well as in the liver. During VLDL delipidation, which is similar to the lipoprotein interactions described above for chylomicron delipidation, vitamin E is transferred to HDL, which can transfer vitamin E to all of the circulating lipoproteins.

Unlike other fat-soluble vitamins, which have specific plasma transport proteins, vitamin E is transported nonspecifically in lipoproteins in the plasma. However, plasma vitamin E concentrations do depend upon secretion of vitamin E in VLDL from the liver (5, 59, 76). Remarkably, only one form of vitamin E, *RRR*- α -tocopherol, is preferentially secreted by the liver, as illustrated in Fig. 19.3. In nascent VLDL isolated from perfusates of livers from cynomolgus monkeys fed 24 hours previously with various deuterated tocopherols, *RRR*- α -tocopherol represented about 80% of the total deuterated tocopherols (77). Thus, the liver, not the intestine, discriminates between tocopherols. The liver contains a mechanism by which *RRR*- α -tocopherol is specifically inserted into nascent VLDL. α -TTP is a likely candidate for this function.

Figure 19.3. Pathways for the preferential delivery of α -tocopherol to peripheral tissues. Chylomicron remnants containing various forms of vitamin E are taken up by the liver. In the liver, the α -tocopherol-transfer protein preferentially incorporates α -tocopherol into nascent very low density lipoproteins (VLDL). Following VLDL secretion into plasma,

lipolysis of VLDL by lipoprotein lipase and hepatic triglyceride lipase results in the preferential enrichment of circulating lipoproteins with *RRR*- α -tocopherol. The metabolism of these lipoproteins results in the delivery of *RRR*- α -tocopherol to peripheral tissues.

Plasma Vitamin E Kinetics

A kinetic model of vitamin E transport in plasma was developed using data from studies with deuterium-labeled stereoisomers of α -tocopherol (*RRR*- and *SRR*-) (78). The mathematical model assumes that intestinal absorption and secretion of the two deuterated tocopherols (*RRR*- and *SRR*- α -tocopherols) into chylomicrons are similar and that the initial inputs into the plasma occur simultaneously for the two labels. In three patients with both ataxia and vitamin E deficiency (AVED), who have genetically defective α -TTP, the fractional disappearance rates of deuterium-labeled *RRR*- and *SRR*- α -tocopherols in plasma were measured. The disappearance rates (1.4 ± 0.6 and 1.3 ± 0.3 pools/day, respectively) were similar for the two stereoisomers, with a half-life of approximately 13 h for both α -tocopherols. Thus, in AVED patients both *RRR*- and *SRR*- α -tocopherols leave the plasma rapidly. In control subjects, the fractional disappearance rate of deuterium-labeled *RRR*- α -tocopherol (0.4 ± 0.1 pools/day) was significantly ($P < .01$) slower than that of *SRR*- α -tocopherol (1.2 ± 0.6). The apparent half-life of *RRR*- α -tocopherol in normal subjects was approximately 48 h, consistent with the “slow” disappearance of *RRR*- α -tocopherol from the plasma (78).

The similarity in the fractional disappearance rates for *RRR*- and *SRR*- α -tocopherols in the nondiscriminator patients, along with the similarity in *SRR*- α -tocopherol fractional catabolic rates between patients and controls, support the idea that *SRR*- α -tocopherol can be used in normal subjects to trace the irreversible loss of vitamin E from the plasma. The differences (0.8 ± 0.6 pools/day) between the *RRR*- and *SRR*- α -tocopherol rates in controls estimate the rate that *RRR*- α -tocopherol, which had left the plasma, was returned to the plasma. Although plasma labeled *RRR*- α -tocopherol concentrations in controls appear to change slowly, both *RRR*- and *SRR*- α -tocopherols leave the plasma rapidly. Because *RRR*- α -tocopherol is returned to the plasma, its apparent turnover is slow. This recirculation of *RRR*- α -tocopherol results in daily replacement of nearly all of the circulating *RRR*- α -tocopherol.

HEPATIC α -TOCOPHEROL TRANSFER PROTEIN

α -TTP (30–35 kDa) was first identified (79), purified, and characterized (80, 81) from rat liver cytosol. It has also been isolated from human liver cytosol (82) and its cDNA sequence reported. The human protein has 94% homology to the rat protein, and some homology both to the retinaldehyde-binding protein in the retina and to sec14, a phospholipid-transfer protein (83). The gene has been localized to the 8q13.1–13.3 region of chromosome 8 (83, 84). It is present only in the liver, not in other tissues; of the various liver cells, it has only been identified in hepatocytes (81). Purified α -TTP transfers α -tocopherol between liposomes and microsomes (80). Both α - and

b-tocopherols are effective competitors, g-tocopherol is about half as effective, and d-tocopherol is about one-third as effective; a-tocopheryl acetate, tocopherol quinone, and cholesterol were ineffective competitors (80). Thus, a-TTP preferentially transfers *RRR*-a-tocopherol (77). Hypothetically, this ability to transfer tocopherol is necessary for the action observed in vivo, because nascent VLDL is secreted from the liver preferentially enriched in *RRR*-a-tocopherol. It remains to be demonstrated that the purified protein transfers a-tocopherol to nascent VLDL during its assembly in hepatocytes.

Other Tocopherol-Binding Proteins

Dutta-Roy et al. (85, 86) reported that both the liver and the heart contain an a-tocopherol-binding protein with a mass of 14.2 kDa. This protein is present in the liver in addition to a-TTP. The 14.2-kDa protein also transfers a-tocopherol in preference to g- or d-tocopherol. They suggest that the 14.2-kDa tocopherol-binding protein might regulate cellular a-tocopherol concentrations. Nalecz et al. (87) also reported the existence of various a-tocopherol-binding proteins in cultured smooth muscle cells. No function has been proposed for these proteins.

DISTRIBUTION TO TISSUES

Vitamin E is transported in plasma lipoproteins in a nonspecific manner. No plasma specific vitamin E–transport proteins have been described. It is likely that the mechanisms of lipoprotein metabolism determine the delivery of vitamin E to tissues. There are at least two major routes by which tissues likely acquire vitamin E: (a) via lipoprotein lipase–mediated lipoprotein catabolism and (b) via the LDL receptor (Fig. 19.2 and Fig. 19.3). In addition, vitamin E rapidly exchanges between lipoproteins and between lipoproteins and membranes and may enrich membranes with vitamin E.

Vitamin E Delivery to Tissues

During chylomicron catabolism, peripheral tissues can acquire vitamin E from lipoproteins, which contain all of the forms of vitamin E that were consumed. Following hepatic secretion of VLDL enriched with a-tocopherol, peripheral tissues take up primarily a-tocopherol. Delivery from both chylomicrons and from VLDL, likely mediated by lipoprotein lipase (88), is important for vitamin E delivery, based on tissue tocopherol concentrations. Patients with abetalipoproteinemia, who malabsorb vitamin E, provide an interesting illustration. In these patients, adipose tissue g-tocopherol is usually undetectable (89, 90). One patient, however, who was treated with an intravenously administered lipid emulsion made from soybean oil, had adipose tissue g-tocopherol concentrations equal to those of a-tocopherol (90). Thus, lipoprotein lipase presumably catabolizes the lipid emulsion and delivers both a- and g-tocopherols to adipose tissue. This mechanism may be particularly important for tissues that express lipoprotein lipase, such as adipose tissue, muscle, and brain (88).

One other important mechanism for the delivery of tocopherols to tissues is via the LDL receptor. Using fibroblasts with and without LDL-receptor activity, Traber and Kayden

(91) demonstrated that LDL containing vitamin E is taken up more effectively by the fibroblasts with functional LDL-receptor activity. Cohn et al. (92) demonstrated that in vivo both LDL-receptor-dependent and -independent pathways are important for tissue uptake of tocopherols.

Circulating blood cells likely obtain their vitamin E by transfer of tocopherols from lipoproteins, especially HDL. Patients with abetalipoproteinemia, who have HDL (66, 67) but do not have chylomicrons, VLDL, LDL, and other lipoproteins containing apolipoprotein B, have only about 1/10th the normal plasma vitamin E concentrations, and their erythrocytes contain about two-thirds of that found in controls (90). Thus, HDLs have an important role in delivering vitamin E to circulating cells. In addition, *RRR*- α -tocopherol-membrane-binding proteins (major component, kDa 65, and a minor component, kDa 125) on human erythrocytes were described by Kitabchi and Wimalasena (93, 94). Specific binding of α -tocopherol to erythrocyte membranes may be involved in the prevention of hemolysis, because α -tocopherol is more effective than other tocopherols in preserving erythrocytes (95).

Vitamin E concentrations were measured in lymphocytes and monocytes in normal subjects and in patients with lymphocyte leukemia (96). The cancer cells had lower concentrations of vitamin E, likely a result of the rapid growth of the cells. Alternatively, the oxidant/antioxidant balance of these cells may be altered.

Tissues with Slow- versus Fast-Turning-over Vitamin E Pools

Deuterated α -tocopherol was used to assess the kinetics and distribution of α -tocopherol into various tissues in rats and in guinea pigs (97, 98). These studies showed that a group of tissues is in rapid equilibrium with the plasma α -tocopherol pool. Tissues, such as erythrocytes, liver, and spleen, quickly replace “old” with “new” α -tocopherol (99). Other tissues, such as heart, muscle, and spinal cord, have slower α -tocopherol turnover times. The brain has the slowest α -tocopherol turnover time by far.

In general, the vitamin E content of the nervous system is spared during vitamin E depletion (100, 101 and 102). Studies in adult beagle dogs demonstrated that the peripheral nerve is the most responsive of the nervous system to vitamin E concentrations in the diet (103). In dogs fed a vitamin E–deficient diet for nearly 2 years, the vitamin E concentrations in peripheral nerves were lower than those in any other nervous tissues and were as low as in most non-nervous tissues. By contrast, in dogs fed a vitamin E–supplemented diet, peripheral nerve concentrations were higher than in other nervous tissues. Thus, it is not surprising that in humans the peripheral nerves (18), albeit the sensory neurons, are the most susceptible to vitamin E deficiency (29). Furthermore, in vitamin E–deficient humans, the vitamin E concentration of sural nerve decreases prior to the appearance of histologic or functional defects (29).

Storage Sites of Vitamin E

The mechanisms for the release of tocopherols from tissues are unknown; no organ functions as a storage organ for α -tocopherol, releasing it on demand. The bulk of

vitamin E in the body is localized in the adipose tissue (104). More than 90% of the human body pool of α -tocopherol is located in the adipose tissue, and more than 90% of adipose tissue α -tocopherol is in fat droplets, not membranes (104). Handelman et al. (105) estimated that 2 years or more are required for ratios of α : γ tocopherols to reach new steady-state levels in response to changes in dietary intake. Thus, analysis of adipose tissue α -tocopherol content yields a useful estimate of the long-term vitamin E status (89, 106).

Although triglyceride, but not vitamin E or cholesterol, is released from adipose tissue during weight reduction in humans (107), the α -tocopherol content is reduced in vitamin E-deficient patients (29, 58, 89, 90). In adult dogs, the adipose tissue also provides a source of vitamin E to the rest of the body (108), while tocopherol depletion from adipose tissue in guinea pigs is extremely slow (109). Thus, the degree of availability of adipose tissue α -tocopherol in humans remains controversial.

METABOLISM AND EXCRETION

Since the tocopheroxyl radical can be reduced back to tocopherol by ascorbate or other reducing agents, the flux through the cyclic radical pathway may be much larger than the flux through the pathway of further metabolism. Liebler and Burr et al. (110, 111) suggest that biologically relevant oxidation products formed from α -tocopherol include 4 α ,5-epoxy- and 7,8-epoxy-8 α (hydroperoxy)tocopherones and their respective hydrolysis products, 2,3-epoxy-tocopherol quinone and 5,6-epoxy- α -tocopherol quinone. However, these products are formed during in vitro oxidation; their importance in vivo is unknown.

Excretion of Vitamin E and Its Metabolites via Bile, Urine, and Feces

The primary oxidation product of α -tocopherol is α -tocopheryl quinone, which can be conjugated to yield the glucuronate after prior reduction to the hydroquinone. The glucuronate can be excreted into bile or further degraded in the kidneys to α -tocopheronic acid, which is excreted in the urine (112). Further oxidation products, including dimers and trimers, as well as other adducts have also been described (31).

Schultz et al. (113) described a novel urinary metabolite of α -tocopherol (2,5,7,8-tetramethyl-2(2'-carboxyethyl)-6-hydroxychromane), which is excreted in the urine when large supplemental doses of *RRR*- α -tocopherol are fed to humans. Doses in excess of 50 mg vitamin E result in excretion of this metabolite. Thus, excretion of this metabolite may indicate saturation of the plasma binding capacity for α -tocopherol (113). Surprisingly, a similar metabolite of γ -tocopherol has been proposed as a natriuretic factor and has been given the name LLU- α (114).

The major route of excretion of ingested vitamin E is fecal elimination, because of its low intestinal absorption. Forms of vitamin E not preferentially used, such as synthetic racemic mixtures or γ -tocopherol (115), are eliminated during the process of nascent VLDL secretion in the liver and are probably excreted in bile (61).

Excretion of Vitamin E via Skin

The skin may be an important route of vitamin E excretion. In the early 1970s, Shiratori (116) infused chylomicrons labeled with [³H]- α -tocopherol into rats and found that nearly 40% was associated with the pelt. Application of these data to humans seemed questionable, since humans do not have fur. However, recent studies in hairless mice show that skin contains various forms of vitamin E similar to those in the diet, while the brain has virtually only α -tocopherol (117). Thus, skin vitamin E may be derived from chylomicrons containing dietary vitamin E. Furthermore, skin sebaceous glands may secrete vitamin E to provide antioxidants to protect cutaneous lipids. If so, this route could be important for vitamin E excretion in humans.

CAUSES OF DEFICIENCY

Vitamin E deficiency occurs only rarely in humans and virtually never results from dietary deficiencies because of the nearly ubiquitous distribution of tocopherols in foods, especially oils and fats (19). Vitamin E deficiency does occur as a result of genetic abnormalities in α -TTP and as a result of various fat malabsorption syndromes, as shown in [Table 19.1](#).

Genetic abnormalities
α -Tocopherol-transfer protein (AVED, ataxia with vitamin E deficiency)
Apolipoprotein B (homozygous hypobetalipoproteinemia)
Micronomal triglyceride-transfer protein (abetalipoproteinemia)
Fat malabsorption syndromes
Chronic cholestasis in children and adults
Idiopathic neonatal hepatitis
Familial cholestatic syndrome
Alagille syndrome
Paucity of interlobular bile ducts
Extrahepatic biliary atresia
Primary biliary cirrhosis
Cystic fibrosis and pancreatic insufficiency
Short bowel syndromes
Crohn's disease
Mesenteric vascular thrombosis
Intestinal pseudoobstruction
Chronic steatorrhea
Blind loop syndrome
Intestinal lymphangiectasia
Celiac disease
Chronic pancreatitis
Total parenteral nutrition

Table 19.1 Disorders Requiring Administration of Supplemental Vitamin E to Prevent Deficiency

Vitamin E Deficiency Caused by Genetic Defects in the α -Tocopherol Transfer Protein

Genetic defects in α -TTP are associated with a characteristic syndrome, AVED (previously called familial isolated vitamin E [FIVE] deficiency). AVED patients have neurologic abnormalities that are similar to those of Friedreich's ataxia (118, 119). The symptoms are characterized by a progressive peripheral neuropathy with a specific

“dying back” of the large-caliber axons of the sensory neurons, resulting in ataxia (120).

These patients respond to oral vitamin E supplements. A dose of 800 to 1200 mg/day usually suffices to prevent further deterioration of neurologic function, and in some cases, improvements have been noted, as reviewed by Sokol (18). Untreated patients have extraordinarily low plasma vitamin E concentrations (as low as 1/100 of normal), but if they are given vitamin E supplements, then plasma concentrations reach normal within hours (120). However, if supplementation is halted, then plasma vitamin E concentrations fall within days to deficient levels.

Traber et al. (5, 76) used deuterated tocopherols to determine the biochemical defect in AVED patients. Based on kinetic data, it appeared that (a) an hepatic a-TTP that preferentially incorporates *RRR*-a-tocopherol into VLDL is required to maintain plasma *RRR*-a-tocopherol concentrations via secretion in nascent VLDL by hepatocytes, (b) nondiscriminators either lack this protein or have a marked defect in the *RRR*-a-tocopherol-binding region of the protein, and (c) patients who discriminate, but have difficulty maintaining plasma *RRR*-a-tocopherol concentrations, have a less severe defect, perhaps a defect in transfer function.

Studies in patients with Friedreich's ataxia led to the characterization of genetic defects in a-TTP. The most common autosomal recessive ataxia is Friedreich's ataxia, which is linked to a defect on chromosome 9 and is characterized by absent tendon reflexes, deep sensory loss, and cerebellar and Babinski signs (121). From a large number of inbred Tunisian families, Ben Hamida et al. (118, 119) identified a small group of patients with ataxia who had defects on chromosome 8, not 9. Subsequent investigation revealed that these patients also had extraordinarily low plasma vitamin E concentrations (119). Ouahchi et al. (4) mapped their genetic defect to chromosome 8q13.1–13.3, the same chromosomal location as a-TTP (83, 84). Most of the patients described by Ouahchi et al. were found to have a truncation of the C-terminal portion of a-TTP.

The genetic defect in a-TTP has now been identified in some of the same patients who were analyzed using deuterium-labeled tocopherols. A truncation of the terminal portion of a-TTP (4, 122) causes an inability to discriminate between *RRR*- and *SRR*-a-tocopherols (123). However, patients who are heterozygous for the a-TTP truncation mutation (4, 122) can discriminate between stereoisomers (4, 122). In addition to truncation mutations, defective transfer function of a-TTP has also been described. A patient who experienced neurologic difficulties only after reaching about 50 years of age (124) preferentially incorporated *RRR*-a-tocopherol into lipoproteins, but at a reduced rate (5). This patient was found to be homozygous for a thymine-to-guanine transversion in the a-TTP gene that causes the histidine at position 101 to be replaced with glutamine (125). Gotoda et al. (125) screened 801 inhabitants near the patient's home on an isolated Japanese island, where 21 heterozygotes were found with this mutation. These heterozygotes had significantly lower serum vitamin E concentrations than a control population. The mutated gene, when expressed in COS-7 cells, produced a functionally defective a-TTP with approximately 11% of the activity of the wild-type a-TTP (125). Thus, the region around histidine 101 must be important for transfer activity. This region has a high degree of homology with both the retinaldehyde-binding

protein present in retina and the yeast sec14 protein (83). Because these latter two proteins are also lipid-binding/transfer proteins, this region of all three proteins may be important for their lipid transfer roles.

Retinitis pigmentosa, a symptom of vitamin E deficiency in humans (126), has been described in patients with AVED (127, 128). Recently, the defective α -TTP gene in three AVED patients with retinitis pigmentosa was described; they all had the histidine 101-transfer defect (128). It is unknown whether the homology with the retinaldehyde-binding protein in the retina is important for α -TTP function in the eye or whether vitamin E deficiency itself causes retinitis pigmentosa. Vitamin E supplementation stops or slows the progression of retinitis pigmentosa caused by vitamin E deficiency (128). This is in contrast to results from a trial of vitamin E and A supplements in patients with retinitis pigmentosa without vitamin E deficiency (129), which showed a beneficial effect of 15,000 IU/day of vitamin A and a possible adverse effect of vitamin E. Therefore, the plasma vitamin E concentrations should be measured in patients with retinitis pigmentosa to evaluate their vitamin E nutriture before supplementation with vitamin E.

Vitamin E Deficiency Caused by Genetic Defects in Lipoprotein Synthesis

Studies of patients with hypobetalipoproteinemia or abetalipoproteinemia (low to nondetectable circulating chylomicrons, VLDL, or LDL) demonstrated that lipoproteins containing apo-B are necessary for effective absorption and plasma transport of lipids, especially vitamin E. These patients have steatorrhea from birth, because of their impaired ability to absorb dietary fat, which also contributes to their poor vitamin E status. Clinical features include steatorrhea, retarded growth, acanthocytosis, retinitis pigmentosa, and a chronic progressive neurologic disorder with ataxia.

Although the two groups of patients both lack apo-B-containing lipoproteins, their underlying genetic defects differ. Homozygous hypobetalipoproteinemia patients have a defect in the apo-B gene and thus any apo-B-containing lipoproteins that are secreted into the circulation turn over rapidly (130, 131). Abetalipoproteinemic patients have genetic defects in MTP (microsomal triglyceride-transfer protein) that prevent normal lipidation of apo-B (132). Thus, the secretion of apo-B-containing lipoproteins is virtually nonexistent. Indeed, apo-B does not leave the endoplasmic reticulum in the absence of lipidation by MTP (133).

Clinically, both groups of subjects become vitamin E deficient and develop a characteristic neurologic syndrome—a progressive peripheral neuropathy—if they are not given large vitamin E supplements (90, 134). Daily doses of 100 to 200 mg/kg, or about 5 to 7 g of vitamin E are recommended (18). In fact, plasma concentrations of vitamin E never reach normal levels. Studies using deuterated tocopherols in five patients with abetalipoproteinemia demonstrated that even with large doses of vitamin E (2 g), plasma concentrations remained less than 1% of normal (90). Despite low plasma concentrations, adipose tissue α -tocopherol concentrations are raised to normal levels in some patients given large vitamin E doses (90).

Vitamin E Deficiency as a Result of Fat Malabsorption Syndromes

Vitamin E deficiency occurs secondary to fat malabsorption because vitamin E absorption requires biliary and pancreatic secretions. Failure of micellar solubilization and malabsorption of dietary lipids lead to vitamin E deficiency in children with chronic cholestatic hepatobiliary disorders, including disease of the liver and anomalies of intrahepatic and extrahepatic bile ducts (18). Children with cholestatic liver disease who have impaired secretion of bile into the small intestine have severe fat malabsorption. Neurologic abnormalities, which appear as early as the 2nd year of life, become irreversible if the vitamin E deficiency is uncorrected (18, 53, 135).

Children with cystic fibrosis can also become vitamin E deficient, because the impaired secretion of pancreatic digestive enzymes causes steatorrhea and vitamin E malabsorption, even when pancreatic enzyme supplements are administered orally (18). More severe vitamin E deficiency occurs if bile secretion is impaired (55, 136, 137 and 138). Winklhofer-Roob et al. (139) proposed that cystic fibrosis patients be supplemented with a daily 400-mg dose of vitamin E so that their plasma α -tocopherol concentrations increase above 26 to 28 μ M. This higher plasma vitamin E concentration protects LDL from in vitro oxidation (139).

Any disorder that causes fat malabsorption can lead to vitamin E deficiency. The list of disorders associated with acquired vitamin E deficiency, assembled by Sokol (18), includes chronic dysfunction or resection of the small bowel, Crohn's disease, mesenteric vascular thrombosis or intestinal pseudoobstruction, blind loop syndrome, intestinal lymphangiectasia, celiac disease, and chronic pancreatitis. The development of neurologic symptoms of vitamin E deficiency in adults who acquire these disorders, however, takes decades. Serum vitamin E levels may fall within 1 to 2 years of acquired lipid malabsorption in adolescents and adults; however, a 10- to 20-year interval between the identification of biochemical vitamin E deficiency and the onset of neurologic symptoms is generally observed in adults (18). The prolonged time for onset of symptoms results from the prior accumulation of vitamin E in most tissues and its relatively slow release from nervous tissues.

Vitamin E supplementation is very difficult to achieve in patients with fat malabsorption syndromes because they malabsorb vitamin E. Sokol (18) suggests treatment with *RRR*- α -tocopherol (not the ester) at 25 to 50 mg/kg/day, advancing by 50 mg/kg/day up to 150 to 200 mg/day if the ratio of serum α -tocopherol to total lipids does not normalize (>0.8 mg/g). The dose should be given at the time of maximal bile flow, several hours before administration of any medication that may interfere with vitamin E absorption (e.g., cholestyramine, large doses of vitamin A or ferrous sulfate). In cases of severe cholestasis, intraluminal bile acid concentrations are well below the critical micellar concentration, which results in failure of vitamin E absorption. Here intramuscular injections of vitamin E, such as Viprimol (Hoffmann-LaRoche, Inc., Nutley, NJ) can be used to provide 1 to 2 mg/kg/day (18). A water-soluble ester of vitamin E, such as *d*- α -tocopherol polyethylene glycol-1000 succinate (TPGS, Eastman Chemical Products, Kingsport, TN), is absorbed when administered orally, appears to be nontoxic, and reverses or prevents neurologic dysfunction (18). However, products like TPGS should

not be used if the patient suffers from renal failure or dehydration, because the excretion of absorbed polyethylene glycol may be impaired (140).

Vitamin E Deficiency in Patients Receiving Total Parenteral Nutrition

Patients receiving total parenteral nutrition (TPN) ideally are provided with all of their required nutrients—vitamin E (10 mg) is given as part of a vitamin mix and as a component of a lipid emulsion that also provides essential fatty acids and calories. Most intravenous preparations of lipid emulsions are made with soybean oil to provide PUFAs. However, the soybean oil emulsions contain high levels of α , but not γ -tocopherol (141). Evaluation of the vitamin E status of TPN patients receiving lipid emulsions suggests that they may be receiving inadequate amounts of α -tocopherol. They have elevated levels of exhaled pentane and ethane—markers of lipid peroxidation in vivo (142) and adipose tissue α -tocopherol concentrations that are half of normal, suggesting depletion of tissue stores of vitamin E (143).

Infusion of PUFAs may lead to an increased requirement for vitamin E in TPN patients. In normal subjects, infusion of lipid emulsions raised γ -tocopherol levels only during the infusion; by 24 hours postinfusion, γ -tocopherol concentrations had returned nearly to baseline (141). Furthermore, patients on long-term TPN may be depleting tissue vitamin E because the lipid emulsions remove α -tocopherol from the plasma lipoproteins, returning it to the liver (141). Thus, lipid emulsions currently used in TPN provide a high intake of PUFAs, which results in increased requirements for lipid-soluble antioxidants without providing sufficient α -tocopherol. These concerns have largely gone unnoticed, probably because of the lengthy interval required for development of vitamin E–deficiency symptoms.

PATHOLOGY OF HUMAN VITAMIN E DEFICIENCY

The primary manifestations of human vitamin E deficiency include spinocerebellar ataxia, skeletal myopathy, and pigmented retinopathy (18). Similarly, when raised on experimental vitamin E–deficient diets, rats and rhesus monkeys develop ataxia and neuroaxonal degeneration in the brainstem, spinal cord, and peripheral nerves, as well as pigmentary degeneration of the retina (18). Hence, the vitamin E–deficiency symptoms observed in humans are similar to those in experimental animals.

A distinct pattern in the progression of neurologic symptoms resulting from vitamin E deficiency in humans has been described (18). Hypo- or areflexia is the earliest symptom observed. By the end of the first decade of life, untreated patients with chronic cholestatic hepatobiliary disease have a combination of spinocerebellar ataxia, neuropathy, and ophthalmoplegia. The progression of neurologic symptoms is slower in children with cystic fibrosis and abetalipoproteinemia. The symptoms of vitamin E deficiency in AVED are similar to those found in these latter patients (120, 144). These observations suggest that there is increased oxidative stress in patients with cholestatic liver disease.

Deficiency in children and adults results in a progressive peripheral neuropathy with a

dying back of the large caliber axons in the sensory neurons, as reviewed (120). The large-caliber, myelinated axons in peripheral sensory nerves are the predominant target in vitamin E deficiency in humans. In deficient humans, diminished amplitudes in sensory nerve action potential are common, whereas delayed conduction velocity, an indicator of demyelination, is unusual. Thus, axonal degeneration rather than demyelination is the primary sensory nerve abnormality; that is, the axons degenerate first, then demyelination occurs.

Axonal dystrophy has been observed in the posterior columns of the spinal cord and the dorsal and ventral spinocerebellar tracts, as reviewed (120). Specifically, swollen, dystrophic axons (spheroids) have been observed in the gracile and cuneate nuclei of the brainstem. Lipofuscin accumulation has been observed in dorsal sensory neurons and peripheral Schwann cell cytoplasm. Electromyographic studies show denervation injury of muscles in patients with advanced vitamin E deficiency. Somatosensory-evoked potential testing has shown a central delay in sensory conduction, correlating with degeneration of the posterior columns of the spinal cord.

REQUIREMENTS AND RECOMMENDED INTAKES

Vitamin E Units

According to the U.S. Pharmacopoeia (145), 1 international unit (IU) of vitamin E equals 1 mg *all-rac*- α -tocopheryl acetate, 0.67 mg *RRR*- α -tocopherol, or 0.74 mg *RRR*- α -tocopheryl acetate. These conversions were based on their relative biologic activities. The current recommended dietary allowance (RDA) for vitamin E is 8 mg for women and 10 mg for men of *RRR*- α -tocopherol or *RRR*- α -tocopherol equivalents (a-TEs) (146) (see also Appendix [Table II-A-2-a-2](#)).

For the purpose of calculating vitamin E intakes in a-TEs, *g*-tocopherol is assumed to substitute for α -tocopherol with an efficiency of 10%, *b*-tocopherol of 50%, and α -tocotrienol of 30%. However, functionally, these forms of vitamin E are not equivalent to α -tocopherol. Deuterated *g*-tocopherol concentrations decrease rapidly, compared with deuterated α -tocopherol, suggesting that the metabolic fate of *g*-tocopherol is quite unlike that of α -tocopherol (60). Thus, sources of PUFAs that have high concentrations of *g*-tocopherol and low concentrations of α -tocopherol, such as corn or soybean oils, may increase the potential for in vivo lipid peroxidation. That is, the PUFAs that are protected from lipid peroxidation by *g*-tocopherol in the oil are not protected after they have been consumed because *g*-tocopherol is not retained by the body (141). Thus, PUFA may more easily “turn rancid” in the body.

Adequacy of Vitamin E Intakes in Normal U.S. Populations

King (147) defined three different approaches to determining normal human nutrient requirements: (a) balance studies, in which nutrient losses are measured in relation to intake; (b) depletion-repletion studies, in which subjects are maintained on diets low or deficient in a nutrient, followed by correction of the deficiency with measured amounts of the nutrient; and (c) the observed intakes of a nutrient by healthy people. Because

vitamin E turns over slowly and there are no functional biomarkers exquisitely sensitive to vitamin E, the intakes of healthy people are the general guideline for establishing adequacy of vitamin E status (146).

The adequacy of vitamin E intakes is often estimated by measurements of plasma concentrations of apparently healthy people in the U.S. The preliminary report of the Third National Health and Nutrition Examination Survey (NHANES III) has just been released (148). The α -tocopherol concentrations (5th to 95th percentiles) in people from age 6 to 80+ ranged from 6.10 to 19.02 $\mu\text{g/mL}$ (14.2–44.2 μM). There was an increase in serum α -tocopherol concentrations associated with puberty that was not entirely normalized by expressing the data per mg serum cholesterol. Cholesterol-adjusted α -tocopherol concentrations (5th to 95th percentiles) were 3.76 to 8.53 $\mu\text{g/mg}$ (3.41–7.67 $\mu\text{mol/mmol}$). The National Research Council estimated that the average daily intakes of α -TEs range from 7 to 11 mg for men, 7.1 for women, and 5.5 mg for children 1 to 5 years of age (146). The RDA was based on these intake data and an estimated average PUFA intake. The committee assumed that if the PUFA intake increases, the vitamin E will increase concomitantly.

Low-Fat Diets

Often patients with elevated cholesterol levels are encouraged to change their dietary habits, increasing PUFA-containing fat intake and decreasing saturated fat intake. Changes in dietary habits to lower plasma lipid levels in patients with elevated lipids or with diabetes may have deleterious effects on vitamin E intakes, because most dietary vitamin E is present in fats (19). This is especially true in subjects who change their diets to lower serum cholesterol by decreasing intake of saturated fats and increasing intake of PUFA-containing fats, usually corn oil or soybean oil, which contain high levels of γ -tocopherol but much less α -tocopherol (19). Intake of oxidizable lipids is thus increased, while intake of α -tocopherol is decreased. To avoid excessive intakes of PUFA, ingestion of monounsaturated fats, such as olive or canola oils, is currently recommended (149).

Supplemental vitamin E may be recommended to prevent inadequate intakes in patients with chronic diseases associated with free radical damage due to oxidative stress. After doses of 400 IU are administered to patients, for example, their LDLs are less susceptible to oxidative stress during subsequent in vitro testing (150).

Assessment of Vitamin E Status in Patients at Risk for Vitamin E Deficiency

As shown in Table 19.2, several parameters can be measured in patients who may be vitamin E deficient. Although low serum or plasma vitamin E concentrations indicate vitamin E deficiency, measurement of plasma levels are insufficient for patients with various forms of lipid malabsorption. Calculation of effective plasma vitamin E concentrations needs to take into account plasma lipid levels. Patients with elevated cholesterol or triglyceride concentrations may have vitamin E levels in the “normal” range, but these may not suffice to protect tissues. For example, Sokol et al. (151) showed that plasma vitamin E concentrations were in the normal range in patients with vitamin E deficiency as a result of cholestatic liver disease, which was also

characterized by extraordinarily high lipid levels.

Measurements of plasma vitamin E concentrations
Normal values are >10 nmol α -tocopherol/mL (or μ M) or 5 μ g/mL
Normal values are >0.8 mg α -tocopherol/g total lipid or 2.8 mg/g cholesterol
Measurements of adipose tissue vitamin E concentrations
>100 μ g α -tocopherol/mg triglyceride
Functional signs of vitamin E deficiency
Increased red cell hemolysis
Increased lipid peroxidation
Increased expired ethane or pentane
Clinical signs of vitamin E deficiency
Neurologic testing—abnormal sensory nerve function
Histopathology of peripheral nerves
Electrophysiologic measurements
Gene testing
Genetic defects in α -tocopherol-transfer protein
Genetic defects on chromosome 8

Table 19.2 Techniques for Assessment of Vitamin E Status

Patients with peripheral neuropathies or retinitis pigmentosa should be assessed for vitamin E deficiency. The ataxia of Friedreich's ataxia is so remarkably similar to that of AVED patients that plasma concentrations of vitamin E in all patients with ataxia should definitely be measured.

Controversial Topics

Epidemiologic studies and some intervention trials indicate a beneficial role of vitamin E supplements in decreasing risk of degenerative diseases, such as cardiovascular disease and atherosclerosis ([152](#), [153](#)), cancer ([154](#)), and cataract formation ([155](#)). Furthermore, large supplements of vitamin E have been proposed to be beneficial in preventing or decreasing the risk of chronic diseases or slowing the ravages of aging. [Table 19.3](#) lists various disorders in which supplemental vitamin E has been proposed to have beneficial effects. Despite the virtual safety of large intakes of vitamin E ([156](#), [157](#)), the use of vitamin E in amounts beyond those that can be consumed in the diet remains controversial.

Premature infants—retinopathy of prematurity (126)
Protection from retrolental fibroplasia
Possible protection of intraventricular hemorrhage
Increased risk of necrotizing enterocolitis or sepsis
Anemia of prematurity (160)
Protection from vitamin E deficiency caused by inappropriate formulas
May be beneficial in physiologic jaundice-anemia of newborn
Cardiovascular disorders
Decreased risk of coronary heart disease (152, 153, 161)
Decreased in vitro LDL oxidation (150, 162)
Decreased in vitro platelet aggregation (163)
Ischemia-reperfusion injury (164)
Immune response
Improved responses in elderly (165)
Cataract (126)
Tardive dyskinesia (166, 167)

Table 19.3 Disorders in Which Supplemental Vitamin E May Be Beneficial

There is also concern about the potential role of vitamin E as a prooxidant. Vitamin E in LDL oxidized in vitro in the absence of aqueous antioxidants is a prooxidant (31, 158, 159). The relatively long lived tocopheroxyl radical acts as a chain-transfer agent, causing the oxidation of LDL core lipids. Thus far, however, there is no evidence that vitamin E has a proantioxidant activity in vivo. But this remains an important issue with respect to the use of vitamin E supplements in humans.

CONCLUSIONS

Nearly 75 years from the time of its discovery, vitamin E remains an elusive molecule. Its potential for decreasing the risks of acquiring chronic disease have spurred the interest of scientists and clinicians worldwide. The description of vitamin E deficiency in patients with genetic abnormalities in human α -TTP has opened new avenues of investigation of α -tocopherol-transfer/binding proteins in various tissues. We are returned to the age-old questions, “What is the function of vitamin E?” and “Why do we need a specific protein that only recognizes α -tocopherol if all of the naturally occurring forms of vitamin E have nearly similar antioxidant functions?”

ACKNOWLEDGMENTS

I wish to express my sincere appreciation both to Professor Lester Packer for his guidance and support as well as to the many people who are listed in the cited joint publications, without whose collaboration those studies could not have been accomplished.

Long periods of time may elapse between the discovery of a given vitamin deficiency disease, isolation and determination of the structure of the vitamin, and final elucidation of its metabolic function. This is true of vitamin K: its deficiency disease, fatal hemorrhage, was discovered in 1929, its isolation and structural determination was accomplished in 1939, and its metabolic function was suspected only after a new amino acid, γ -carboxyglutamic acid (Gla), was discovered in bovine prothrombin in 1974. It is now established that vitamin K is part of a membrane-bound carboxylase system that participates in the posttranslational carboxylation of a number of vitamin K–dependent proteins. The γ -glutamyl carboxylase has been isolated and sequenced, its gene cloned, and progress has been made in determining its transmembrane segments and active site. It is now clear that vitamin K–dependent proteins include not only those involved in coagulation, but others with functions in bone, kidney, and other tissues.

HISTORICAL OVERVIEW

Vitamin K was discovered by Henrik Dam in Copenhagen in 1929 in studies of sterol metabolism in chicks fed fat-free diets. He observed quite unexpectedly that some of the chicks developed hemorrhages under the skin, in muscle, and in other tissues and that blood, occasionally taken for laboratory examinations, showed delayed coagulation. The antihemorrhagic factor was found to be fat soluble. Similar observations were made in 1931 by MacFarlane and his coworkers in Canada and in 1933 by Holst and Halbrook at the University of California.

By 1934, Dam and coworkers had extended their work to show that none of the established vitamins could prevent the hemorrhagic disease they had described, and they named the new vitamin "K" (for *Koagulation*). They demonstrated that vitamin K was distributed in liver, hemp seeds, and green leafy vegetables. In Dam's laboratory, Schonheyder discovered in 1936 that the hemorrhagic disease was due to the absence of prothrombin activity in the plasma. About the same time, Almquist and Stokstad discovered that fish meal, particularly after putrefaction, was a good source of the vitamin. Efforts were then initiated to isolate the new factor from both alfalfa and putrefied fish meal.

In 1939, Doisy and his colleagues and Dam and his colleagues announced the isolation of vitamin K₁ from alfalfa. It was identified as 2-methyl-3-phytyl-1,4-naphthoquinone. In addition, Doisy's group reported the isolation of a related but not identical vitamin K from putrefied fish meal, which they named vitamin K₂.

In 1941, Campbell and Link discovered that the active agent in spoiled clover that caused a hemorrhagic disease in cattle, first described by Schofield in 1922, was bishydroxycoumarin (dicumarol) and that this compound was antagonistic to vitamin K. The availability of 4-hydroxycoumarin drugs also provided new tools for investigation of the complexities of blood coagulation. In the next decade, three additional vitamin K-dependent coagulation factors were discovered: proconvertin (factor VII), Stewart factor (factor X), and Christmas factor (factor IX) (1). During the past 25 years, four more vitamin K-dependent coagulation factors (protein C, protein S, protein Z, and a new growth-arrest-specific factor [Gas 6]) have been discovered. Two of these (proteins C and S) are anticoagulants, and Gas 6 is homologous to protein S (2).

In 1968, studies at the University of Lund by Ganrot and Nilehn showed that when the concentration of prothrombin was measured immunochemically in normal and coumarin-anticoagulated human subjects, the antigenic equivalents in coumarin-treated subjects did not decrease in proportion to the biologic activity as measured by the clotting time. They concluded that coumarin anticoagulant therapy (and by inference, vitamin K deficiency) interfered with the normal synthesis of prothrombin and produced an abnormal prothrombin, modified in some way to make it biologically inactive but immunologically reactive.

The study of the chemical properties of bovine prothrombin from normal and

anticoagulated cows was then undertaken in several laboratories. In 1974, Stenflo et al. (3) in Sweden, Nelsestuen et al. (4) in the United States, and Magnusson and coworkers (5) in Denmark independently reported that the difference between normal and abnormal prothrombin was the presence of a new amino acid in normal prothrombin, γ -carboxyglutamic acid (Fig. 20.1). This carboxylated glutamic acid was not present in the prothrombin of animals given coumarin drugs or on vitamin K-deficient diets. It was therefore concluded that vitamin K acts to alter the structure of the vitamin K-dependent proteins posttranslationally by facilitating carboxylation of selected glutamate residues in their primary structures. This discovery revolutionized ideas about the function of vitamin K and led to studies of the enzymology of the vitamin K-dependent γ -glutamyl carboxylase and related vitamin K enzymes in the microsomes of liver, bone, and other tissues. The early history of vitamin K research has been extensively reviewed elsewhere (1, 6) and citations to all of the above discoveries are documented.

Figure 20.1. Structure of γ -carboxyglutamic acid (Gla). Gla is a tricarboxylic acid that is strong base but decomposes with γ -decarboxylation in strong acid. Its isoelectric point is pH 3.0.

CHEMISTRY AND NOMENCLATURE

Compounds with vitamin K activity all contain the 2-methyl-1,4-naphthoquinone nucleus with a lipophilic side chain at position 3. Vitamin K₁, now known as phyloquinone, was identified as 2-methyl-3-phytyl-1,4-naphthoquinone (Fig. 20.2). It is the only homologue of vitamin K synthesized by plants. Vitamin K₂, isolated from fish meal, was identified as menaquinone-7. The menaquinone family of vitamin K₂ homologues is a large series of vitamins containing unsaturated isoprenyl side chains, which vary in length and are designated MK-*n*. Menaquinone-4 (MK-4) is synthesized in animals and birds from the provitamin menadione (2-methyl-1,4-naphthoquinone, formerly known as vitamin K₃) by enzymatic alkylation with diggeranyl pyrophosphate (7). The alkylating enzyme has been partially purified and characterized from chick and rat liver microsomes. The other

menaquinones are products of bacterial biosynthesis and range from menaquinone-7 to menaquinone-13 (8). Partially saturated menaquinones, menaquinone-9-H and menaquinone-8-H, are known. The molecular weight of vitamin K₁ is 450.68 g/mol and of vitamin MK-7 is 648.97 g/mol.

Figure 20.2. Structures of vitamin K homologues that are derivatives of 2-methyl-1,4-naphthoquinone: phylloquinone (vitamin K₁), menaquinone (vitamin K₂), and menadione (vitamin K₃).

FOODS AS A SOURCE OF VITAMIN K

Phylloquinone is widely distributed in both animal and vegetable foods and varies from less than 2 nM (<0.1 µg/100 g) in citrus fruits, to 22 nM (1 µg/100 mL) in cow's milk, and to more than 8.8 µmol/kg (400 µg/100 g) in spinach, kale, and turnip greens. Menaquinones, on the other hand, are absent from most ordinary foods but are present to the extent of 200 nmol/kg (13 µg/100 g) in liver and 300 nmol/kg in certain cheeses (9). The principal components are MK-8, MK-9, and MK-10. Natto, a fermented soybean preparation consumed by Asians, can contain 10 to 20 µmol/kg (1–2 mg/100 g) of MK-7 (10). Various methods have been used to measure vitamin K in foods. Because of the sensitivity of vitamin K to light, however, precautions must be taken to protect the vitamin during extraction and analysis.

Methods of Assay

For many years the only satisfactory procedure for determination of vitamin K activity of foods was a curative bioassay based on the response of deficient chicks to the added food. In this method, the prothrombin level was measured with Russell's viper venom and the response of unknowns was compared with the dose-response curve using phylloquinone as a standard. The sensitivity of the chick bioassay is 0.22 µmol (0.1 mg) phylloquinone per kilogram of food. Such assays, however, did not identify the form of vitamin K present in the material assayed and tended to overestimate the concentration

of phylloquinone (11). Furthermore, the various homologues vary in their biologic activity when fed. Matschiner and Doisy found that menaquinone-1 had only 1% of the biologic activity of phylloquinone, whereas MK-4, MK-5, and MK-7 were identical to phylloquinone in activity. MK-2 and MK-10 each gave about 25% of the activity of phylloquinone. These data demonstrated that the very short chain and very long chain homologues were less active by mouth than phylloquinone, although MK-6, MK-7, MK-8, and MK-9 were as much as 25 times more potent than K₁ when injected intracardially.

More recently, vitamin K has been determined by chemical methods in which fat-solvent extraction of desiccated tissues is followed by column and thin-layer chromatography, and then by high-pressure liquid chromatography (HPLC) using both direct and reverse-phase columns. Vitamin K homologues are detected in the HPLC effluents by ultraviolet absorption, electrochemical techniques, or fluorescence of hydroquinone derivatives (12). Such methods have improved both the sensitivity and accuracy of vitamin K measurement. Use of combined gas chromatography (GC)-mass spectrometry allows measurements of vitamin K homologues in the femtomole range.

Analytical Values

The new set of values presented in Table 20.1 is based on two recent studies using advanced techniques for the measurement of phylloquinone. The first is the Total Diet Study (TDS) conducted annually by the FDA/USDA to monitor the safety and nutritional quality of the U.S. food supply. Some 264 core foods were identified from the 1987–1988 National Food Survey and analyzed at the USDA Human Nutrition Research Center at Tufts University (11). This work was complemented by a parallel study in Great Britain conducted by Shearer et al. (9, 13). These compilations are the most complete ever and provide the physician and dietitian with a suitable database for estimating vitamin K₁ intake.

Milk and milk products		Vegetables	
Butter	30.0	Asparagus	70
Cheddar	7.8	Beetroot, green	46
Milk (whole)	1.0	Broccoli	147
Milk (skimmed)	0.2	Broadbean sprouts	250
Eggs		Cabbage	110
Eggs (whole)	11.0	Celery	5
Meat and meat products		Celery	440
Beef	0.1	Kale	226
Beef liver	3.0	Lettuce	25
Chicken liver	0.3	Peas, green	33
Ground beef	2.4	Peas	1
Hams	0.1	Spinach	415
Lamb chops	4.6	Tomato	5
Pork tenderloin	0.1	Turnip	1
Fats		Turnip greens	650
Olive oil	56	Fruits

Carrots	1.8	Lehrbier	0.1
Shredded wheat	1.5	Beer	<0.1
		Tobacco	
		Cigarettes	5000

Data from references 9, 11, 13, 16.

Table 20.1 Average Vitamin K Content (µg/100 g) of Ordinary Foods

The variation in vitamin K₁ content of foods within food groups is conspicuous. For example, foods within the cereal and bread and meats groups can vary from 2.2 to 220 nmol/kg (0.1–10 µg/100 g). Fruits vary in their phyloquinone content from 2.2 nmol/kg (0.1 µg/100 g) in oranges to 88 nmol/kg (4.0 µg/100 g) in pears. Fats and oils also vary greatly, from 66 nmol/kg (3 µg/100 g) in corn oil to 4.4 mol/kg (198 µg/100 g) in soybean oil. Vegetables also vary, from 22 nmol/kg (1 µg/100 g) in turnips to 16.1 µmol/kg (726 µg/100 g) in kale.

Human milk contains about 6 nM (2–3 µg/L) phyloquinone; cow's milk contains about 22 nM (6–17 µg/L). Tobacco (not a typical food) is one of the richest sources of phyloquinone and contains 0.11 mmol/kg (5000 µg/100 g). When smoked, a small percentage of vitamin K is volatilized and can be absorbed through the mucous membranes, the nasopharynx, bronchi, and alveoli. The values for fruits, vegetables, and cereals shown in [Table 20.1](#) are subject to significant variation depending on the soil and climatic conditions where the plant was grown. [Table 20.2](#) compares the recommended mean dietary intakes of vitamin K₁ as stratified by age and gender with actual intakes measured in the Total Diet Study of the USDA. The estimated vitamin K₁ intake of about 100 µg/day is much lower than previously estimated (150–500 µg) ([11](#)) and closer to the recommended dietary allowance (RDA). There is, however, no doubt that some persons ingest more vitamin K than indicated in [Table 20.2](#) ([14](#)).

Table 20.2 Estimated Versus Recommended Mean Dietary Intakes of Vitamin K₁ Stratified by Age and Gender

ABSORPTION, DISTRIBUTION, AND METABOLISM

Absorption of phyloquinone and the menaquinones requires bile and pancreatic juice for maximum effectiveness. Dietary vitamin K is absorbed in the small bowel, is incorporated into chylomicrons, and appears in the lymph. The efficiency of absorption varies widely depending on the source of the vitamin K and the vehicle in which it is

administered and may be as low as 10% or as high as 80% (5). When isotopically labeled phylloquinone was administered to animals (16) or man by mouth in doses ranging from the physiologic to the pharmacologic, the vitamin appeared in the plasma within 20 minutes, peaked at 2 hours, and then declined exponentially to low values over 48 to 72 hours, reaching fasting levels of 1 to 2 nM (0.5–1.0 ng/mL). During this period, the vitamin K was transferred from chylomicron to chylomicron remnants. Vitamin K in these remnants can be taken up into hepatic, bone, and spleen cells. In the liver, some of the phylloquinone is stored, some oxidized to inactive end products, and some resecreted with very low density lipoprotein (VLDL), after which the phylloquinone appears in low-density lipoprotein (LDL) and high-density lipoprotein (HDL). In fasting persons, Kohlmeier et al. (16) found that approximately 50% of plasma phylloquinone is carried in the VLDL, about 25% in LDL, and about 25% in HDL.

Between 8 and 30% of administered radioactive phylloquinone in animals and man (17) is recovered in the urine, and 45 to 60% of the administered dose is excreted in the feces over a 5-day period. One-third of the fecal radioactivity was unchanged vitamin K₁ and the remainder were oxidized products. Administration of nonabsorbable lipids, such as mineral oil or squalene, or malabsorption of fat because of disease of the bowel greatly reduces absorption of vitamin K (18).

In hyperlipidemias, the turnover of lipoproteins is reduced and transfer of vitamin K to tissues impaired. As a result, vitamin K levels are increased in fasting plasma. A mutant form of apolipoprotein E (E2), a component of chylomicron remnants that binds poorly to hepatic receptors, reduces the delivery of vitamin K to tissues (9). Similar observations have been made with respect to other hyperlipidemias (8).

The distribution of phylloquinone in the plasma of healthy adults has been studied by several investigators. Sadowski et al. (19) studied 326 fasting individuals: 131 ranged in age from 20 to 49 years, and 195 from 65 to 92 years. The range of phylloquinone concentrations was 0.29 to 2.64 nM (0.13–1.2 ng/mL). Age was not a significant variable. The raw data were skewed to the high side (median, 0.86 nM; mean, 1.01 nM), but the skewed curve was made to conform to a normal distribution by logarithmic transformation. Since the diet is a major determinant of the fasting phylloquinone level, values on the high side may reflect high intakes of phylloquinone and values on the low side may reflect low intakes of phylloquinone. It is difficult, however, to set a level that represents “vitamin K deficiency,” since levels required to maintain normal levels of the coagulation factors are extremely low. Furthermore, the level required for maintenance of normal bone metabolism has not been determined. Similar data on plasma phylloquinone in normal humans were obtained by Shearer et al. (13).

As techniques for measuring vitamin K homologues improved, the high-molecular-weight menaquinones (MK-6, MK-7, and MK-8) as well as phylloquinone could be detected in plasma. In addition to MK-6, MK-7, and MK-8, even higher-molecular-weight menaquinones (MK-9 to MK-13) of bacterial origin (*Staphylococcus aureus*, *Bacteroides vulgatus*, *Bacillus subtilis*, and the actinomycetes) are absorbed from the terminal ileum and are found in the liver. Table 20.3 shows average values for phylloquinone and the menaquinones in plasma and liver. Early analysis (29) showed that phylloquinone made up about 50% of hepatic vitamin K, but

more recent data show that phylloquinone makes up only 10% of hepatic vitamin K (10, 16, 19).

	Plasma	Liver
K ₁	1.24 ± 0.84	18 ± 9
MK-5		12 ± 8
MK-6		12 ± 13
MK-7	0.62 ± 0.39	71 ± 44
MK-8	0.71 ± 0.45	40 ± 54
MK-9		3 ± 2
MK-10		79 ± 32
MK-11		94 ± 39
MK-12		17 ± 7
MK-13		6 ± 3

Table 20.3 Distribution of Vitamin K Homologues in Human Plasma and Liver (pmol/g)

Wiss et al. observed that the principal excretory metabolite of phylloquinone in the rat is a γ -lactone that appears to be excreted as a glucuronide. Vitamin K-2,3-epoxide has also been identified as a metabolite of vitamin K in animals and is metabolized to a homologous lactone (21, 22).

The turnover of vitamin K in the animal body is rapid, and the total body pool is surprisingly small. Bjornsson et al. (23) infused 300 μ g of ³H-phylloquinone into human volunteers with and/or without previous drug loading with warfarin or clofibrate. The initial half-time ($t_{1/2a}$) for the first exponential phase was 26 ± 8 minutes, and the average terminal half-time ($t_{1/2b}$) was 166 ± 9 minutes under all conditions. Shearer et al. (24) obtained similar results with a 2.2- μ mol (1.0-mg) intravenous dose of ³H-phylloquinone in that $t_{1/2a}$ equaled 20 to 24 minutes and $t_{1/2b}$ equaled 120 to 150 minutes. From data on the volume of distribution and clearance rate, Bjornsson et al. (25) calculated the turnover rate to be 0.4/hr, suggesting that the body pool turned over every 2.5 hours. More recently, Olson et al. (26), using 0.66 nmol (0.3 μ g, 10 μ Ci) of ³H-phylloquinone and longer periods of observation, reported that the phylloquinone pool turned over metabolically about once per day. From daily intakes of vitamin K of about 0.22 μ mol/day (100 μ g/day) and the turnover time of 24 hours, the body pool sizes were estimated to be 0.22 μ mol (100 μ g) or 3.1 nmol/kg (1.5 μ g/kg) body weight. This body pool of vitamin K is smaller than that for vitamin B₁₂ and is exceptionally low for a fat-soluble vitamin.

A rapid turnover of phylloquinone in humans is also supported by the studies of Usui et al. (10), who observed the changes in the concentration of plasma and hepatic phylloquinone in 22 surgical patients, half of whom were placed on a diet containing 5 μ g of vitamin K for 3 days prior to surgery. During this period, plasma phylloquinone

declined from 1.19 to 0.47 nM in patients on the low-K₁ diet and from 1.44 to 1.16 nM in those on the house diet. Liver biopsies showed that hepatic phylloquinone was 6.8 nM/kg on the low-K₁ diet, while the controls had a value of 28 nM/kg. Assuming a liver size of 1.2 kg, the authors calculated that during the time patients were on the low-K₁ diet, their total liver phylloquinone declined from 15 to 5 µg, or a fall of 66% in 3 days. A logarithmic plot of their data against time gives a t_{1/2} of 1.5 days, in fairly good agreement with the findings of Olson et al. (26). Total menaquinones in the liver of patients before and after receiving the low-K₁ diet were not significantly changed (238 vs. 274 nmol/kg). Kindberg and Suttie (27) also observed a rapid turnover of phylloquinone in the livers of rats (t_{1/2} = 24 h).

If the body pool is of the order of 3.1 nmol/kg (1.4 µg/kg) as calculated by Olson et al. (26), about 80 µg would be present in the patients studied by Usui et al. (10). If, further, only 15 µg (less than 20%) is present in the liver, the remaining body phylloquinone must be distributed among all the tissues containing g-glutamyl carboxylase. Hodges et al. (28) measured the vitamin K content of bone with respect to both phylloquinone and menaquinones and found levels as high as those in liver. Since bones make up 8.6% of the body weight (about four times that of the liver), it follows that about 60 µg of vitamin K (75%) would be found in the skeletal system, and the remaining 7% would, no doubt, be found in other tissues containing g-glutamyl carboxylases.

When menadione (2-methyl-1,4-naphthoquinone) is administered to animals or man, only a small amount (0.05–1.0%) is converted to MK-4 (29). The principal metabolites of menadione are the sulfate and glucuronide of dihydromenadione. The claim that phylloquinone may be converted to MK-4 in animal tissues is based on indirect evidence (30) and requires further study.

PHYSIOLOGIC FUNCTION

Regulation of Clotting-Protein Synthesis

The seven vitamin K–dependent coagulation proteins shown in [Table 20.4](#) (with one exception, protein S) are proenzymes that are converted to serine proteases during coagulation. All require calcium for activation, a phenomenon mediated by their g-carboxyglutamate residues. The vitamin K–dependent procoagulant factors (II, VII, IX, and X) form the core of the proteolytic cascade leading to fibrin formation in hemostasis as shown in [Figure 20-3](#). The intrinsic system, which is operative within the circulation, is activated by surface-mediated reactions involving high-molecular-weight kininogen and prekallikrein. They initiate a series of reactions that result in activation of factor XII to XIIa, the activation of XI to XIa, and the conversion of factor X to Xa. The extrinsic system, which is switched on by cell injury, requires tissue factor (TF, 46 kDa), which is an intrinsic membrane glycoprotein tightly associated with phospholipid. TF also has a high affinity for plasma factor VII, which it converts to factor VIIa. The factor VIIa-TF complex then converts factor X to Xa by limited proteolysis.

Characteristic	Factor				Protein		
	II	X	IX	VII	C	S	Z
Plasma concentration (µg/L)	100	10	3	1	5	25	3
Molecular weight (kDa)	71.6	58.8	56.8	50.0	62.0	70.7	62.0
Carbohydrate (%)	8	15	17	13	11	8	10
Number of chains	1	2	1	1	2	1	1
Number of Gla residues	10	11	12	10	9	11	13

Table 20.4 Characteristics of the Vitamin K–Dependent Coagulation Proenzymes

Figure 20.3. The clotting factor cascade. Factors II, VII, IX, and X and proteins C and S contain Gla and are vitamin K dependent. The first four factors occupy the core of the clotting scheme; protein C is an anticoagulant protein that inactivates factors Va and VIIIa and inhibits the conversion of factor II to IIa. Protein S is a cofactor for protein C and enhances its rate of activation by thrombin. Thrombomodulin further enhances the activation of protein C by thrombin. Antithrombin III also inhibits the intrinsic cascade. Ca^{2+} is required to activate Gla-containing factors. Factors V (accelerator globulin) and VIII (antihemophilic globulin) are cofactors. Factor XIII is a transpeptidase.

The final common pathway begins with the prothrombinase complex (factor Xa, Va, calcium, and phospholipid) on the platelet membrane that converts prothrombin (factor II) to thrombin (IIa), which in turn converts fibrinogen to fibrin. Two cofactors not dependent on vitamin K, factor VIII (the antihemophilic globulin) and factor V (accelerator globulin), are important in the middle stages of the cascade. Factor V is a peptide (290 kDa) that is cleaved by thrombin to factor Va, a carbohydrate-rich two-chain fragment (163 kDa). Factor VIII is a glycoprotein (330 kDa) that circulates in a

complex with von Willebrand factor and is also cleaved to yield a two-chain VIIIa (140 kDa).

Protein C is an anticoagulant that serves as a brake on the speed of the intrinsic cascade through a feedback loop involving thrombin. When thrombin is made from prothrombin, thrombomodulin, a 75-kDa thrombin receptor on the surface of endothelial cells, combines with thrombin. As a result, the affinity of thrombin for fibrinogen, factor V, and platelets is reduced and its affinity for protein C is increased, which results in the activation of protein C. Activated protein C_a inhibits factors VIIIa and Va and the conversion of prothrombin to thrombin, thus slowing its own production. A recently discovered mutation in factor V (Leiden) in some persons prevents activation of protein C, which can lead to thrombosis (31). Protein S, another vitamin K–dependent protein, enhances the activity of protein C_a in the presence of phospholipid. This system normally provides feedback control and balance in the coagulation cascade. The other antagonist to thrombin is antithrombin III (58 kDa), for which heparan sulfate in the endothelium is a cofactor. Antithrombin III has a wide spectrum of antiprotease activities inhibiting thrombin as well as coagulation factors XIIa, XIa, IXa, and Xa.

Clearly, the coagulation cascade is tightly regulated by both procoagulants and anticoagulants, some of which are vitamin K dependent. Because most vitamin K–dependent coagulation factors are synthesized in the liver, hepatectomy (or severe liver disease) results in lowered plasma levels of these factors and reduced renal sensitivity to administration of vitamin K. Kemkes-Matthis and Matthis recently reported that protein Z promotes the association of thrombin with phospholipid surfaces (32). They observed that protein Z is not synthesized in patients with severe liver disease, which may contribute to the hemorrhage suffered by such patients.

All the genes that code for the seven vitamin K–dependent plasma coagulation factors have been cloned, and the complementary DNA (cDNA) sequences have been determined for all but protein Z (33). The size, composition, and location of each gene are shown in [Table 20.5](#). Typical of the genes for vitamin K–dependent proteins is the gene for prothrombin, which is located on chromosome 11 at p11-q12. It is approximately 24 kilobases long and contains 13 introns (which are not translated) and 14 exons. The messenger RNA (mRNA) for prothrombin is about 2000 nucleotides long and contains a noncoding region of 97 base pairs and a poly A tail of 27 base pairs. As shown in [Figure 20-4](#), mature prothrombin contains 579 amino acids and three carbohydrate chains at residues 78, 100, and 373, accounting for 8.2% of the 71.6-kDa molecule. As synthesized, however, prothrombin has a 43-amino acid leader sequence containing both signal and propeptide residues. The prosegment, which contains 18 amino acids, is the recognition site for the g-glutamyl carboxylase and is similar in sequence to prosegments in other vitamin K–dependent proteins.

Factor	Gene (kb)	Exons	Introns	Chromosome
II	21	14	13	11
VII	13	8	7	13
IX	34	8	7	X
X	25	8	7	13
C	11	9	8	2
S	80	15	14	3

Table 20.5 Genes of Vitamin K–Dependent Proteins and Their Chromosome Locations

Figure 20.4. Structure of human prothrombin. A linear model of the nascent peptide is shown at the *top*. It has three components, a signal segment of 25 amino acids, a basic prosegment of 18 amino acids (*in black*), and a coding portion of 579 amino acids. The signal segment is cleaved by a signal peptidase on the luminal side of the rough endoplasmic reticulum (RER). After carboxylation of 10 N-terminal Gla residues in the mature peptide, the prosegment is cleaved in the Golgi apparatus before secretion. The *second linear drawing* shows the mature prothrombin secreted into plasma, which has an N-terminal alanine and a C-terminal glutamic acid. The thrombin portion is *crosshatched*. Prothrombin is split at arginine 271 by activated factor X to generate prethrombin-2, which is converted into an active two-chain, disulfide-linked thrombin by a second factor X_a clip at arginine 320. The thrombin formed autocatalytically splits prothrombin and fragment 1,2 at arginine 156 to yield prethrombin-1 and fragments 1 and 2. The 10 Gla residues in fragment 1 are at positions 7, 8, 15, 17, 20, 21, 26, 27, 30, and 33, and the carbohydrate moieties are at positions 78, 100, and 373.

Vitamin K–Dependent g-Glutamyl Carboxylase

The vitamin K–dependent g-glutamyl carboxylase is a membrane-bound component of the endoplasmic reticulum. It has been solubilized (34, 35) by various detergents and, in the soluble form, retains most of the properties of the microsomal system. The system requires a Glu-containing peptide substrate, O₂, CO₂, and either vitamin K plus NADH (the reduced form of nicotinamide adenine dinucleotide) or a vitamin K hydroquinone. CO₂, not HCO₃⁻, is the active form of carbon dioxide incorporated into the g-carboxyl group of peptide-bound glutamate (Gla_p) (36). Adenosine triphosphate (ATP) is not required, and biotin is not involved. Reduced vitamin K functions as a cosubstrate in the carboxylation reaction, but also as a cofactor because it is regenerated by two reductases in separate reactions. The overall carboxylation reaction is

Under physiologic conditions, the oxidation of KH₂ to KO (vitamin K-2,3 epoxide) is coupled to the fixation of CO₂ in the g position of peptide-bound glutamate to form Gla_p. Coupling depends upon the availability of CO₂ in the reaction mixture; in its absence, the enzyme functions as an epoxidase. The *K_m* for bicarbonate is between 0.2 and 0.4 mM (about 1% of the bicarbonate concentration in the plasma), in equilibrium with 0.01 to 0.02 mM CO₂ at intracellular pH. The rate of g-carboxylation in vitro is conveniently measured by adding H¹⁴CO₃⁻ to the reaction medium and determining the radioactivity incorporated into peptide-bound glutamic acid. Artificial substrates such as Phe-Leu-Glu-Glu-Leu are CO₂ acceptors in this reaction, although at much higher concentrations than the physiologic substrates.

Efforts to purify the vitamin K–dependent g-glutamyl carboxylase began in 1974 in several laboratories. By 1987, the best purification of the carboxylase from liver microsomes was 400 times. In 1989, Hubbard et al. (37) claimed they had purified the vitamin K–dependent carboxylase (77 kDa) to homogeneity (about 10,000 times from bovine microsomes) using synthetic propeptides as affinity columns, but alas, this carboxylase preparation was later shown to be extensively contaminated with a ubiquitous microsomal binding protein (BiP) also known as GRP-78.

In 1991, Wu et al. (38) reported purification of the g-glutamyl carboxylase (94 kDa) to near homogeneity (about 70,000 times from bovine microsomes) by affinity chromatography and shortly thereafter cloned the human gene for the carboxylase (39). Starting with a nucleotide coding for a 37-amino acid sequence from the bovine g-glutamyl carboxylase, these investigators screened a cDNA library from bovine liver and found three partial clones. An *Eco*RI cDNA fragment of 280 bp from the bovine library was then used to screen a human erythroleukemia (HEL) cDNA library, and one clone of the gene for the human carboxylase with an internal *Eco*RI site was obtained.

Several observations indicate that the entire coding sequence was contained within that cDNA: (a) the methionine identified as the first amino acid is the only in-frame methionine between a stop codon 27 nucleotides upstream and the first tryptic peptide 195 nucleotides downstream; (b) the open reading frame codes for 758 amino acids and predicts a molecular weight of 87,542, which, if one takes into account that the protein is glycosylated, agrees with the 94 kDa estimated by its mobility in SDS-polyacrylamide gel electrophoresis; and (c) the cDNA codes for functional carboxylase in mammalian cells.

The enzyme activity coded for by the human cDNA was expressed in human kidney 293 cells using the vector pCMV5 with/without the enzyme cDNA. Forty-eight hours after transfection, cells were harvested, microsomes prepared, and g-glutamyl carboxylase activity determined by standard techniques using $^{14}\text{CO}_2$ and phe-leu-glu-glu-leu (FLEEL) as substrates. Under all conditions, including activation by $(\text{NH}_4)_2\text{SO}_4$ and a 19-residue peptide from profactor IX, the microsomes programmed by enzyme cDNA resulted in an increase in activity of 9- to 27-fold over the mock-transfected cells.

In 1992, Berkner et al. (40) reported the isolation of a g-glutamyl carboxylase with high activity and an apparent molecular mass of 98 kDa measured on SDS-polyacrylamide gels. In the same year, Kuliopulos et al. (41) reported that by use of the affinity label *N*-bromoacetyl-FLEEL- ^{125}I Y for the carboxylase, the molecular mass of 94 kDa was confirmed. It is likely that the enzyme isolated by Berkner et al. (40), alleged to have a molecular mass of 98 kDa (a 4% error in estimation), is identical with the carboxylase first isolated by Wu et al. (38), but cloning and functional analysis of the 98-kDa protein will be necessary to prove it.

The nucleotide sequence of the human g-glutamyl carboxylase gene is 88% homologous to the gene for the bovine carboxylase (42), which also has a 758-amino acid reading frame. Eight of nine potential *N*-glycosylation sites are in the hydrophilic carboxyl-terminal half of the carboxylase, which projects into the lumen of the endoplasmic reticulum. There is a minimum of three hydrophobic transmembrane sites in the N-terminal portion of the protein and maybe as many as seven. The carboxylase and soybean lipoxygenase share 19.3% identity over a space of 198 amino acids from residues 468 to 666 (38).

In 1995, Roth et al. (43) produced a series of mutants of recombinant g-glutamyl carboxylase with progressively larger COOH-terminal deletions. Recombinant wild type (residues 1–758) and mutants of the carboxylase terminating at residues 711, 676, and 572 were expressed in baculovirus-infected Sf9 cells. The kinetic behavior of mutant carboxylase, Cbx 711, was unchanged from the wild type. The mutant Cbx 676, however, retained a normal propeptide binding site, but the K_m for KH_2 had risen 23-fold and rate of epoxidase activity had fallen to 10%. The shortest mutant, Cbx 572, lacked both carboxylation and epoxidation activities. These results suggest that all but 47 residues at the C-terminal end contribute to the enzymatic activity of g-glutamyl carboxylase.

Finally, Wu et al. (44), by using chemical cross-linking reactions, limited trypsin digestion, and polyclonal antibodies against synthetic polypeptides, localized the propeptide binding site on the luminal lipoygenase-like domain of g-glutamyl carboxylase. Their limited tryptic digestion resulted in a 60-kDa C-terminal peptide and a 30-kDa N-terminal peptide joined by a disulfide bond. A tryptic fragment that cross-links to the propeptide substrate is immunochemically specific to the 60-kDa portion. They conclude that the propeptide binding site lies carboxyl-terminal to residue 438.

Thus, the location of the active site on the g-glutamyl carboxylase is currently controversial. All laboratories have identified a range of sites from residues 218 to 676 that contribute to the overall activity of the carboxylase. The location of cysteines required for activity, however, is still unsolved. Figure 20-5 presents a hypothesis that might account for these disparate findings. The N-terminal end of the molecule is clearly the zone of the transmembrane segments. Figure 20-5 shows five such segments, although the incomplete data support a range of three to seven such segments. The C-terminal end clearly projects into the lumen where the carboxylation occurs, and the present data indicate that only the terminal 47 residues are dispensable. It is likely that the C-terminal portion folds to provide an area of confluence of several residues necessary for g-glutamyl carboxylation. Since epoxidation is required for carboxylation, these reactions must be linked around a single active site. Finally, it must border the membrane because of the lipid solubility of vitamin K.

Figure 20.5. A proposed cellular location of g-glutamyl carboxylase. Several N-terminal transmembrane segments of the enzyme span the membrane of the endoplasmic reticulum (ER) and then project into the lumen where carboxylation of peptide-bound glutamate occurs. Attempts to localize the “active site” of this enzyme have led to the view that most of the C-terminal part of the enzyme contributes residues to a cooperative site that is near the luminal membrane.

The biochemical mechanism of the vitamin K–dependent carboxylation is still under study. A mechanism proposed by Larson and Suttie for the coupling of carboxylation

and epoxidation in the vitamin K–dependent carboxylase is shown in [Figure 20-6 \(45\)](#). The reaction is presented as an ordered mechanism with three partial reactions. The first event is the combination of the enzyme with KH_2 and O_2 to yield a ternary enzyme-substrate complex that forms KHOOH , a hydroperoxide of vitamin K hydroquinone. This was initially visualized as the product of a reaction with oxygen at position 2 of the naphthoquinone ring, although now it appears that the initial attack is on the 1-carbon. This step is inhibited competitively by chlorophylloquinone and tetrachloropyridinol. The propeptide binds to the enzyme and provides the substrate for proton abstraction. Epoxidation can occur in the absence of peptide and CO_2 , but peptide addition stimulates carboxylation and enhances epoxidation.

Figure 20.6. Mechanism for the coupling of carboxylation and epoxidation in vitamin K–dependent Gla synthesis. KH_2 , vitamin K hydroquinone; KH-OOH , vitamin K hydroperoxide (which rearranges to an alkoxide moiety); KO , vitamin K-2,3-epoxide; GLUp , peptide-bound glutamate; GLAp , peptide-bound g-carboxyglutamate.

Larson and Suttie (45) proposed that the hypothetical vitamin K-hydroperoxy anion was sufficiently basic to remove the g-methylene proton from peptide-bound glutamate. Olson's group, however, argued that the organic hydroperoxy anion was insufficiently basic ($\text{pK}_a = 9$) to remove a proton from the g-methylene group and suggested an inductive mechanism for the labilization of the g-methylene proton (46). On the basis of the study of a model system, Dowd and Ham suggested that the oxygen addition to reduced vitamin K results in formation of an extremely basic epoxy alkoxide anion ($\text{pK}_a = 27$) (47). This phenomenon, known as *base strength amplification*, provides a base of sufficient strength to remove a proton from the g-carbon of peptide-bound glutamate. The proposed sequence of metabolic steps is shown in [Figure 20-7](#). The first postulated step is ionization of the hydroquinone to give vitamin KH^- , followed by reaction with oxygen to form a peroxide that in turn rearranges via the K-dioxetane to the alkoxide. After removal of a proton from the g position of peptide-bound glutamate, vitamin K-2,3-epoxide and water are formed.

Figure 20.7. Proposed intermediates in the rearrangement of the initial vitamin K peroxide derivative to “achieve base amplification” and promote proton abstraction from peptide-bound glutamate.

Vitamin K Cycle

The vitamin K cycle is shown in [Figure 20-8](#). In essence it is a salvage pathway for vitamin K, a vitamin present in only nanomolar quantities in liver and other tissues. In this cycle, vitamin K-2,3-epoxide, a product of the carboxylation reaction, is reduced to the quinone by a dithiol-dependent epoxide reductase. The regenerated vitamin K is then reduced to vitamin K hydroquinone by one of several enzymes, at least one driven by a dithiol and several by reduced forms of NADPH. The dithiol dependent reductases for both the epoxide and the quinone are strongly inhibited by warfarin; the NADPH-dependent dehydrogenases are relatively insensitive to warfarin ([48](#)). The net effect of the cycle is the conversion of vitamin K-2,3-epoxide formed in the carboxylation reaction to vitamin K hydroquinone, which becomes available as a substrate for another round of carboxylation. In this way, vitamin K acts catalytically for Gla synthesis. Because of the low level of vitamin K in tissues and the relatively low intake of vitamin K (~60–100 μg/day), the cycle is vital to maintain the integrity of the vitamin K system.

Figure 20.8. The vitamin K cycle occurs in the hepatic endoplasmic reticulum. Carboxylation and epoxidation are catalyzed by the same enzyme. The dithiol-dependent reductions of vitamin K epoxide and vitamin K are extremely sensitive to the action of coumarin anticoagulants such as warfarin (warf). NADPH-dependent dehydrogenases are not inhibited by warfarin.

Adult humans excrete about 40 μmol of γ -carboxyglutamic acid (Gla) per day. Gla is liberated during the catabolism of K-dependent proteins and appears in the urine unchanged. For every mole of Gla formed in the body, 1 mole of vitamin K must be converted to its 2,3-epoxide. Since the daily intake of vitamin K is normally about 0.22 μmol (100 μg) per day, it follows that the cycle must make 200 revolutions per day under usual conditions. If, on the other hand, vitamin K intake is reduced to 0.01 μmol (5 μg) per day, the cycle must make 4000 revolutions per day to maintain normal Gla synthesis in K-dependent proteins. The K_m of γ -glutamyl carboxylase for KH_2 must be of the order of 10 nM in vivo to accomplish Gla synthesis under conditions of minimum intake of vitamin K and much below the K_m of 20 to 30 μM reported for the purified carboxylase.

Differences in vitamin K requirements may have more to do with the integrity of the vitamin K cycle than metabolic transformations of vitamin K. The difference between the requirements for vitamin K in the rat and chick (which is higher) is due to the activity of the vitamin K cycle (49).

Bone and Kidney Proteins Containing γ -Carboxyglutamate

Two vitamin K-dependent bone proteins have been discovered in the last 20 years. The first is bone Gla protein (BGP, or osteocalcin) secreted by osteoblasts and discovered independently by Hauschka et al. (50) and Price et al. (51) in 1975. The second is the matrix Gla protein (MGP) discovered in bone, dentin, and cartilage by Price et al. in 1985 (52). BGP, a water-soluble 49-residue protein with a molecular weight of 5700, contains three Gla residues at positions 17, 21, and 24 and one disulfide bond.

BGP is one of the most abundant noncollagenous proteins in bone, accounting for 15 to 20% of noncollagen proteins in most vertebrates, and appears to be derived from osteoblasts. The concentration in bone is about 5 mg/g. Small amounts of BGP are found in plasma: about 8 ng/mL in men and 5 ng/mL in women. These values are increased in patients with metabolic bone disease (53). In vitro, BGP binds strongly to hydroxyapatite and inhibits its formation. Both of these properties are lost when the Gla residues are decarboxylated. The nascent peptide of BGP contains a 23-residue leader sequence, a 26-residue propeptide, and, as indicated, a 49-residue mature protein that is not homologous with the coagulation proteins. The 26-residue propeptide, however, appears to serve as the recognition site for the γ -glutamyl carboxylase.

BGP occurs in both fully carboxylated and undercarboxylated (ucBGP) forms in plasma, which presumably represents the state of BGP in bone. Knapen et al. (54) compared the BGP concentration in pre- and postmenopausal women. They found that although the total immunoreactive BGP was the same in both groups, the hydroxyapatite-binding capacity (HAB) was 80 to 100% in normal young women but significantly reduced in older women (~50%). Both groups were given vitamin K₁ (1 mg per os), and BGP was measured 14 days later. In the postmenopausal group, vitamin K increased the level and the HAB capacity of BGP, decreased calcium excretion, and caused a decrease in urinary hydroxyproline excretion. Hodges et al. (55) observed depressed levels of both phylloquinone and menaquinones in the plasma of patients with osteoporotic fractures of the spine and femoral neck. Phylloquinone was reduced from a normal value of 1.1 to 0.21 nM (0.5–0.1 ng/mL), and the menaquinones (MK-7 and MK-8) from 0.70 to 0.06 nM (0.45–0.04 ng/mL). Hodges et al. (56) observed a fall in both plasma and bone levels of phylloquinone and menaquinones in elderly women with hip fracture.

MGP is a 79-residue protein with a molecular weight of 8700 that contains Gla residues at position 2, 37, 41, 48, and 52. It is only 20% homologous with BGP and has different properties, being highly insoluble in neutral salt solutions. This insolubility reflects a strong tendency to self-associate. MGP is found in the organic matrix of bone, dentine, and cartilage and does not react with hydroxyapatite. The nascent peptide of MGP contains a 19-residue signal sequence but no propeptide. It does, however, have an internal sequence of amino acids in the mature protein from residues 15 to 30 that is homologous with the propeptide in the other vitamin K–dependent proteins. This sequence appears to serve as the recognition site for the g-glutamyl carboxylase (53).

Protein S, a cofactor for protein C, is also synthesized in osteoblasts and plays an undefined role in bone metabolism. Protein S, unlike the other vitamin K–dependent coagulation factors, does not yield a protease on limited proteolysis. In fact, its C-terminal portion resembles a steroid-binding protein. Children with inherited protein S deficiency not only suffer from the complications of thrombosis, but also have osteopenia with reduced mineral density and even vertebral compression fractures (57).

Microsomes from embryonic chick bone contain a vitamin K–dependent g-glutamyl carboxylase that can carboxylate endogenous bone protein and Glu-containing pentapeptides (58). Warfarin inhibits the synthesis of both BGP and MGP. Unlike the coagulation proteins synthesized in the liver, however, vitamin K does not overcome the effect of warfarin on BGP and MGP synthesis (53). This appears to result from the lack of an NADP-linked reductase for vitamin K in bone tissue. This nonresponsiveness of bone tissue to vitamin K in animals on warfarin permits study of the role of the vitamin K–dependent proteins in bone without risk of hemorrhage. Synthesis of both BGP and MGP, furthermore, is regulated by 1,25-dihydroxyvitamin D₃ in cultured osteosarcoma cells (59). More recently, it has been demonstrated that both retinoic acid receptors and vitamin D hormone receptors may form heterodimers that bind to the osteocalcin promoter in MCF-7 cells (60). This permits a synergy between retinoic acid and 1,25-dihydroxyvitamin D₁ in cultured osteocarcinoma cells. These findings suggest that BGP and MGP mediate some actions of vitamin D on bone. Although the present data show that deficiency of BGP does not affect bone structure repairs or fractures, plasma

BGP is elevated in metabolic bone disease (53). It is concluded that BGP may stimulate bone remodeling and mobilization of calcium, whereas MGP is associated with the inhibition of growth-plate mineralization.

Several cases of the Conradi-Hünemann teratogenic type of chondrodysplasia punctata were reported in infants born to mothers taking warfarin during the first trimester (61). This defect appears to result from a deficiency of BGP and MGP during embryogenesis.

At present it is known that γ -glutamyl carboxylase occurs in liver, bone, cartilage, dentin, kidney, placenta, pancreas, spleen, lung, testis, smooth muscle, fibroblasts, atherosclerotic plaques, and a wide variety of tumor cells (62). All of these extrahepatic Gla-proteins appear to resemble the bone type more than the liver type.

COUMARIN ANTICOAGULANT DRUGS

The coumarin anticoagulant agents (Fig. 20.9) inhibit the biosynthesis of prothrombin and other vitamin K-dependent factors in the liver and others in extrahepatic tissues and thus cause factor deficiencies in the plasma and elsewhere. Bell and Matschner (63) first proposed that warfarin inhibited the vitamin K epoxide reductase and prevented the operation of the vitamin K cycle, a view that has been extensively confirmed. The S(2) enantiomer of warfarin is five times more active than the R(+) enantiomer and binds more intensely to vitamin K epoxide reductase (64). The dithiothreitol (DTT)-driven vitamin KO reductase is not the only reductase blocked by warfarin; a similar DTT-dependent vitamin K reductase also is inhibited (65). This combined attack by coumarin anticoagulants reduces KH₂ to ineffective levels and stops carboxylation. The warfarin receptor, first described by Searcey et al. (66) in pharmacologic studies, has been identified as the vitamin K epoxide reductase (67). The DTT-driven vitamin K reductase has a very low K_m compared with the NADPH-dependent vitamin, and under physiologic conditions is the pathway used. DTT is used in the laboratory as a reductant for the vitamin KO reductase, but several physiologic dithiols may serve as reductants including thioredoxin, reduced lipoic acid, and a protein disulfide isomerase (132). It is somewhat surprising that the vitamin KO reductase has never been isolated and characterized.

Figure 20.9. Structures of two 4-hydroxycoumarin drugs.

Overdosage can occur in patients who receive coumarin drugs to prevent thrombosis in coronary artery disease or pulmonary embolic disease. Intravenous administration of pharmacologic doses of vitamin K₁ reinitiates prothrombin and other vitamin K-dependent factor synthesis in the liver within minutes by bypassing the blocked DTT-dependent vitamin K reductase in the liver. As noted above, this does not occur in bone. Water-soluble derivatives of menadione (e.g., Synkayvite) are largely ineffective against the coumarin anticoagulant drugs because, as mentioned above, the rate conversion to MK-4 is so slow that pharmacologically effective levels of the alkylated vitamin are not obtained.

VITAMIN K DEFICIENCY

Primary vitamin K deficiency is uncommon in healthy adults. Several factors protect adults from a lack of vitamin K: (a) widespread distribution of vitamin K in plant and animal tissues, (b) the vitamin K cycle, which conserves the vitamin, and (c) the microbiologic flora of the normal gut, which synthesizes menaquinones that can contribute to the requirement for vitamin K, although the exact contribution is still uncertain. On the other hand, vitamin K deficiency in the breast-fed newborn remains a major worldwide cause of infant morbidity and mortality (68). Reduced levels of the vitamin K-dependent coagulation factors in adults are largely secondary to disease or drug therapy. Bleeding is the major manifestation of vitamin K deficiency, whether the cause is genetic deletion, inadequate dietary intake, or antagonism of vitamin K by drugs. Easy bruisability and mucosal bleeding (especially epistaxis, gastrointestinal hemorrhage, menorrhagia, and hematuria) occur in vitamin K deficiency. Blood may ooze from puncture sites or incisions following trauma, and life-threatening intracranial hemorrhage can occur in infants.

The gene for γ -glutamyl carboxylase is located on chromosome 2 (69). The rare hereditary lack of all the vitamin K-dependent coagulation factors, which is presumed to be due to lack of the carboxylase, has been described in seven patients in the world literature. The victims of this genetic disorder demonstrate all of the signs of vitamin K deficiency.

The causes of acquired vitamin K deficiency are discussed below.

Hemorrhagic Disease of the Newborn

Newborn infants represent a special case of vitamin K nutrition because (a) the placenta is a relatively poor organ for the transmission of lipids, (b) the neonatal liver is immature with respect to prothrombin synthesis, (c) breast milk is low in vitamin K, and (d) the infant gut is sterile during the first few days of life. As a result, a sizable number of

infants develop hemorrhagic disease of the newborn (HDN). In normal infants, plasma concentrations of prothrombin and the other vitamin K–dependent factors are about 20% of adult values at birth, and they rise slowly to adult values at 3 weeks if vitamin K intake is adequate. If prothrombin values fall below 10%, HDN appears. HDN generally occurs 1 to 7 days postpartum and may be manifested by cutaneous, gastrointestinal, intrathoracic, or, in the worst cases, intracranial bleeding. Late hemorrhagic disease (LHD) occurs 1 to 3 months postpartum and has the same clinical manifestations as HDN. It is usually associated with malabsorption or liver disease. If the mother has ingested hydantoin anticonvulsants, cephalosporin antibiotics, or coumarin anticoagulants, the incidence of all types of HDN is increased. About 30% of full-term infants have descarboxyprothrombin (PIVKA II) in their plasma during the first week of life (70). The level of phylloquinone in the plasma of newborn infants is less than 0.22 nM (0.1 ng/mL). As food is taken, the levels gradually climb to normal adult values over a period of weeks. Some infants, however, who are breast-fed and who have received no prophylactic vitamin K at birth develop late HDN during the 3rd to the 8th weeks of life (68). These infants may have some abnormality of liver function in addition to low vitamin K levels. In any event, they require intensive vitamin K therapy. Premature infants are even more susceptible to vitamin K deficiency than are full-term ones. Because the requirement for vitamin K in the newborn is estimated to be 11.1 nmol/day (5 µg/day), the very low content of vitamin K in human milk (2.2 to 4.4 nM [1–2 µg/L]) accounts for the predisposition of breast-fed infants to develop the hemorrhagic syndrome (71). Because breast milk is sterile and delays colonization of the gut with bacteria, it is recommended that breast-fed babies receive 2.2 µmol (1 mg) of phylloquinone (Aqua MEPHYTON) intramuscularly at birth.

Infants of mothers on hydantoin anticonvulsants should have prophylactic vitamin K because diphenylhydantoin is an antagonist to vitamin K (72). Neonatal complications such as diarrhea, malabsorption, cystic fibrosis, idiopathic cholestasis, atresia of the bile duct, and prolonged parenteral nutrition are all indications for intramuscular or intravenous vitamin K administration to infants.

Dietary Inadequacy

Healthy adult subjects fed low–vitamin K diets (11–89 nmol/day; 5–40 µg/day) for several weeks demonstrate a fall in plasma vitamin K levels from 2.2 to 1.1 nM (1.0 to 0.5 ng/mL) but no significant change in plasma prothrombin values. In unusual cases, self-imposed dietary restriction may induce hypoprothrombinemia with hemorrhage responsive to oral vitamin K. Dietary deficiency of vitamin K is manifested more quickly following surgery and in debilitated patients, with or without antibiotics (73).

In protein-calorie malnutrition, amino acid deprivation may cause hypoprothrombinemia that is not responsive to vitamin K but that does respond to protein feeding. Aging per se does not seem to increase the vitamin K requirement or alter the vitamin K cycle (14).

Total Parenteral Nutrition

With the advent of subclavian vein catheterization in 1968 for long-term total parenteral nutrition (TPN) of both surgical and medical patients unable to eat, new nutritional

deficiency syndromes have been reported, including hemorrhage due to vitamin K deficiency. It is advisable to give doses of 2.2 μmol (1 mg) of phylloquinone per week (equivalent to about 0.3 μmol , or 150 μg , of vitamin K per day) to patients on TPN.

Malabsorption Syndrome

Depression of the vitamin K–dependent coagulation factors is frequently found in the malabsorption syndromes and in other gastrointestinal disorders (e.g., biliary obstruction, cystic fibrosis, sprue, celiac disease, ulcerative colitis, regional ileitis, and short bowel syndrome) (74). Severe abnormalities of coagulation with extensive bleeding are common in biliary obstruction, but they do occur with sufficient frequency in other forms of malabsorption to be a concern of physicians caring for these patients. One complication of ileojejunostomy for morbid obesity is hemorrhage due to vitamin K deficiency. Patients with malabsorption should be treated with all the fat-soluble vitamins. Vitamin K should be given orally in doses of 2.2 to 4.4 $\mu\text{mol}/\text{day}$ (1–2 mg/day) or parenterally in doses of 2.2 to 4.4 $\mu\text{mol}/\text{week}$ (1–2 mg/week).

Liver Disease

Patients with parenchymal liver disease may have hypoprothrombinemia and an elevation in plasma descarboxyprothrombin (75). They are unable to use vitamin K in the biosynthesis of vitamin K–dependent clotting factors, usually because of destruction of the rough reticulum in the hepatocyte. Patients with liver disease should be challenged with vitamin K to determine the extent of the blockade of prothrombin synthesis; however, there is no need to give repetitive high doses of vitamin K if the patient is refractory to a single intravenous dose of 22 μmol (10 mg) of vitamin K (76).

Drug Therapy

Various drugs, including the 4-hydroxycoumarins, salicylates, certain broad-spectrum antibiotics, and vitamins A and E in pharmacologic doses, antagonize the action of vitamin K.

Coumarin- and Salicylate-Induced Hemorrhagic Disease

The coumarin anticoagulant drugs can induce serious hypoprothrombinemia and even hemorrhage by blocking the vitamin K epoxide and vitamin K reductases. Some of the contributory causes are reduction in dietary intake of vitamin K, ingestion of interfering drugs, and inadvertent alteration of the anticoagulant dosage schedule. Coumarin drugs, in rare cases, may cause coumarin skin necrosis. This condition probably occurs because coumarin drugs inhibit biosynthesis of the anticoagulant protein C before they affect the levels of the procoagulant factors, II, XII, IX, and X. The temporary imbalance may in fact stimulate local coagulation in venules, with resulting thrombosis (77). Salicylates in large doses may also depress vitamin K–dependent factors by inhibiting the vitamin K epoxide reductase. When overdosage with or without bleeding occurs, the anticoagulant should be discontinued, 22 μmol (10 mg) of vitamin K₁ should be given parenterally, and prothrombin times should be monitored until they are in a satisfactory

range.

Broad-Spectrum Antibiotics

One source of vitamin K in humans is their own intestinal bacteria. Vitamin K, however, is not well absorbed from the colon. It is unclear whether the microorganisms synthesizing absorbable menaquinones in the intestine reside in the ileum or reside in the colon with reflux into the ileum where absorption of vitamin K is possible.

Sulfaquinoxaline, neomycin, and other broad-spectrum antibiotics can sterilize the bowel, which may contribute to vitamin K deficiency. Certain broad-spectrum cephalosporin antibiotics (moxalactam, cefamandole) cause vitamin K-reversible hemorrhage in man (77, 78). Lipsky (79) reported that the N-methylthiotetrazole moiety of these antibiotics blocks vitamin K-dependent peptide carboxylation in Triton-solubilized rat liver microsomes in a dose-dependent manner. However, Shearer et al. (80) concluded that those antibiotics oppose vitamin K by inhibiting hepatic vitamin K epoxide reductase.

Megadoses of Vitamins A and E

Megadoses of the fat-soluble vitamins A and E antagonize vitamin K. It has been recognized since 1944 that hypervitaminosis A in the rat leads to hypoprothrombinemia that can be prevented by the administration of vitamin K (81). A close relationship between the amount of dietary retinol (or retinoic acid) given and the severity of vitamin K deficiency was observed (82). The effect of vitamin A is more severe in males than in females, and retinoic acid is more effective than vitamin A acetate. Because parenterally administered retinoic acid failed to increase the vitamin K requirement, it was concluded that excess vitamin A reduced the absorption of vitamin K. Reduced plasma prothrombin levels have been reported in humans intoxicated with vitamin A (83).

Large amounts of vitamin E also antagonize the action of vitamin K in animals (84). Olson and Jones (85) observed that high dietary intakes of vitamin E in rats increased the vitamin K requirement. Vitamin E does not appear to affect vitamin K uptake or distribution from the gut, nor does vitamin E directly affect the vitamin K-dependent carboxylase in vitro. Bettger et al. (86) found α -tocopherolquinone to be a more potent antagonist of vitamin K activity in the rat than is *d*- α -tocopherol.

Dowd and Zheng (87) have proposed that the methene isomer of α -tocopherol quinone forms a covalent linkage with a thiol within the active site of γ -glutamyl carboxylase. Vitamin K deficiency in a human subject taking megadoses of vitamin E was reported by Corrigan and Marcus (88). Bleeding was observed in a middle-aged man taking 5 mg warfarin and 1200 IU vitamin E each day. Upon discontinuation of megavitamin E therapy, the bleeding tendency disappeared and the prolonged prothrombin time normalized.

EVALUATION OF NUTRITIONAL STATUS

Evaluation of individual persons for vitamin K status requires proper application of the classical medical approach to a patient, namely, take a history, do a physical examination, and conduct appropriate laboratory tests.

History

The medical history should include questions about hemorrhage in the mouth or from the nose, from the stomach and intestinal tract (hematemesis and melena), kidney (hematuria), and beneath the skin (ecchymoses). Persons at risk for vitamin K deficiency include newborn infants and adults who are on diets devoid of green, leafy vegetables and animal foods or who have malabsorption, osteoporosis, injury, or renal disease. A careful medical history should include questions about these risk factors and use of coumarin anticoagulant drugs. In addition, the diet history should include a list of foods frequently eaten, a 24-hour recall of foods eaten, and occasionally a 3-day diary.

Physical Examination

Evidence should be sought for a bleeding tendency, the cardinal sign of vitamin K deficiency. This can present in one or more of the following ways: bleeding from the nose or mouth; ecchymoses in the groin, around the collar line, or in the legs; splinter hemorrhages under the nails or in the conjunctiva; melena (gross or occult); hematuria; and hematemesis. Pallor may be a sign of previous bleeding. The perifollicular hemorrhages in the skin characteristic of scurvy are not seen in vitamin K deficiency.

Laboratory Tests

Reduction in prothrombin and other vitamin K–dependent factors (X, IX, VII, and protein C) below 50% in the plasma is an accepted indicator of vitamin K deficiency. Measurement of plasma phylloquinone, which requires reverse-phase high-pressure liquid chromatography, does not correlate too well with vitamin K status ([18](#)). The range of normal is 0.3 to 2.6 nM (0.15–1.0 ng/mL), with a mean of 0.9 nM ([12](#)). Restriction of vitamin K may lower plasma vitamin K levels about 50% in given individuals, usually without altering the level of plasma coagulation proteins. The most sensitive indicator of vitamin K deficiency is the amount of des-g-carboxyprothrombin (DCP) in the plasma measured by a specific antibody ([89](#)). In healthy persons, the DCP concentration is zero; in persons with vitamin K deficiency, liver disease, or both, the values can rise to 30% of the total prothrombin (~0.5 μ M). Other, more indirect methods measure the ratio of prothrombin activity to total immunochemical equivalents of prothrombin (II:Ag ratio) or the ratio of a thromboplastin-activated (Simplastin) prothrombin time to that activated by *Echis carinatus* venom (S:E ratio). In vitamin K deficiency, these ratios fall. Recently, the measurement of uncarboxylated osteocalcin has been used to verify the diagnosis of vitamin K deficiency ([62](#), [90](#)).

Finally, urinary Gla can be measured as an index of vitamin K–dependent protein catabolism. A single value of Gla in the urine has little significance, although a given individual may show a lower urinary Gla level when put on a vitamin K–restricted diet

(14).

NUTRITIONAL REQUIREMENTS

The vitamin K requirement of mammals is met by a combination of dietary intake and microbiologic biosynthesis in the gut. Genetic factors influence the vitamin K requirement in both animals and humans, because males require more vitamin K per kilogram of body weight than females do. As regards the intestinal flora, in conventional rats, the vitamin K requirement is about 22 nmol (10 µg) per kg of body weight per day, whereas in germ-free rats the requirement is more than doubled, to about 56 nmol (25 µg) per kg per day (91).

Over the past 30 years, several attempts have been made to estimate the vitamin K requirement in humans. In 1967, Frick et al. (92) studied 10 patients victimized by stroke who were unable to take food by mouth and were given intravenous fluids containing electrolytes, dextrose, and water-soluble vitamins together with parenteral antibiotics to suppress intestinal flora. Seven of these patients developed vitamin K deficiency 21 to 28 days after interruption of oral nutrition, as indicated by a decline in vitamin K–dependent factors II, VII, and X to levels of 10 to 15% of normal. They were given intravenous doses of phylloquinone between 0.015 and 1.5 µg/kg body weight. Although small responses in factor levels were observed at levels below 0.24 µg/kg, physiologically significant changes required 0.5 to 1.0 µg/kg/day.

In 1971, O'Reilly (93) reported a study of four volunteers maintained on a purified diet containing 55 nmol vitamin K₁ per day (about 25 µg) and given antibiotics to suppress bacterial synthesis of menaquinones for 5 weeks. These subjects maintained their plasma prothrombin activity in the range of 70 to 100%, which led to the conclusion that the human requirement for vitamin K was of the order of 0.5 µg/kg/day.

In 1984, Olson et al. (26) fed four healthy young males an elemental diet (Vivonex) containing less than 10 µg phylloquinone per day for 8 weeks, during which time no change in factors II, VII, IX, and X or prothrombin antigen activity was observed. Neomycin or vitamin E was given to two of the four subjects during the second 4-week period without effect on vitamin K–dependent factors. Their average plasma phylloquinone level decreased from 2.2 nM (1.0 ng/mL) to 1.1 nM (0.5 ng/mL) over that period. It was concluded that their short-term vitamin K requirement was of the order of 0.2 µg/kg day.

In 1987, Allison et al. (94) reported on the results of a study of 33 normal volunteers fed a vitamin K–deficient diet containing from 2 to 5 µg of phylloquinone for 13 days. Starting on the 4th day, 10 groups of three volunteers each were given a range of antibiotics (which included therapeutic doses of two aminopenicillins, a macrolide antibiotic, a trimethoprim-sulfamethiazole, and six cephalosporins). Three of the cephalosporins contain the N-methylthiotetrazole (NMTT) moiety reported to induce vitamin K deficiency. Although 12 of the 33 persons complained of diarrhea during the experimental period, there were no other adverse effects. No significant changes in prothrombin time (11.5–13 sec) or factor VII levels were noted. Plasma phylloquinone levels declined 66% from 3.1 ± 2.0 nM (SD) to 0.88 ± 0.66 nM (1.4 ± 0.9 – 0.4 ± 0.3

ng/mL), both values within the normal range for plasma phylloquinone. The Simplastin:Ecarin (S:E) clotting ratios were found to be 1.03 ± 0.20 in a normal population (range, 0.64–1.42). Seventeen of the volunteers had S:E ratios below 0.6 and nine were above 0.6 after 13 days on the vitamin K–dependent diet with antibiotics. There appeared to be no difference between the effects of various types of antibiotics, including those cephalosporins with the NMTT side chains. The authors concluded that 5 μg of dietary vitamin K was adequate to maintain coagulation homeostasis during this relatively short period and suggested that the RDA of 1 $\mu\text{g}/\text{kg}$ in healthy persons was too high.

In 1988, Suttie et al. (95) studied 10 college-aged nonsmoking males who modified their diets by avoiding vitamin K–rich foods for 3 weeks. Their vitamin K intake dropped from 178 nmol/day (80 $\mu\text{g}/\text{day}$) to about 89 nmol/day (40 $\mu\text{g}/\text{day}$), with a change in plasma phylloquinone from 2.00 ± 0.44 nM (0.90 ± 0.20 ng/mL) to 1.1 ± 0.44 nM (0.50 ± 0.20 ng/mL) during a 3-week period. There was no change in prothrombin time, although there was a 10% change in S:E clotting ratio and a 20% decrease in urinary Gla excretion.

The claim of Suttie et al. (95) that they induced a vitamin K deficiency in healthy college students on diets containing 40 μg of phylloquinone for 27 days is questionable. Furthermore, the S:E ratio was within normal limits (0.911 ± 0.09) according to the criteria given by Allison et al. (1.03 ± 0.20) (94).

In 1993, Ferland et al. (14) reported that a subclinical vitamin K deficiency was produced in 32 healthy subjects consisting of groups of male and female subjects ages 20 to 40 years and 60 to 80 years. All volunteers were initially fed a baseline diet of ordinary foods containing 100 μg of phylloquinone per day. This baseline period was followed by a 13-day depletion period during which the subjects were fed a weighed diet containing less than 10 μg of vitamin K₁ per day. After depletion, each subject entered a 16-day repletion period consisting of four stages, lasting 4 days each, during which they were fed supplements of 5, 15, 25, and 45 μg of vitamin K₁ per day.

On the house diet, the plasma phylloquinone values of both young and elderly subjects declined 30 to 40%, from initial values of 1.25 to 0.77 nM (0.56–0.35 ng/mL) in the older group and 1.08 nM to 0.45 nM (0.48–0.2 ng/mL) in the younger group. It appears that both groups were taking considerably more vitamin K than 100 $\mu\text{g}/\text{day}$ during their ad libitum period. On the deficient diet, plasma phylloquinone declined further, from 0.77 nM (0.35 ng/mL) to 0.22 nM (0.1 ng/mL) in the elderly and from 0.45 nM (0.2 ng/mL) to 0.15 nM (0.07 ng/mL) in the young group. Both plasma K₁ levels were below the normal range. Gla excretion declined only 10% in the young and not at all in the elderly. There was no change in factor VII and protein C levels. A change in descarboxyprothrombin (PIVKA II) was detected by one antibody (but not a second one), which showed an infinitesimal rise in PIVKA II (about 2 ng/mL) equivalent to 0.002% of the prothrombin level. The addition of 5, 15, and 25 μg of vitamin K to the basal diet showed no significant change in plasma prothrombin levels, although 45 μg gave a positive response. These investigators calculated that the total expected turnover of known vitamin K–dependent coagulation factors could account for only 64% of the total Gla excreted, suggesting that bone Gla-proteins plus others must account for the difference.

The greater lability of phylloquinone levels and Gla synthesis in young persons suggests that they have a higher turnover rate for vitamin K₁ and (as the authors mention) lower hepatic concentrations of phylloquinone than elderly persons.

The available data do not conclusively establish the requirement for vitamin K in humans, mostly because none is a long-term study. These studies are also complicated by the fact that the coagulation factors do not respond to reduction of vitamin K intakes from more than 1 µg/kg to 0.2 µg/kg. The other feature not well studied is the requirement of bone cells for vitamin K. Plasma BGP is partially uncarboxylated in older persons and appears to respond to large doses of vitamin K. Further studies are needed to quantify the response as a function of dose.

NUTRITIONAL ALLOWANCES

The RDAs for vitamin K were set by the Food and Nutrition Board for children and adult men and women for the first time in the 10th edition of *Recommended Dietary Allowances* (1989) (96). RDAs are defined as the levels of intake of essential nutrients that, on the basis of current scientific knowledge, are judged to be adequate to meet the needs of all healthy persons.

Because the database for setting requirements for vitamin K in man is small, and because the RDA should be at least two standard deviations above the mean requirement, the values presented in [Table 20.6](#) are considerably higher than the estimated requirements. This is appropriate because the available data do not include information about the requirements for bone and kidney metabolism.

Category	Age (years) or Condition	Weight (kg)	Vitamin K* (µg)
Infants	0-0.5	6	5
	0.5-1.0	9	10
Children	1-3	13	15
	4-6	20	20
	7-10	28	30
Males	11-14	45	45
	15-18	66	65
	19-24	72	70

*1 µg Vitamin K₁ = 2.2 mmol.

Table 20.6 Food and Nutrition Board (NAS/NRC) Recommended Dietary Allowances for Vitamin K (1989)

TOXICITY

There are no reports of toxic effects of phylloquinone at 500 times its RDA. Although this lack of toxicity is true for phylloquinone, it is not true of the vitamin precursor, menadione (2-methyl-1,4-naphthoquinone) unsubstituted in the 3 position, and its water-soluble derivatives such as Synkayvite. Menadione can combine with sulfhydryl groups in membranes and cause hemolytic anemia, hyperbilirubinemia, and kernicterus in infants (97). Menadione should no longer be used as a therapeutic form of vitamin K.

HISTORICAL LANDMARKS

Although Neiching, the Chinese medical book, mentioned beriberi in 2697 BC it was not known for centuries that this illness was due to thiamin deficiency. In 1884, Takaki, a surgeon general of the Japanese navy, concluded beriberi was caused by a lack of nitrogenous food components in association with excessive intake of nonnitrogenous food. In 1890, Eijkman, a Dutch physician working in Java, discovered that fowl fed boiled polished rice developed polyneuritis that resembled beriberi in man and this polyneuritis could be prevented by rice bran or polishings. In 1911, Funk, a chemist working at the Lister Institute in London, was convinced that he had isolated the antiberiberi principle possessing an amine function from rice bran extracts. He named it "vitamine." His crystalline substance was shown later to have little antineuritic activity. In 1926, Jansen and Donath, Dutch chemists working in Java, succeeded in isolating and

crystallizing antiberiberi factor from rice bran extracts. By 1934 Williams, a U.S. chemist, had isolated a sufficient quantity of thiamin so that its structure could be determined. Its synthesis was accomplished in 1936. In 1937, Lohman and Schuster discovered that the active coenzyme form of thiamin was thiamin pyrophosphate (TPP; cocarboxylase) ([Fig. 21.1](#)) ([1](#), [2](#) and [3](#)).

Figure 21.1. Structural formulas of thiamin and thiamin pyrophosphate.

CHEMISTRY AND NOMENCLATURE

The chemical name of thiamin, formerly known as vitamin B₁, vitamin F, aneurine, or thiamine, is

3-(4-amino-2-methylpyrimidin-5-ylmethyl)-5-(2-hydroxyethyl)-4-methylthiazolium ([Fig. 21.1](#)) ([4](#)). The free vitamin is a base. It is isolated or synthesized and handled as a solid thiazolium salt, i.e., thiamin hydrochloride or thiamin mononitrate. The synthesis of thiamin is accomplished by either the pyrimidine and thiazole rings being prepared separately and condensed via the bromide or the pyrimidine ring being synthesized and the thiazole ring formed in situ on it. The molecular weight of thiamin hydrochloride is 337.28 g/mol ([1](#), [3](#)), whereas that of the free base is 265.36 g/mol. The molecular weight of the free base is used in calculating molar amounts from mass units.

Thiamin hydrochloride is a white crystalline substance. It is readily soluble in water, only partly soluble in alcohol and acetone, and insoluble in other fat solvents. In the dry form it is stable at 100°C. Thiamin in aqueous solutions is quite stable below pH 5 to heat and to oxidation; above pH 5 it is destroyed relatively rapidly by autoclaving and at pH 7.0 or above by boiling. Thiamin is readily cleaved at the methylene bridge by sulfite treatment at pH 6.0 or above into 2-methyl-4-amino-5-methyl-pyrimidylsulfonate and 4-methyl-5-(2-hydroxyethyl) thiazole. At pH 8.0 or above, thiamin turns yellow and is destroyed by a complex series of irreversible reactions. In strong alkaline solution in the presence of oxidizing agents such as potassium ferricyanide, thiamin is converted to thiochrome, a fluorescent derivative that is used to determine thiamin content. Thiamin is precipitated by iron and ammonium citrate, tannin, and various alkaloids. Thiamin

forms esters at the hydroxethyl side chain with various acids. The most important esters are thiamin monophosphate (TMP), TPP, and thiamin triphosphate (TTP) ([1](#), [2](#) and [3](#)).

BIOLOGIC ACTIVITY

Both pyrimidine and thiazole moieties are needed for its vitaminic activity, which is maximal when only one methylene group bridges the two moieties. In the thiazole portion, the quaternary nitrogen and a hydroxyethyl group at carbon 5 are needed, as is the amino group at carbon 4 in the pyrimidine portion. Several thiamin antagonists, including oxythiamin, pyrithiamin, and amprolium, produce thiamin deficiency in animals ([1](#), [2](#) and [3](#)).

DIETARY CONSIDERATIONS

Thiamin status is affected by diet and a variety of other factors.

Food Sources

Thiamin, although found in a large variety of animal and vegetable products, is abundant in only a few foods. Excellent sources of thiamin are yeast, lean pork, and legumes, which contain 22.6 to 90.5, 2.7 to 3.9, and 2.0 to 3.8 μmol (6–24, 0.72–1.04, and 0.53–1.00 mg) of thiamin per 100 g edible portion, respectively. In cereal grains, thiamin is low in the endosperm but high in the germ. The thiamin contents in rice bran, home-pounded rice, and milled rice are 7.5 to 15.1, 0.3 to 0.5, and 0.1 to 0.15 $\mu\text{mol}/100$ g (2–4, 0.08–0.14, and 0.02–0.04 mg/100 g), respectively. Thiamin is absent from fats, oils, and refined sugars. Milk and milk products, seafood, fruits, and vegetables are not good sources ([1](#), [3](#), [5](#)).

Factors Affecting Thiamin Status

Thiamin status depends on its bioavailability in food products, ethanol consumption, the presence of antithiamin factors (ATFs) in the diet, and folate and protein status ([3](#)).

Thiamin Losses Resulting from Food Processing

pH. Thiamin is rapidly destroyed above pH 8. Thus, addition of sodium bicarbonate to green beans and peas to retain their green color or to dried beans to soften their skins inactivates thiamin ([1](#), [3](#)).

Temperature. Thiamin is also destroyed at high temperature. Thiamin losses during meat cooking and canning, bread baking, and vegetable cooking are 25 to 85%, 5 to 35%, and 0 to 60%, respectively. In pasteurization, sterilization, spray-drying, roller-drying, and condensation of milk, thiamin losses are 9 to 20%, 30 to 50%, 10%, 15%, and 40%, respectively. Freezing does not affect the thiamin content of foods. Processing foods at higher temperatures and under alkaline conditions in the presence of oxygen or other oxidants leads to formation of thiamin sulfides and disulfides,

thiochrome, and other oxidation products. Only thiamin sulfides and disulfides still retain the biologic activity of thiamin (1, 3).

Solubility. Since thiamin is highly water soluble, significant amounts are lost in discarded cooking water (3, 5, 6).

Other Factors. Thiamin is also destroyed by x-rays, g-rays, UV irradiation, and sulfites that form in treating dehydrated fruits with SO₂ (1, 3).

Ethanol Ingestion

Thiamin deficiency in chronic alcoholics is caused by multiple factors, including a low thiamin intake, impaired intestinal absorption, defective phosphorylation, and an apotransketolase deficiency. Ethanol given orally or intravenously also inhibits intestinal thiamin uptake (3, 7).

ATFs

Two types of ATFs exist: thermolabile and thermostable.

Thermolabile ATFs. The thermolabile ATFs include thiaminase I (EC 2.5.1.2) and II (EC 3.5.99.2). Thiaminase I is found in the viscera of freshwater fish, in shellfish, in ferns, in a limited number of sea fish and plants, and in several microorganisms, including *Bacillus thiaminolyticus* and *Clostridium thiaminolyticus*. Thiaminase I cleaves thiamin by an exchange reaction with an organic base or a sulfhydryl compound via a nucleophilic displacement on the methylene group of the pyrimidine moiety of thiamin. Thiaminase II is found in several microorganisms, including *Bacillus aneurinolyticus*, *Candida aneurinolytica*, *Trichosporon*, and *Oospora*. It hydrolyzes thiamin to 2-methyl-4-amino-5-hydroxymethyl pyrimidine and 4-methyl-5-(2-hydroxyethyl)thiazole. Thiamin is accessible to thiaminases when tissues are broken up at pH 4 to 8 or when excreted from cells. Thiaminases act during food storage or preparation prior to ingestion or during passage through the gastrointestinal tract. Thus, habitual intakes of raw freshwater fish, with or without fermentation, raw shellfish, and ferns are risk factors for the development of thiamin deficiency (3, 5, 6).

Thermostable ATFs. Thermostable ATFs have been demonstrated in ferns, tea, betel nut, some vegetables, other plants, and even in some animal tissues. In animal tissues, myoglobin, hemoglobin, and hemin may be involved. The ATFs found in plants and vegetables are related to *ortho*- and *para*-polyphenolic compounds such as caffeic acid (3,4-dihydroxycinnamic acid), chlorogenic acid [3-(3,4-dihydroxycinnamoyl)quinic acid], and tannic acid (tannin). The antithiamin activity of polyphenols requires a pH of 6.5 or above and oxygen. At high pH, polyphenols ionize, and the thiazole moiety of thiamin is ruptured at carbon 2 to yield the SH form of thiamin. In the presence of oxygen, polyphenols oxidize and polymerize to yield active quinones and relatively less active polymerized products. Quinones interact with the SH form of thiamin to give thiamin disulfide. Further hydrolysis and oxidation yield inactive products. Ascorbic acid and

other reducing agents prevent formation of these quinones and thiamin disulfide.

Divalent cations, such as Ca^{2+} and Mg^{2+} , augment precipitation of thiamin by tannin, thereby making thiamin less bioavailable. Consequently, ascorbic, tartaric, and citric acids present in many fruits and vegetables protect thiamin, presumably by sequestering the divalent cations. Drinking tea, coffee, or decaffeinated coffee and chewing tea leaves or betel nut deplete thiamin in humans. Ascorbic acid intake improves the thiamin status of subjects (3, 5).

Folate and Protein Status

Subjects with folate or protein deficiency show a significant reduction in the maximum absorption of ^{35}S -thiamin. Thus the maximum absorption of ^{35}S -thiamin is increased after correction of the protein-energy malnutrition of alcoholics (7).

METABOLISM

Ingested thiamin is fairly well absorbed, rapidly converted to phosphorylated forms, stored poorly, and excreted in the urine as a variety of hydrolyzed and oxidized products.

Absorption

The small intestine absorbs thiamin by two mechanisms: active transport ($<2 \mu\text{mol/L}$) and passive diffusion ($>2 \mu\text{mol/L}$). A specific sodium- and energy-dependent carrier seems to exist. In this regard, a specific thiamin-binding protein is associated with thiamin transport across the cell membrane of *Escherichia coli*. Active thiamin absorption is greatest in the jejunum and ileum. The exit of thiamin from the serosal side of the mucosal cell depends on Na^+ and on adenosine triphosphatase (ATPase) at the serosal pole of the cell (1, 3). The intestinal transport of ^{35}S -thiamin in humans is rate limiting, with a V_{max} of $31.5 \mu\text{mol}$ (8.3 mg) and a K_m of $45.6 \mu\text{mol}$ (12.0 mg) (7).

Transport

Thiamin is carried by the portal blood to the liver. In normal adults, 20 to 30% of thiamin in the plasma is protein bound, all of which appears to be TPP (8). The transport of thiamin into erythrocytes seems to be a facilitated diffusion process, whereas it enters other cells by an active process (1, 3). Erythrocytes contain mainly TPP (8).

Tissue Distribution and Storage

The average total amount of thiamin in a normal adult is approximately 0.11 mmol (30 mg). High concentrations are found in the skeletal muscles, heart, liver, kidneys, and brain. About 50% of the total thiamin is present in muscles. The biologic half-life of ^{14}C -thiamin in the body is 9 to 18 days. Because thiamin is not stored in large amounts

in any tissue, a continuous supply of thiamin is necessary (1, 3).

Metabolic Modification

Of the total thiamin in the body, about 80% is TPP, 10% is TTP, and the remainder is TMP and thiamin. The three tissue enzymes known to participate in formation of the phosphate esters are thiamin pyrophosphokinase, which catalyzes the formation of TPP from thiamin and ATP; TPP-ATP phosphoryl transferase, which catalyzes the formation of TTP from TPP and adenosine triphosphate (ATP); and thiamin pyrophosphatase, which hydrolyzes TPP to form TMP. Of 25 to 30 urinary metabolites of thiamin in rats and humans, pyrimidine carboxylic acid, thiazole acetic acid, and thiamin acetic acid predominate (Fig. 21.2) (1, 3).

Figure 21.2. Thiamin catabolism and its catabolites.

Excretion

Thiamin and its metabolites are mainly excreted in the urine. Very little thiamin is excreted in the bile. Early milk contains a low thiamin level. Thiamin administered by oral or parenteral routes is rapidly converted to TPP and TTP in the tissues. Thiamin in excess of tissue needs and storage capacity is rapidly excreted in the urine in the free form (1, 3, 8).

FUNCTIONS

Thiamin, in the form of TPP, serves biochemically as the coenzyme of α -keto acid decarboxylation and transketolation. In a more physiologic context, thiamin functions in neurophysiologic processes (1, 2 and 3).

Biochemical Functions

In mammalian systems, TPP functions as the Mg^{2+} -coordinated coenzyme for the active aldehyde transfers, which include the oxidative decarboxylation of α -keto acids and the transketolase reaction. The key feature of TPP is that the carbon atom between the nitrogen and sulfur atoms in the thiazole ring is much more acidic than most CH groups. It ionizes to form a carbanion, which readily adds to the carbonyl group of α -keto acids or ketoses. The positively charged ring nitrogen of TPP then acts as an electron sink to stabilize formation of a negative charge, which is necessary for decarboxylation. Protonation then gives hydroxyethyl TPP (1, 3, 5).

Oxidative Decarboxylation of α -Keto Acids

Pyruvate, α -ketoglutarate, and branched-chain α -keto acids undergo oxidative decarboxylation. The net reaction of the oxidative decarboxylation of pyruvate catalyzed by the pyruvate dehydrogenase complex is

In addition to CoA and NAD^+ , TPP, lipoic acid, and flavin adenine dinucleotide (FAD) also serve as coenzymes. The pyruvate dehydrogenase complex, which is an organized assembly of three enzymes localized in the mitochondria, sequentially catalyzes the conversion of pyruvate into acetylCoA (1, 3, 5).

The net reaction in the oxidative decarboxylation of α -ketoglutarate, which takes place in the tricarboxylic acid cycle and is catalyzed by the α -ketoglutarate dehydrogenase complex, is

The coenzyme requirements and the steps in the formation of succinylCoA are analogous to the oxidative decarboxylation of pyruvate (1, 3, 5).

Oxidative decarboxylation of the three branched-chain α -keto acids, α -ketoisocaproate, α -keto- β -methylvalerate, and α -ketoisovalerate, yield isovalerylCoA, α -methylbutyrylCoA, and isobutyrylCoA, respectively. These reactions are catalyzed by the branched-chain α -keto acid dehydrogenase complex, which is analogous to those for pyruvate and α -ketoglutarate (1, 3, 5).

Transketolase Reaction

A TPP-dependent transketolase found in the cytosol catalyzes the reversible transfer of a glycolaldehyde moiety from the first two carbons of a donor ketose phosphate to the aldehyde carbon of an aldose phosphate in the pentose phosphate pathway. These

reactions are ([1](#), [3](#))

Neurophysiologic Functions

Thiamin has been implicated in neurotransmission and nerve conduction ([1](#), [2](#) and [3](#)).

Neurotransmission

In thiamin-deficient rats, acetylcholine turnover and acetylcholine utilization are reduced in the cerebral cortex, midbrain, diencephalon, and brainstem; the synthesis of catecholamines decreases in brain, including significant reductions in the norepinephrine content of cortex, hippocampus, and olfactory bulbs; the uptake of serotonin by cerebellar synaptosomes decreases; 5-hydroxyindoleacetic acid, a serotonin catabolite, significantly increases without alteration of tryptophan levels; and brain levels of glutamate, aspartate, γ -aminobutyrate, and glutamine are reduced ([2](#)).

Nerve Conduction

As originally postulated by von Muralt, thiamin may play a role in neurophysiology independent of its coenzyme function. Some evidence supporting this view follows: (a) thiamin antagonists adversely affect impulse conduction in peripheral nerves; (b) thiamin and thiamin pyrophosphatase are localized in nerve cell membranes but not in the axoplasm; (c) thiamin is released from membrane preparations of brain, spinal cord, and sciatic nerves by electrical stimulation; and (d) phosphorylated derivatives of thiamin are associated with sodium channel proteins. Thus, TTP may play a fundamental role in the control of sodium conductance at axonal membranes ([1](#), [2](#) and [3](#)) as well as in other neurologic processes.

Functional Consequences of Thiamin Deficiency

The lack of thiamin in animals and humans affects the cardiovascular, muscular, nervous, and gastrointestinal systems. Cardiac failure, muscle weakness, peripheral and central neuropathy, and gastrointestinal malfunction have been observed in both animals and humans on diets restricted in thiamin. Although the precise biochemical defects responsible for the pathophysiologic manifestations of thiamin deficiency are not established, thiamin may well play three major roles at the cellular level. The first involves energy metabolism, largely related to the oxidative decarboxylation of α -keto acids, the inhibition of which leads to a failure in ATP synthesis. The second is concerned with synthetic mechanisms, as reflected by the importance of the transketolase reaction for the formation of NADPH and pentoses. The third deals with the functions of neurotransmitters and nerve conduction, as described above. In Wernicke's disease, failure of energy metabolism predominantly affects neurons and

their functions in selected areas of the central nervous system. Glial changes may be caused by biochemical lesions that affect transketolase and nucleic acid metabolism. Membranous structures are visibly altered and secondary demyelination ensues ([3](#), [5](#)).

PATHOGENESIS OF THIAMIN DEFICIENCY AND CLINICAL MANIFESTATIONS

Thiamin deficiency in free-living populations and hospitalized patients can be caused by inadequate intake, decreased absorption, defective transport of thiamin, impaired biosynthesis of TPP, an increased requirement, and enhanced loss of thiamin. These mechanisms may reinforce each other.

High-Risk Situations

Populations vulnerable to the development of beriberi are breast-fed infants whose nursing mothers are thiamin deficient; adults who have high carbohydrate intake derived mainly from milled rice, with or without consumption of ATFs; and chronic alcoholics. Dietary factors are major causes of thiamin deficiency in Asia, whereas alcoholism is of greatest concern in the West. An increase in thiamin requirement because of strenuous physical exertion, fever, pregnancy, lactation, or adolescent growth may precipitate clinical manifestations in persons with marginal thiamin status. Other persons at risk are renal patients on dialysis, patients receiving parenteral nutrition, hypermetabolic patients, and patients with congestive heart failure treated with furosemide ([1](#), [2](#), [3](#), [5](#), [6](#), [7](#), [9](#), [10](#), [11](#), [12](#) and [13](#)).

Clinical Manifestations

The clinical manifestations of beriberi vary with age and with the organ systems involved. The disease is divided into infantile and adult forms ([3](#), [6](#), [10](#), [11](#)).

Infantile Beriberi

Infantile beriberi most commonly occurs between the ages of 2 and 3 months. Infants may present with cardiac (acute fulminating), aphonic, or pseudomeningitic forms or a combination thereof. Infants with cardiac beriberi usually experience an acute attack that includes a loud piercing cry, cyanosis, dyspnea, vomiting, tachycardia, and cardiomegaly; death may occur within a few hours after the onset unless thiamin is administered. The striking feature in aphonic beriberi is the tone of the child's cry, which varies from hoarseness to complete aphonia. Infants with pseudomeningitic beriberi exhibit vomiting, nystagmus, purposeless movement of the extremities, and convulsion accompanied by a normal cerebrospinal fluid (CSF) ([3](#), [6](#), [10](#)).

Adult Beriberi

Children and adults may present with dry (paralytic or nervous), wet (cardiac), or

cerebral (Wernicke-Korsakoff syndrome) forms of beriberi.

Dry Beriberi. The predominant features in dry beriberi are peripheral neuropathy, which is characterized by a symmetric impairment of sensory, motor, and reflex functions affecting the distal segments of limbs more severely than the proximal ones, calf muscle tenderness, and difficulty in rising from a squatting position ([3](#), [6](#), [10](#), [11](#)).

Wet Beriberi. In addition to peripheral neuropathy, common signs found in wet beriberi include edema, tachycardia, wide pulse pressure, cardiomegaly, and congestive heart failure. Some patients have abnormal electrocardiograms, including a prolonged QT interval, flat or inverted T waves in the precordial leads, and relatively low QRS-complex voltage. Typical hemodynamic findings in wet beriberi include high cardiac output and low peripheral and pulmonary vascular resistances. However, low cardiac output does not exclude the diagnosis of wet beriberi. Some patients experience sudden onset of a cardiac manifestation known as acute fulminant, or “shoshin,” beriberi. The predominant features are tachycardia, dyspnea, cyanosis, cardiac enlargement, and circulatory collapse ([3](#), [6](#), [10](#), [11](#)).

Wernicke-Korsakoff Syndrome. Although alcoholism is the major cause of thiamin deficiency in Wernicke-Korsakoff syndrome, iatrogenic causes, including parenteral glucose administration and chronic dialysis, can aggravate the syndrome in patients with marginal thiamin status. The diagnosis of Wernicke's disease or encephalopathy is based on the triad of ocular motor signs, ataxia, and derangement of mental functions ([2](#), [3](#), [5](#), [14](#)). (See also [Chapter 95](#).)

The ocular motor signs are the most readily recognized abnormalities and include a paresis or paralysis of abduction that is accompanied by horizontal diplopia, strabismus, and nystagmus; in advanced cases, there may be complete loss of ocular movement, and the pupils may become miotic and nonreactive. The ocular motor signs are attributable to lesions in the brainstem affecting the abducens nuclei and in the eye movement centers of the pons and rostral midbrain.

The ataxia affects stance and gait. The persistent ataxia is related to the loss of neurons in the superior vermis of the cerebellum; extension of the lesion into the anterior parts of the anterior lobes accounts for the ataxia of individual movements of the legs.

A derangement of mental function is found in about 90% of patients and takes one of the following three forms: (a) a global confusional-apathetic state, the most common form, characterized by profound listlessness, inattentiveness, indifference to the surroundings, and disorientation; (b) a disproportional disorder of retentive memory, i.e., Korsakoff amnesic state; or (c) the symptoms of alcohol withdrawal, found in a relatively small number of patients. The amnesic defect is related to lesions in the diencephalon, more specifically to those in the medial dorsal nuclei of the thalamus.

Wernicke's disease and Korsakoff's psychosis are not separate diseases. Korsakoff's psychosis is the psychic component of Wernicke's disease. Thus the clinical manifestations should be called Wernicke's disease when the amnesic state is not evident and the Wernicke-Korsakoff syndrome when both the ocular-ataxic and the

amnesic manifestations are present (2, 3, 14).

Although the specific role of thiamin in Wernicke-Korsakoff syndrome is established and most of the patients with Wernicke-Korsakoff syndrome are alcoholics, only a few alcoholics are affected. Genetic abnormalities in erythrocyte transketolase (ETK) may underlie a predisposition to Wernicke-Korsakoff syndrome (2, 3, 5, 14). However, investigation of the hysteric properties of human transketolase with emphasis on its dependency on TPP concentration has revealed a substantial lag in the formation of active holotransketolase as well as interindividual differences and cell type variation from the same individual in the lag period. These individual differences in the loss of transketolase activity during thiamin deficiency may explain, at least in part, the differential sensitivity to deficiency demonstrated by tissues and individuals (15).

Treatment

Thiamin should be promptly administered to beriberi patients. The daily dosage usually ranges from 0.19 to 0.38 mmol (50–100 mg) given intravenously or intramuscularly for 7 to 14 days, after which 0.04 mmol (10 mg)/day should be administered orally until the patient fully recovers. To prevent recurrence of beriberi, patients should be advised to change their dietary habits and to stop drinking alcohol (3, 6, 11).

The rationale underlying administration of a large dose of thiamin is to (a) replenish thiamin stores, which is consistent with the positive correlation between thiamin concentration in serum and CSF (16); (b) stimulate the TPP-dependent reactions maximally, which is consistent with the aforementioned thiamin-dependent hysteric behavior of human transketolase (15); and (c) improve cardiovascular disorders. In regard to the latter, thiamin treatment reduces cardiac output and increases vascular resistance in beriberi patients who show high cardiac output and low peripheral and pulmonary vascular resistance. Similarly, thiamin treatment increases cardiac output in those showing low cardiac output (17). The parenteral route is used initially to ensure the bioavailability of thiamin.

Several thiamin derivatives, especially thiamin propyl disulfide (TPD) and thiamin tetrahydrofurfural disulfide (TTFD), are useful for oral administration to beriberi patients because they produce a significantly higher thiamin level in the blood, erythrocytes, and CSF than does thiamin hydrochloride or TPP at the same oral dose of 50 mg. Indeed, given orally, they are as effective as parenteral administration of thiamin hydrochloride or TPP to healthy subjects (18). Patients with cardiac beriberi also respond dramatically to daily intravenous administration of 50 mg of TTFD (19).

Response to Thiamin Administration

In wet beriberi, improvement within 6 to 24 hours after thiamin administration is characterized by reduced restlessness; the disappearance of cyanosis; reduction in heart rate, respiratory rate, and cardiac size; and clearing of pulmonary congestion. Dramatic improvement after thiamin treatment is also observed in infants with cardiac

beriberi ([3](#), [6](#), [10](#), [11](#)).

It is difficult to use the response to thiamin administration as a criterion for immediate diagnosis in dry beriberi or in infants with aphonia because more time elapses before improvement is observed. Disappearance of impaired sensation and recovery of motor weakness occur 7 to 120 days and within 60 days, respectively, after thiamin treatment ([3](#), [6](#), [10](#), [11](#)).

The response of patients with Wernicke's disease to thiamin treatment follows a characteristic course. Ocular palsies may begin to improve within hours to several days after administration of thiamin. Sixth nerve palsies, ptosis, and vertical gaze palsies recover completely within 1 to 2 weeks in most cases, but vertical gaze-evoked nystagmus may persist for months. Ataxia improves only slowly and approximately half of patients recover incompletely. Apathy, drowsiness, and confusion also recede gradually ([14](#)).

Effects of thiamin treatment on the Korsakoff amnesic state vary. Recoveries range from complete or almost complete in less than 20% of patients to slow and incomplete in the remainder. The residual state is characterized by large gaps in memory, usually without confabulation, and an inability of the patient to sort out events in their proper temporal sequence ([14](#)).

EVALUATION OF THIAMIN STATUS

The subject's history, laboratory tests, and physical examination are the basis for evaluating thiamin status in humans ([20](#)).

Subject's History

Dietary assessment, demographic data, medical history, family history, and psychosocial history should be recorded for each subject, because all of these factors can affect thiamin status. Several dietary methods, including dietary scan, dietary record, and/or 24-hour dietary recall, have been used to assess thiamin intakes in various populations. Comparisons are then made between mean thiamin intakes and the recommended dietary allowances (RDAs) for thiamin. For instance, northern Thai villagers and the male North American population aged 65–75 years had mean daily thiamin intakes of 2.1 and 5.3 μmol , (0.56 and 1.40 mg), respectively ([21](#), [22](#)), which are 51% and 116% of the RDAs for thiamin for the North American population ([23](#)).

Laboratory Tests

Various biochemical tests have been developed to detect thiamin deficiency and assess the adequacy of thiamin status in humans. These include the measurement of urinary thiamin excretion; blood thiamin level; thiamin concentration in the CSF; blood pyruvate, lactate, and α -ketoglutarate levels; erythrocyte transketolase activity (ETKA); and the thiamin pyrophosphate effect (TPPE) on ETKA ([1](#), [2](#), [3](#), [5](#), [6](#), [9](#), [10](#), [11](#) and [12](#), [16](#)).

At present the most reliable and feasible method of evaluating human thiamin adequacy is the measurement of ETKA and the percentage enhancement resulting from added TPP, which is known as the TPPE. The diagnostic criterion for human thiamin inadequacy consists of a low ETKA, usually accompanied by a TPPE of 16% or above. However, in chronic thiamin deficiency, the TPP added in vitro cannot restore ETKA fully; under such conditions, TPPE may be in the normal range of 0 to 15%. Thus both ETKA and TPPE must be considered in assessing the adequacy of thiamin status (3, 6, 10, 11 and 12). However, thus far there is no general agreement on the normal levels of ETKA because different methods are used to determine ETKA in various laboratories. The reference range of ETKA in our laboratory is 126 to 214 International Units, which is equivalent to the number of moles of sedoheptulose-7-phosphate formed per minute per liter of erythrocytes (12).

Physical Examination

Although physical signs of beriberi appear in the last stage of thiamin deficiency, physicians should be able to detect such developing abnormalities in patients for immediate and long-term nutritional management (20). Delay in diagnosing beriberi affects the morbidity and mortality rates of patients. Beriberi should be suspected in breast-fed infants of thiamin-deficient mothers. Infants with beriberi have a loud piercing cry, dyspnea, cyanosis, cardiac failure, and aphonia (3, 6, 10).

Common suggestive signs in dry beriberi include glove and stocking hypoesthesia of pain and touch sensations, loss of ankle and/or knee reflexes, tenderness at the calf muscle, difficulty in rising from the squatting position, and aphonia. However, other possible known causes of peripheral neuropathy must be carefully ruled out (3, 10, 11).

Patients with wet beriberi exhibit both peripheral neuropathy and edema. Those with severe cases show tachycardia, wide pulse pressure, cardiac enlargement, and pulmonary congestion (3, 10, 11).

Wernicke's disease must be suspected in chronic alcoholics presenting with the triad of ocular motor signs, ataxia, and derangement of mental functions. The diagnosis of Wernicke-Korsakoff syndrome should be made in those having both the ocular-ataxic and amnesic manifestations (14).

SUBCLINICAL THIAMIN DEFICIENCY

There is concern about the impact of persisting subclinical or borderline thiamin deficiency on the health status of a population. Subjects with subclinical thiamin deficiency show an increased risk of beriberi when stressed with extreme physiologic or pathologic conditions, including pregnancy, lactation, high physical activity, infection, and surgery. The presence of subclinical deficiency is well illustrated in a study of Japanese university students (24). Routine physical examination of 766 students revealed irritability with mild cardiovascular signs in 42. Of these 42 students, 15 (35.7%) had whole blood thiamin levels below 190 nmol/L (<50 ng/mL). In review of

2754 chest x-ray films, 93 students had cardiothoracic ratios over 50%; of these 93 students, 44 had whole blood thiamin levels below 50 ng/mL. Analysis of the lifestyles of 59 students with low whole blood thiamin levels revealed that 50 to 60% ate their meals in restaurants and 39 to 47% did not eat breakfast. Furthermore, 86% of students with cardiac enlargement and low blood thiamin levels undertook strenuous exercise daily; only 20% were aware of their own abnormalities. Cardiothoracic ratios were improved in 63% of 83 subjects by limiting their strenuous exercise and providing nutritional advice.

More studies are needed to verify subclinical thiamin deficiency in those having psychologic, cardiovascular, and neurologic symptoms. Dietary assessment and laboratory tests should be conducted in populations with chronically low thiamin intake, and appropriate dietary guidelines should be implemented to improve their thiamin status.

REQUIREMENTS AND RECOMMENDED INTAKES

Since thiamin is essential for the metabolism of carbohydrates and branched-chain amino acids, the recommended thiamin intake is expressed in terms of total caloric intake. The current RDAs for thiamin in the United States are 1.9 $\mu\text{mol}/4184 \text{ kJ}$ (0.5 mg/1000 kcal) for children, adolescents, and adults, and 1.5 $\mu\text{mol}/4184 \text{ kJ}$ (0.4 mg/1000 kcal) for infants. These recommendations are based on assessment of the effects of varying levels of dietary thiamin on the occurrence of deficiency signs, on the excretion of thiamin or its metabolites, and on ETKA. A minimal thiamin intake of 3.8 $\mu\text{mol}/\text{day}$ (1.0 mg/day) is recommended for adults, even though they might consume less than 8368 kJ (2000 kcal) daily. An additional thiamin intake of 1.5 $\mu\text{mol}/\text{day}$ (0.4 mg/day) is recommended throughout pregnancy to accommodate maternal and fetal growth and increased maternal caloric intake. To account for both the thiamin secretion in milk and increased energy consumption during lactation, an increment of 1.9 $\mu\text{mol}/\text{day}$ (0.5 mg/day) is recommended throughout lactation (23) (see also Appendix [Table II-A-2-a-2](#)). The 1989 recommended dietary intakes of thiamin in Thailand agree with values in the United States (25).

The 1988 United States recommended daily intakes vary from the 1989 RDA by only a few tenths of a mg (see Appendix [Table II-A-2-c-1](#) and related [Table II-A-c-2](#) and [Table II-A-c-3](#)) (26).

Patients with thiamin deficiency can be treated with physiologic doses of thiamin. However, patients with thiamin-responsive disease only respond to pharmacologic doses of thiamin. These disorders include thiamin-responsive megaloblastic anemia, thiamin-responsive lactic acidosis, thiamin-responsive branched-chain ketoaciduria, and subacute necrotizing encephalopathy (3, 5, 9).

TOXICITY

Excessive amounts of ingested thiamin are rapidly cleared by the kidneys. No evidence exists of thiamin toxicity by oral administration (3, 23).

Abbreviations: **ATP**—adenosine triphosphate; **ATPase**—adenosine triphosphatase; **CSF**—cerebrospinal fluid; **ETKA**—erythrocyte transketolase activity; **FAD**—flavin adenine dinucleotide; **RDAs**—recommended dietary allowances; **TMP**—thiamin monophosphate; **TPD**—thiamin propyl disulfide; **TPP**—thiamin pyrophosphate; **TPPE**—thiamin pyrophosphate effect; **TTFD**—thiamin tetrahydrofurfural disulfide; **TTP**—thiamin triphosphate.

The “water-soluble B” fraction, reported by McCollum and Kennedy in 1916 to contain an antiberiberi substance (1), was subsequently shown by Emmett and Luros (1920) (2) and Smith and Hendrick (1926) (3) to contain at least a second more heat-stable antipellagra factor, which was termed B₂. It soon became apparent that this B₂ fraction was a complex containing a yellow growth factor called riboflavin in England and vitamin G in the United States, as well as the subsequently identified pellagra-preventive factor (niacin) and the rat antidermatitis factor (vitamin B₆). Although a water-soluble, yellow fluorescent compound was known in the latter part of the 19th century (4) to occur in such natural materials as whey, association of the pigment with vitaminic properties was not secured until its isolation in 1933 by several groups (5, 6 and 7). Terms applied to riboflavin indicated the origin (e.g., lactoflavin [milk], ovoflavin [egg], hepatoflavin [liver], and uroflavin [urine]). Meanwhile, by 1932 Warburg and Christian in Germany had isolated a yellow respiratory ferment (now called “old yellow enzyme”) from yeast (8). This flavoprotein was soon dissociated into a protein apoenzyme and a yellow prosthetic coenzyme that was clearly similar to riboflavin (9). Stern and Holiday (1934) found that the coenzyme was an alloxazine derivative (10), and Theorell (1934) demonstrated that it was a phosphate ester (11).

By 1935, the groups of Kuhn at Heidelberg (12, 13) and Karrer in Zurich (14, 15) had synthesized the vitamin. Theorell, in 1937, secured the structure of the simpler coenzyme as riboflavin 5'-phosphate (flavin mononucleotide, or FMN) (16). By 1938, Warburg and Christian had isolated and characterized the more abundant but complex prosthetic group, flavin-adenine dinucleotide (FAD), and showed its participation as the coenzyme of D-amino acid oxidase (17, 18, 19 and 20). More recently, diverse natural flavins have been found that have alterations in the side chain or ring system of the basic flavin structures (21). No fewer than four 8a-modified forms of FAD occur covalently attached to important flavoproteins in the mammal: the N(3)-histidyl-linked succinate and sarcosine dehydrogenases of the inner mitochondrial membrane, S-cysteinyllinked monoamine oxidase of the outer mitochondrial membrane, and the N(1)-histidyl-linked L-gluconolactone oxidase of the liver microsomal fraction.

CHEMISTRY, INCLUDING PRINCIPAL ANALOGUES

Riboflavin (vitamin B₂) was chemically specified as 6,7-dimethyl-9-(1'-D-ribityl)isoalloxazine, but with evolution of systematic nomenclature is now correctly given as 7,8-dimethyl-10-(1'-D-ribityl)isoalloxazine. The free vitamin is a weak base normally isolated or synthesized as a yellowish orange amorphous solid. The 5'-hydroxymethyl terminus of the ribityl side chain in the vitamin is reacted to become an orthophosphate ester in the simpler coenzyme, FMN, which can be further enlarged to the more complex and frequently encountered FAD with a pyrophosphate-bridged adenylate moiety (Fig. 22.1). The molecular weight of riboflavin is 376.4; thus, 1 mg riboflavin equals 2.66 μmol.

Figure 22.1. Riboflavin and flavin mononucleotide (FMN) as components of flavin-adenine dinucleotide (FAD).

There are some natural variations on the parent vitaminic structure, such as the 8-dimethylamino group of roseoflavin produced by *Streptomyces davawensis* (22, 23), the side-chain aldehyde and acid products (schizoflavins [24]) resulting from oxidation of the 5'-hydroxymethyl of riboflavin by a fungal enzyme narrowly specific for the vitamin (25, 25a), and 5'-glycosides of riboflavin, which can be formed by plant and animal species (26). Several natural variants of the coenzyme forms are listed in Table 22.1.

Structure	Chemical Name
	Riboflavin (FMN)
	7,8-Dimethyl-8-hydroxyalloxazine (Lumichrome)
	7,8-Dimethyl-8-hydroxy-10-methylalloxazine (Lumiflavin)
	7,8-Dimethyl-8-hydroxy-10-methyl-10H-isoalloxazine (FMN)
	7,8-Dimethyl-8-hydroxy-10-methyl-10H-isoalloxazine-5-phosphate (FAD)

Table 22.1 Naturally Occurring Variants of Flavin Mononucleotide (FMN) and Flavin-Adenine Dinucleotide (FAD)

Chemical syntheses of riboflavin and similar isoalloxazines have been accomplished by several routes (27), most of which were adapted from the earlier procedures of Kuhn and Karrer and from modifications introduced by Tishler, Massey, and their associates (28, 28a).

Riboflavin is only modestly soluble in aqueous solutions, though strong acid flavinium salts formed at low pH (<1) and flavin anion formed at alkaline pH (>10) are considerably more soluble. Neutral and slightly alkaline solutions are yellow with a long-wavelength absorption band near 450 nm. Strongly acidic flavin solutions are paler, because their primary absorbance shifts with intensification to about 385 nm. Solutions of the neutral oxidized (quinoid) form of the vitamin are strongly fluorescent, with an emission wavelength at 525 nm. Riboflavin also has phosphorescent character reflecting triplet state reactivity following light excitation. One consequence of flavin photochemistry is the photolability of the side chain. Riboflavin is photodegraded ultimately to yield vitaminically inactive lumiflavin (7,8,10-trimethyl-isoalloxazine) under alkaline conditions and lumichrome (7,8-dimethylalloxazine) at all pH values, especially in neutral to acidic solutions. Flavins are chemically and biologically reduced, often through the radical (semiquinone) forms, to the nearly colorless, nonfluorescent 1,5-dihydro forms that rapidly reoxidize upon exposure to air (oxygen).

Chemical syntheses of flavocoenzymes involve phosphorylation of riboflavin (29), commonly with chloro phosphoric acid, to form crude FMN, which is purified chromatographically. Conversion of FMN to FAD usually involves condensation of activated AMP, such as adenosine-5'-phosphoromorpholidate, with an FMN salt (30, 31). Extension of these techniques has been useful in forming coenzyme analogues (32).

BIOLOGIC ACTIVITY RELATING TO STRUCTURE

Numerous analogues of riboflavin and the coenzyme derivatives have been tested in

whole organisms (33) and with apoflavoproteins (21, 28a, 34), respectively. In general, the full D-ribityl side chain is needed, though weak vitaminic activity has been found with the D-arabo configuration. Interestingly, flavin-dependent alcohol oxidase from methylotropic yeasts contains an araboflavin adenine dinucleotide (a-FAD) that is autocatalytically derived from the accompanying FAD (35). D-Galactoflavin is an antagonist. In addition to a normal pyrimidinoid portion, both 7- and 8-methyl substituents are required for optimal vitaminic activity, though sparing with corresponding monoethyl analogues has been reported. The 7,8-dihaloflavins are inhibitors, as is isoriboflavin with a 6,7-dimethyl structure. The 5'-phosphate, commonly occurring as the dianionic ester, is needed for binding in FMN-dependent systems, and an additional 5'-AMP moiety is needed with FAD-dependent enzymes.

ABSORPTION, TRANSPORT, METABOLISM, AND EXCRETION

The processes by which riboflavin and lesser amounts of natural derivatives are released by digestion of complexes with food proteins and then absorbed, transported, and metabolically altered have been reviewed fairly comprehensively (21). Salient features are that coenzyme forms of the vitamin (mainly FAD and less FMN) are released from noncovalent attachment to proteins as a consequence of gastric acidification. Nonspecific action of pyrophosphatase and phosphatase on the coenzyme forms occurs in the upper gut. Several percent of 8a-(amino acid)riboflavins originally in covalent attachment to certain enzymes, such as mitochondrial succinate dehydrogenase or monoamine oxidase, and traces of other ring and side-chain substituted flavins are also released by these actions following proteolysis. The vitamin is primarily absorbed in the human in the proximal small intestine by a saturable transport system that is rapid and proportional to dose before leveling off at 66.5 μmol (25 mg) of riboflavin. Bile salts appear to facilitate uptake, and a modest amount of the vitamin circulates via the enterohepatic system. Active transport at lower levels of intake may be Na^+ dependent and involve phosphorylation. An Na^+ -dependent active transport process was suggested by studies on riboflavin uptake in rat intestine in vivo (36) and in vitro (37, 38); however, recent studies using Caco-2 human intestinal epithelial cells indicate that the uptake is Na^+ independent (39).

In the human, some of the riboflavin circulating in blood plasma is loosely associated with albumin, though significant amounts complex with other proteins. A subfraction of IgG binds avidly to a small portion of the total free flavin in blood (40), and several immunoglobulins contribute significantly to the circulatory transport of the vitamin (41). As found earlier in other mammals such as the cow (42), pregnancy increases the level of a riboflavin carrier protein in humans as well (43), and there are differential rates of uptake for the vitamin at the maternal and fetal surfaces of the placenta (44). Entry of riboflavin into mammalian cells appears to be carrier mediated (facilitated) at physiologic concentrations, but diffusion contributes to entry at higher levels (45, 46). Uptake exhibits relative specificity, and a riboflavin-binding protein has been found in the plasma membrane of rat liver cells (47). The parenchymal hepatocyte does not depend on Na^+ for riboflavin import (48) as does the renal proximal tubular cell (49). In all cases, metabolic trapping dependent on cytosolic flavokinase follows passage of the vitamin through the plasma membrane, which also contains nonspecific alkaline phosphatase

that can catalyze release of vitamin from its internal phosphate ester (45).

Metabolic interconversions of flavins at the cellular level are outlined in [Figure 22.2](#). Conversion of riboflavin to coenzymes occurs within the cellular cytoplasm of most tissues, but particularly in the small intestine, liver, heart, and kidney (21, 45, 50). The obligatory first step is the adenosine triphosphate (ATP)-dependent phosphorylation of the vitamin catalyzed by flavokinase. The FMN product can be complexed with specific apoenzymes to form several functional flavoproteins, but most is further converted to FAD in a second ATP-dependent reaction catalyzed by FAD synthetase (pyrophosphorylase). It seems likely that the biosynthesis of flavocoenzymes is tightly regulated and dependent on riboflavin status (51). Thyroxine and triiodothyroxine stimulate FMN and FAD synthesis in mammalian systems (52, 53), which seems to involve a hormone-mediated increase in an active form of flavokinase (54). As a product of the synthetase, FAD is also an effective inhibitor at this step and may regulate its own formation (55). FAD is the predominant flavocoenzyme in tissues, where it is mainly complexed with numerous flavoprotein dehydrogenases and oxidases. Interaction between coenzyme and apoenzyme usually involves a characteristic dinucleotide-binding fold with the amino acid fingerprint of GXGXXG (56). Less than 10% of the FAD can also become covalently attached to specific amino acid residues of a few important apoenzymes. Examples include the 8a-N(3)-histidyl FAD within succinate dehydrogenase and 8a-S-cysteinyl FAD within monoamine oxidase, both of mitochondrial localization. Turnover of covalently attached flavocoenzymes requires intracellular proteolysis, and further degradation of the coenzymes involves nonspecific pyrophosphatase cleavage of FAD to adenosine monophosphate (AMP) and FMN and action by nonspecific phosphatases on FMN. A 5'-nucleotidase purified from human placenta possesses specific FAD pyrophosphatase activity when stimulated with cobalt (57).

Figure 22.2. Cellular interconversions of flavins.

Because little riboflavin is stored as such, the urinary excretion reflects dietary intake and catabolic and photodegradative events (45). The diverse flavin-related products

identified in the urine of humans and other mammals are shown in [Figure 22.3](#). Both 7- and 8-hydroxy methylflavins appear in urine from the human and rat and are the result of microsomal mixed-function oxidases ([58](#)). 7-Hydroxymethylriboflavin (7a-hydroxyriboflavin) also appears as the only significant catabolite of the vitamin in human plasma ([59](#)). Smaller amounts of side-chain degradation products such as lumichrome, 10-formylmethylflavin, and 10-(2'-hydroxyethyl)flavin are also excreted and may largely result from intestinal microorganisms ([60](#), [61](#) and [62](#)). Traces of 8a-flavin peptides and catabolites are found in urine and feces ([62](#), [63](#)). The α -D-glucoside attached to the side-chain 5'-position of riboflavin has been detected in liver ([26](#)) and urine ([64](#)), even though it is easily taken in and hydrolyzed by hepatocytes to liberate the free vitamin ([65](#)). A 5'-riboflavinyl peptide ester also occurs in human urine ([66](#)). For normal adults eating varied diets, riboflavin accounts for 60 to 70% of urinary flavin, 7-hydroxymethylriboflavin for 10 to 15%, 8a-sulfonylriboflavin for 5 to 10%, 8-hydroxymethylriboflavin for 4 to 7%, riboflavinyl peptide ester for 5%, and 10-hydroxyethylflavin for 1 to 3%, with traces of lumiflavin and varyingly the 10-formylmethylflavins and carboxymethylflavins ([45](#)).

Figure 22.3. Urinary flavins and products related to riboflavin and 8a-flavocoenzymes.

Secretion of flavin into milk, an early recognized source ([4](#)) that came to be called lactoflavin, has been reexamined with better techniques for separation and identification. In milk from both cows ([67](#)) and humans ([68](#)), the flavin in highest concentration other than the free vitamin is FAD, which can account for over a third of total flavin. Much of this is hydrolyzed to FMN during pasteurization. Fairly significant quantities of the 10-(2'-hydroxyethyl) flavin are notable, because this catabolite has antivitaminic activities as reflected in competitive inhibition of both cellular uptake ([48](#)) and subsequent flavokinase-catalyzed phosphorylation of riboflavin ([69](#)). Hence, this catabolite, which may reach 10 to 12% of flavin in cow's milk, subtracts from the biologic activity of the food. Several percent of both 7- and 8-hydroxymethylriboflavins are also present, with more of the former. Smaller amounts of other catabolites, including the 10-formylmethylflavin and lumichrome, account for most of the rest.

BIOCHEMICAL AND PHYSIOLOGIC FUNCTIONS

In bound coenzymic form, riboflavin participates in oxidation-reduction reactions in numerous metabolic pathways and in energy production via the respiratory chain. A variety of chemical reactions are catalyzed by flavoproteins (21, 50, 70). The redox functions of a flavocoenzyme, illustrated in Figure 22.4, include one-electron transfers, during which the biologically encountered, neutral, oxidized quinone level of flavin is half reduced to the radical semiquinone, which can exist in natural pH ranges as a neutral or anionic species. Further electron transfer can lead to a fully reduced hydroquinone. Additionally, a single-step two-electron transfer from substrate to flavin can occur with hydride ion transfer, as from reduced pyridine nucleotide, or by base abstraction of a substrate proton together with carbanion addition (21).

Figure 22.4. Physiologically relevant redox states of flavocoenzymes.

There are flavoprotein-catalyzed dehydrogenations that are both pyridine nucleotide-dependent and -independent, reactions with sulfur-containing compounds, hydroxylations, oxidative decarboxylations, dioxygenations, and reduction of O₂ to hydrogen peroxide. The intrinsic abilities of flavins to be varyingly potentiated as redox carriers upon differential binding to proteins, to participate in both one- and two-electron transfers, and in reduced (1,5-dihydro) form to react rapidly with oxygen permit wide scope in their operation.

DEFICIENCY AND EXCESS

Though riboflavin has a wide distribution in foodstuffs, many people live for long periods on low intakes; consequently, minor signs of deficiency are common in many parts of the world (71). Moreover, the deficiency encountered almost invariably occurs in combination with deficiency of other water-soluble vitamins (45). Clinical deficiency of riboflavin has been induced by feeding a riboflavin-deficient diet, by administration of an

antagonist such as galactoflavin, or both. The deficiency syndrome is characterized by sore throat, hyperemia and edema of the pharyngeal and oral mucous membranes, cheilosis, angular stomatitis, glossitis (magenta tongue), seborrheic dermatitis, and normochromic, normocytic anemia associated with pure red cell cytoplasia of the bone marrow (72). However, some of these symptoms, such as glossitis and dermatitis, when encountered in the field may have resulted from other complicating deficiencies. Severe riboflavin deficiency can also affect the conversion of vitamin B₆ to its coenzyme and even curtail conversion of tryptophan to niacin (45).

Toxicity from ingestion of excess riboflavin by experimental animals or humans is doubtful. The human gastrointestinal tract may be able to absorb less than 30 mg of riboflavin from a single dose orally administered (73, 74). Pharmacokinetic analysis of riboflavin dynamics in healthy humans reflects the expected saturability of plasma levels, with excretion enhanced by renal tubular secretion (75). The limited solubility and absorptivity of this vitamin as encountered in multivitamin preparations and in natural foodstuffs and its ready excretion (which is typical of water-soluble vitamins) normally preclude a health risk. There is one report of electroencephalogram (EEG) abnormalities in two patients during long-term treatment with riboflavin and niacin (76).

CAUSES OF DEFICIENCY

Pure, uncomplicated riboflavin deficiency is probably never encountered in patients but is accompanied by multiple nutrient deficiencies. Ariboflavinosis can result from primary and secondary factors that commonly affect supply or use of other nutrients as well (77). Inadequate dietary intake, most commonly related to limited availability of food but sometimes exacerbated by poor storage or processing, remains the major cause. Anorectic persons rarely ingest adequate amounts of riboflavin and other nutrients.

Decreased assimilation results from abnormal digestion, absorption, or both. Lactose intolerance as a result of lactase insufficiency, mostly encountered among blacks and Asians, argues against consuming milk, which is a good source of the vitamin. Malabsorption can result from tropical sprue, celiac disease, malignancy and resection of the small bowel, and gastrointestinal and biliary obstruction. Poor absorption also results from disorders that increase motility and decrease gastrointestinal passage time, such as diarrhea, infectious enteritis, and irritable bowel syndrome.

Rarely encountered, but usually significantly improved by therapeutic treatment with riboflavin, are certain inborn errors in which the genetic defect affects formation of a normal flavoprotein. This category includes fatty acid desaturases in which specific defects have been found for the mitochondrial FAD-dependent dehydrogenases for short-chain (78), long-chain (79), and multichain acyl-CoAs (80). The young patients have a lipid storage myopathy, often accompanied by carnitine insufficiency, and exhibit glutaric aciduria (81, 82, 83, 84 and 85). Low FMN-dependent pyridoxine-5'-phosphate oxidase activity caused by erythrocytic deficiency of FMN, confirmed by response to oral riboflavin, was reported in most patients with D-glucose-6-phosphate dehydrogenase deficiency in two studies (86, 87). Such cases seem to involve an accelerated conversion of FMN to FAD so that glutathione reductase is saturated. This contrasts with heterozygous β -thalassemia, in which there is an inherited slow erythrocytic

conversion of riboflavin to FMN, a decrease in subsequent FAD, and high stimulation of the erythrocytic glutathione reductase by extraneous FAD (86, 88, 89).

Defective use can result from disturbances in hormonal production, certainly as related to thyroid hormone (52, 53), but is less likely to be affected by oral contraceptives (90). Phenothiazine derivatives appear to impair use of riboflavin (91).

Increased destruction of riboflavin occurs during treatment of neonatal jaundice with phototherapy (92, 93). In this case, the side chain of the vitamin is photochemically destroyed, as it is involved in the photosensitized oxidation of bilirubin to more polar excretable compounds (94, 95). The finding that phenobarbital induces microsomal oxidation of the 7-methyl function of the vitamin (58) lends credence to the belief that long-term use of barbiturates may jeopardize flavin status.

Enhanced excretion of riboflavin occurs in catabolic patients undergoing nitrogen loss. The relationship of the vitamin to protein status has long been recognized. Certain antibiotics and phenothiazine drugs also increase excretion of riboflavin (96, 97).

Increased requirements can, of course, result from one or more of the factors mentioned above. For example, protein-calorie malnutrition commonly accompanies diminution in both absorption and use of riboflavin. Systemic infections even without gastrointestinal involvement sometimes lead to increased requirements that can result from decreased intake, defective absorption, poor utilization, and increased excretion.

DIETARY CONSIDERATIONS

The requirement for riboflavin, in contrast to thiamin, does not increase when energy use is increased (98). Because of the interdependence of protein, energy intake, and metabolic body size, however, recommended dietary allowances (RDAs) calculated on these three bases do not differ significantly. Because RDA values are given in milligrams (98a), this mass unit has been used here. Nonetheless, 1 μmol riboflavin equals 0.376 mg, or inversely, 1 mg riboflavin equals 2.66 μmol . Thus, 0.4, 0.6, 1.2, and 1.7 mg riboflavin can be expressed as 1.06, 1.6, 3.2, and 4.5 μmol , respectively. Clinical signs of deficiency in adults can be prevented with intakes of riboflavin above 0.4 mg/1000 kcal, but more than 0.5 mg/1000 kcal may be required to maintain tissue reserves in adults and children, as reflected in urinary excretion, red cell riboflavin, and erythrocytic glutathione reductase. From these considerations, the riboflavin allowances are now computed as 0.6 mg/1000 kcal for people of all ages. 1989 RDAs ranged from 0.4 mg/day for early infants to 1.7 mg/day for young adult males (see Appendix [Table II-A-2-a-2](#)). However, for elderly people and others whose daily calorie intake may be less than 2000 kcal, a minimum of 1.2 mg per day was recommended. Because pregnancy imposes extra demands, as reflected by decreased excretion and elevated FAD stimulation of erythrocytic glutathione reductase activity, an additional 0.3 mg/day was recommended. The lactating woman secretes approximately 35 μg /100 mL of milk for an output of about 0.26 mg/day (750 mL) during the first 6 months and 0.21 mg/day (600 mL) during the second 6 months. Because the utilization of additional riboflavin for milk production is assumed to be 70%, an additional intake of 0.5 mg was

recommended for the first 6 months and 0.4 mg for the second.

The 1998 RDAs for riboflavin are less (0.2–0.5 mg/day) than the 1989 RDAs for those ages 14 and above (see Appendix [Table II-A-2-c-1](#)) ([98a](#)).

Small amounts of riboflavin, occurring largely as digestible coenzymes, are present in most plant and animal tissue. Especially good sources are eggs, lean meats, milk, broccoli, and enriched breads and cereals ([99](#)). Such losses as occur during cooking are largely due to leaching of the heat-stable but light-sensitive flavins into water. (See Appendix [Table IV-A-23-a](#) for the riboflavin content of common foods.)

When supplementation or therapy with riboflavin is warranted, oral administration of 5 to 10 times the RDA usually is satisfactory ([96](#)).

METHODS FOR ASSAY AND STATUS DETERMINATION

Numerous biochemical methods are aimed at the separation and quantitation of the diverse natural flavins ([100](#), [101](#)). Among the more sensitive are those that invoke specific binding, such as riboflavin with egg white riboflavin-binding protein, FMN with apoflavoquinone, and FAD with apoproteins for D-amino acid oxidase or glucose oxidase. However, nutritional status is commonly assessed by measuring urinary excretion of the vitamin in fasting, random, or 24-hour specimens or by load return tests, measurement of erythrocyte riboflavin concentration, and determination of the erythrocyte glutathione reductase activity coefficient ([77](#), [102](#)).

Urinary riboflavin can be measured by fluorometric as well as by microbiologic procedures. Under conditions of adequate intake, the amount excreted per day is more than 0.32 μmol (120 μg), or at least 0.21 μmol (80 μg) are excreted per gram of creatinine. The rate of excretion expressed as mg/g creatinine is greater for children than for adults, who normally have 80 $\mu\text{g/g}$ or more but fall below 27 $\mu\text{g/g}$ when deficient. Conditions causing negative nitrogen balance and the administration of antibiotics and certain psychotropic drugs (phenothiazine) increase urinary riboflavin as a consequence of tissue depletion and displacement, respectively. A load return test augments the applicability to a given case. Only high-performance liquid chromatography (HPLC) of suitable extracts followed by specific identification of each flavin can distinguish the natural vitamin from other urinary flavins ([62](#)).

Erythrocytic riboflavin can also be determined either fluorometrically or microbiologically. Because changes are rather small, there is some problem with sensitivity and interpretation of results. Nevertheless, values below 27 nmol (10 μg)/dL cells should be considered to reflect a deficient status, compared with 40 nmol/dL or more (\approx 15 $\mu\text{g/dL}$) for an acceptable status. Again, HPLC has been used to monitor more exactly the riboflavin composition of human blood ([75](#), [103](#)).

Currently, riboflavin status is most commonly assessed by determination of FAD-dependent glutathione reductase activity in freshly lysed red cells, as detailed for routine clinical use ([104](#)) from the procedure described by Sauberlich et al. ([105](#)).

Activities of holo and apo forms of glutathione reductase in erythrocyte hemolysates are measured before and after addition of FAD, respectively, by spectrophotometric determinations of NADPH (the reduced form of nicotinamide-adenine dinucleotide phosphate) oxidation. Values obtained are expressed in terms of "activity coefficients," or ACs, ($AC = DA_{340}$ with FAD/ DA_{340} without FAD), which represent the degree of stimulation of apoenzyme resulting from addition of FAD in vitro. An AC of 1.0 indicates no stimulation and only the presence of holoenzyme as a result of excess FAD (and riboflavin) in the original erythrocytes. Guidelines suggested for such coefficients are <1.2, acceptable; 1.2 to 1.4, low; >1.4, deficient. Though it is currently the biochemical method of choice for assessing riboflavin status, the erythrocyte glutathione reductase assay has some drawbacks (77). The test cannot be used in persons with glucose 6-phosphate deficiency because of an increased avidity in the reductase for FAD in this disease, which occurs in about 10% of black Americans. In vitro treatment of blood with inosine and adenine elevates activity coefficients (106).

Abbreviations: FAD—flavin adenine dinucleotide; FMN—flavin mononucleotide.

HISTORICAL BACKGROUND

Niacin (also known as nicotinic acid), a member of the B group of vitamins, was initially studied because of its association with pellagra. This nutritional deficiency disease was first described by Casal (1) in 1735 as “mal de la rosa,” with the classic symptoms of dermatitis, diarrhea, and dementia, with death as the eventual outcome. Early this century, an epidemic of pellagra in the southern United States (2), initially thought to be of infectious origin, was noted to be associated with poor nutrition, inadequate meat and milk intake, and use of corn as the principal constituent of the diet. This disease seems now to be endemic in India and parts of China and Africa (3).

In 1922, Goldberger and Tanner (4) suggested that pellagra was an amino acid deficiency. Later, Elvehjem et al. (1937) demonstrated that nicotinic acid and nicotinamide (5) isolated from liver cured black tongue, the canine counterpart of pellagra, and in the same year, Fouts et al. (6) reported that niacin cured human pellagra. In 1949, tryptophan was shown to reverse the symptoms of pellagra (7). In 1961, Goldsmith et al. (8) quantified the conversion of tryptophan to niacin by monitoring such niacin metabolites as N^1 -methylnicotinamide and N^1 -methyl-5-carboxamide-2-pyridone. They found that, on average, 60 mg of tryptophan was equivalent to 1 mg of the vitamin. Elucidation of the biochemical pathway for conversion of tryptophan to nicotinic acid mononucleotide (NicMN) (Fig. 23.1) took more than 10 years, from 1950, when Knox and Mehler (9) showed that the first step in the biodegradation of tryptophan to *N*-formylkynurenine was catalyzed by tryptophan pyrrolase, to 1963, when Nishizuka and Hayaishi (10) showed that quinolinic acid reacts with phosphoribosepyrophosphate (PRPP) to form NicMN, a reaction catalyzed by the enzyme quinolinic acid phosphoribosyltransferase. In this period of time, it was also

shown (11) that NicMN was the substrate for NMN:ATP adenylyltransferase, which catalyzed its conversion to nicotinic acid adenine dinucleotide (NicAD). NicAD is the immediate precursor of nicotinamide adenine dinucleotide (NAD) (Fig. 23.2), which plays a critical role in redox and ADP-ribose transfer reactions. The pathway that synthesizes niacin from tryptophan is primarily found in the liver but has also been reported in the kidney (12).

Namase, nicotinamidase; -E represents a bond to a protein.

Nicotinamide can be recycled to nicotinic acid by nicotinamidase ([Fig. 23.2](#)). Metabolically, nicotinic acid cannot, however, be directly converted to nicotinamide, which is rather produced from NAD in ADP-ribose transfer or NAD glycohydrolase reactions ([13](#)).

CHEMISTRY AND NOMENCLATURE

The structures of niacin, also known as nicotinic acid or pyridine-3-carboxylic acid, and nicotinamide, which is also termed niacinamide, are shown in [Figure 23.3](#). The pyridine ring is substituted at position 3 by a carboxylic acid group in nicotinic acid and by a carboxamide moiety in nicotinamide. The nitrogen in the pyridine ring of niacin is positively charged when it is a component of NAD. This cationic nitrogen confers unique chemical properties to NAD ([Fig. 23.4](#)). For example, in oxidation-reduction reactions catalyzed by dehydrogenases, addition at position 4 of the pyridine ring of a hydride derived from a reduced substrate yields reduced NAD (NADH) and an oxidized substrate ([12](#)) ([Fig. 23.5](#)).

Figure 23.3. Chemical structures of niacin and nicotinamide and their metabolites. A unique metabolite of niacin is nicotinic acid (glycine conjugate of niacin). The main metabolites of nicotinamide are *N*¹-methylnicotinamide and its 2- and 4-pyridone analogues.

Figure 23.4. Structure of nicotinamide adenine dinucleotide.

Figure 23.5. General reaction of oxidation-reduction of NAD(P) by dehydrogenases.

The positive charge on the nitrogen of the pyridine ring in NAD makes the glycosidic bond (Fig. 23.6 and Fig. 23.7) that links the ribose to nicotinamide a target for nucleophilic attack, leading to nicotinamide release and substitution at the electrophilic ribose 1' carbon. These reactions are carried out by enzymes that replace the nicotinamide of NAD with nucleophilic acceptor molecules. The acceptors can be amino acids in target proteins, as in reactions catalyzed by monoadenosine diphosphate ribosyltransferases (ADPRTases) (13). In the substitution reaction, the ADP-ribose moiety of NAD is transferred to an acceptor amino acid, hence the name transferase. When the acceptor is the nitrogen at position 1 of the adenine moiety of NAD, cyclic ADP-ribose (Fig. 23.6) is formed in a reaction catalyzed by ADP-ribosyl cyclase (14, 15). In cells, cyclic ADP-ribose is believed to regulate Ca^{2+} influx (15). For the nuclear enzyme poly(ADP-ribose) polymerase (PARP), the acceptor nucleophile is the hydroxyl group in the 2' position of a ADP-ribose monomer (forming 1' to 2' glycosidic linkages), already attached to a protein (this reaction is also catalyzed by PARP, which transfers

ADP-ribose from NAD to a carboxylate group of an acceptor protein). Sequential additions of ADP-ribose molecules produce a long polymer with branches occurring, on average, every 40 to 50 residues (Fig. 23.8), which may have a role in DNA repair (16) and chromatin structure (17). Finally, the acceptor nucleophile may be water, a reaction catalyzed by NAD glycohydrolases (NADases)(18) that yields free ADP-ribose and nicotinamide.

Figure 23.6. Structure of cyclic ADP-ribose (cADPR) and its 2'-phosphate analogue (14, 35, 38).

Figure 23.7. Formation of ADP-ribose from NAD. NADases can hydrolyze NAD to form ADP-ribose; some of them catalyze cyclic ADP-ribose formation first and subsequently ADP-ribose, via their intrinsic ADP-ribosyl cyclase and cyclic ADP-ribosyl hydrolase activities, respectively (35).

Figure 23.8. PolyADP-ribose polymer (56). The first monomer unit of ADP-ribose is linked to an acceptor protein through an α -glycosidic linkage on a carboxylate group. The linear polymer is formed with ADP-ribose units linked via α -1''-2'-glycosidic linkages and branches occurring, on average, every 40 to 50 residues via α -1''-2''-glycosidic linkages. Chemically, the glycosidic linkages attaching ADP-ribose units correspond to acetal bonds, which are acid sensitive (99); -E represents a bond to a protein.

DIETARY CONSIDERATIONS

Significant amounts of niacin are found in meat (especially red meat), liver, legumes, milk, eggs, alfalfa, cereal grains, yeast, fish, and corn (19). Although milk and eggs contain small amounts of preformed niacin, their content of tryptophan provides more than sufficient niacin equivalents. Red meat is reported to be one of the best sources of niacin equivalents because of its abundance of preformed niacin and tryptophan. As mentioned, tryptophan can provide niacin nutriture and it is generally believed that 60 g of the amino acid is converted to 1 g of the vitamin. Assuming that 1% (wt/wt) of proteins is tryptophan, 60 g of protein could provide 600 mg of tryptophan or 10 niacin equivalents (NE, 1 niacin equivalent equals 1 mg of either nicotinic acid or nicotinamide, which in turn corresponds to 8.13 mmol). Quantitatively, the major use of this amino acid is in protein biosynthesis. In humans, the amount of tryptophan converted to niacin depends on nutritional history (20) and hormonal factors (21). If there is a deficiency of tryptophan and niacin in the body, tryptophan is used primarily to maintain protein synthesis rather than to replenish niacin pools. Oral contraceptives and pregnancy may somewhat increase tryptophan conversion to niacin (21).

The role of dietary corn in causing pellagra led to the concept of amino acid imbalance as a potential cause of niacin deficiency (22). Corn, which contains significant amounts of niacin and tryptophan, also contains a high proportion of leucine, which inhibits the synthesis of NAD in isolated red blood cells (23), an effect counteracted by isoleucine and valine. Niacin and tryptophan requirements are also increased by threonine, cystine, methionine, and, to a lesser extent, phenylalanine (24). Although mature cereal grains are reported to contain 70% of niacin in a biologically unavailable form (3), in Mexico and Central America, populations with diets based on corn do not suffer from

pellagra. This may be related to the fact that in the preparation of tortillas, treatment of corn with alkali increases niacin availability (25).

Coffee, another common dietary constituent, is reported to contain an alkaloid known as trigonelline (*N*¹-methylnicotinic acid) that, in the presence of heat and acid, can form nicotinic acid. This reaction occurs during coffee bean roasting, leading to a 30-fold increase in niacin content (26).

METABOLISM: ABSORPTION, DISTRIBUTION, AND EXCRETION

Niacin and its amide adduct are absorbed through the intestinal mucosa by simple diffusion. Fifteen to 30% of niacin is bound to protein, and this vitamin-protein complex is taken up by tissues. Adipose tissue is responsible for the rapid clearance of niacin after an intravenous dose. Metabolic trapping, in which niacin and nicotinamide are converted to NAD, accounts for retention of these vitamins (27). Neutral niacin as a zwitterionic species with a carboxylic anion ($pK_a = 4.5$) and quaternary nitrogen cation may partition as a lipid-soluble molecule. In contrast, nicotinamide is lipid soluble only in the neutral form (i.e., with an uncharged nitrogen in the pyridine ring). Receptor-mediated uptake of nicotinamide has, however, been reported recently (28).

Niacin and nicotinamide are metabolized via different pathways. In liver, the major product of pharmacologic doses of niacin is the glycine conjugate, nicotinuric acid (Fig. 23.3), whereas the main metabolites of nicotinamide are *N*¹-methylnicotinamide and its oxidized products, 2- and 4-pyridones (29) (Fig. 23.3). Niacin and nicotinamide metabolites formed in the liver are excreted in urine. Quantification of excretion of nicotinuric acid and *N*¹-methylnicotinamide and its pyridones is useful in evaluating niacin nutriture. Since metabolism of niacin is a saturable process, the rate of niacin and nicotinamide ingestion affects their plasma levels.

FUNCTIONS

Niacin, nicotinamide, and tryptophan are precursors of NAD and NADP. These nucleotides are key components of oxidation-reduction reactions, ATP synthetic pathways, and ADP-ribose transfer reactions. In oxidation-reduction reactions, dehydrogenases use NAD/P(H) as coenzymes to oxidize or reduce a substrate. Position 4 of the pyridine ring, which in the reduced form contains two proquiral hydrogens, is the site of oxidation or reduction (12). Dehydrogenases use specifically one of the two hydrogens of the reduced NAD (see Fig. 23.5). For example, alcohol dehydrogenase from yeast and the cardiac isoenzyme of lactate dehydrogenase (LDH) use hydrogen H_b (Fig. 23.5), whereas hepatic glucose dehydrogenase and yeast glucose-6-phosphate dehydrogenase only use hydrogen H_a (30). The difference in wavelengths of maximal absorbance by NAD/P (254 nm) and NADH/PH (340 nm) is used in many assays involving dehydrogenases. NADP is directly formed from NAD by phosphorylation catalyzed by a specific kinase found in mammalian liver (12). A phosphatase has also been described that converts NADP to NAD (12).

NADP dehydrogenases are preferentially involved in anabolic reactions (e.g., synthesis of fatty acids and cholesterol [31]). In contrast, NAD is used in catabolic reactions to transfer the potential free energy stored in macronutrients such as carbohydrates, lipids, and proteins to NADH, which is then used to form ATP, the primary energy currency of the cell.

NAD Glycohydrolases
