In the last 30 years, the importance of the high-energy glycosylic bond between the anomeric carbon of ribose and the quaternary nitrogen of the pyridine moiety of NAD and NADP (Fig. 23.4) in the biologic function of pyridine nucleotide coenzymes has been recognized. Early attempts to elucidate the role of NADases in vivo were fueled by the observation that isoniazid, which is a pyridine derivative used for tuberculosis treatment (2), could inhibit many NADases (32) and that this treatment could precipitate pellagra, especially in malnourished populations (33). The studies on NADases originally focused on their ability to catalyze transglycosylation reactions in vitro (18). In 1989, Lee et al. (34) reported that a metabolite of NAD, cyclic ADP-ribose (Fig. 23.6), could release Ca^{2+} from endoplasmic reticulum in sea urchins by use of ryanodine receptors. In 1993, Kim et al. (35) showed that NADases from canine spleen and from *Bungarus fasciatus* have dual activity (Fig. 23.7): (a) ADP-ribosyl cyclase and (b) cyclic ADP-ribose hydrolase, resulting in the net hydrolysis of NAD to ADP-ribose and nicotinamide. These findings raised the possibility that the elusive role of NADases could be related to signal transduction by formation of a second messenger, cyclic ADP-ribose. It is unclear whether all NADases possess this dual activity. Cyclic ADP-ribose formation and degradation by some NADases and the observation that CD38 (36) (a cell-surface antigen of T and B lymphocytes) possesses NADase and ADP-ribosyl cyclase activities renewed interest in the biologic function of NADases. The fact that CD38 is an ectoenzyme also raises the question of availability of NAD in the extracellular milieu.

In 1996, two newly recognized products of the NADases/ADP-ribosyl cyclases (e.g., canine spleen enzyme and CD38) were shown to release Ca^{2+} from the endoplasmic reticulum. One of these products is nicotinic acid adenine dinucleotide-2'-phosphate (NicADP) (37), which is more potent than cyclic ADP-ribose; the second is cyclic ADP-ribose-2'-phosphate (38), which is as potent as cyclic ADP-ribose in releasing Ca^{2+} . Thus, NADases/ADP-ribosyl cyclases are among the few enzymes that can use both NAD and NADP as substrates. NicADP could be formed by the transglycosylation reaction of NADP with nicotinic acid catalyzed by NADases. This product may be involved in the physiologic responses to pharmacologic doses of niacin.

Mono ADP-Ribosyltransferases

NAD functions also in mono-ADP-ribosylation, the transfer of ADP-ribose from NAD to target proteins. This posttranslational modification was first characterized by use of bacterial toxins that possess intrinsic ADP-ribosyltransferase (ADPRTase) activity as well as receptor-binding components that target them to specific cells. The first toxin ADPRTase described was diphtheria toxin (39), which inhibits protein synthesis by

ADP-ribosylating elongation factor 2, thereby inhibiting protein synthesis (Table 23.1). Later, it was demonstrated that *Pseudomonas aeruginosa* exotoxin A (40) catalyzes the same reaction. Cholera toxin and *Escherichia coli* heat-labile enterotoxin (41) ADP-ribosylate G_{sa}, the a subunit of the heterotrimeric guanine nucleotide-binding (G) protein, which couples cell surface receptors that activate adenylyl cyclase to the cyclase catalytic unit. Cholera toxin-catalyzed ADP-ribosylation inhibits the GTPase activity of G_a, resulting in stabilization of an active G_a • GTP form and persistent activation of the cyclase. ADP-ribosyltransferase activity of cholera toxin is enhanced by ADP-ribosylation factor (ARF) (42), a GTP-dependent eukaryotic protein that functions in intracellular vesicular trafficking (43). Pertussis toxin modifies the G_i, G_o, and G_{ta} subunits (44), proteins involved in regulating adenylyl cyclase, phospholipid turnover, and photoreceptor activation, respectively. ADP-ribosylation by pertussis toxin results in uncoupling of the modified G_a from receptor, thereby stabilizing the inactive heterotrimeric G protein.

Source of ADPRT Toxin	Target Protein	Protein Function
<i>Corynebacterium diphtheriae</i> and <i>Pseudomonas aeruginosa</i> (also cholera and <i>Escherichia coli</i> heat-labile enterotoxin)	Elongation factor 2	Protein synthesis in prokaryotes
<i>Clostridium botulinum</i> C3 <i>Clostridium botulinum</i> exoenzyme <i>Bacillus cereus</i> neurotoxin <i>Spizidium differentiae</i> -enterotoxin (E) of <i>Staphylococcus aureus</i>	Gta	GTP binding subunit of heterotrimeric G protein that activates membrane signal transduction
<i>C. botulinum</i> C2 <i>Clostridium perfringens</i> iota toxin <i>Clostridium sporostere</i> <i>Clostridium difficile</i> (differs from toxin A and B)	Rho GTP	Small GTP binding protein that regulates formation of actin stress fibers in eukaryotic growth factors
<i>C. botulinum</i> C2 <i>Clostridium perfringens</i> iota toxin <i>Clostridium sporostere</i> <i>Clostridium difficile</i> (differs from toxin A and B)	Nonmuscle G-actin (β and γ isoforms)	Components of the cytoskeleton that form microfilaments (F-actin)
<i>P. aeruginosa</i> exotoxin S	critical Ras, Rap, Ral, Rab3, and Rab4	Key components of signaling pathway; regulate cell proliferation, differentiation, and intracellular vesicle trafficking (all bind GTP)
<i>Bordetella pertussis</i>	G _i , G _o , and G _{ta}	Subunit of heterotrimeric G protein that activates membrane signal transduction (all bind GTP)

Table 23.1 ADP-Ribosylation of Endogenous Proteins by Bacterial Toxins

Some strains of *Clostridium botulinum* produce a C3 ADP-ribosyltransferase (45) that ADP-ribosylates the ~20-kDa guanine nucleotide-binding protein, Rho, and a C2 toxin that ADP-ribosylates the cytoskeletal protein nonmuscle actin (46) (Table 23.1). Modification by either toxin abolishes the biologic activity of the proteins. *Clostridium perfringens* (46) produces a toxin similar in function to C2, named iota toxin, which also ADP-ribosylates actin. *P. aeruginosa* exotoxin S (47) uses as substrates Ras, Ral, Rap 1A, Rab3, and Rab4, all ~20-kDa guanine nucleotide-binding proteins (48). ADP-ribosylation by exotoxin S requires members of the 14-3-3 family of eukaryotic proteins (49). These proteins are very well conserved through evolution with biologic functions that involve signal transduction (e.g., protein kinase C activity), cellular proliferation (e.g., binding protooncogene products), Ca²⁺-dependent exocytosis, and activation of tyrosine and tryptophan hydroxylase, enzymes involved in the synthesis of the neurotransmitters catecholamine and serotonin, respectively (50).

Eukaryotic ADPRTase counterparts of the toxins have been found, although their physiologic functions are not clear. A unique ADP-ribosyltransferase attached to the surface of skeletal and cardiac muscle cells through a glycosylphosphatidylinositol (GPI) anchor has recently been described by Zolkiewska et al. (51). Its substrate, integrin $\alpha 7$, is part of a heterodimer ($\alpha 7\beta 1$) that interacts with extracellular matrix protein, laminin, and is regulated developmentally. Another GPI-anchored ADPRTase, reported by Wang et al. (52), may regulate the response of cytotoxic T cells.

To date, the amino acids known to be modified by different mono-ADPRTases are arginine, cysteine, asparagine, diphthamide, histidine, and hydroxyl-containing amino acids (serine, threonine, and tyrosine) (53).

Poly(ADP-Ribose) Polymerase

Poly(ADP-ribose) polymerase (PARP), first described in 1966 by Chambon et al. (54), also uses NAD as a substrate. It is a nuclear enzyme that is activated by DNA strand breaks and synthesizes very large polymers of up to 200 ADP-ribose molecules, with branches approximately every 40 to 50 residues (55). PARP protein targets are histones and PARP itself (13). The carboxylate of glutamate, aspartate, and a C-terminal lysine can serve as ADP-ribose acceptors (13). Extensive studies with inhibitors of PARP showed its importance in DNA repair (56). Additional evidence comes from studies with PARP antisense mRNA (17) and mutant PARP cell lines (57). Cytotoxicity due to PARP activation may result from NAD reduction, i.e., energy depletion and cell death (58). More recent studies also implicate PARP in apoptosis (59), possibly via upregulation of the tumor suppressor gene p53 (60). Surprisingly, after disruption of the PARP gene, mice did not show a widespread appearance of tumors (61). Cells with this genotype were able to repair methylation damage caused by *N*-methyl-*N*'-nitro-*N*-nitroguanidine, MNNG, an alkylating agent (base excision repair) and photoproduct damage induced by UV radiation (nucleotide excision repair). Spontaneous skin cancer appeared in older PARP-knockout mice, however, which may be related to lack of the PARP protective mechanism, allowing mutated cells to survive and go through the stages of carcinogenesis. These findings suggest that the role of PARP might be related to the cellular response to environmental stress (62). Curiously, pellagra, which could limit PARP activity as a result of NAD deficiency, is characterized by a dermatitis similar to the "skin disease" of the knockout mice.

NAD also plays an important role in the ligation step during maturation of eukaryotic tRNA, in which a unique product is ADP-ribose 1",2"-cyclic-phosphate (63).

DEFICIENCY AND MANIFESTATIONS

Niacin deficiency causes pellagra. The classic symptoms of this disease in the late stages are *dermatitis*, characterized by pigmented rash, especially in areas exposed to sunlight; *diarrhea*; and *dementia*, with symptoms including anxiety, insomnia and, in advanced stages, disorientation, hallucinations, and delirium (64). "Necklace" lesions on the lower neck, described by Casal (1), indicate advanced disease. Early stages of the

dermatitis include skin thickening, scaling, and hyperkeratinization in sun-exposed areas. Inflammation of mucous membranes also occurs, with soreness of the tongue, stomatitis, esophagitis, urethritis, proctitis, and vaginitis. Intestinal inflammation leads to diarrhea. Advanced stages of pellagra can be cured with nicotinamide in intramuscular doses of 50 to 100 mg three times a day for 3 to 4 days, followed by similar quantities orally supplemented with 100 g protein per day.

Since the biotransformation of tryptophan to nicotinic acid requires several vitamins and minerals ([Fig. 23.1](#)), diets lacking these nutrients can predispose to pellagra ([1](#)). Vitamin B₆ is involved in several steps of tryptophan catabolism and increases production of tryptophan metabolites in animals and humans. As noted, isoniazid therapy of tuberculosis can cause niacin deficiency by depletion of pyridoxal phosphate ([65](#)) (vitamin B₆). Deficiency of copper, required for the conversion of tryptophan to *N*-formylkynurenine, can block niacin synthesis ([66](#)), and lack of riboflavin, required for the conversion of kynurenine to 3-hydroxykynurenine, increases excretion of kynurenine and kynurenic acid after a tryptophan load ([67](#)). It is not surprising, therefore, that riboflavin deficiency results in some of the same symptoms as niacin deficiency (e.g., stomatitis, cheilosis, and raw tongue) ([26](#)).

Hartnup's syndrome (an autosomal recessive disorder) is characterized by impaired synthesis of niacin from tryptophan, which results in pellagra-like symptoms ([68](#)). The disease results from defective absorption of tryptophan in the intestine and/or increased renal excretion ([69](#)). Treatment with nicotinamide in large doses (40–250 mg/day) markedly improves the dermatitis and neurologic problems ([70](#)).

EVALUATION OF NUTRIENT STATUS

Niacin nutriture has been assessed in several ways by a variety of methods. Bernofsky ([71](#)) described the use of Dowex-1 formate chromatography to separate pyridine nucleotides and *N*¹-methylnicotinamide.

Other methods used to assess niacin intake include quantification of pyridine nucleotides, (NAD/H) and (NADP/H), accurate determination of which depends on the method of extraction, since acid destroys NADH and NADPH and alkali degrades NAD and NADP. A method devised by Lowry et al. (1961) ([72](#)) to measure NAD and NADP is based on the sequential use of two dehydrogenases. The oxidized product is measured by adding extra pyridine nucleotide and an appropriate dehydrogenase, and the resulting pyridine nucleotide is finally quantified fluorometrically. A modification of this method by Slater and Sawyer ([73](#)) in 1961 and later by Nisselbaum and Green ([74](#)) in 1969 replaced one of the dehydrogenases with thiazolyl blue, which is reduced by NADH and NADPH, via phenazine methosulfate, to form a purple compound, formazan, in an amount proportional to the concentration of the coenzymes (oxidized and reduced). This assay uses appropriate dehydrogenases specific for either NAD or NADP. This method has been used to measure these pyridine nucleotides in tissue and blood.

Measurement of *N*¹-methylnicotinamide and its 2-pyridone derivative in urine ([75](#)) has

been used to monitor niacin nutriture. Urinary levels of *N*¹-methylnicotinamide below 0.8 mg/day indicate niacin deficiency (76). A ratio of *N*¹-methyl-5-carboxamide-2-pyridone to *N*¹-methylnicotinamide of 1.3 to 2 is considered normal; it is less than 1 in niacin deficiency (77). Niacin status can also be assessed by measuring its physiologically active forms, NAD(H)/NADP(H).

Fu et al. (78) investigated possible markers of niacin nutriture in erythrocytes. The study spanned 12 weeks and was divided into four periods: stabilization, depletion, repletion, and high intake. Like the results in cultured cells (79), NADP levels were the same in all four periods, while NAD levels decreased significantly during the depletion period. It was proposed that an NAD:NADP ratio higher than 1 reflects adequate niacin nutriture and a ratio below 1, niacin deficiency. Since tryptophan concentrations in blood fell very rapidly from 11.5 to 6.1 mg/mL during the depletion period, it was suggested that the combination of NAD:NADP ratio and tryptophan concentration in erythrocytes could be used to assess severe niacin deficiency. In this study, leucine given with tryptophan did not affect blood levels of NAD and NADP, a finding inconsistent with the proposal that leucine interferes with tryptophan use in NAD biosynthesis.

REQUIREMENTS AND RECOMMENDED INTAKE

Prevention of pellagra requires 11.3 to 13.3 NE/day. The recommended dietary allowance (RDA) of 1989 was 15 to 20 NE/day in adult males and 13 to 15 in females, with caloric intake of no less than 2000 kcal (3) (see also Appendix [Table II-A-2-a-2](#)). The 1998 RDAs for niacin for children and adults are 1 to 3 mg/day less than the 1989 RDAs (100). The use of NE is based on the fact that dietary tryptophan can replace niacin. There is significant controversy about the correct ratio of tryptophan to niacin; it has been reported that 60 mg of tryptophan provides 1 mg of niacin, with a variation of about 30% (SD) among individuals (80).

There are no data concerning relevant niacin requirements in pregnancy and lactation. Based on an average increase in energy expenditure of 300 kcal/day during pregnancy, the niacin RDA for pregnant women was increased by 2 units. During lactation, women who breast feed provide 750 mL/day of milk that contains 1.0 to 1.3 NE. Taking this into consideration, as well as the increase in caloric expenditure during lactation, the niacin RDA may be increased by 5 NE/day. Although there are no data for infants and children, 5 to 9 NE/1000 kcal intake are assumed to suffice in infants, and 18 NE/1000 kcal in adolescents (3).

American women, 19 to 50 years old, consume, on average, 700 mg of tryptophan daily, whereas men in the same age range consume 1100 mg. These amounts represent 16 and 24 NE for women and men, respectively (3). After addition of preformed niacin in the diet, the values are 27 NE for women and 41 NE for men.

NIACIN AS PHARMACOLOGIC AGENT

Niacin in large doses (1–3 g/day) is antihyperlipidemic (81). Nicotinamide is being investigated as preventive therapy for insulin-dependent diabetes and is used currently

to treat Hartnup's syndrome (69). Different pharmacologic responses to niacin and nicotinamide are consistent with the fact that these compounds, although obviously related, are metabolized differently by cells. Niacin and tryptophan share two common intermediates in pathways leading to NAD (Fig. 23.2). The first is NicMN, a substrate for NMN:ATP adenylytransferase, which catalyzes synthesis of the second common intermediate, NicAD. NicAD requires transamination to form NAD. In contrast, NMN is used directly for NAD synthesis via the nuclear enzyme NMN:ATP adenylyltransferase (which also can use NicMN as a substrate) (12). Fewer metabolic reactions are needed to convert nicotinamide than nicotinic acid to NAD, which may explain why nicotinamide is more effective in restoring NAD pools in niacin deficiency (Fig. 23.2).

Niacin decreases triglyceride levels in blood by lowering very low density lipoproteins (VLDL)(82). It is also effective in increasing high-density lipoprotein (HDL), while usually reducing low-density lipoprotein, LDL (83). Niacin treatment can result in a regression of atherosclerotic plaques and overall reduction in patient mortality (84, 85).

In 1990, the Familial Atherosclerosis Treatment Study (84) compared two lipid-lowering treatments. The first included lovastatin (an inhibitor of hydroxymethylglutaryl CoA reductase, a rate-limiting enzyme in the biosynthesis of cholesterol) and colestipol (which sequesters bile acids and interferes with lipid absorption). The second regimen included niacin with colestipol. In the control group, LDL levels fell slightly (7%); those in the niacin/colestipol group decreased by 32%, and those in the lovastatin/colestipol group, by 46%. Increases of 5% in HDL levels in the control group, 15% in the lovastatin/colestipol group, and 43% in the niacin/colestipol group were observed. The lovastatin/colestipol- and niacin/colestipol-treated groups showed a 50% decrease in the frequency of stenosis progression, a dramatic increase in stenosis regression, and a 73% decrease in frequency of cardiovascular events. Another landmark study, the Cholesterol-Lowering Atherosclerosis Study (CLAS I and II) (85), reported the effects of niacin/colestipol therapy on coronary atherosclerosis over a span of 6 years. The findings included significant differences in nonprogression (52% drug vs. 15% control) and regression (18% drug vs. 6% control) of coronary artery lesions.

Nicotinamide can prevent macrophage- (86) or interleukin 1b–induced b-cell damage in vitro (87), and treatment of mice with nicotinamide significantly decreased development of alloxan- and streptozotocin-induced (88) or spontaneous (89) insulin-dependent diabetes mellitus (IDDM). Nicotinamide protection appears to result, at least in part, from inhibition of interleukin 1b–induced nitric oxide production and from serving as a radical scavenger (90). In 1994, evidence for a role of nitric oxide activation of PARP in neurotoxicity was reported (91). This background provided the rationale for investigation of the effect of nicotinamide on prevention of the onset of IDDM in humans. IDDM is an autoimmune disease associated with b-cell destruction in the pancreatic islets of Langerhans and appearance of circulating antibodies long before the manifestation of insulin deficiency (92). Two marker antibodies can be used to identify people at risk. The one against glutamic acid decarboxylase and the other against islet cell antigen (ICA) were associated with risks of 17 and 20%, respectively, for onset of IDDM within 5 years (93). When both antibodies are present, the risk is 90%.

Compelling evidence of the effectiveness of nicotinamide in preventing or delaying the

onset of IDDM was obtained in a study in Auckland, New Zealand (94). Of 81,993 children aged 5 to 7 years, 33,658 were selected randomly, and 20,195 of these agreed to be tested for ICA antibodies. Children with 20 units or more of ICA and those with 10 units of ICA plus first-phase insulin release (a measure of b-cell function) below 100 mmol/L were treated with nicotinamide. The incidence of IDDM was compared in those two groups (the 20,195 children who accepted ICA screening and the 13,463 who were randomly chosen but were not screened) as well as a third (termed random control) group. Incidence rates per 10^5 exposure years in the three groups were 20.1 for the control, 8.1 for those treated, and 15.1 for the chosen group that refused to be tested. A large trial of nicotinamide for prevention or delay in onset of IDDM is now in progress, with Canada and 18 European countries participating.

Nicotinamide and nicotinic acid have also been postulated to be important in carcinogenesis (95). The proposed role is based on the requirement for NAD to support proper functioning of PARP. It is suggested that proper repair of DNA damage by involvement of functional PARP, which requires abundant NAD, would prevent or retard, in the long term, the multistage process of carcinogenesis. The current hypothesis for cancer prevention is that if small amounts of DNA damage occur, optimal PARP activity in the presence of adequate NAD pools would be efficiently involved in repairing it (the precise role of PARP in DNA repair has not been defined) so that mutation is limited. If more DNA damage occurs, a functional PARP would trigger apoptosis, probably via increased p53, or cause cell death by NAD depletion, thus preventing survival of a putative mutated, and perhaps eventually carcinogenic, cell.

AVAILABLE FORMULATIONS OF NIACIN

As described above, niacin is used in large doses to treat hyperlipidemia. These doses are provided in two different formulations: modified-release niacin and regular crystalline niacin (96). Recommended doses are 1.5 to 2 g/day of modified niacin or up to 3 g/day of regular niacin. The advantage claimed for modified-release niacin over regular niacin is absence of the flushing that occurs in some patients after ingestion of large doses of unmodified niacin, but there is evidence that modified-release niacin is more likely to lead to gastrointestinal problems and hepatotoxicity. Since the flushing reaction caused by regular niacin can be prevented by acetylsalicylic acid or by starting therapy with lower doses of niacin and since the gastrointestinal and hepatotoxicity side effects of niacin may necessitate stopping therapy, regular niacin is recommended for treating hyperlipidemia.

TOXICOLOGY

Nicotinamide is excreted in urine as N^1 -methylnicotinamide and its 2- and 4-pyridone derivatives. With the large doses of nicotinamide used to prevent onset of IDDM, the hepatic pathways involved in formation of its metabolites become saturated. This has raised concern that diversion of methylation equivalents required for anabolic pathways to nicotinamide methylation may lead to growth retardation in children (97). Side effects of pharmacologic doses of niacin used to treat hyperlipidemia are cutaneous flushing, pruritus, urticaria, nausea, vomiting, diarrhea, bloating, and constipation. Premedication with aspirin is used to control the flushing reaction. Caution is recommended in patients

with unstable angina and in gout-predisposed patients. Some elevation in concentrations of liver enzymes (e.g., aspartate aminotransferase and alkaline phosphatase) may occur in the circulation (98). In some instances, hepatotoxicity may require stopping niacin treatment. Niacin may cause insulin resistance, which requires compensatory insulin secretion and, in patients with dysfunctional pancreatic β cells, may cause hyperglycemia. Patients with diabetes mellitus, therefore, require special monitoring during niacin treatment.

Abbreviations: **ADP-ribose**—adenosine 5-diphosphoribose; **ADPRT-ases**—ADP-ribosyltransferases; **ARF**—ADP-ribosylation factor; **GPI**—glycosylphosphatidylinositol; **GTP**—guanosine 5-triphosphate; **GTPases**—GTP hydrolases; **HDL**—high-density lipoprotein; **IDDM**—insulin-dependent diabetes mellitus; **LDL**—low-density lipoprotein; **NAD**—nicotinamide adenine dinucleotide; **NADases**—NAD glycohydrolases; **NicADP**—nicotinic acid adenine dinucleotide-2'-phosphate; **NicMN**—nicotinic acid mononucleotide; **PARP**—poly(ADP-ribose) polymerase.

Since the discovery and identification of the structure of vitamin B₆ some 50 years ago, our knowledge of the functions of vitamin B₆ and the quantitative need for this vitamin has advanced significantly (1). Gyorgy and Lepkovsky were among the first to isolate vitamin B₆ in crystalline form. In the subsequent decade, Snell and coworkers were instrumental in elucidating the various forms of vitamin B₆ and developing microbiologic analytical techniques for measuring these forms in biologic systems (1, 2). Vitamin B₆ is recognized for its importance in diverse metabolic reactions and physiologic actions important for overall well-being.

CHEMISTRY

Vitamin B₆ is the name for derivatives of 3-hydroxy-5-hydroxymethyl-2 methyl pyridine (3). The four position can be found as the methylhydroxy (pyridoxine), the aldehyde (pyridoxal), or the methylamine (pyridoxamine). Each of these forms can also be phosphorylated at the five position (Fig. 24.1). Pyridoxal 5'-phosphate (PLP) and pyridoxamine 5'-phosphate (PMP) are the active coenzyme forms, with PLP being the

primary form of biologic interest.

Figure 24.1. Forms, interconversion, and metabolism of vitamin B₆. (From Leklem JE. Nutr Today 1988;Sept/Oct:5, with permission.)

The free forms of vitamin B₆ are considered to be relatively labile, with the degree of lability influenced by pH. All three forms are relatively heat stable in an acid medium but heat labile under alkaline conditions (4). The hydrochloride and base forms are readily soluble in water and only minimally soluble in common organic solvents. In aqueous solution, the forms are light sensitive, but this sensitivity is also pH dependent. Pyridoxine hydrochloride is the form of vitamin B₆ most commonly found in vitamin pills and used in fortification of foods.

The coenzyme forms of vitamin B₆ are PLP and PMP. The PLP form is found covalently bound to enzymes via a Schiff base with the ε-amino group of lysine. In the formation of the Schiff base, the strong electron-attracting character of the pyridine ring and the subsequent withdrawal of electrons from one of the three substituents (R group, hydrogen, or carboxyl group) attached to the α-carbon of the amino acid substrate are key features in most enzymatic reactions (5). Nearly 100 enzymatic reactions (6) have been reported in which PLP plays a coenzyme role (6, 7). Although transamination reactions account for 40% of the PLP-catalyzed reactions, several other classes of reactions involve the α-, β-, or γ carbon of amino acids.

FOOD SOURCES AND FORMS

An understanding of the various forms and the quantities of these forms in foods is important in the evaluation of the bioavailability and metabolism of vitamin B₆. The methods used to determine the amount of vitamin include microbiologic (8) and high-performance liquid chromatography (9) techniques. The relative proportion of each of the three forms in foods varies considerably. Table 24.1 contains data on the total amounts (see also Appendix Table II-A-2-a), the relative proportion of the three forms,

and the level of the pyridoxine glucoside form of vitamin B₆ in selected foods. This latter form of vitamin B₆ has been isolated from plant foods such as rice bran and identified as 5'-O-(β-D-glycopyranosyl) pyridoxine (10). To date only plant foods have been found to contain this interesting form of vitamin B₆ (11). The absence of the glucoside form in animal products suggests it does not have a biologic function. In plants it may be a storage form of vitamin B₆. In general, plant foods contain predominately pyridoxine, while animal products contain primarily pyridoxal and pyridoxamine (mainly as the phosphorylated forms (4)).

Food	Pyridoxine, mg (average/100g)	Pyridoxine (average/100g)
Vegetables

Table 24.1 Vitamin B₆ and Pyridoxine Glucoside (PNG) Content of Commonly Consumed Foods^a

Food processing and storage may affect the vitamin content of foods (12, 13). Losses of 10 to 50% have been reported for a wide variety of foods and processing techniques. Pyridoxine added to flour and baked into bread is stable (14). Thermal processing (15) and low-moisture storage of certain foods results in reductive binding of the two aldehydes, pyridoxal and pyridoxal 5'-phosphate, to proteins via ε-amino groups of their lysyl residues. Such derivatives possess low or even antivitamin B₆ activity (16). Conversion of pyridoxine to 6-hydroxypyridoxine in the presence of ascorbic acid has been reported (17).

ABSORPTION AND BIOAVAILABILITY

Absorption

A proper assessment of the requirement of vitamin B₆ requires an understanding of how much vitamin B₆ is biologically available (i.e., absorbed and usable). Absorption of the several forms of vitamin B₆ has been examined primarily in animals (18) and to a limited extent in humans (19). The three primary forms of vitamin B₆ are absorbed to a major

extent by a nonsaturable passive process (20), mainly in the jejunum (21). After hydrolysis of the phosphorylated forms by alkaline phosphatase and their uptake into the intestine, each can be phosphorylated and thus retained (a process referred to as metabolic trapping). However, forms of vitamin B₆ exit from the basolateral membrane side of the intestine, mainly nonphosphorylated.

Bioavailability

Studies in both animals and humans (22, 23) have provided information on the relative availability of vitamin B₆. A summary of the studies in humans is given in Table 24.2. Generally, more than 75% of vitamin B₆ is available in most foods studied (22). Human studies show an inverse relationship between the amount of pyridoxine glucoside (PNG) in the diet and bioavailability (24). However, PNG is absorbed and partially converted to 4-pyridoxic acid. In human studies, about 58% of the PNG was found to be bioavailable (25). PNG also appears to alter metabolism of coingested pyridoxine in rats (26) and may have a similar effect in humans. Food processing (formation of α-pyridoxyl-lysine) and fiber may also limit availability.

Food	Estimated Bioavailability
Whole wheat bread	>85%
Cooked wheat bran	>85%
Wheat, rice, corn brans	60–65%
Peanut butter	63%, compared with tuna
Bananas	98%, compared with tuna
Hazelnuts	96%, compared with tuna
Soybeans	41%, compared with tuna
Orange juice	50%, compared with pyridoxine

Table 24.2 Studies in Which Bioavailability of Vitamin B₆ from Foods Has Been Assessed in Humans

TRANSPORT AND METABOLISM

Vitamin B₆ is transported in the blood both in plasma and in red cells. PLP and PL are both bound to albumin (27), with PLP binding more tightly. In the red cell, both PLP and PL are bound to hemoglobin (28, 29). The extent of red cell involvement in vitamin B₆ transport, however, remains to be determined (30).

The liver is the primary organ responsible for metabolism of B₆ vitamers (27, 31). As a result, the liver supplies the active form of vitamin B₆, PLP, to the circulation and other

tissues. [Figure 24.1](#) depicts the interconversion of the B₆ vitamers and the enzymes involved. The three nonphosphorylated forms are converted to their respective phosphorylated forms by pyridoxine kinase, with zinc and ATP as cofactors ([32](#)). Pyridoxamine 5'-phosphate and pyridoxine 5'-phosphate can then be converted to PLP via a flavin mononucleotide (FMN) oxidase ([33](#)).

Phosphorylated forms can be hydrolyzed by alkaline phosphatases ([31](#), [32](#)). The pyridoxal that results from this dephosphorylation, as well as that derived from dietary sources, can then be converted to 4-pyridoxic acid (4-PA) in a nonreversible reaction involving FAD and an aldehyde oxidase ([32](#)). This reaction occurs in human liver, but the extent to which it occurs in other tissues is not known. Based on studies using human liver preparations, rates for the major reactions of vitamin B₆ metabolism have been determined and indicate that conversion of PL to 4-PA is favored ([34](#)). PL kinase is more active than PLP phosphatase. Because of the role of riboflavin coenzymes in the pathway, riboflavin status may affect vitamin B₆ metabolism ([35](#)).

Because PLP is a highly reactive molecule and readily forms a Schiff base with proteins, high cellular concentrations of PLP may be detrimental. The activity of the aldehyde (pyridoxal) oxidase in human liver appears to suffice, however, to convert excess PL to 4-PA and thus prevent high levels of PLP from accumulating ([32](#)).

In the circulating plasma, PLP and PL comprise nearly 75–80% of the total vitamin B₆ ([4](#), [36](#), [37](#)). Pyridoxine (PN) is the next most common form, and while PN is taken up into tissues and can be converted to PNP, many tissues lack sufficient oxidase activity to convert PNP to PLP ([38](#)). While information on kinetics of vitamin B₆ metabolism in humans is limited, studies in pigs (biochemically similar to humans) found that little PLP and PL from the circulation is recycled by the liver back to PLP in the plasma ([39](#)). PL is extensively recycled, probably in muscle and other tissues, via conversion to PLP and subsequent binding to protein.

Several body pools of B₆ exist ([40](#)). The major pool is in muscle, where most of the vitamin B₆ is present as PLP bound to glycogen phosphorylase ([41](#)). The total body pool of vitamin B₆ is estimated to be 1000 μmol, of which 800 to 900 μmol is present in muscle ([42](#)). Turnover of the various pools varies, depending on the metabolic state and nutritional well-being of the organism ([4](#)). Turnover of PLP in the plasma has been associated with a two-compartment model ([4](#), [43](#)), and turnover of the slowly turning over pool is estimated to be 25 to 33 days.

FUNCTIONS

The numerous functions of vitamin B₆ in humans are complex, multifaceted, and interrelated. Because of the reactivity of PLP with amino acids and several nitrogen-containing compounds, the biochemical functions of vitamin B₆ center around these molecules ([44](#)). In these biochemical functions, PLP serves as a versatile catalyst in a diverse number of reactions; a review of the mechanism of PLP-catalyzed reactions

is available (45). In the case of glycogen phosphorylase, the phosphate group of PLP probably is involved in the coenzyme role (46). The role of PLP can be viewed from a systems/cellular perspective. These systems/cellular processes are listed in Table 24.3. A brief description and other highlights of each of these follows.

Cellular Process of Enzyme System	SystemFunction
1-Carbon metabolism, steroid modulation	Immune
Transaminases, glycogen phosphorylase	Gluconeogenesis
Tryptophan metabolism	Niacin formation
Heme synthesis, O ₂ affinity, transaminases	Red cell metabolism
Lipid and neurotransmitter synthesis	Nervous system
Binding of PLP to lysine of steroid receptor	Steroid (hormone) function

From Leklem JE. Vitamin B₆. In: Machlin LJ, ed. Handbook of vitamins. 2nd ed. New York: Marcel Dekker, 1991:341-82, with permission.

Table 24.3 Systems or Cellular Processes in Which Pyridoxal 5'-Phosphate Functions

Gluconeogenesis

PLP is involved in gluconeogenesis via its role in transamination reactions (44) and in the action of glycogen phosphorylase (41, 46). However, a low intake of vitamin B₆ (0.2 mg/day, vs. “normal” intake of 1.8 mg/day) in humans for 4 weeks did not adversely affect fasting plasma glucose levels but did result in impaired glucose tolerance (47). Glycogen phosphorylase activities in liver and muscle are reduced in vitamin B₆-deficient rats (41, 48), but a deficiency of the vitamin, per se, does not result in mobilization of the vitamin B₆ (PLP) stored in muscle (49). However, in rats, a caloric deficit does lead to decreased muscle phosphorylase content (50). Thus, the reservoir of vitamin B₆ in muscle seems to be used only when gluconeogenesis increases.

Niacin Formation

Direct conversion of tryptophan to niacin involves a PLP-requiring enzyme, kynureninase. After 4 weeks of feeding women a diet containing 0.2 mg/day of vitamin B₆, the total urinary excretion of the two major niacin metabolites, *N*'-methyl-2-pyridone-5-carboxamide and *N*'-methylnicotinamide, in response to a tryptophan load test (2 g) was moderately less than that excreted when 1.8 mg of vitamin B₆ was fed (44, 51). Thus, a low intake (<1.0 mg/day) of vitamin B₆ had only a slight effect on the conversion of tryptophan to niacin.

Lipid Metabolism

The role of vitamin B₆ in lipid metabolism remains controversial. Animals fed diets deficient in either polyunsaturated fatty acids or vitamin B₆ showed similar visual signs and symptoms (52). Vitamin B₆-deficient rats fed high-protein (70%) diets developed fatty livers in some studies (53) but not in others. Increased levels of linoleic and d-linolenic acid and decreased levels of arachidonic acid in liver phospholipids have been observed in B₆-deficient rats (54, 55). The changes in fatty acid levels may be related to altered phospholipid levels due to high levels of S-adenosylmethionine inhibiting methylation of phosphoethanolamine (56). This latter effect would tie together altered amino acid metabolism (homocysteine) and the changes in phospholipids and associated fatty acids.

The relationship between vitamin B₆ and cholesterol also remains controversial (57). In humans, a deficiency of vitamin B₆ is not associated with a significant change in serum cholesterol (4). Although supplemental intakes of vitamins in general or vitamin B₆ per se alter serum cholesterol levels (either decrease or prevent an increase) (4), there are no definitive studies on the effect of supplemental vitamin B₆ on serum cholesterol level. Nonetheless, plasma PLP levels are positively correlated with plasma HDL-cholesterol levels and negatively correlated with total cholesterol and LDL-cholesterol levels in monkeys (58).

Erythrocyte Metabolism and Function

In the erythrocyte, PLP is a coenzyme for transaminases. Both PLP and PL bind to hemoglobin. PL binds to the α -chain of hemoglobin and increases O₂ binding affinity, while PLP binds tightly to the β -chain and lowers O₂ binding affinity, a situation that may be important in sickle-cell anemia (59). A severe chronic deficiency of vitamin B₆ can lead to hypochromic, microcytic anemia. In addition, some patients with sideroblastic anemia and other anemias do respond favorably to PN therapy (60, 61).

Nervous System

Several in-depth reviews on the functions of vitamin B₆ in the nervous system are available (62, 64). PLP is a coenzyme for enzymatic reactions that lead to the synthesis of several neurotransmitters, including serotonin (from tryptophan), taurine, dopamine, norepinephrine, histamine, and d-aminobutyric acid. Neurologic abnormalities in human infants (65) and animals (62) deficient in vitamin B₆ have been seen. Infants fed a formula in which the vitamin B₆ was destroyed during processing showed abnormal EEG tracings and convulsions (65). Treatment with 100 mg of vitamin B₆ corrected the EEG abnormalities. Adults fed a diet low in vitamin B₆ and high in protein (for 3, 4 weeks) also had abnormal EEGs (66), while those fed similar diets for a shorter period of time (<21

days) had no abnormal EEGs.

Extensive studies in animals fed varying intakes of vitamin B₆ showed that the progeny of vitamin B₆-deficient dams had altered fatty acid levels in the cerebellum and cerebrum of the brain (64, 67). Other changes in nerve cells, including reduced g-aminobutyric acid levels (68) and altered amino acid levels, have been observed. These findings point to a need for adequate vitamin B₆ during nervous system development.

Immune Function

Vitamin B₆ intake has a significant impact on immune function (69). In both animal (70) and human studies (71, 72), a low intake of vitamin B₆ or decreased status is associated with impaired immune function. Decreased interleukin-2 production and lymphocyte proliferation are seen with vitamin B₆ depletion in humans (72). These effects on the immune system are probably mediated via altered 1-carbon metabolism, particularly the activity of serine hydroxymethyltransferase (73) and/or hormone modulation.

Hormone Modulation

Litwack et al. demonstrated that PLP binds to steroid receptors (74). PLP also binds to a second site on the steroid receptor and inhibits the binding of the steroid receptor to DNA (75). In further studies, the level of mRNA for liver cytosolic aspartate aminotransferase was sevenfold higher in vitamin B₆-deficient rats than in control rats. Furthermore, the DNA-binding activity of the glucocorticoid receptor was enhanced by vitamin B₆ deficiency (76). The increased amount of mRNA for cytosolic aspartate aminotransferase in vitamin B₆-deficient animals suggests that this steroid-responsive enzyme is regulated in part by the intracellular PLP concentration. Thus, in B₆-sufficient animals, steroid responsiveness is lower than that in B₆-deficient animals. Reactions between PLP and receptors for estrogen, androgen, progesterone, and glucocorticoid at physiologic concentrations of PLP suggest that the vitamin B₆ status of an individual may have significance in endocrine-mediated diseases.

VITAMIN B₆ STATUS

Determination of the vitamin B₆ status of an individual is of paramount importance in understanding the relationship between health and nutrient intake, factors that influence the requirement for vitamin B₆, and factors that affect the overall metabolism of vitamin B₆. Vitamin B₆ status can be assessed in three ways: direct methods, indirect methods, and dietary intake (77). [Table 24.4](#) lists several indices used to evaluate vitamin B₆ status and suggested values for adequate status. A recent review of vitamin B₆ status is available (78).

Index	Adequate Status*
Direct	
Plasma pyridoxal 5'-phosphate	>30 nmol/L
Plasma total vitamin B ₆	>40 nmol/L
Urinary 4-pyridoxic acid	>3.0 μmol/day
Urinary total vitamin B ₆	>0.5 μmol/day
Indirect	
Erythrocyte alanine transaminase index	<1.25
Erythrocyte aspartic transaminase index	<1.80
2-g L-Tryptophan load; urinary xanthurenic acid	<65 μmol/day
3-g L-Methionine load; urinary cystathionine	<350 μmol/day
Diet intake	
Vitamin B ₆ intake; weekly average	>1.25-1.5 mg/day
Vitamin B ₆ : protein ratio (mg/g)	≥0.016

From Leklem JE. *J Nutr* 1990;120:1503-7, with permission.
 *1 μmol B₆ = 160 mg.

Table 24.4 Indices Used to Assess Vitamin B₆ Status and Suggested Minimal Values for Adequate Status

Direct Methods

Direct methods measure one or more of the metabolites of the B₆ vitamers. Currently, the most frequently used direct measure is plasma PLP concentration. Support for its use comes from both animal models (79) and human studies (4). However, use of PLP as a status index is controversial (78). Proper evaluation of plasma PLP concentration requires an understanding of factors that influence this level. Table 24.5 lists several such factors and the qualitative change that has been observed (4). Ideally, one would prefer to measure PLP in tissues. Erythrocyte PLP level may be useful as an additional index (78, 80). Until methodologic problems are resolved and further data are available, the use of this measure as an index of vitamin B₆ status is open to question. Plasma total vitamin B₆ and plasma PL concentrations are additional direct measures that have utility. Since PL is the form that enters the cell, its measurement may be more relevant than that of PLP.

Factor	Effect on Plasma PLP
Diet	
↑ Vitamin B ₆	↑
↑ Protein	↓
↑ Glucose	↓, acute
↓ Bioavailability	↓
Physiologic	
↑ Exercise, aerobic	↑, acute
↑ Age	↓
Pregnancy	↓
↑ Alkaline phosphatase activity	↓
Smoking, chronic	↓

Table 24.5 Factors Influencing Plasma PLP Concentration

Urinary direct methods include measurement of the major metabolic product 4-PA and of total vitamin B₆ (the sum of the nonphosphorylated and phosphorylated forms). Under normal conditions, 40 to 60% percent of the daily vitamin B₆ intake is excreted as 4-PA (81). Similarly, urinary B₆ vitamers represent 8 to 10% of the daily intake (19). Urinary 4-PA excretion is considered a short-term indicator of status. Excretion reflects and is influenced by vitamin B₆ intake over a 1- to 4-day period. To use urinary total vitamin B₆ properly as an indicator of status requires several 24-h urine collections during 1 to 3 weeks. Our knowledge of the factors (dietary and physiologic) that affect urinary 4-PA and total vitamin B₆ is limited primarily to the effect of protein intake (82, 83). As protein intake increases, urinary 4-PA excretion decreases (4).

Indirect Methods

The indirect measures of vitamin B₆ status currently used are based on products of metabolic pathways or specific enzymes that require PLP. Thus, they indirectly reflect PLP levels in certain tissues. Therefore, they do not necessarily reflect the total vitamin B₆ content in tissues, nor do they always reflect circulating levels of PLP or B₆ vitamers. The most common indirect measures used are (a) urinary metabolites of the tryptophan pathway or the methionine pathway and (b) erythrocyte transaminase activity and stimulation (77). Other, less common tests are urinary oxalate excretion and EEG patterns.

Tryptophan and Methionine Load Tests

The tryptophan load test, one of the most widely used indices of vitamin B₆ status (84), is based on the fact that several steps in the major catabolic pathway of tryptophan are PLP dependent. A 2-g oral load of L-tryptophan is administered, and the urinary excretion of metabolites such as xanthurenic acid and kynurenic acid is determined. Brown has questioned the use of this test on the basis of an adverse effect on tryptophan metabolism by factors independent of vitamin B₆ intake (85).

The methionine load test has also been used as an indirect measure of vitamin B₆ status. Like the tryptophan load test, this test is considered primarily to reflect hepatic levels of vitamin B₆. The methionine pathway has four PLP-dependent steps. The step catalyzed by cystathionase, in which cystathionine is cleaved to form homoserine and cysteine, appears to be especially sensitive to vitamin B₆ deficiency. Indeed, this metabolite is excreted in elevated amounts following a 3-g methionine load (86). There may be a protein effect similar to that seen for tryptophan. With the recent interest in plasma homocysteine levels and coronary heart disease, there have been several

studies of the effect of vitamin B₆ on plasma homocysteine (87, 88). While vitamin B₆ deficiency increases plasma homocysteine following a methionine load (89), it appears that folic acid is relatively more important than vitamin B₆ in modifying plasma homocysteine levels (88).

Erythrocyte Transaminase (Aminotransferases)

Measurements of erythrocyte alanine aminotransferase (EALT, or EGPT) and aspartic acid aminotransferase (EAST, or EGOT) transaminase activity and/or stimulation are commonly used indirect indices of vitamin B₆ status. They are considered long-term measures of vitamin B₆ status because of the life span of erythrocytes (77). Activities of the respective transaminases are measured in vitro in the presence and absence of excess PLP (90). From this the percentage stimulation is calculated:

$$\% \text{ Stimulation} = [(A_s - A_u)/A_u] \times 100\%$$

where A_s is stimulated activity and A_u is unstimulated activity.

Based on studies in women, EALT activity (index and percentage stimulation) is more sensitive to vitamin B₆ intake (91). However, the relative activity of EALT is only 5% of that of EAST. The EALT enzyme is also more likely to lose activity when erythrocytes are frozen. Because no long-term studies (>6 weeks) have measured transaminase activities after different levels of vitamin B₆ were fed, the utility of transaminase activity measures as an index of a specific vitamin B₆ intake is unknown. Also, the temporal relationship between enzyme activity measurement and intake of vitamin B₆ is little understood. A further consideration in using transaminase data as a status indicator is the existence of three phenotypes of EALT (92).

Dietary Intake of Vitamin B₆ and Protein

A proper assessment of vitamin B₆ status and interpretation of blood or urinary measures requires determination of both vitamin B₆ and protein intakes. Because carbohydrates may also play a role in B₆ utilization, intake of carbohydrate should also be documented (77). Vitamin B₆ status in a healthy population is best assessed by using a direct measure, an indirect measure, and appropriate dietary information. While these measures may be useful in certain clinical conditions, numerous factors that can influence metabolism of vitamin B₆ may preclude proper assessment (93).

VITAMIN B₆ DEFICIENCY

Any vitamin deficiency can be assessed by both outward clinical signs and biochemical/functional tests. Clinical signs usually occur in the later stages of deficiency. [Table 24.6](#) lists the signs commonly seen with rather severe and chronic vitamin B₆

deficiency (4). Those seen in infants were first observed because of an error in food processing of formula that was subsequently fed to infants (65). In the earlier stages of vitamin B₆ deficiency, direct measures of vitamin B₆ status would be expected to become lower and indirect measures to become abnormal. EAST and EALT activity (and % stimulation) do change in vitamin B₆ deficiency (91) but only with chronic deficiency.

Signs Occurring Primarily in Infants	Signs Occurring Primarily in Adults
Abnormal electroencephalogram pattern	Stomatitis
Convulsions	Cheilosis
	Glossitis
	Irritability
	Depression and confusion

Table 24.6 Clinical Signs of Vitamin B₆ Deficiency

REQUIREMENTS

Since vitamin B₆ is involved in so many areas of metabolism and physiologic functions, establishing proper and adequate requirements is imperative. Numerous factors can influence a vitamin B₆ requirement (4), and for most of these we lack adequate information on their quantitative effect. The 1989 version (93) of the recommended dietary allowance (RDA) for vitamin B₆ for various age groups is summarized in [Table 24.7](#) (see also Appendix [Table II-A-2-a-2](#)). These RDAs are generally lower than prior RDAs for vitamin B₆ (i.e., 1974, 1980 versions), especially for adult men and women. The 1998 RDAs are even lower for children (0.5–0.8 mg/day), for adults (0.1–0.8 mg/day), and for pregnant and lactating women (0.1–0.3 mg/day) (see Appendix [Table II-A-2-c-1](#) and related [Table II-A-2-c-2](#), [Table II-A-2-c-3](#) and [Table II-A-2-c-4](#).) (93a).

Age Group (in years) or Condition	Vitamin B ₆ (mg/day)		Vitamin B ₆ Protein* (mg/g)		
Infants: 0-0.5	0.3		0.023		
0.5-1.0	0.6		0.043		
Children:	1-3		0.063		
	4-9		0.046		
	7-10		0.050		
	Males	Females	Males	Females	
Adults:	11-14	1.7	1.4	0.038	0.030
	15-18	2.0	1.5	0.034	0.030
	19-24	2.0	1.6	0.034	0.035
	25-50	2.0	1.6	0.032	0.032
	51+	2.0	1.6	0.032	0.032
Pregnant			2.2		
Lactating	1st 6 months		2.1		
	2nd 6 months		2.1		

From Food and Nutrition Board, National Research Council. Recommended dietary allowances, 10th ed.

*This ratio was derived by dividing the RDA for vitamin B₆ by the RDA for protein for the respective age group. The RDAs for vitamin B₆ for adults were established by using twice the RDA for protein (1.0 g/day for males and 700 g/day for females) and a vitamin B₆ protein ratio of 0.016 mg/g. 1 mg B₆ = 1.91 μmol.

Table 24.7 Recommended Dietary Allowances (1989) for Vitamin B₆ and Associated Vitamin B₆ Protein Ratios^{1,2}

Of the factors affecting vitamin B₆ need, protein has been studied in greatest detail. Protein intake is inversely correlated with plasma PLP concentration and urinary 4-PA excretion, in both men (82) and women (83). Under conditions of low intakes of vitamin B₆, protein intake is directly correlated with excretion of tryptophan metabolites (83). Bioavailability of vitamin B₆ would be expected to affect its requirement. Vitamin B₆ status decreases in women fed a diet high in PNG (27% of intake), reflecting an increased vitamin B₆ requirement of about 15% (24). Exercise may also increase vitamin B₆ requirement (94). Since the vitamin B₆ content of human milk has been determined (4) and found to be influenced by intake (95), the vitamin B₆ needs of infants can be assessed. The current RDA for infants up to 0.5 years old is 0.3 mg (1.8 μmol), which would require an intake of 1.5 to 2 L of milk (assuming a vitamin B₆ content of 0.75 to 1.0 μmol/L). Based on a normal breast milk volume of 650 to 750 mL/day, an infant would receive only 30 to 50% of the current RDA. However, infants in the U.S. do not show signs of vitamin B₆ deficiency, which suggests that the current RDA for vitamin B₆ for infants is too high. Intake of 0.10 to 0.16 mg/day appears adequate (96).

The effect of sex and age (4) on vitamin B₆ requirements has received only minimal attention. In studies of vitamin B₆ metabolism in males and females, plasma PLP levels tend to be lower in females than in males. Several studies suggest that vitamin B₆ status decreases with age (4, 97), especially plasma PLP levels. However, the application of such findings to requirements is not known. The vitamin B₆ RDAs for adult males and females are based on metabolic studies, vitamin B₆ intake data, and protein intakes of populations (92). Metabolic studies in older adults (98), as well as those in younger adult women (83, 99), suggest that the current RDA is too low and that at least 2.0 mg/day (or 0.020 mg/g protein) may be more appropriate. The current RDAs are based primarily on the protein–vitamin B₆ interrelationship. For adults, a value of 0.016 mg of

vitamin B₆ per gram of protein has been set.

CLINICAL CONDITIONS

Several reviews have examined the relationship between vitamin B₆ nutrition and disease states (100, 101). In a number of disease states, an apparent alteration of vitamin B₆ metabolism is reflected in altered tryptophan metabolism or decreased plasma PLP concentration. For example, tryptophan metabolism has been found to be altered in asthma (103), diabetes (104), breast and bladder cancer (85), and rheumatoid arthritis (105); plasma PLP concentration is decreased in asthma (106), renal disease (107), alcoholism (108), coronary heart disease (109), breast cancer (110), Hodgkin's disease (111), sickle-cell anemia (53), diabetes (112), and smoking (113). Many of these studies determined only one measure of vitamin B₆ status; thus, the extent to which the true status is compromised is unknown.

Vitamin B₆ (as pyridoxine hydrochloride) has been used as a preventive agent or as a therapeutic agent for several diseases. Papers from conferences on this aspect of vitamin B₆ are available (102, 114). Disorders treated with PN include Down's syndrome, autism, hyperoxaluria, gestational diabetes, carpal tunnel syndrome, depression, and diabetic neuropathy (101). In nearly every case, there has been limited therapeutic benefit. However, the dose of PN and length of administration has varied from study to study, making evaluation of efficacy difficult.

DRUG-VITAMIN B₆ INTERACTION AND TOXICITY

The widespread use of clinical drugs in our society necessitates understanding the effect of drug use on vitamin B₆ metabolism. Table 24.8, taken in part from a review by Bhagavan (114), lists several drugs that affect vitamin B₆ metabolism. In many cases, the drugs either react with PLP, induce PLP-dependent enzymes, or interfere with vitamin B₆ metabolism (115, 116). In most cases, administration of PN corrects altered vitamin B₆ metabolism. The effect of excess vitamin B₆ (>10 mg/day) on drug efficacy remains to be determined but should be considered in cases in which the drug reacts directly with PLP.

Drug	Effect on Vitamin B ₆ Metabolism/Function
Isoniazid (hydrazines)	Reacts with PL and PLP
Cycloserine	Reacts with PLP, forms oxime
L-3,4-Dihydroxyphenylethylamine	Reacts with PLP, forms tetrahydroquinoline derivative
Penicillamine	Reacts with PLP, forms thiazolidine
Ethinylestradiol, mestranol	Increased enzyme levels and retention of PLP in tissue
Ethanol	Increased catabolism of PLP
Theophylline, caffeine	Inhibition of pyridoxal kinase

Table 24.8 Drug-Vitamin B₆ Interactions

The use of high doses of PN (500–1000 mg/day) to treat certain disorders, such as premenstrual syndrome and other neurologic diseases, has resulted in a small number of instances of neurotoxicity (117) and photosensitivity (4). These symptoms are rarely if ever seen with doses of 2 to 250 mg and usually are seen only with chronic use (118).

HISTORICAL INTRODUCTION

Independent research paths in microbiology and medicine led to the isolation and characterization of pantothenic acid (1, 2). Components of the vitamin B₂ complex, derived from liver, were separated and individually tested for their effects on specific animal disorders. One of the last purification steps was the separation of pantothenic acid from vitamin B₆; this was accomplished by adsorption chromatography in which pyridoxol and its derivatives (vitamin B₆) adsorbed to fuller's earth, while pantothenic acid remained in the filtrate. Whereas vitamin B₆ cured rats of the dermatitis produced by vitamin B₂ deficiency, dermatitis in chicks was cured only by the filtrate component, subsequently known as the "chick antidermatitis factor." This factor was identical, by biochemical and physiologic criteria, to the pantothenic acid that R. J. Williams had earlier demonstrated to be essential for the growth of yeast.

R. J. Williams and R. T. Major successfully synthesized pantothenic acid in 1940 (2). It was not until 1947, however, that F. Lipmann and colleagues (3) demonstrated that its biologically functional form was coenzyme A (CoA), an essential cofactor for biologic acetylation reactions, such as acetylation of sulfonamide in the liver and of choline in the brain. Pantothenate-containing CoA has since been shown to be essential to the respiratory tricarboxylic acid cycle, fatty acid synthesis and degradation, and many other metabolic and regulatory processes. The accepted biochemical structure of CoA was published in 1953 (4).

CHEMISTRY

Microorganisms synthesize pantothenic acid (1, 2, 5) by an amide linkage between pantoic acid and b-alanine (Fig. 25.1). Pantetheine, an essential growth factor for the yogurt-producing bacterium *Lactobacillus bulgaricus*, consists of a

b-mercaptoethylamine group added to pantothenate in humans. CoA (Fig. 25.1) is composed of 4 ϕ -phosphopantetheine linked by an anhydride bond to adenosine 5 ϕ -monophosphate, which is modified by a 3 ϕ -hydroxyl phosphate. The sulfhydryl group of pantetheine is the active site of esterification to acetate and acyl groups.

Figure 25.1. Coenzyme A and intermediates.

In addition to functioning within CoA, 4 ϕ -phosphopantetheine is also found covalently linked to certain proteins (6), especially those involved in fatty acid metabolism. Fatty acid synthetase and the acyl carrier protein of bacteria and mitochondria are linked to 4 ϕ -phosphopantetheine by a phosphodiester bond via serine. Phosphopantetheine is also linked to citrate lyase of anaerobic bacteria and to enzymes involved in the nonribosomal synthesis of the peptide antibiotics tyrocidin and gramicidin S.

CoA and pantothenate-modified proteins participate in acyl group transfer and condensation reactions (5). In acyl group transfer, nucleophilic addition to the carbonyl group that is thioesterified to CoA leads to new ester bond formation and displacement of CoA. As a leaving group, CoA facilitates the transfer of acetyl or acyl groups. In condensation reactions, the α -carbon of the acyl group is acidified by its proximity to the thioester with CoA, and it attaches to an electrophilic center, leading to carbon-carbon bond formation or cleavage. Both types of reactions occur during fatty acid synthesis (7). Malonate is transferred from CoA to the enzyme-linked phosphopantetheine and acetate is transferred to an enzyme sulfhydryl group. After these acyltransferase reactions, there is condensation between the pantetheine-linked malonate and the introduced acetate or the growing fatty acid chain. In the tricarboxylic acid cycle of respiratory metabolism, acetyl-CoA condenses with oxaloacetic acid to yield citric acid.

DIETARY CONSIDERATIONS: FOOD SOURCES

Pantothenic acid is widely distributed in cells and tissues, being essential to all forms of life. Rich dietary sources are liver, kidney, yeast, egg yolk, and broccoli, which contain more than 50 μg pantothenate/g dry weight (2). Especially high levels of pantothenate

are found in royal bee jelly (511 µg/g) and in ovaries of tuna and cod (2.32 mg/g). The pantothenate content of human milk increases fivefold within 4 days after parturition (2) from 2.2 to 11.2 µmol/L (48–245 µg/dL), a level similar to that in cow's milk. Pantothenic acid is relatively stable at neutral pH. However, cooking is reported to destroy 15 to 50% of the vitamin present in raw meat (2), and processing of vegetables causes pantothenate losses of 37 to 78% (8).

The average American diet has been estimated to provide 5.8 mg pantothenate/day. A study of adolescents (9) showed that despite a pantothenate intake of less than 4 mg/day by some subjects, blood concentrations of the vitamin were in the normal range (0.91–2.74 µmol/L). Excess pantothenate appeared to be eliminated by excretion, which was highly correlated with dietary intake.

Synthetic D-pantothenate, the active enantiomer, is available as a calcium or sodium salt. However, multivitamin preparations commonly contain its more stable alcohol derivative, panthenol, which is converted by humans to pantothenic acid (10).

METABOLISM

After ingestion in dietary sources, CoA is hydrolyzed in the intestinal lumen to pantothenic acid, which is absorbed into the bloodstream by sodium-dependent transport (11). Sodium cotransport is also the mechanism by which pantothenate is subsequently taken up from the plasma by most cells.

The first step in the synthesis of CoA is phosphorylation of pantothenic acid (Fig. 25.1), which is catalyzed by pantothenate kinase; this constitutes the primary regulatory site of CoA synthesis in bacteria and rat heart (12). Phosphorylation is followed by the ATP-dependent condensation of 4 ϕ -phosphopantothenic acid with cysteine, whose product, 4 ϕ -phosphopantetheine, is decarboxylated to yield 4 ϕ -phosphopantetheine (13). CoA is formed by sequential transfers of adenosine monophosphate and phosphate from ATP to 4 ϕ -phosphopantetheine. All the enzymes required for CoA synthesis are present in the cytoplasm. Nevertheless, mitochondria must also be a final site of synthesis, since 95% of CoA is found in mitochondria and CoA does not cross the mitochondrial membranes (12).

Multiple hydrolytic steps liberate pantothenic acid from CoA, with the unique, final reaction being the hydrolysis of pantetheine to cysteamine and pantothenate, which is excreted in urine (14).

FUNCTIONS

Cellular Metabolism

Pantothenate, usually in the form of CoA, performs multiple roles in cellular metabolism (5), being central to the energy-yielding oxidation of glycolytic products and other metabolites through the mitochondrial tricarboxylic acid cycle. In the first step of the cycle, acetyl-CoA condenses with oxaloacetate to yield citrate, and subsequently,

succinyl-CoA provides energy for GDP phosphorylation. The β -oxidation of fatty acids and the oxidative degradation of amino acids also depend on CoA, which makes the catabolic products available to the respiratory tricarboxylic acid cycle.

Pantothenic acid is required for synthesis of many essential molecules. Synthesis of fatty acids and membrane phospholipids, including regulatory sphingolipids, requires pantothenate, and synthesis of the amino acids leucine, arginine, and methionine includes a pantothenate-requiring step. CoA is required for synthesis of isoprenoid derivatives, such as cholesterol, steroid hormones, dolichol, vitamin A, vitamin D, and heme A. Succinyl-CoA is essential to the synthesis of d-amino-levulinic acid, which is the precursor of both the corrin ring in vitamin B₁₂ and the porphyrin rings in hemoglobin and the cytochromes. CoA contributes an essential acetyl group to the neurotransmitter acetylcholine and to serotonin in its conversion to melatonin, as well as to the sugars *N*-acetylglucosamine, *N*-acetylgalactosamine, and *N*-acetylneuraminic acid, components of glycoproteins and glycolipids.

Protein Modification

Acetylation of Proteins

Amino-Terminal Acetylation. Most soluble proteins are N-terminally modified with an acetate group that is donated by CoA (15). The terminal methionine is usually cleaved and the second amino acid, typically alanine or serine, becomes acetylated cotranslationally on its α -amino group. It was proposed earlier that acetylation protected cellular proteins from degradation, based on *in vitro* assays. More recent experiments showed that N-acetylated proteins were also subject to ubiquitin-dependent degradation, if the assay mixtures included EF-1a, the translation elongation factor (16). Nevertheless, the importance of N-terminal acetylation was demonstrated genetically in *Saccharomyces cerevisiae*, in which a defect in N-terminal acetyltransferase activity disrupted cell cycle progression and sexual development (17). There was no evidence of protein instability due to the lack of acetylation. N-terminal acetylation appears to alter the structure of certain proteins. For example, it increases the N-terminal α -helical content of calpactin I, a calcium-binding protein that requires acetylation to assemble with its regulatory subunit (18).

Mammalian peptide hormones become N-terminally acetylated as they are processed from polyprotein precursors (6). This type of posttranslational addition of acetate strongly affects hormone activity. Pro-opiomelanocortin is the precursor of both adrenocorticotropin (ACTH), a steroidogenic hormone, and β -lipotropin, a lipolytic hormone. ACTH is processed in turn to α -melanocyte-stimulating hormone (MSH), and β -lipotropin is processed to the opioid β -endorphin. The products α -MSH and β -endorphin both become acetylated, but they differ in the tissues in which they are acetylated. Both become N-terminally acetylated in the intermediate pituitary, but only MSH is acetylated in brain, and neither is acetylated in the anterior pituitary. Acetylation has different effects on the activities of these two hormones, stimulating the activity of α -MSH but inactivating β -endorphin, which becomes unable to bind to opioid receptors. A single *N*-acetyltransferase activity has been identified in the intermediate, but not the anterior, lobe of rat and bovine pituitary. This activity may modify both hormones,

providing a mechanism for differentially activating two products of a single precursor.

Internal Acetylation. Two major classes of proteins undergo reversible acetylation on the ϵ -amino group of internal lysine residues: histones and α -tubulin. In addition, protamines and the high-mobility-group proteins HMG1 and HMG2, which bind DNA, are subject to acetylation. The nucleosome is composed of the core histones, a tetramer of histones H3 and H4 and two dimers of histones H2A and H2B, around which is wrapped 146 bp of DNA. All these core histones of the octamer become acetylated within their amino-terminal regions; the internucleosomal histone H1 has no internal acetylation sites. Histones H3 and H4 each have four possible acetylation sites. In mammalian histone H3, lys-14 is the preferred acetylation site, followed by lys-23 and lys-18 (19). H4 becomes monoacetylated at lys-16, with further modification at lys-12, followed by lys-8 and lys-5. In histone H2B, lys-12 and lys-15 are acetylated before lys-5 and lys-20. There is only one acetylation site in histone H2A.

Histone acetylation, which neutralizes the charge of lysine residues, appears to weaken interactions between nucleosomes that depend on histone N-terminal tails. The presence of highly acetylated H3 and H4 affects nucleosomal structure. Acetylated chromatin has a more open, unfolded conformation, as indicated by its increased sensitivity to nucleases and its increased salt solubility (20). Gel electrophoresis shows that acetylation leads to decompaction of the chromatin fiber (21). Hyperacetylation of H3 and H4 decreases the negative supercoiling within nucleosomes, as indicated by reduction in the linking number change per nucleosome (22).

Histones that are highly acetylated tend to be associated with newly synthesized DNA or with DNA that is transcriptionally active, but different sites on the histones may become acetylated during these two processes. Furthermore, there is only transient acetylation of newly synthesized histones as they assemble with replicating chromatin, whereas the histones of transcriptionally active chromatin are continually and dynamically acetylated.

The acetylated chromatin fraction from chick embryo erythrocytes was immunoselected and found to be strongly enriched in actively transcribed α -D-globin gene sequences (23). There is not a strict correspondence, however, between acetylated chromatin and transcribed DNA. The presence of acetylated histones extended from the transcribed region into the interspersed, nontranscribed DNA of the β -globin locus (24). Furthermore, acetylated histones were contemporaneously associated with two globin genes that are expressed at different times during development (23). Similarly, association of acetylated chromatin with the platelet-derived growth factor B gene occurred prior to its induction by phorbol esters (25). These findings suggest that histone acetylation may be a precondition for transcription but does not specify which genes are expressed. Binding of transactivating factors is necessary for specific gene transcription, and in vitro experiments suggest that histone acetylation is required for proteins to bind to chromatin, for example, binding of TFIID to the 5S RNA gene (26). A transcriptional regulator of yeast, GCN5p, was shown to be a histone acetyltransferase. Its association with other transcriptional factors may account for targeting of the acetyltransferase to specific chromatin sites (27).

Mutation of acetylable lysines in either histone H3 or H4 of yeast produced contrasting effects on gene transcription. A neutral replacement of lys-16 in H4 led to derepression of the silent mating locus, suggesting that this locus may be activated by H4 acetylation at lys-16 (28). In contrast, transcription of the *GAL1* and *PHO5* genes was inhibited by similar mutations in H4 (29). However, when acetylable lysines in H3 were mutated, *GAL1* was strongly activated. These different effects on *GAL1* transcription are mirrored in the effects of mutated H3 and H4 N termini on chromatin structure of the *GAL1* promoter, since mutation of H4, but not of H3, made chromatin in the promoter region assume a more closed conformation (30).

During DNA replication, newly synthesized histones become transiently acetylated on their N-terminal tails. Deposition of histones onto DNA is a two-step process: H3/H4 tetramers are deposited first, followed by H2A/H2B dimers. H4 is diacetylated before it is deposited onto DNA and before it assembles with the other newly synthesized core histones (31). In the absence of DNA synthesis, newly synthesized H3 and H4 remain cytosolic, whereas H2A and H2B exchange preferentially into acetylated chromatin regions. Histone acetylation during deposition inhibits binding of the linker histone H1 to newly assembled chromatin, thereby reducing higher-order nucleosome interactions (32).

Microtubules are essential components of the cellular cytoskeleton, affecting cell shape and motility, and are central to chromosome segregation in nuclei. They are also the major structure within flagella and cilia. Microtubules are assembled from α - and β -tubulin dimers that polymerize and depolymerize dynamically. A subset of the α -tubulin within microtubules becomes acetylated on lys-40 (33). α -Tubulin acetylation occurs in the assembled microtubule, which is a better substrate than the tubulin dimer for acetylation (6). Deacetylation appears to be coupled to depolymerization of microtubules. Several observations suggest that acetylation may stabilize microtubules: (a) the acetylated microtubules are more stable to depolymerizing agents such as colchicine and (b) drugs that stabilize microtubules, like taxol, induce α -tubulin acetylation (6). Tubulin turnover in neurons was found to be much slower in the neurite shafts, where acetylated α -tubulin was concentrated, than in the cell body and growth cones (34).

Acetylated microtubules, detected by an antibody against the modified tubulin, are not distributed randomly in cells (6). They tend to be excluded from growing, motile regions of cells. In dorsal root ganglion neurons, acetylated α -tubulin is absent from growth cones at neurite tips, and it is excluded from the leading-edge microtubules of migrating 3T3 cells. In chick muscle fibers, acetylated microtubules underlie motor endplates, where they contribute to vesicle and organelle transport, but they are absent from the growing regions of cells (35). Individual axonal microtubules actually have separate regions of acetylated and unacetylated α -tubulin along their length, with the older regions corresponding to the acetylated domains (36). There is also nonrandom distribution of acetylated microtubules during mitosis and meiosis. In unfertilized mouse oocytes, for example, acetylated α -tubulin was mainly at the poles during meiotic metaphase; the spindle became acetylated at anaphase; and by telophase only the midbody microtubules were acetylated (37). The nonrandom distribution of acetylated

microtubules is also associated with cell differentiation. In developing mouse embryos, acetylated microtubules that were associated with the cell cortex before differentiation relocated to the basal part of the cell cortex as cellular asymmetry developed. After asymmetric cell division, acetylated microtubules concentrated in the inside, rather than the outside, cells (38).

Acylation of Proteins

A wide variety of cellular proteins are covalently modified with long-chain fatty acids donated by CoA. This type of modification affects the location and activity of many central proteins, including those involved in signal transduction. The two fatty acids commonly added to proteins are myristic acid, a rare 14-carbon saturated fatty acid, and the more abundant 16-carbon palmitic acid (Table 25.1). These two fatty acids are attached to proteins by distinct mechanisms, and they affect proteins differently. The myristoylation reaction that has been best characterized is irreversible and occurs cotranslationally through amide linkage to the α -amino group of an N-terminal glycine. In contrast, palmitate is added posttranslationally, forming a reversible ester bond with a cysteine or serine residue. The hydrophobicity of palmitate results in strong membrane association of the acylated protein, whereas the less hydrophobic myristoylation leads either to weak membrane association or to protein interactions.

Myristate	Palmitate	Nonyl
G _i /G _o protein α subunits	G protein α subunits	Raf, Raf
transducin	p38 ^γ , p38 ^β	Raf proteins
ADP proteins	actin	G protein γ subunits
Src, Src	Raf, Raf	nucleo-lamina II and III
protein kinase A	MAPK1	phosphorylase kinase
cytochrom	CD-molecule Eukaryotes	phosphor kinase
NADK2	Adenylyl	
myosin	lipoprotein (L, P, J)	
192D cytochrome c, oxidase	e.g. E. coli myoglobin	
actin	Myoglobin-binding protein	
gap, VEG, VEG	myosin/myosin	
light heavy chain	myosin	
cytochrome bc ₁ L	myosin actin/myosin	
TGF α	myosin actin/myosin	
cytochrome c oxidase, bc ₁ L	myosin actin/myosin	
Gard II	CDK, CDK, CDK, P-selectin	
	HLA-B heavy chain	
	Sera I	
	myosin, spectrin, myosin	
	myosin	
	actin

	HLA-B heavy chain	

Table 25.1 Proteins (in text) That are Modified with Fatty Acids or Isoprenyl Groups

Myristoylation. There are strict sequence requirements for N-terminal myristoylation of a protein (39). An N-terminal glycine, originally in the second position, is absolutely required, and a small, neutral subterminal residue and a sixth-position serine are preferable. Myristoyl-CoA is strongly preferred by the myristoyl-transferase over other acyl-CoA donors (39). Disruption of the gene for N-myristoyl transferase in yeast was recessively lethal, demonstrating that myristoylation is essential for cell viability (40). Myristoylated proteins are located in the cytoplasm, as well as associated with various membranes, including the plasma membrane, the endoplasmic reticulum, and the nuclear membrane. Myristoylation, which is irreversible, commonly combines with other

protein modifications to regulate a protein's localization or activity. These other modifications may include palmitoylation, isoprenylation, phosphorylation, and GTP or calcium binding.

Small GTP-binding proteins comprise an extensive group of cellular proteins that become modified by myristate and palmitate, as well as by isoprenyl groups. Among these proteins, the heterotrimeric G proteins, composed of α , β , and γ subunits, mediate transmembrane signaling from membrane receptors to effector proteins, in response to hormone, neurotransmitter, and other agonists. The α subunits of the G_i and G_o subfamilies are N-terminally myristoylated, a modification reported to affect interaction of α with the $\beta\gamma$ subunits and to be required for signal transduction by α_{i2} (41). Prior myristoylation increases the protein's membrane affinity, which is required for the addition of palmitate to α subunits (42). By separate mutations, it was determined that each of the lipid modifications contributes to the association of α_o with membranes. Furthermore, myristoylation appears to independently increase the affinity of α_i for adenylyl cyclase, the effector protein (43). The α subunit of transducin, the rhodopsin-stimulated G protein of photoreceptors, is heterogeneously modified at its N terminus with myristate, laurate, and unsaturated 14-carbon fatty acids. The nature of the attached fatty acid affects the strength of the interaction of transducin α with $\beta\gamma$ and may influence the speed of visual excitation (44).

ADP-ribosylation factors (ARFs) are small monomeric GTP-binding proteins involved in vesicular transport that are N-terminally myristoylated. ARFs cycle between soluble and membrane-associated forms, regulated by GTP hydrolysis and guanine nucleotide exchange. The mammalian ARF protein is the principal coat component of non-clathrin-coated vesicles, and its binding to Golgi membranes marks the site of vesicle budding. A comparison of myristoylated and nonmyristoylated ARF5 indicated that acylation is essential for ARF5 to bind to Golgi membranes in a GTP- and temperature-dependent manner and to function in transport (45). Myristoylation appeared to stabilize the N terminus of ARF1 in an amphipathic α helix, conducive to membrane binding, and it also stabilized the interaction of ARF1 with GTP, thereby integrating membrane and GTP binding with protein activation (46).

Another large family of proteins that are N-terminally myristoylated are the Src and Src-related tyrosine kinases. The Src protein from Rous sarcoma virus is responsible for cell transformation by the oncogenic virus, and the protein requires N-terminal myristoylation to associate with the plasma membrane and to transform cells. Addition of a less hydrophobic analogue of myristic acid prevented v-Src association with membranes (47). The cellular Src protein requires myristoylation for its activity in mitosis, presumably because c-Src is activated by a membrane-bound phosphatase (48).

The catalytic subunit of cAMP-dependent protein kinase is also myristoylated at its N terminus. Membrane association of the catalytic subunit is independent of myristoylation, instead being dependent on the regulatory subunit until dissociation by cAMP. However, myristoylation appears to increase the thermal structural stability of the kinase, possibly by stabilizing an intramolecular interaction between the N-terminal domain and an internal hydrophobic surface (49). The B subunit of calcineurin, the

calmodulin-dependent phosphatase targeted by cyclosporine, is also N-terminally myristoylated. This modification at least partially contributes to the protein's membrane association (50).

The myristoylated alanine-rich C kinase substrate protein (MARCKS) cross-links actin filaments and likely is involved in cytoskeletal rearrangements during neuronal transmitter release, leukocyte activation, and growth factor-induced mitosis. The binding of MARCKS to the plasma membrane is regulated by a phosphoryl-myristoyl switch. N-terminal myristoylation provides one of the two initial membrane binding sites, but upon cell activation, phosphorylation occurs within the second, basic binding site, leading to dissociation of MARCKS from the membrane (51). Recoverin is an N-myristoylated protein of retinal cells that regulates the light excitation of rhodopsin by responding to changing levels of calcium. In a calcium-myristoyl switch, the binding of calcium to recoverin exposes the N-myristoyl group, which can then bind to membranes (52). Recoverin is heterogeneously acylated, like the retinal transducin α subunit. The more hydrophobic the N-terminal acyl group, with myristate being the most hydrophobic, the more recoverin inhibits the light-dependent phosphorylation of rhodopsin at high calcium concentrations (53).

Enzymes that are N-terminally modified with myristate include NADH-cytochrome b_5 reductase, which is located at the outer membrane of microsomes and mitochondria (54). The endothelial nitric oxide synthase (eNOS), which functions in smooth muscle relaxation, requires myristoylation to localize to membranes and become modified with palmitate (55).

N-Terminal myristoylation of viral structural proteins, such as the gag polyprotein precursor, VP2, and VP4, is required for formation of mature mammalian retroviruses, papovaviruses, and picornaviruses, respectively (6). Fos and Jun are transcriptional activators that dimerize to form the AP-1 complex that activates genes containing the phorbol response element (TRE). An interesting functional conversion of Fos has resulted from substituting its N-terminus with the gag N-terminus to produce the oncogenic viral FBR v-fos. FBR v-fos has lost the ability to activate genes from the TRE promoter, but it has gained the ability to activate unique genes in chondrosarcomas (56). This oncogenic change in function is due to the N-terminal myristoylation inherited from gag, since mutation at the myristoylation site converted FBR v-fos activation specificity to the original c-fos specificity.

A small number of proteins are internally myristoylated on the ϵ -amino group of lysine residues. This modification has been characterized especially for proteins of the immune system. The heavy chain of μ immunoglobulins becomes myristoylated during transport to the surface of developing B cells (57). Precursors of the cytokines interleukin (IL)-1a and -1b and the precursor of tumor necrosis factor (TNF)-a are all myristoylated on lysine residues. The mature processed forms of IL-1a and -1b are secreted, but a portion of the IL-1a myristoylated precursor remains as a plasma membrane-associated protein (58). Similarly, a portion of the acylated precursor of TNF-a remains unprocessed and membrane associated and is active in mediating inflammation, like the mature TNF-a (59).

Cytochrome *c* oxidase is the terminal electron carrier of the respiratory chain in the inner mitochondrial membrane. Its subunit 1, the core catalytic subunit, is modified by myristic acid on an internal lysine (60). There likely is an N-myristoylating activity in mitochondria, since the cytochrome oxidase subunit 1 is encoded by mitochondrial genes and synthesized within mitochondria.

Palmitoylation. In contrast to the *N*-myristoyl transferase, enzymes that transfer palmitate to proteins show little substrate specificity, either for the fatty acyl-CoA donor or for the peptide sequence at the site of acylation. The reversibility of palmitate addition, unlike that of myristate, allows palmitoylation to have a regulatory function.

All heterotrimeric G protein α subunits, except α_t , are thioesterified to palmitate near their N termini, frequently at the subterminal cysteine. The G_{sa} subunit, which transmits hormonal stimulation to adenylyl cyclase, requires palmitate modification to bind to the plasma membrane and to stimulate cAMP synthesis (61). Palmitoylation provides a mechanism for regulating α_s activity; following hormonal activation and GTP binding, α_s is rapidly depalmitoylated and dissociates from the membrane. Palmitoylation of α_i and α_o subunits, which are also myristoylated, is required for their strong association with membranes and contributes to their binding to $\beta\gamma$ subunits (42). Dual acylation of these G protein α subunits appears to target them to plasma membrane caveolae, via association with glycosylphosphatidylinositol (GPI)-anchored membrane proteins (42).

Although Src itself is not palmitoylated, several Src-related tyrosine kinases are acylated with palmitate near their N termini, as well as being myristoylated. This dual acylation is necessary for the kinases' association with GPI-anchored proteins in the outer plasma membrane. When palmitoylated cys-3 and cys-6 in p59^{lyn} and cys-3 and cys-5 in p56^{lck} were mutated to serines, the kinases no longer associated with decay-accelerating factor (DAF), a GPI-anchored protein (62). The reverse mutations in p60^{src}, from serines to cysteines, caused the Src protein to associate uncharacteristically with DAF.

Nitric oxide synthases (NOS) produce the signaling molecule nitric oxide. The endothelial form of NOS (ecNOS), which has a role in smooth muscle relaxation, is dually acylated with palmitate and N-terminal myristate (55). Addition of the agonist bradykinin leads to depalmitoylation of ecNOS and its simultaneous dissociation from membranes, which is followed by ecNOS phosphorylation. Palmitoylation likely regulates this change in localization of ecNOS.

Most viral and cellular Ras proteins, monomeric GTP-binding proteins, are esterified to palmitate. Palmitoylation near the carboxyl terminus is required for oncogenic viral Ras proteins to bind to the plasma membrane and transform cells; palmitoylation strengthens the weak membrane affinity conferred on Ras by C-terminal modification with an isoprenyl group (63). The mammalian Ras protein is an essential component of the mitogen-activated protein (MAP) kinase signaling cascade. The function of Ras is to direct the protein kinase Raf to the plasma membrane, and palmitoylation or a polybasic domain is required for this localization and the activation of MAP kinase (64). Palmitoylation of the Ras2 protein of yeast is also required for its efficient membrane

localization but not for its interaction with adenylyl cyclase (65).

Palmitate modification also occurs on proteins associated with intracellular membranes. Palmitoyl-CoA is required in vitro to reconstitute vesicular transport through the Golgi stacks (66). Addition of acyl-CoA was necessary both for budding of vesicles from donor Golgi and for fusion of vesicles with acceptor Golgi cisternae. Furthermore, vesicle budding was inhibited by addition of a nonhydrolyzable analogue of palmitoyl-CoA or an acyl-CoA synthetase inhibitor. The cation-dependent mannose 6-phosphate receptor (CD-MPR) transports acid hydrolases from the trans-Golgi network to a prelysosomal compartment. Palmitoylation of cys-34 in the cytoplasmic tail prevents receptor movement from the prelysosomal endosomes to the lysosomes (67). Mutation of cys-34 caused the receptor to accumulate in dense lysosomes and impaired its ability to sort cathepsin D to lysosomes.

Many plasma membrane-anchored receptors are acylated with palmitate. One prominent group of palmitoylated receptors are those that are coupled to heterotrimeric G proteins. These receptors have a similar domain structure consisting of an extracellular N terminus, seven transmembrane α -helices, and an intracellular C terminus, leading to three intracellular and three extracellular loops. The C-terminal tail has a conserved cysteine whose palmitoylation has been characterized in many of these receptors, including rhodopsin, the dopamine (D_1 and D_2) receptors, b_2 -adrenergic receptor, α_{2A} -adrenergic receptor, thyrotropin-releasing hormone receptor, and the choriogonadotropin receptor. Acylation appears to lead to formation of a fourth intracellular loop. Palmitoylated cys-322 and cys-323 of the retinal photoreceptor rhodopsin were shown by fluorescence quenching to be integrated into the cell membrane (68). The regulatory functions of palmitate addition vary for these receptors. For both the dopamine D_1 receptor (69) and the b_2 -adrenergic receptor (70), palmitate is attached to the receptor shortly after its exposure to agonist, and acylation contributes to agonist-dependent desensitization of the receptor. It is also important for coupling of the b_2 -adrenergic receptor with G_s . Palmitoylation contributes to downregulation of the number of α_{2A} -adrenergic receptors (71), but it slows internalization of thyrotropin-releasing hormone and choriogonadotropin receptors after prolonged exposure to agonist (72).

Other transmembrane receptors that are palmitoylated are the iron-transferrin receptor, the insulin receptor, and the nicotinic acetylcholine receptor (6). Palmitate addition to the asialoglycoprotein receptor was found to activate the receptor for ligand binding; it is suggested that receptor deacylation leads to ligand dissociation (73). A membrane glycoprotein of rat adipocytes becomes palmitoylated on an extracellular domain in response to insulin and energy depletion (74). Two cysteines become acylated at the cytoplasmic-membrane junction of CD4, the surface glycoprotein of T lymphocytes and macrophages that is involved in antigen recognition and serves as receptor for the human immunodeficiency virus (75). Palmitoylation of a CD44-related lymphoma glycoprotein was shown to be required for its binding to ankyrin, which connects the cell membrane to the cytoskeleton (76). The heavy chain of the human histocompatibility antigen HLA-B is thioesterified to palmitate (6), and platelet P-selectin is palmitoylated

on a cysteine in its cytoplasmic tail (77).

Palmitate is attached to several membrane proteins that are linked to the cytoskeleton. In erythrocytes, the anion transport protein Band 3 is palmitoylated (78) and is linked to Band 4.2, a major myristoylated membrane protein (79). Band 4.2, in turn, is linked to ankyrin, which is palmitoylated. The palmitate-modified population of the spectrin b subunit is more tightly membrane-associated than the unmodified spectrin (80). Vinculin, fibronectin, a subpopulation of actin (6), and gap junction proteins of heart and eye lens (81) also become palmitoylated.

Several neuronal proteins are modified with palmitate. The proteolipid subunit of brain myelin, which is acylated on a threonine residue, was the first palmitoylated protein to be identified (6). Acylation of multiple cysteines in the cysteine string proteins (csp) appears to be a mechanism for attaching csp to vesicles, where they interact with presynaptic calcium channels (82). Acetylcholinesterase, which degrades the neurotransmitter acetylcholine, is anchored in the cell membrane by palmitoylation (83). Glutamic acid decarboxylase (GAD₆₅), which is located in synaptic vesicles of g-aminobutyric acid (GABA)-secreting neurons and in microvesicles of pancreatic b cells, may also be anchored in the membrane by palmitoylation (84).

Protein palmitoylation appears to play an important role during neuronal development. In elongating axons, GAP-43 is a major component of growth cone membranes, and SNAP-25 is a synaptic protein involved in later stages of axon growth. The reversible palmitoylation of both these proteins is proposed to influence growth cone motility and process outgrowth in developing brains (85). Palmitoylation of GAP-43, at two cysteines near its N terminus, keeps GAP-43 membrane bound and inhibits its stimulation of G_o. Nitric oxide has been found to inhibit acylation of neuronal proteins, including GAP-43 and SNAP-25 (85). This inhibition is likely the mechanism by which nitric oxide causes growth cone collapse in cultured neurites and in vivo.

Isoprenylation of Proteins

Like synthesis of other isoprenoid compounds, farnesyl and geranylgeranyl synthesis requires CoA. One of these two isoprenoids is added to the mature carboxyl-terminal cysteine of specific proteins (Table 25.1). All Ras proteins have an isoprenyl and a methyl group added to the mature C terminus and have a second modification nearby, either palmitoylation of a cysteine or a polybasic region (63). Both modifications are required for viral Ras proteins to transform cells. The Ras proteins themselves are modified with a 15-carbon farnesyl group, and inhibitors of farnesyl-transferase are effective antitumor agents in Ras-transformed cells. Farnesylation of yeast Ras2p appears to be important for adenyl cyclase activation (86). A critical function of the mammalian Ras protein in the MAP kinase signaling cascade is to direct the protein kinase Raf to the plasma membrane. When Raf itself was engineered to have a farnesylation site, Ras proved to be unnecessary for signal transduction (87). Normal Ras function requires the farnesyl moiety specifically. Substitution of the more hydrophobic geranylgeranyl, while not interfering with transformation by viral Ras,

caused cellular Ras proteins to become strong inhibitors of cell growth (88).

In contrast to Ras, Ras-related proteins are isoprenylated with the 20-carbon geranylgeranyl group, frequently on two neighboring cysteines (89). The multiple Ras-related mammalian Rab proteins help to regulate specific stages of vesicular transport to the cell surface (89). Through binding to vesicles, Rab proteins appear to target them to specific acceptor membranes. The cycling of Rab proteins between membranes and cytosol is related to membrane budding and fusion. Association of Rab proteins with organellar membranes requires their modification with geranylgeranyl. This isoprenylation is also needed for Rab to interact with its GDP dissociation inhibitor (GDI), which releases Rab from membranes (90). The Rab escort protein (REP), a protein with sequence homology to GDI, assists in the geranylgeranylation of Rab, and a defect in REP has been implicated in retinal degradation or choroideremia (91).

The β subunit of heterotrimeric G proteins is also modified by geranylgeranyl, except for the β subunit of retinal transducin, which is farnesylated. Isoprenylation of β is not required for its dimerization with the α subunit, but it is required for membrane targeting of the $\alpha\beta$ dimer and for productive interactions of the dimer with γ subunits, receptors, and effector proteins (92).

Other cellular proteins that are isoprenylated include the nuclear lamins A and B (93). Both the α and β subunits of phosphorylase kinase, the activator of glycogen phosphorylase, are modified with farnesyl (94). The retinal rhodopsin kinase is also farnesylated, a modification necessary for its membrane association in response to photon stimulation (95).

DEFICIENCY

Pantothenic acid deficiency in humans is rare. Naturally occurring deficiency has been detected only under conditions of severe malnutrition. In World War II, prisoners of war in the Philippines, Japan, and Burma experienced numbness in their toes and painful burning sensations in their feet. These symptoms of nutritional melalgia were relieved specifically by pantothenic acid (96). Pantothenate deficiency has been experimentally induced in humans by administering analogues of pantothenic acid, in combination with a pantothenate-deficient diet. The antagonist *w*-methylpantothenate produced headache, fatigue, insomnia, intestinal disturbances, and paresthesia of hands and feet. There was also a decrease in the eosinopenic response to ACTH, loss of antibody production, and increased sensitivity to insulin (97). Effects of a pantothenate-restricted diet have been studied in many animals (2). Rats developed hypertrophy of the adrenal cortex, followed by hemorrhage and necrosis; monkeys showed depressed heme synthesis and became anemic. Chickens developed dermatitis and poor feathering, and they also displayed axon and myelin degeneration within the spinal cord.

Administration of pantothenate antagonists to humans has also occurred unintentionally, with deleterious side effects. Hopantenate is an analogue of pantothenic acid, in which GABA replaces β -alanine. Hopantenate was used in Japan, as an agonist of GABA, to cerebrally stimulate retarded individuals and to alleviate tardive dyskinesia symptoms induced by tranquilizers. Treatment with hopantenate produced severe side effects in

patients, including lactic acidosis, hypoglycemia, and hyperammonemia, ultimately leading to acute encephalopathy (98). These effects were replicated in dogs given hopantenate and were shown to be due to induction of pantothenic acid deficiency. Dogs given an equivalent amount of pantothenic acid along with the calcium hopantenate did not develop the disorders (99).

Pantothenic acid has beneficial effects in cases not clearly related to pantothenate deficiency. Addition of pantothenate increased skeletal muscle energy metabolism in the murine model of Duchenne muscular dystrophy (100). It also protected rats against peroxidation and liver damage produced by carbon tetrachloride (101). Furthermore, in vitro, pantothenate dampened neutrophil (PMN) response to stimulatory peptides and cytokines (102). Apparently because of its antiinflammatory properties, pantothenic acid improved surgical wound healing.

EVALUATION OF NUTRIENT STATUS

Hydrolytic enzymes are required to release the pantothenate component of CoA for assays of pantothenic acid in biologic material other than urine. Microbiologic assays with yeast and lactobacilli have been used to determine the pantothenic acid content of blood, urine, and tissues (10). The exchange of radioactive b-alanine into pantothenic acid, which is catalyzed by pantothease, is one technique for measuring pantothenate concentration in food sources (103), and a radioimmunoassay has also been used for quantitation (104).

RECOMMENDED INTAKES FOR HUMANS

Formal recommended dietary allowances (RDAs) have not been established for pantothenic acid, but the estimated safe and adequate dietary intakes of pantothenate are 18 to 32 μmol (4–7 mg) for adults (Appendix Table II-A-2-a-3). Among younger age groups, 9 μmol (2 mg) were recommended daily for infants, and 18 to 23 μmol (4–5 mg) for children 7 to 10 years of age (105) in the 1989 RDA (Appendix Table II-A-2-a-2). The 1998 levels are presented as Adequate Intakes rather than RDAs. They are in the range of 1.7 to 3 mg/day for infants and children, 5 mg/day for adults, and 6 and 7 mg/day, respectively, for pregnant and lactating women (Appendix Table II-A-2-c-1) (106).

HISTORY

Early reports of disease now recognizable as probable folate deficiency include those of Channing (1), Barclay (2), and Osler (3). In 1937, Wills and her associates described a macrocytic anemia in Hindu women in Bombay, usually associated with pregnancy (4), that responded to therapy with a commercial preparation of autolyzed yeast called Marmite; these workers produced a similar macrocytic anemia in monkeys, which responded to a “Wills factor” present in crude, but not in purified, liver extracts.

The more-purified liver extract was found to be a fairly pure solution of vitamin B₁₂, whereas Wills factor from the crude liver extract was found to be folic acid. This was clarified by advances in knowledge of folic acid (e.g., purification of pteroylglutamic acid in 1943 [5], its crystallization in the same year [6], and its synthesis and structural identification in 1946 [7]).

Folic acid has proved to be the same as the Wills factor; the “vitamin M” contained in

dried brewers' yeast that corrected the deficiency anemia, leukopenia, diarrhea, and gingivitis of monkeys (8); the "vitamin Bc" contained in yeast that corrected the deficiency syndrome in chicks, characterized by anemia and growth failure; and the Norite eluate factor of liver, essential to the growth of *Lactobacillus casei* (9) (and therefore also called "*L. casei* factor") (10, 11). Sulfanilamide was shown to act by competitive inhibition of a bacterial metabolite, *para*-aminobenzoic acid. This metabolite was later found to be an essential component of *L. casei* factor (11, 12), that is, of folic acid.

The term *folic acid* was coined in 1941 by Mitchell et al. because they found this material in a leafy vegetable (spinach) (13). At that time, it was not recognized that vitamin B₁₂, not folic acid, was the active ingredient in the oral liver therapy that Minot and Murphy reported in 1926 as successful in treating pernicious anemia (for which work they received the Nobel Prize in Medicine in 1934) (14). Considerable progress has since been made in our understanding of the metabolic role of folic acid in health and disease and of the use of folate antimetabolites in the treatment of some infectious diseases and cancers.

CHEMISTRY

Pteroylglutamic acid (PGA), the common pharmaceutical form of folic acid, is not present as *such* in significant quantity in either the human body or the various foods from which folates were isolated. Folates are present in various reduced, metabolically active, coenzyme forms, often conjugated in peptide linkage. During the extraction procedures, these labile active forms are either destroyed by oxidation or oxidized and converted to PGA, the most stable form of the vitamin. Not until they are reduced by metabolic systems present within gut and other tissue cells do these stable forms become metabolically active folates. The Trinity College (Dublin, Ireland) group has shown that consumption of more than 266 µg of synthetic folic acid (PGA) results in absorption of unreduced PGA, which may interfere with folate metabolism over a period of years (15, 16, 16a).

Figure 26.1 (17) presents the structural formula of folic acid (PGA, PteGlu or PteGlu₄; PGA), the reference compound of the folate vitamin forms. The major subunits of the molecule are the pteridine moiety linked by a methylene bridge to *p*-aminobenzoic acid, which is joined by peptide linkage to glutamic acid. Because of its unique stability, it is the synthetic pharmaceutical form used for folate food fortification and in folate-containing supplements.

Figure 26.1. Structural formula of folic acid (PGA). (From Herbert V. Drugs effective in megaloblastic anemia: vitamin B₁₂ and folic acid. In: Goodman LS, Gilman A, eds. The pharmacological basis of therapeutics. 5th ed. New York: Macmillan, 1975;1324–49, with permission of Macmillan Publishing.)

Crystalline folic acid is yellow (molecular weight, 441.4 g/mol). The free acid is almost insoluble in cold water; the disodium salt is more soluble about 1.5 g/dL (34.0 nmol/L). Injectable solutions are prepared by dissolving folic acid in isotonic sodium bicarbonate solution or by using the disodium salt. Folic acid is destroyed at a pH below 4 but is relatively/stable above pH 5, with no destruction in 1 hour at 100°C. The molecule usually splits into pteridine and *p*-aminobenzoyl glutamate.

Recommendations of an advisory panel to several commissions on nomenclature are as follows: “Folate and folic acid are the preferred synonyms for pteroylglutamate and pteroylglutamic acid, respectively. The term folates may also be used in a generic sense to designate any member of the family of pteroylglutamates, or mixtures of them, having various levels of reduction of the pteridine ring, one-carbon substitutions, and numbers of glutamate residues (18).” The term *folacin* is obsolete and no longer used.

PGA, an oxidized compound, is not normally found as such in foods or in the human body in significant concentrations. The forms that are found in such sources are the reduced forms indicated in Figure 26.2. They differ from the parent compound by virtue of one to three structural modifications. First, all are reduced folates and, except for 7,8-dihydrofolate, all are 5,6,7,8-tetrahydrofolates (THF). Second, as indicated in Figure 26.2, various one-carbon adducts may be linked to THF at the N-5, N-10, or N-5,10 positions, conferring on folates their role as one-carbon carriers. N5-Formyl THF (folinic acid, citrovorum factor) represents nonenzymatic conversion of folate during processing of natural materials (19). Third, the number of glutamate residues may vary from one to seven, and sometimes up to 11, each linked by peptide bonds between its amino group and the γ -carboxyl group of the preceding glutamate (Fig. 26.1).

Figure 26.2. Structures and nomenclature in the folate field. The table above the formula lists some of the possible one-carbon adducts formed with THFA. (From Herbert V. Drugs effective in megaloblastic anemia: vitamin B₁₂ and folic acid. In: Goodman LS, Gilman A, eds. The pharmacologic basis of therapeutics. 5th ed. New York: Macmillan, 1975;1324–49, with permission of Macmillan Publishing.)

UNITS OF MEASUREMENT AND METHODS OF ASSAY

Normal human serum contains 5 to 16 ng/mL (11.33–36.25 nmol/L) of folic acid activity (i.e., PteGlu equivalents) (1 ng = 10⁻⁹ g). These tiny quantities could be measured only microbiologically, as originally described in 1959 (20), until a radioisotopic assay was described in the 1970s (21, 22). The dominant form of folate in serum and red cells is 5-methyl THF (Fig. 26.2); folate assays must thus be able to measure this derivative. The only microbiologic assay that adequately measures serum and red cell folate uses *L. casei*. Similarly, the only radioassays that accurately measure serum folate are those that measure 5-methyl THF. Simultaneous radioisotope determinations of serum vitamin B₁₂ and folate can be done in the same sample (23). The results correlate well with those of other radioassays.

Because serum folate is labile, falsely low values for serum folate activity occur if the serum has not been protected against oxidative destruction before assay, by storing the serum frozen, storing it in the absence of a reducing agent such as ascorbate, or both. (However, ascorbate may destroy B₁₂ in storage.) Larger quantities of folate activity than those normally present in human serum may be measured chemically, fluorometrically, by paper and thin-layer chromatography, enzymatically, or by animal assay (24).

ABSORPTION

Food folate is absorbed primarily from the proximal third of the small intestine, although it can be absorbed from the entire length of the small bowel (25). Folate in food is primarily in polyglutamate form. Before absorption, the “excess” glutamates must be

split off the side chain of the vitamin molecule by enzyme conjugases (pteroylpolyglutamate hydrolase). The products of conjugase action are detectable in the intestinal lumen before absorption and are due to a surface-active brush border conjugase that is functionally and chromatographically distinguishable from intracellular conjugase. The bioavailability of ingested folate monoglutamates (PteGlu) is significantly greater than that of folate polyglutamate (PteGlu_n) in humans, presumably because the latter must be hydrolyzed (25). The folate hydrolase (conjugase) in the brush border of small intestinal enterocytes, though much less abundant than intracellular folate hydrolase, is more than adequate for digestion of the 1989 recommended dietary allowance (RDA) of 3 µg (6.8 nmol) folate/kg body weight, simplified as 200 µg/day for adult males and 180 µg/day for fertile females (25a). Conjugase action may be specifically inhibited by food factors described in yeast and beans and may be nonspecifically impaired at acid pH. The altered activity of the brush border folate hydrolase in certain diseases and following exposure to drugs such as salicylazosulfapyridine, alcohol, and diphenylhydantoin appears to play a significant role in causing malabsorption and deficiency of folate (25, 26). The discovery that jejunal folate hydrolase shares gene homology with a prostate-tumor-specific protein and a neuronal enzyme implies folate hydrolase may relate to both brain development and carcinogenesis (26a).

Impaired mucosal transport of monoglutamyl folates after deconjugation probably accounts for most instances of folate malabsorption. Active mucosal transport is accelerated by glucose and galactose and impaired by unidentified factors present in many foods. However, studies using mild folate binder (see below) suggest that folate uptake in the gut is facilitated by prior binding. A small but relatively unchanging percentage of ingested folate is absorbed by passive diffusion after deconjugation (15, 16, 16a), as is the case with vitamin B₁₂. Passive diffusion may also account for absorption of unreduced synthetic PGA eaten as a bolus in excess of 266 µg (15, 16, 16a).

Folic acid absorbed from the intestine at physiologic concentrations is largely converted in the gut lumen and enterocytes (26) to reduced forms and then methylated or formylated; at higher concentrations, it is transported through the enterocytes without such modification (15, 16, 16a, 27). However, reduced and formylated or methylated forms of folate are transferred faster from the intestine to the circulation than is folic acid (28). How folate is transported from the enterocytes to the lamina propria of the villi or the circulation is poorly understood; a carrier-mediated system was suggested and is now identified (see next section) (29).

TRANSPORT, DISTRIBUTION, STORAGE, AND EXCRETION

Binding Proteins and Transport

Folate in plasma appears to be distributed in three fractions; free folate and that loosely bound to low-affinity binders are similar in magnitude; much less is bound to high-affinity binders (Fig. 26.3 [30]). Low-affinity binding is a nonspecific property of many different plasma proteins, including albumin, and is similar to nonspecific binding of bilirubin and

various drugs. It was detected many years ago using ultrafiltration, equilibrium dialysis, and gel filtration. The potential binding capacity is several hundred times greater than the amount of folate in serum. Early data showing failure to half-saturate these binders at high concentrations of free folate indicate that the affinity constant (K_e) of the system is less than 10^4 L/mol, which might be compared with the 10^6 L/mol affinity constant of the carrier-mediated cell transport system for folate (31).

Figure 26.3. Flow chart of folate metabolism in man. *Circled numbers* identify individual steps in folate metabolism. In mammals, the same enzyme catalyzes reactions 12, 14, and 19, and another single enzyme catalyzes both steps 16 and 21. *THF*, tetrahydrofolate; *DHF*, dihydrofolate. (From Herbert V. In: Beeson PB, McDermott W, eds. Textbook of medicine. 14th ed. Philadelphia: WB Saunders, 1975.)

Study of the high-affinity serum folate binders was initiated by the discovery of such binders in chronic myeloid leukemia cells and in serum of the same patients (32). These binders are also demonstrable in granulocytes from some nonleukemic subjects and are released into the serum by these cells. Although their release has not yet been detected in most normal subjects, all human (and animal) serum contains these binders, which more often than not are largely saturated (33).

Only one class of high-affinity serum folate binders is thought to exist. These binders are glycoproteins with a molecular weight of about 40,000; they are probably synthesized in, and released from, granulocytes but are modified in liver and perhaps in kidney (33). They have binding constants (K_e) of approximately 10^{-10} mol/L of folic acid and of the order of 10^{-8} mol/L of 5-methyl THF, the main forms of folate present in serum. Although these affinities indicate that binder would be only half saturated at usual serum methyl THF concentrations, saturation normally averages 67%. This higher-than-expected saturation may be due to the binding of small quantities of nonmethyl unsubstituted folates on binders. Because of their low concentration in plasma, these binders carry less than 5% of serum folate.

Their physiologic function has not yet been demonstrated, but they may play a role in (a) delivering folate to liver, similar to the role of haptocorrin in vitamin B₁₂ transport; (b) controlling folate distribution, breakdown, and excretion in deficient states; and (c) transporting oxidized folates from cerebrospinal fluid to blood. They are also present in milk, where they may enhance folate absorption from gut, and they may be related to membrane protein-mediated folate uptake. High-affinity folate-binding protein found in human serum appears to have a higher affinity for folic acid (PteGlu) than for reduced folate (34). Folate-binding proteins in several tissues closely resemble the serum binders (31).

Folate is delivered to bone marrow cells, reticulocytes, liver, cerebrospinal fluid, and renal tubular cells against a concentration gradient in a manner that suggests energy-dependent carrier-mediated transport (35). The transport constant (K_m) of these systems is about 10^{-6} M. Methyl THF, which accounts for almost all serum folate, appears to be transported more efficiently than folic acid across the intestinal cells and into the cells of the body. A cell membrane folate receptor protein identified in 1992 by Antony (36) and shown by Anderson et al. (37) to produce, by potocytosis, epithelial cell accumulation of methyl THF, is involved in folate transport into many cell types and across intestine, placenta, and choroid plexus barriers. A soluble form of the receptor has been identified in plasma, saliva, milk, seminal fluid, and amniotic fluid (38, 39).

Storage

Normal total-body folate stores range from 5 to 10 mg (11.3–22.6 μ mol), of which approximately half is in the liver. It has been suggested that the enterohepatic circulation, which transports about 0.1 mg (0.226 μ mol) of biologically active folate daily, is important in the maintenance of serum folate levels.

Most stored folate is present as polyglutamates (19), which have far greater molecular size and charge than monoglutamates. Transport across cell walls probably requires hydrolysis to monoglutamates, and the enzymes responsible for polyglutamate synthesis and hydrolysis are thus thought to play a major role in folate storage. These enzymes are known, respectively, as polyglutamate synthetase and conjugase (pteroylpolyglutamate hydrolase; γ -glutamyl-carboxypeptidase) (26). Conjugase is under partial hormonal control. Some of the folate-dependent reactions shown in [Figure 26-3](#) are altered by varying glutamyl chain lengths. Folate polyglutamate synthetase has been purified from human liver and organs of other mammals; the enzyme is relatively unstable and is found in low quantity. Folate monoglutamates are the circulating and transport forms, whereas polyglutamates are the main intracellular storage forms of this vitamin. Recent evidence indicates that folate polyglutamates are the preferred substrates and active coenzyme forms in various one-carbon metabolism pathways and thereby regulate these metabolic processes (31). Excesses of oral synthetic PGA, if absorbed intact as the oxidized form, may interfere with folate metabolism (15, 16, 16A, 39).

Excretion

Folate is excreted in urine and bile in metabolically active and inactive forms. Urinary excretion of the biologically active material occurs after glomerular filtration of the free fraction and reabsorption of some filtered folate by active transport across the tubular cell wall. The principal breakdown product of folate in urine, acetamidobenzoylglutamate, suggests that the principal route of folate catabolism occurs through oxidative cleavage of the folate molecule at the 9-10 bond, with acetylation of the *p*-aminobenzyl moiety in the liver before excretion (40). Some workers believe that scorbutic patients may lose large amounts of folate through irreversible oxidation of 10-formylfolate and excretion of the latter in the urine (41). We agree.

As mentioned above, about 100 µg of biologically active folate is excreted in the bile daily. Studies with radioactive tracer folates indicate that a large proportion of injected radioactivity is excreted in the bile as a biologically inactive compound that is not a product of 9-10 cleavage but which is not well characterized. Alcohol interferes with the folate enterohepatic cycle. In chronic alcoholics, all six major causes of folate deficiency (see “[Causes of Nutritional Deficiency](#)”) may occur simultaneously (42). For these reasons, nearly all alcoholics are in negative balance, and about 80% are clinically folate deficient.

NUTRITIONAL REQUIREMENTS IN HEALTH

The term *minimal daily requirement* (MDR), as used in this chapter, means the minimum *from exogenous sources* required to sustain normality, with *normality* defined as the absence of any biochemical hypofunction that is correctable by addition of greater quantities of the vitamin. By this definition, the MDR for folate is approximately 50 µg (113.3 nmol) for adults.

The MDR can be reduced to a formula: $MDR = UBS \div D$, where *MDR* is the minimal daily requirement of nutrient from exogenous sources, *UBS* is the usable body stores of nutrient, and *D* is the number of days required to develop tissue deficiency after cessation of absorption from exogenous sources of nutrient (with appropriate correction for incomplete cessation of absorption) (42, 43). Utilization rate is constant in the normal person but becomes first-order as negative balance progresses. As suggested previously, one can predict the time needed for any given nutrient deficiency to develop in any given person after reduction or cessation of absorption of the nutrient if one knows (or can reasonably estimate) the MDR for the nutrient and its utilizable body stores.

The RDA for folate intentionally greatly exceeds the MDR to produce some measurable amount of body stores to allow for normal variation in use and transiently increased requirements (see below). There is a tendency to err on the side of larger body stores when information is incomplete. Small storage surpluses of nutrients are rarely detrimental, whereas small deficits may result in deficiency over a long period of subtle

negative balance.

The Food and Agricultural Organization (FAO) and World Health Organization (WHO) Expert Group in 1987 recommended a daily dietary intake of folate for adults of 3.1 µg (2.3 nmol)/kg of body weight, to equal a daily intake of 200 µg (453.33 nmol) for a 65-kg man and 170 µg (128 nmol) for a 55-kg woman (44) (Appendix [Table II-A-8-a](#)). This amount provides sufficient stores to prevent deficiency for 3 to 4 months of zero intake. To meet the added needs of pregnant women, FAO/WHO recommends a supplement from day zero of pregnancy of 200 to 300 µg (453.33–680.0 nmol) daily, so that the daily folate intake is no less than 350 µg (793.33 nmol) (or 7 µg/kg body weight), and a supplement of 100 µg (226.67 nmol) daily during lactation (i.e., a total of 5 µg, or 11.33 nmol, per kilogram body weight). The 1989 RDA (see Appendix [Table II-A-2-a-2](#)) ranged from 25 µg (56.7 nmol) for young infants to 35 µg for those 6 to 12 months old; and 50, 75, and 100 µg (227 nmol) for those 1 to 3, 4 to 6, and 7 to 10 years old, respectively. Recommendations were 150 µg for males and females from 11 to 14 years of age; thereafter, the recommendations were 200 µg for males and 180 µg for females. (The basic figure of the 1989 RDA was approximately 3 µg/kg body weight for adolescents and nonpregnant adults. This is the same figure as was recommended by Herbert [45, 45A].) The recommendation for pregnant women was 400 µg; for lactating women it was 280 µg for the first 6 months and 260 µg for the second 6 months (25a). On a percentage basis these values were appreciably below the 1980 RDAs.

The 1998 recommended intakes of folate of the Food and Nutrition Board Institute of Medicine (Appendix [Table II-A-2-c-1](#)) (45b) are appreciably greater than those of the 1989 RDA (Appendix [Table II-A-2-a-2](#)) (45c). In comparison to the latter, the 1998 recommendations are approximately double for infants, three times or so for children, two to three times for all males of age 9 years or older, more than double for nonpregnant females, and appreciably more for pregnant and lactating women. The increases stem from the recent evidence indicating the need for more folate to minimize neural tube defects in pregnant women and other vascular changes induced by hyperhomocysteinemia (see also new data in Appendix [Table II-A-2-c-3](#) and [Table II-A-2-c-4](#)).

The daily folate requirement is increased by factors that increase metabolic rate (e.g., infection and hyperthyroidism) and those that increase cell turnover (e.g., hemolytic anemia, rapid tissue growth in the fetus, and malignant tumors). Folate consumption by individual cells is proportional to their rate of one-carbon-unit transfer. As noted above, alcohol interferes with folate use and thus increases folate requirement.

Natural Sources of Folate

Unlike vitamin B₁₂, which is present only in animal protein, folates are ubiquitous in nature, being present in nearly all natural foods (see Appendix [Table IV-A-23-a](#)). Again unlike vitamin B₁₂, folate is highly susceptible to oxidative destruction: 50 to 95% of the folate in food may be destroyed by protracted cooking or other processing, such as canning, and all folate is lost from refined foods such as sugars, hard liquor, and hard candies. Foods with the highest folate content per unit of dry weight include yeast, liver

and other organ meats, fresh green vegetables, and some fresh fruits.

The naturally occurring folates are active metabolic forms, usually in polyglutamate linkage (19) (with pteroylheptaglutamates dominant in yeast). Conjugases present in vegetable and mammalian tissues (46) (including human intestine) liberate pteroyldiglutamates and pteroylmonoglutamates from the conjugates, thereby making the folate available for absorption. As mentioned above, about 90% of the monoglutamate is absorbed by humans when ingested alone, but this percentage is markedly decreased in the presence of many foods, irrespective of whether the folate was derived from or added to the food (47).

CAUSES OF NUTRITIONAL DEFICIENCY

In the final analysis, nutritional deficiency means that the amount of a biologically active nutrient in one or more intracellular systems is inadequate to sustain normal biochemical functions. Such inadequacy presents in one or more of six basic categories: inadequate ingestion, inadequate absorption, inadequate utilization, increased requirement, increased excretion, and increased destruction. Any one or combination of these three inadequacies and three excesses may result in nutritional deficiency. [Table 26.1](#) presents the currently known possible etiologic factors in each of these six categories that may produce a nutritional deficiency of folic acid. The ensuing sections will discuss in more detail mechanisms of inadequate absorption and utilization of folic acid.

Table 26.1 Causes of Folic Acid Deficiency

FOLATE DEPLETION: PROGRESSION AND DETECTION

The sequence of events in developing folate deficiency in man is depicted in [Figure 26.4](#) and [Figure 26.5](#). The stages are as follows (42):

Figure 26.4. Biochemical and hematologic sequence of events in developing dietary folate deficiency in man. (From Herbert V. *Trans Assoc Am Physicians* 1962;75:307.)

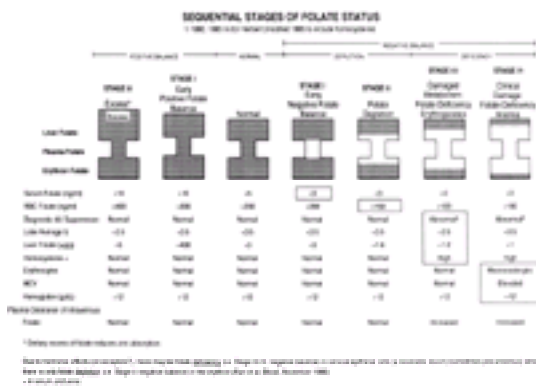

Figure 26.5. Sequence of events in developing folate deficiency. Earliest abnormalities in each stage are *boxed*.

Stage 1: Early negative nutrient balance is characterized by a fall in serum folate to below 3 ng/mL (6.8 nmol/L). Body folate stores are not detectably affected; red cell folate level is above 200 ng/mL (453.3 nmol/L).

Stage 2: Folate depletion is indicated by low serum folate and characteristically by a fall in erythrocyte folate below 160 ng/mL (362.67 nmol/L) (and *pari passu* by a fall in hepatic folate content).

Stage 3: Folate-deficient erythropoiesis is indicated by defective DNA synthesis, abnormal diagnostic deoxyuridine (dU) suppression test results correctable *in vitro* by

folates, and granulocyte nuclear hypersegmentation.

Stage 4: Clinical folate deficiency is manifested by gross macroovalocytosis, elevated mean corpuscular volume (MCV), and anemia.

More than half of folate-depleted individuals who have not yet reached the stage of anemia are missed by screening tests that do not recognize that folate depletion may precede anemia by months.

METABOLIC FUNCTIONS AND INTERRELATIONSHIPS

DNA Synthesis

As illustrated in [Figure 26.3](#), both vitamin B₁₂ and folic acid are required for synthesis of thymidylate and thus of DNA. A vitamin B₁₂-containing enzyme removes a methyl group from methyl folate and delivers it to homocysteine, thereby converting homocysteine to methionine (methyl-homocysteine) and regenerating THF, from which the 5,10-methylene THF involved in thymidylate synthesis is made. Methyl folate is the predominant form of folate in human serum and liver and probably also in other body storage depots for folate. Because methyl folate may only return to the body's folate pool via a vitamin B₁₂-dependent step, patients with vitamin B₁₂ deficiency have much of their folate “trapped” as methyl folate, which is metabolically inactive. This “folate trap” hypothesis helps explain the hematologic damage of vitamin B₁₂ deficiency that is not clinically distinguishable from that of folate deficiency ([48](#)). In both instances, the hematologic defect results from lack of adequate 5,10-methylene THF, whose methyl group is transferred in the conversion of deoxyuridylate to thymidylate used for DNA synthesis during the S (synthesis) phase. In either deficiency, inadequate DNA synthesis causes many hematopoietic cells to die in the bone marrow, possibly without ever completing the S phase of cell replication (i.e., a form of “ineffective erythropoiesis”) ([49](#)).

The DNA damage caused by folate (or vitamin B₁₂) deficiency increases the risk of cancer ([50](#), [51](#) and [52](#)). Megaloblastosis (the presence of giant germ cells) results from slowed DNA synthesis of any cause. The finely stippled sievelike open chromatin in megaloblasts suggests a defect in nuclear maturation. The precise molecular basis of megaloblastic maturation is obscure. Poor thymidylate synthesis (due to folate and/or vitamin B₁₂ deficiency) may fail to promote elongation of DNA chains in the presence of a relatively normal capacity to initiate DNA synthesis. This process occurs, presumably, because the lowered thymidylate concentrations suffice for “initiation” but not for “elongation” of the DNA chain by polymerase ([53](#)). Alternatively, the defect may permit “illicit” incorporation of thymidylate precursors (such as deoxyuridylate) into DNA, with subsequent cleavage of the DNA containing the illicit nucleotide ([54](#)). Decreased synthesis and methylation of arginine-rich nuclear histone may contribute to megaloblastic maturation in pernicious anemia.

Morphologic changes are most striking in bone marrow cells, with the “ineffective

hematopoiesis” resulting in peripheral blood pancytopenia (anemia, leukopenia, and thrombopenia) (55). However, megaloblastosis occurs in all duplicating cells of the body (56) and may be strikingly noted in the epithelial cells of the entire alimentary tract, producing glossitis and variable degrees of megaloblastosis along the entire alimentary tract epithelium. It is not yet clear why gut changes associated with vitamin B₁₂ deficiency are often related to constipation, whereas those associated with folate deficiency are more commonly related to diarrhea. These differences may be connected to phenomena other than the nutrient deficiency per se.

“Packaging” Folate in Cells

Another important interrelationship of these two vitamins is the involvement of vitamin B₁₂ in the transport and storage of folate in cells. In vitamin B₁₂ deficiency, transport of methyl THF into both bone marrow cells and transformed lymphocytes is impaired, a defect that is corrected by addition of vitamin B₁₂ (57). Similarly, humans and experimental animals with vitamin B₁₂ deficiency have low erythrocyte folate and decreased liver folate stores. These defects are probably due to failure of vitamin B₁₂-dependent homocysteine:methionine transmethylation (see Chapter 27 and Chapter 34). Failure to remove the methyl group from folate, which causes an intracellular “methyl trap,” may interfere with dissociation of the carrier-folate complex at the inner cell wall and may impair transport into the cell. It does impair folate storage, because THF is preferred over methyl THF as a substrate for polyglutamate synthetase (58, 59).

This “heat-labile” form of 5,10-methylene-THF reductase, an enzyme present in one of several forms depending on an individual's genetic blueprint, has become of central importance in studies of hyperhomocysteinemia (see Chapter 34). “Heat-labile” forms of this enzyme result in abnormal folate metabolism; that is, a biochemically induced deficiency of intracellular folate. More information on this rapidly developing area of research can be found in references 60, 61, 62 and 63, and in abstracts of papers presented at the Second International Conference on Homocysteine Metabolism (64).

Nerve Damage

Folate deficiency does not damage myelin, as does vitamin B₁₂ deficiency, but it is associated with a high frequency of irritability, forgetfulness, and often hostile and paranoid behavior. These phenomena often strikingly improve within 24 hours of the start of therapy with folic acid. Other neurologic sequelae attributed by some to folate deficiency have been reviewed elsewhere (65), but the association has not been convincingly demonstrated. Homocysteine, which builds up in folate deficiency, may be a neurotoxin as well as a vasculotoxin.

SELECTIVE NUTRIENT DEFICIENCY

An important area of nutrition research concerns selective nutrient deficiency in one cell line or one tissue but not another in the same patient. This condition can result from one

tissue obtaining food folate first, as do intestine cells when food folate is decreased. Another cause may be the presence of a more effective mechanism for folate uptake and a less effective one for folate rejection and relative loss in one cell line compared with another. Selective folate deficiency can occur, for example, in white cells but not in red cells (66). Therefore, lymphocytes (which in their resting form in the human blood appear impervious to vitamin B₁₂ and folic acid, and to other nutrients such as nicotinamide) can be used to measure past nutrient deficiency up to 2 months after therapy; they can also reveal covert folate deficiency in patients who lack macroovalocytosis because of coincident iron deficiency or hemoglobinopathy (48, 67). Only when lymphocytes are making DNA do they appear to be pervious to nutrients (48, 65).

FOLATE IN NUTRIENT METABOLISM

Protein and Fat

Folate is involved in protein synthesis through its role in the synthesis of the amino acid methionine, and possibly in other ways as well. Because methionine is involved in making available more of the lipotropic substances choline and betaine, this is another area in which folate may play a role in lipid metabolism.

FOLATE IN ONE-CARBON-UNIT TRANSFERS

Folate coenzymes are concerned with mammalian metabolic systems involving transfer of a one-carbon unit (Fig. 26.3). These reactions include (a) de novo purine synthesis (formylation of glycinamide ribonucleotide [GAR] and 5-amino-4-imidazole carboxamide ribonucleotide (AICAR)); (b) pyrimidine nucleotide biosynthesis (methylation of deoxyuridylic acid to thymidylic acid); (c) conversions of three amino acids—the interconversion of serine and glycine (which also requires vitamin B₆), catabolism of histidine to glutamic acid, and conversion of homocysteine to methionine (which also requires vitamin B₁₂); (d) generation of formate into the formate pool (and formate use, which relates to the formate starvation hypothesis of Chanarin et al. [49]); and (e) methylation of small amounts of transfer RNA. Folate is not involved in the physiologic methylation of biogenic amines (68).

There is no evidence of ascorbate involvement in reduction of PGA to tetrahydrofolic acid, a reaction mediated by folate reductases, but it may protect tetrahydrofolic acid against further oxidative destruction in vivo as it does in vitro.

With wide recognition of the vasculotoxicity of homocysteine, much folate (and vitamin B₁₂) research is focused on homocysteine metabolism (64, 69, 70 and 71). The Hordaland Homocysteine Study (71a) of 18,043 middle-aged subjects found 67 with very high (>40 μmol/L) plasma homocysteine, of whom 73.1% had homozygosity for the C 677T mutation in the methylene tetrahydrofolate reductase gene (73.1% of cases versus 10.2% of controls). All also had lower plasma folate and cobalamin levels than controls; 10% had overt vitamin B₁₂ deficiency. Flynn et al. (71b) found 49% of 171

“healthy” elderly, mean age 65, had malabsorption of vitamin B₁₂, and, of these, 60% had serum homocysteine greater than 17.5 μmol/L. An excellent review was recently published (71c).

ROLES IN THERAPY

The only established therapeutic use of folic acid is in treating deficiency of the vitamin. Prophylactic use can prevent about 2000 neural tube defect babies in the U.S. annually (72). Claims made for nutritional value in clinical situations in which deficiency of the vitamin does not clearly exist are without established foundation, except with respect to neural tube defects (72, 73, 73a, 74).

When the deficiency is only of folate, only that vitamin should be used for therapy. Use of folic acid to treat a patient whose deficiency is of vitamin B₁₂ often produces temporary hematologic improvement, but does not adequately lower toward normal vasculotoxically elevated serum homocysteine levels due to vitamin B₁₂ deficiency (71). Furthermore, it allows the neurologic damage of the underlying vitamin B₁₂ deficiency to progress, often to an irreversible state (75). Folate supplementation produces unpredictable intra-individual variations in serum homocysteine levels (75a). The causes of folate deficiency in humans are listed in Table 26.1 and Table 26.2 lists the symptoms and signs of megaloblastic anemia.

Table 26.2 Clinical Picture of the Megaloblastic Anemias

In malaria zones, moderate folate deficiency may actually be desirable. Das et al. (76) have shown that mild folate deficiency protects against malaria in primates by making it impossible for malaria parasites to double their DNA and divide in red cells (77). Currently, Herbert and colleagues are studying the possible prevention of malaria in Africa by producing chronically low red cell folate without anemia with daily oral

phenytoin in alternate new cases of epilepsy (65).

Critically Ill Patients

It is rarely necessary to institute immediate therapy before determining whether the cause of megaloblastic anemia is folate deficiency, vitamin B₁₂ deficiency, both, or neither. Major indications for *emergency* therapy include severe thrombocytopenia (platelet count $\leq 50,000/\text{mm}^3$) associated with bleeding, severe leukopenia (white cell count $\leq 3000/\text{mm}^3$) associated with infection, infection itself, coma, severe disorientation, marked neurologic damage, severe hepatic disease, uremia, or other debilitating illness complicating the anemia. The anemia itself is not a problem because the dyspnea and occasional angina that may accompany a hematocrit below 15 volumes % are relieved by transfusion of one or two units of packed erythrocytes. Transfusion is unwarranted in the absence of *symptoms* of anemia. When venous pressure is elevated, transfusion of packed erythrocytes should be accompanied by withdrawal of equivalent or slightly smaller quantities of whole blood, which will reduce rather than raise the venous pressure. Transfusion of whole blood without withdrawal of blood has been responsible for acute rises in venous pressure with resultant irreversible congestive failure in elderly patients with megaloblastic anemia and unrecognized elevated venous pressure. Ideally, venous pressure should be determined before transfusion and monitored during both the transfusion of packed cells and the simultaneous withdrawal of whole blood. An alternative to exchange transfusion is parenteral injection of a diuretic before the administration of blood.

When, for one of the reasons discussed above, immediate vitamin therapy is necessary before etiologic diagnosis, a sample of blood is drawn to determine baseline status with respect to both vitamins, and then 100 μg (76.0 nmol) of vitamin B₁₂ and 15 mg (34 μmol) of folic acid are given intramuscularly, followed by 100 μg (75.0 nmol) of vitamin B₁₂ intramuscularly and 5 mg (11.3 μmol) of folic acid by mouth daily for 1 week. Such treatment produces excellent hematologic response except in patients whose hematopoiesis is suppressed by infection, uremia, chloramphenicol administration, or some other factor.

By producing megaloblastic enterocytes resulting in malabsorption, folate deficiency can produce secondary vitamin B₁₂ deficiency, and vitamin B₁₂ deficiency can produce secondary folate deficiency (78). Many recent studies finding relatively low red cell folate in elderly persons along with "normal" serum total vitamin B₁₂ erroneously diagnosed folate deficiency whereas the correct diagnosis was vitamin B₁₂ deficiency (69). Had they measured holotranscobalamin II (69, 78), they would have correctly diagnosed inability to absorb vitamin B₁₂, with low red cell folate because vitamin B₁₂ is necessary both to get folate into red cells and to keep it there (78).

Folate Deficiency

For combined differential diagnosis and therapy, the patient is treated with 100 μg (226.67 nmol) of folic acid orally daily (if the suspected diagnosis is folate

malabsorption). This dosage produces a maximal hematologic response in patients with folate deficiency but does not produce hematologic response in patients with vitamin B₁₂ deficiency (79). As in treated vitamin B₁₂ deficiency, treatment of folate deficiency returns subnormal leukocyte and platelet levels to normal within 1 week of the start of therapy, at approximately the time of the reticulocyte peak.

Therapy with doses of folic acid above 0.1 mg (226.67 nmol) daily is desirable when the folate deficiency state is complicated by conditions that may suppress hematopoiesis (e.g., unrelated systemic diseases), conditions that increase folate requirement (e.g., pregnancy, hypermetabolic states, alcoholism, hemolytic anemia), and conditions that reduce folate absorption. Therapy should then consist of 0.5 to 1 mg (1.33–2.266 μmol) daily. There is no evidence that doses greater than 1 mg (2.266 μmol) daily have any greater efficacy; additionally, loss of folate in the urine becomes roughly logarithmic as the amount administered exceeds 1 mg (2.266 μmol). In fact, there is evidence that doses above 1 mg daily for a sustained period of time may be harmful (15, 16 and 16a, 39).

Maintenance therapy is normally 0.1 mg (226.67 nmol) of folic acid daily for 1 to 4 months, which then should be discontinued only if the diet contains at least one fresh fruit or fresh vegetable daily. If the daily folate requirement is increased by increased metabolic or cell turnover, the daily maintenance dose should be 0.2 to 0.5 mg (0.453–1.133 μmol).

Ideal nutritional therapy for dietary folate deficiency is the ingestion of one fresh fruit or one fresh vegetable daily. Such a diet would probably eliminate nutritional folate deficiency from the earth (80). At present, nutritional folate deficiency probably affects approximately a third of all the pregnant women in the world (81).

Prevention of Folate Deficiency

Pregnant women should receive folate supplements from day zero of pregnancy. Supplements have also been recommended in clinical disorders that increase the risk of folate deficiency. However, major problems have been encountered in the delivery of such supplements to patients. Because of resultant gastrointestinal upsets, significant numbers of pregnant women do not ingest iron tablets given to them. Tablets containing both iron and folate may be better tolerated, inasmuch as the adverse gastrointestinal effects of iron ingestion may be decreased when folic acid is simultaneously ingested (82). However, the iron in the mixed supplement should not exceed the 30 mg (0.54 mmol) daily iron pregnancy supplement. The largest component of the problem is that antenatal care is not available for, or taken advantage of by, large numbers of pregnant women, particularly in populations in which folate deficiency is common.

As an alternative approach to alleviating the problem, a series of studies was devised to determine the feasibility of fortifying staple foods with folic acid. When the data generated in these studies were judged against criteria delineated by an Expert Committee of the FAO/WHO (83), such fortification appeared feasible, inexpensive, effective, and safe in populations with a demonstrable need for increased dietary levels

of folic acid. Fortification by preventing megaloblastic anemia can mask vitamin B₁₂ deficiency until there is neurologic damage (78, 84, 85). The WHO and other bodies have recommended that authorities concerned with populations in which folate deficiency is common should initiate trials to determine the feasibility and effectiveness of food fortification with folate (86).

Since the fetal neural tube (see Chapter 95) is formed early in pregnancy, all fertile nonblack females should ensure themselves of a diet adequate to provide 0.3 to 0.4 mg of folic acid daily or take such a supplement (72, 85). To eliminate neural tube defects that are due to a genetic defect in handling folate (72, 73 and 74), the Food and Drug Administration (FDA) has mandated that folate be added to grain fortification, effective January 1, 1998 (74, 75, 85). Because African American fertile females do not have the gene defect that causes folate-treatable neural tube defects but do have a gene for early pernicious anemia, the FDA has been petitioned to mandate that vitamin B₁₂ also be added (85). Another reason to add vitamin B₁₂ is that, in the elderly, vitamin B₁₂ deficiency is much more common than deficiency of folate (71).

TOXICITY

Folic acid ingested in the reduced forms active in humans is nontoxic in man, not only in small doses but also in doses that exceed the minimal daily adult human requirement (50 µg) by 20 times. Being water soluble, excesses tend to be excreted in the urine rather than, like fat-soluble vitamins, being stored in tissues. Folic acid appears to require binding to polypeptides as a precondition of storage; amounts that exceed the limited binding capacity in serum and tissues tend to be excreted rather than retained.

Daily doses of up to 15 mg (34 µmol) in healthy humans without convulsive disorders are without clear toxic effects; this daily dose is well below the amount that could lead to precipitation of crystalline folic acid in the kidneys (such precipitation produces renal toxicity in rats given massive doses of folic acid). One questionable instance of an allergic reaction to folic acid has been reported in man (87). Very large amounts of folic acid in its pharmaceutical oxidized form (PGA) may be noxious to the nervous system; can reverse the antiepileptic effects of phenobarbital, phenytoin, and primidone; and have provoked seizures in patients otherwise under control on anticonvulsant therapy (65, 88).

Although no such effect has been observed in controlled studies using oral doses of 15 mg (34 µmol) folic acid daily, experimental and clinical evidence demonstrates that very high concentrations of folic acid can have a convulsant effect (89). The convulsant dose in normal rats was shown in one study to be 45 to 125 mg (102 to 283.3 µmol) if administered intravenously and 15 to 30 mg (34 to 68 µmol) if preceded by induction of a focal cortical lesion. Convulsions have been reported in one of eight epileptics given parenteral folic acid under electroencephalographic monitoring. This reaction occurred after rapid intravenous infusion of 14.4 mg (32.64 µmol) of folic acid, which presumably elevated serum folate concentration in the cerebral vessels several times higher than folic acid ingestion would have (65). Anticonvulsant drugs and folic acid compete for absorption across the intestinal epithelial cells and at the brain cell wall (88). Evidence

in uncontrolled studies suggests increased fit frequency in epileptics given oral therapeutic doses of folic acid. To date, no such effect of oral folic acid has been demonstrated in carefully conducted controlled trials. Being a physician-attorney aware of malpractice law, I recommend giving it only if absolutely necessary.

Oral folic acid supplements of 350 mg (793.3 μmol) daily reduce zinc absorption and may be a problem where maternal zinc depletion and intrauterine growth retardation are common (90).

HISTORICAL INTRODUCTION

The early history of the chemistry and biochemistry of the corrinoid cobalamin (vitamin B₁₂) has recently been reviewed by Linnell and Bhatt (1) and by Stubbe (2) and can be summarized as follows. Vitamin B₁₂ was isolated in 1948, simultaneously in the United States and in England. Discovery of its extraordinary three-dimensional structure by x-ray crystallography and the deep red color of the oxidized corrin ring subsequently led to identification of the carbon-cobalt bond in the two active cofactor forms of the vitamin, namely, adenosylcobalamin (adoCbl) and methylcobalamin (methyl Cbl). In 1958, adoCbl was identified as the coenzyme for glutamate mutase in microorganisms and, in the next year, for methylmalonyl-CoA mutase in mammals. Methyl Cbl was first synthesized and shown to be the main form of vitamin B₁₂ in the plasma in 1963. Later in 1963, methyl Cbl was demonstrated to be the cofactor required for methylation of homocysteine to methionine by *N*⁵-methyltetrahydrofolate (*N*⁵-methyl-THF-glu₁₋₅) via methionine synthase. By 1979 the biosynthetic pathways of vitamin B₁₂ had been elucidated and its synthesis was achieved.

The history of the clinical relevance of vitamin B₁₂ deficiency has been reviewed by Weatherall (3) and Wickramasinghe (4). Deficiency of vitamin B₁₂ produces two

diseases in man, megaloblastic anemia and a specific neuropathy called vitamin B₁₂-associated neuropathy or subacute combined degeneration of the cord. These complications are seen mainly in pernicious anemia, the first description of which has been variously ascribed to James Coombe (1824), Thomas Addison (1855), and Anton Biermer (1872) (4). Paul Ehrlich first described megaloblastosis in the bone marrow (1880) (4). German physicians described the neuropathic appearance of the spinal cord as a *lachen felden* (field of holes), and in 1990, the clinical syndrome was described in detail.

The disease was universally fatal in 1 to 3 years following diagnosis. The therapeutic breakthrough came in 1926 when George Minot, working with William Murphy, demonstrated that feeding a daily diet of lightly cooked beef liver induced a remission of the anemia within months. Subsequently, beef was shown to contain an extrinsic factor (vitamin B₁₂) that required an intrinsic factor (IF) for its normal absorption. IF was produced by the gastric secretion of normal stomachs but not those of patients with pernicious anemia. IF was shown to complex with vitamin B₁₂ to produce an “anti pernicious anaemia principle” that was required for its uptake and transport by a specific receptor on the ileal enterocytes in the terminal ileum in man.

CHEMISTRY AND NOMENCLATURE

Vitamin B₁₂ is a member of a family of related molecules called corrinoids, a term used for all compounds that contain a corrin nucleus made up of a tetrapyrrolic ring structure (Fig. 27.1). The corrinoids and their related compounds are discussed elsewhere (5).

Figure 27.1. Structure of vitamin B₁₂.

The center of the tetrapyrrole contains a cobalt ion that can be variously attached to methyl, deoxyadenosyl, hydroxy, or cyano groups. The former two are the naturally active forms, the latter two are converted into them in vivo. The methyl form attaches to

methionine synthase, and the adenosyl form to methylmalonyl CoA mutase.

NUTRITION/DIETARY CONSIDERATIONS

Vitamin B₁₂ is synthesized by bacteria, which is its only source. It is present in virtually all forms of animal tissues, which acquire the vitamin indirectly from bacteria. Thus, vitamin B₁₂ is not present in plants and thus does not occur in vegetables or fruit. The dietary intake of vitamin B₁₂ is about 5 µg/day when it is complexed with IF, which is the maximum capacity of the ileal receptors (5). When pharmacologic doses are used, 1% of the dose is absorbed by passive diffusion.

The highest levels of dietary vitamin B₁₂ occur in animal liver, reflecting the fact that 50% of the body stores are in this organ. Levels in excess of 100 µg/100 g occur in beef and mutton. Dietary meat and fish are also good sources of the vitamin (5). By contrast, the level of the vitamin is 0.36 µg/100 mL in cow's milk and is 0.04 µg/100 mL in human milk from Caucasian mothers on a mixed diet. This level falls by a factor of 3 to 4 in mothers on a strict vegetarian diet (5).

The vitamin B₁₂ dietary requirements for children, adult males, and females, and during pregnancy and lactation are described elsewhere (6) (Table 27.1) (see also Appendix Table II-A-2-a-1, Table II-A-2-a-2, Table II-A-2-a-3 and Table II-A-2-c-1 [U.S.A.], Table II-A-3-b [Canada], and Table II-A-7-a, Table II-A-7-b and Table II-A-7-c [Australia]). Dietary intake may be low in elderly patients and in strict vegetarians (also termed *vegans*). This can produce low serum vitamin B₁₂ levels and raised levels of the substrates of the two mammalian enzymes for which vitamin B₁₂ is a coenzyme, namely, methylmalonic acid (MMA) and the total of homocysteine and homocystine (tHcy). The evidence that these plasma changes induce significant megaloblastic anemia or neuropathy remains tentative. These changes may signal the presence of cobalamin-responsive neuropsychiatric symptoms (7).

ABSORPTION AND TRANSPORTATION

The cobalamins are bound with high affinity by glycoproteins, a group of proteins with varying carbohydrate component that have similar antigenic properties and occur in all mammalian tissues. One of them, IF, is required for normal absorption of vitamin B₁₂. The other glycoproteins include haptocorrins (Hc) (also called R binders, TC I and III, or cobalaphilin) and TC II. TC II binds to vitamin B₁₂ in the terminal ileal cells and transports it in the plasma to the cells of the body (8). Absorption of vitamin B₁₂ via IF and its specific IF ileal enterocyte cell-wall receptor (IFCR), and its transport by TC II in the body, summarized in [Figure 27.2](#) is discussed in detail elsewhere (9, 10).

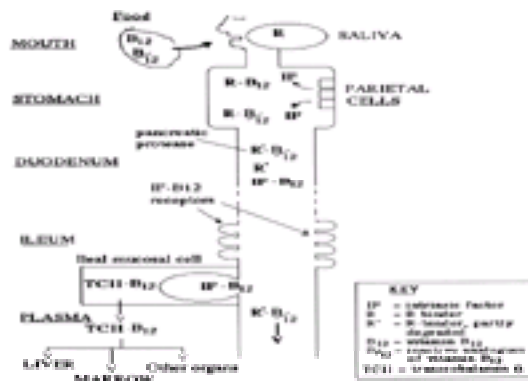

Figure 27.2. Mechanism of vitamin B₁₂ absorption.

Characterization of the cDNA on chromosome II encoding IF synthesis demonstrated both its source and structure. Human IF is secreted by gastric parietal cells but is also present in fundal chief cells and antral G cells of the gastric mucosa and in the salivary glands (9). IF secretion depends on a variety of stimuli, including gastric histamine and acetylcholine. Both IF and TC II bind to the α -axial ligand of cobalamin. For cobalamins to bind IF and TC II requires a rearrangement of their Co-N bond. Thus IF and TC II cannot bind noncobalamin corrinoids. Haptocorrins are more nonspecific because they bind to the corrin ring of the corrinoid.

In the stomach, dietary vitamin B₁₂ is initially released from its organic binding by the action of gastric acid and pepsin. The vitamin, which is predominantly methyl Cbl and adoCbl, is then bound by Hc, which has a markedly higher affinity for Hc than for IF at acid pH. In the intestine, however, the pH rises and this in combination with the partial proteolytic digestion of the Hc binder by pancreatic enzymes that do not affect IF, leads to vitamin B₁₂ being released and transferred to IF. Only IF-bound Cbl is absorbed by

the IFCR.

Hc-bound cobalamins are not absorbed and are excreted in the feces. The function of Hc in the intestinal lumen may well be to remove cobalamin analogues produced by food preservative techniques, cooking, and intestinal microflora, which might otherwise interfere with transfer of vitamin B₁₂ to IF or have toxic effects if absorbed.

The IFCR consists of two b units situated in the ileal cell wall, with two flanking a units that bind to IF glycoprotein and lock the IF-Cbl complex into the receptor (9). Up to 0.2% of the total body pool of cobalamin is excreted per day in bile, bound to Hc. Also, apoptosis of intestinal mucosal cells containing cobalamin occurs at a constant rate. The partial proteolytic removal of Hc from cobalamin and subsequent reabsorption of the latter by the IFCR in the terminal ileum may constitute an enterohepatic cycle of the vitamin that amounts to more than 1.0 µg vitamin B₁₂ per day. This may explain why vitamin B₁₂ absorption specifically occurs in the final 60 cm of the ileum.

IF-bound OH-cobalamin uptake by the IFCR in the brush border microvilli of the ileal mucosal cells depends on the presence of calcium, a pH above 6, and components in bile. Once internalized in the ileal cell by endocytosis, cobalamin is liberated and IF degraded by separate mechanisms related to the prelysosomal acidic region. The absorbed cobalamin is converted to methyl Cbl and adoCbl, probably within the mitochondria of the ileal cell, and appears in the portal blood bound to TC II approximately 3 hours after absorption (9). TC II, whose half-life is only 6 minutes (11), is essential for physiologic transport of cobalamins to all cells in the body where it is endocytosed by specific cell wall receptors (10). In man, in contradistinction to other animals, 90% of cobalamin circulating in the blood is bound to TC I, whose half-life is 9.3 to 9.8 days. TC I-bound Cbl is probably only available to vitamin B₁₂ storage cells such as liver and reticuloendothelial cells (11).

METABOLISM

The TC II-Cbl complex is internalized by adsorptive endocytosis using a specific high-affinity cell surface receptor, as discussed by Fenton and Rosenberg (10). TC II is then degraded by lysosomal proteases, releasing the cobalamin, which exits from the lysosome and is converted to either methyl Cbl in the cytosol, where it binds to methionine synthase, or to adoCbl in the mitochondria, where it binds to methylmalonyl-CoA mutase. Methionine synthase and methylmalonyl-CoA mutase are synthesized by the endoplasmic reticulum. The former remains in the cytosol, and the latter in the mitochondria. Both are 90 to 100% in the holo form. A potential alternative mechanism of taking up TC I-Cbl into hepatocytes is reviewed elsewhere (10).

The total body content of vitamin B₁₂ in adults is 3 to 5 mg, of which 50% is in the liver (5). AdoCbl accounts for more than 70% of cobalamin in liver, erythrocytes, brain, and kidney; methyl Cbl accounts for only 1 to 3%. Plasma cobalamin is mainly methyl Cbl (60–80%); the remainder is OH-Cbl and adoCbl. Since 90% of circulating cobalamin is bound to TC I, most of the methyl Cbl must travel with this Hc. The significance of these

dramatic differences in distribution is unclear.

Excretion of cobalamin occurs via cellular apoptosis into the gastrointestinal tract, kidney, and skin. This is exceedingly slow, since total gastrectomy, which reduces physiologic cobalamin absorption to virtually zero, only produces a cobalamin deficiency sufficient to induce megaloblastic anemia after a period of 4 to 7 years (5). As explained above, this is due to the reabsorption of secreted vitamin B₁₂ by the IFCR, forming an enterohepatic circulation.

FUNCTIONS

The two enzymes for which vitamin B₁₂ is a coenzyme in mammalian cells are methylmalonyl-CoA mutase and methionine synthase.

Mechanisms of Action of Methionine Synthase

Crystallization of *Escherichia coli* methionine synthase by Ruma Banerjee and colleagues has allowed description of how one 27-kDa domain of its total 136kDa binds to methyl Cbl (12) (Fig. 27.3) (see [2] for references and discussion). This protein binds dimethylbenzimidazole, the a ligand of vitamin B₁₂, in a hydrophobic pocket that is displaced away from the cobalt ligand to the edge of the tetracorrin plate. In its place His⁷⁵⁹ from methionine synthase acts as an axial cobalt ligand. The methyl group on the b ligand, which is itself protected by hydrophobic residues on methionine synthase, is now transferred to homocysteine by a suggested protonation/deprotonation shuttle that converts six-coordinate Cob (III) to four-coordinate Cob (I). Cob (I) is then remethylated back to Cob (III) either by N⁵-methyl-THF-Glu, which is the usual sequence, or in the event of Cob (I) becoming oxidized to Cob (II), which occurs every 100 to 2000 cycles in vitro, by the universal methylator AdoMet (2). The interesting potential for methionine synthase to shuttle both Cob (II) and Cob (I) to Cob (III) may also explain how the 5'-deoxyadenosyl B ligand of cobalamin is used by the mutase enzymes that use the Cob (II) cofactor form (2). The ability of Cob (II) to shuttle to Cob (III) suggests that methionine synthase might have a similar ligand to the adoCbl-requiring mutase enzymes, since recent evidence suggests a similar linkage of the dimethylbenzimidazole a ligand-binding pocket and His⁷⁵⁹ to the a Cob-N ligand (2).

Figure 27.3. Mechanism of cobalamin involvement in methionine synthase. Reprinted from Stubbe J. Science 1994;266:1663–4, with permission.

Mechanism of Action of Methylmalonyl-CoA Mutase

Methylmalonyl-CoA mutase requires adoCbl as a cofactor. The associated disturbances caused by adoCbl deficiency and defects of methylmalonyl-CoA mutase function have been reviewed elsewhere (10, 13). A series of compounds, including the amino acids, valine, isoleucine, methionine, and threonine, along with cleavage products of cholesterol, thymine, and odd-chain fatty acids, is then metabolized via propionyl-CoA or methylmalonyl semialdehyde to methylmalonyl-CoA. At high concentrations propionyl-CoA can, in association with oxaloacetic acid and citrate synthase, produce 2-methylcitric acids I and II. S-Methylmalonyl-CoA is usually converted to succinyl-CoA via S, R-methylmalonyl-CoA racemase, and subsequently the adoCbl-dependent R-methylmalonyl-CoA mutase. In the context of vitamin B₁₂ deficiency, methylmalonyl-CoA mutase function is impaired and S-methylmalonyl-CoA is then converted to MMA via a non-vitamin-B₁₂-dependent enzyme, S-methylmalonyl-CoA hydrolase. MMA is in turn converted to unknown metabolites. Consequently, in vitamin B₁₂ deficiency, levels of methylmalonyl-CoA, its hydrolytic product MMA, and 2-methylcitric acids I and II are elevated in both plasma and urine (14).

Biochemistry of Methylcobalamin and Methionine Synthase

Methionine synthase stands at the junction between two important metabolic processes of internal metabolism: the synthesis of DNA and RNA via purine and pyrimidines and the methylation reactions via AdoMet (15, 16) (Fig. 27.4). These processes are achieved in the main via passage of carbon moieties from serine, which is easily synthesized from glucose. The β carbon of serine via serine hydroxymethyltransferase and THF-glu₅ synthesizes N⁵,N¹⁰-methylene-THF-glu₅ and glycine in the cytoplasm. The glycine carbon 2 can also be used to produce N⁵,N¹⁰-methylene-THF-glu₅ via a complex reaction that is only found in mitochondria (16). N⁵,N¹⁰-methylene-THF-glu₅ then stands at a metabolic crossroads. It can (a) synthesize thymidylate from deoxyuridylate monophosphate, which in turn produces one of the pyrimidine bases of DNA, (b) be converted to N¹⁰-formyltetrahydrofolate pentaglutamate, which is used for the insertion of carbons 2 and 8 into the purine ring, or (c) be reduced via methylene reductase to N⁵-methyl-THF-glu₅, which is used to remethylate homocysteine to produce first methionine via methionine synthase and then adoMet via the S-adenosylmethionine synthetase (see Chapter 26).

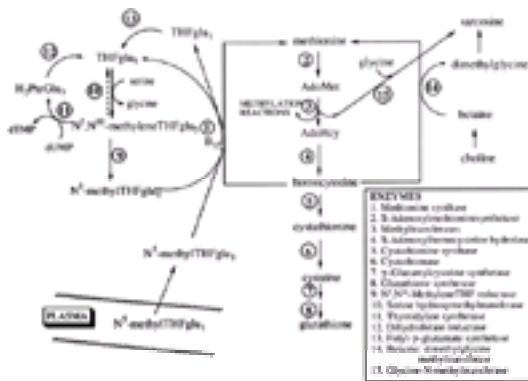

Figure 27.4. Biochemistry of methyl Cbl and methionine synthase.

The other function of methionine synthase is to act as the gatekeeper for entry of folate into the cell. Folate circulates in the plasma as N^5 -methyl-THF-glu₁. When it enters a cell, it can only remain inside if it is immediately demethylated by conversion of homocysteine to methionine and THF-glu₁ via methionine synthase. THF-glu₁ is then converted to THF-glu₅ via folyl-g-glutamyl synthetase. This enzyme has been synthesized and cloned; its function is described in detail elsewhere (17) (see [Chapter 1](#)). Since the avidity of methionine synthase for N^5 -methyl-THF-glu₁ is orders of magnitude lower than for N^5 -methyl-THF-glu₅, N^5 -methyl-THF-glu₁ is only demethylated by methionine synthase if there is no N^5 -methyl-THF-glu₅ available. This occurs on two occasions: (a) during cell division, when the cell reduces its intracellular folate content by 50% and the daughter cells must take up plasma folate to bring the intracellular folate level back to normal, and (b) when deficiency, inhibition, or impaired function of methylene reductase reduces synthesis of N^5 -methyl-THF-glu₅.

Control of Methionine Synthase Function

The relative availability of the substrates of methionine synthase, tHcy and N^5 -methyl-THF-glu, and of its cofactor methyl Cbl control its activity. These in turn are strictly regulated by the amount of dietary methionine and its product, AdoMet, in the cell (15) (see [Chapter 34](#)).

At times of dietary methionine excess, the level of AdoMet, the universal methylator, is high. This maintains the methylation reactions that are essential for internal metabolism, especially in the liver, pancreas, kidney, and brain. So far, 35 methylation reactions have been described in mammalian cells. These methylation reactions are controlled by the product of the methylation process, AdoHcy, which is a competitive inhibitor of AdoMet. Thus, the ratio of AdoMet to AdoHcy, the so-called methylation ratio, controls these methylation reactions to varying extents. The one exception is glycine-*N*-methyl transferase, which converts glycine to sarcosine via AdoMet. This enzyme is controlled

not by AdoHcy but by N^5 -methyl-THF-glu (16). So, in the liver, when methionine and AdoMet are in excess, AdoMet is demethylated by glycine- N -methyltransferase to form AdoHcy and sarcosine. AdoHcy is then converted to adenosine and tHcy by AdoHcy hydrolase. tHcy, when present in high concentrations, is catabolized via cystathionine synthase, the so-called transulfuration pathway, to cystathionine, cysteine, and glutathione. It is important for the cell to maintain the normal concentration of tHcy. Homocysteine, if it accumulates, will tend to re-form AdoHcy via AdoHcy hydrolase, since the equilibrium constant of the reaction strongly favors the back reaction (16a).

These events are controlled by the level of Adomet. Adomet in excess causes (a) inhibition of methylene reductase, the enzyme responsible for conversion of N^5, N^{10} -methylene-THF-glu₅ to N^5 -methyl-THF-glu₅ (the latter is therefore not available either to remethylate homocysteine back to methionine via methionine synthase or to inhibit glycine- N -methyl transferase) and (b) activation of hepatic cystathionine synthase which controls the transulfuration pathway. In other cells such as nerve cells the catabolic pathway is less important.

When dietary methionine is lacking, the reverse occurs. AdoMet is now reduced, threatening the methylation reactions, and inhibition of methylene reductase is released, allowing synthesis of N^5 -methyl-THF-glu₅ which is then available (a) to remethylate whatever tHcy is available to maintain methionine levels and (b) to inhibit glycine- N -methyl transferase and accordingly prevent removal of the now scarce AdoMet. Furthermore, AdoMet deficiency reduces cystathionine synthase induction, which is necessary for the catabolic transulfuration pathway described above, to retain available tHcy for remethylation and methionine synthesis. tHcy conversion to cystathionine occurs via cystathionine synthase, which has a high K_m , while remethylation of Hcy to methionine via methionine synthase has a low K_m . The result is that under normal circumstances Hcy is remethylated rather than catabolized at a ratio of 3:1(18). The catabolic pathway may only become dominant postprandially following a high cellular influx of exogenous methionine (19). A high tHcy concentration also enhances methionine synthase activity, all available N^5 -methyl-THF-glu₅ being used to synthesize methionine (20).

Pathogenesis

In contradistinction to the checks and counterchecks that exist to control the supply of AdoMet via folate and methionine (described above), the body has no mechanisms to control the effects of vitamin B₁₂ deficiency. This results in a series of clinical complications:

Definite association

1. Megaloblastic anemia
2. Neuropathy associated with vitamin B₁₂

Possible association

3. Atheroma causing coronary thrombosis, strokes, and peripheral vascular disease
4. Neural tube defects
5. Hepatic steatosis

DISEASES ASSOCIATED WITH METHYLCOBALAMIN DEFICIENCY

Megaloblastic Anemia

The inhibition of methionine synthase resulting from vitamin B₁₂ deficiency leads to reduced synthesis of methionine and THF-glu₅ and accumulation of tHcy and N⁵-methyl-THF-glu₅ (21) (see [Chapter 88](#)). The reduction in THF-glu₅ leads to reduced availability of N⁵,N¹⁰-methylene-THF-glu₅ for conversion of deoxyuridine monophosphate to thymidylate for DNA synthesis. The deficiency is further exacerbated by reductions in methionine and Adomet levels. This, as explained above, leads to reduced suppression of methylene reductase, which causes whatever N⁵,N¹⁰-methylene-THF-glu₅ was available for thymidylate synthesis to be converted to N⁵-methyl-THF-glu₅, which under physiologic conditions is an irreversible reaction. This forms the basis of the “methyl trap” hypothesis for production of megaloblastic anemia in vitamin B₁₂ deficiency.

Since N⁵-methyl-THF-glu₁, the form of folate taken up by the cell from the plasma, is a poor substrate for folyl-g-glutamate synthetase (17), N⁵-methyl-THF-glu₁ is very poorly incorporated into the methyl Cbl-deficient cell. The resultant cellular THF-glu₅ deficiency in turn causes intracellular folate deficiency. The *megaloblastic anemia* induced by vitamin B₁₂ deficiency is caused by this intracellular folate deficiency. It is thus not surprising that it is morphologically identical to that associated with folate deficiency, as described elsewhere (4) (see also [Chapter 88](#)).

Neuropathy Associated with Vitamin B₁₂ Deficiency

The neuropathy associated with vitamin B₁₂ deficiency has been described elsewhere ([7, 22] and [Chapter 95](#)). The pathogenesis of the neuropathy relates to changes in the methylation ratio (23). As explained above, the ratio of AdoMet to AdoHcy in brain tissue is usually greater than 4:1. When methionine synthase is inhibited because of vitamin B₁₂ deficiency, homocysteine and AdoHcy accumulate, and methionine and AdoMet synthesis is impaired, causing the methylation ratio to fall. The methylation reactions are inhibited, inducing a state of hypomethylation and impaired synthesis of (among others) myelin basic protein. Other organs such as the liver and kidney can remethylate homocysteine to methionine via betaine methyltransferase at the same time as it converts betaine to dimethylglycine ([Fig. 27.4](#)). However, the brain does not possess

betaine methyltransferase and relies on methionine synthase for endogenous synthesis of methionine and AdoMet at times of dietary methionine deprivation. Evidence that this complication is related to a derangement of the relationship between AdoMet and AdoHcy is discussed in detail elsewhere (23).

Neuropathy Induced in Animals by Nitrous Oxide (N₂O) Inhalation. Chronic inhalation of N₂O leads to a neuropathy in the monkey that is histologically similar to the neuropathy associated with vitamin B₁₂ deficiency in the human. N₂O irreversibly inhibits methionine synthase, and oral methionine given prophylactically significantly ameliorates the lesion. N₂O-induced neuropathy in the pig is associated with a fall in the brain methylation ratio, which in turn reduces brain O and N protein methylation. The particular protein hypomethylation that leads to the neuropathy remains to be determined.

Neuropathy Associated with N₂O Inhalation in Humans. Acute N₂O inhalation produces megaloblastic anemia, while chronic intermittent N₂O inhalation induces a neuropathy similar to vitamin B₁₂ deficiency (7). Patients who are already vitamin B₁₂ deficient are at particular risk of N₂O-induced neuropathy, which can be prevented by pretreatment with methionine (24).

Congenital Deficiency of Enzymes Concerned with AdoMet Synthesis. Congenital deficiency of methylene reductase, methionine synthase, and AdoMet synthase (25, 26) and inborn errors of methylcobalamin synthesis (Cbl E and G) (26) lead to changes similar to those in the vitamin B₁₂-deficient brain. Methylene reductase malfunction in particular causes AdoMet deficiency and the neuropathy, because the ensuing deficiency of N⁵-methyl-THF-glu₅ would (as explained above) lead to enhanced glycine methyl transferase activity. Thus AdoMet would continue to be demethylated, producing AdoHcy and sarcosine, even when AdoMet levels were low. The absence of any anemia in methylene reductase-deficient patients who get the neuropathy is strong clinical evidence in favor of the methyl trap hypothesis. The clinical presentation of the neuropathy has been described elsewhere (7).

Atheroma

Raised levels of tHcy in the blood and urine are a risk factor for vascular disease, whether affecting coronary, carotid, or peripheral artery and peripheral veins. The raised tHcy levels are usually caused by an abnormality in, or impaired function of, one of the three enzymes that control homocysteine metabolism (27). Cystathionine synthetase deficiency blocks the transsulfuration pathway, which produces the classical form of homocysteinemia. Reduced activity of methylene reductase induces a deficiency in N⁵-methyl-THF-glu₅ and impairs remethylation of tHcy as do cobalamin mutants (Cbl C, D, E, and G) that impair the function of methionine synthase (Fig. 27.4) (26).

Dietary deficiency of the vitamins folate, cobalamin, and pyridoxine (Chapter 24) also raises homocysteine levels (14), especially in the elderly, since these vitamins are

essential for the normal function of methylene reductase, methionine synthase, and cystathionine synthase, respectively. It seems probable that elevating tHcy levels long enough to induce atheromatous changes in the arterial endothelium may require both a genetic variant relating to one of three enzymes and a deficiency of the relevant vitamin. In particular, this is probably true of folate deficiency in association with the thermolabile variant of methylene reductase (27). Pernicious anemia patients do not have an increased incidence of atherosclerosis at autopsy, for reasons that are currently obscure. It may relate to the relative duration of the raised tHcy before diagnosis and treatment (28).

Neural Tube Defects

One study has suggested that deficiency of vitamin B₁₂, as well as folic acid, is a risk factor for neural tube defects (29). (See discussion elsewhere [30] and [Chapter 34](#) and [Chapter 95](#).)

Hepatic Steatosis

The pathogenesis of hepatic steatosis is associated with methionine and choline deficiency, and ethanol is also known to inhibit methionine synthase (31).

Mechanisms of Cobalamin Deficiency/Malfunction

Dietary Deficiency

Vegans who eat no animal-derived food develop vitamin B₁₂ deficiency (5). Functional deficiency of vitamin B₁₂ is common in the elderly, especially those living in institutions. The effect of dietary deficiency in the pathogenesis of vitamin B₁₂-related diseases remains uncertain, especially since (as explained above) the enterohepatic circulation preserves vitamin B₁₂ that would otherwise be lost by gastrointestinal secretion and apoptosis.

Disorders of Cobalamin Absorption

The methods whereby vitamin B₁₂ is malabsorbed have been discussed elsewhere (9, 10).

Malabsorption of Food Cobalamin. Patients with hypochlorhydria, such as occurs in the elderly and postgastrectomy patients, may exhibit malabsorption of dietary cobalamin. Gastric acid releases cobalamin from its organic setting in food before it is taken up by Hc binders in the acidic pH of the stomach (32). Nevertheless, there is a discrepancy between patients who have low plasma vitamin B₁₂ levels and those with impaired absorption. Patients with Hc deficiency and myelopathy have been reported, but the pathogenesis is not understood (10).

Pancreatic Insufficiency. Reduced secretion of pancreatic enzymes and bicarbonate leads to impaired digestion of Hc and elevation of intestinal pH, both of which are necessary for transfer of cobalamin from Hc binders to IF. This is the mechanism of the cobalamin malabsorption that characterizes chronic pancreatic diseases (9).

Pernicious Anemia. The amount of IF secreted by normal subjects exceeds what is required to capture the Hc-bound B₁₂ released in the alkaline milieu of the duodenum. The number of upper intestinal sites now known to synthesize and secrete IF means that gastric atrophy alone probably cannot suffice to reduce the luminal IF concentration below a critical level. Antibodies to IF, which inhibit the function of any remaining IF produced by sites outside the gastric mucosa, are also necessary. Two types of antibodies, “blocking” and “binding,” occur both in the serum, where they are innocuous, and in the intestinal lumen. These antibodies adhere to different sites on the IF-cobalamin complex and interfere differently with its uptake by the ileal IFCR, thus causing cobalamin malabsorption.

Congenital forms of impaired IF secretion also occur. One fails to produce an immunologically recognizable IF. Another produces a binder that is immunologically reactive to IF antibodies but is physiologically inactive because of a lack of affinity with the ileal IFCR.

Grasbeck-Immerslund Syndrome. The Grasbeck-Immerslund syndrome is associated with a low serum vitamin B₁₂ level, megaloblastic anemia, and normal gastric and intestinal function; it usually presents between 1 and 5 years of age. Cobalamin absorption is not corrected by the addition of normal human IF with vitamin B₁₂. This syndrome is likely to be due to a series of defects in receptor uptake, enzymatic removal of IF, transfer to TC, and export to the portal venous system (8).

Infestation of the Intestinal Lumen. An abnormal connection between the colon and the small intestine or stagnation in diverticula, blind loops, or strictures leads to contamination of the small intestine with colonic bacteria at concentrations greater than 10⁵ organisms per dL. This constitutes the “contaminated small bowel syndrome,” characterized by steatorrhea and vitamin B₁₂ deficiency. The latter is caused by competitive uptake of cobalamins by the microorganisms.

Diphyllobothrium latum, a fish tapeworm that infests the upper intestine, is a further example of competition for the vitamin between host and parasites. It occurs particularly in Scandinavian countries.

AIDS. Patients with AIDS are known to develop plasma vitamin B₁₂ deficiency, thought to be due to a failure of IF-B₁₂ complex uptake by the ileal IFCR. The pathogenic significance, if any, remains to be determined (33).

Disorders of Transport

Transcobalamin II deficiency usually presents within the 1st or 2nd month of life. It is potentially lethal and is associated with vomiting, weakness, failure to thrive, and megaloblastic anemia. Neurologic complications ensue associated with immunological deficiencies. The defect in TC II takes different forms: it may be absent, may be immunologically normal but fail to bind cobalamin, or may bind cobalamin but not be taken up by cell-wall receptors. The level of circulating serum vitamin B₁₂ is normal, since in humans 90% is bound to TC I(9).

Transcobalamin I deficiency may also occur, but since it has no significant physiologic function, it is not associated with any known disease state.

Inherited Disorders of Cobalamin Metabolism

The inherited disorders of cobalamin metabolism, described elsewhere (1, 9) (Fig. 27.5), may be of particular interest because milder variants similar to those described for methylene reductase may exist but be undiscovered. Any cyano- or hydroxycobalamin in the diet or intestinal lumen that is not converted to adenosyl- or methylcobalamin during absorption and transport is rapidly metabolized to these forms in the cell. Defects in conversion to the active forms of the vitamin produce nine distinct mutant forms of the vitamin (discussed in detail elsewhere [1, 9, 13]).

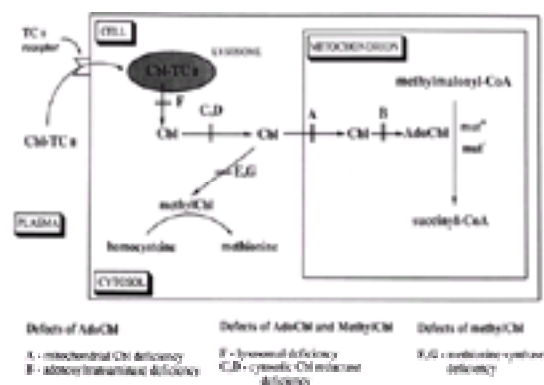

Figure 27.5. Defects of cobalamin metabolism.

Disorders of Adenosylcobalamin (Cbl A and Cbl B) and Methylmalonyl-CoA

Mutase. Two distinct genetic loci are responsible for synthesis of two defective forms of adoCbl, Cbl A and Cbl B. Cbl A and Cbl B differ in the intramitochondrial conversion of OH-Cbl to adoCbl. There are also two distinct variants of methylmalonyl-CoA mutase, one has no mutase in the cells (mut⁰) and the other is abnormal (mut⁻). The only clinical

difference between mut^0 and mut^- and adoCbl A and B is that the former presents within weeks, while Cbl A and Cbl B present later (months to 1 year).

The major metabolic changes are methylmalonic aciduria, metabolic acidosis, ketonemia, hyperammonemia, hyperglycinemia, and hypoglycemia. Bone marrow suppression in the form of anemia, leukopenia, and thrombocytopenia may also be present. Neither megaloblastic anemia nor neurologic disease occur (9, 13).

Defects of Cellular Methyl Cbl and AdoCbl Synthesis. Three mutant cobalamins (Cbl C, Cbl D, and Cbl F) are characterized by methylmalonic acidemia, homocysteinemia with or without hypercystathionemia and hypomethionemia, and megaloblastic anemia. Patients may present early with failure to thrive or in early adulthood with neurologic disorders such as dementia and myelopathy. In contrast to Cbl A and Cbl B mutants, hyperglycinemia and hyperammonemia does not occur. Cbl C, the commonest and most severe of these mutations, may also result in muscular hypotonia, developmental delay, microcephaly, seizures, and ocular retinal changes (9). Cbl D, a rarer and less severe mutant, is associated with neuromuscular abnormalities, and Cbl F has a similar clinical picture, which is occasionally associated with abnormal vitamin B₁₂ absorption and a low serum cobalamin level. Cbl C and D are due to defects in cytosolic metabolism, and Cbl F to a defect in lysosomal efflux. Treatment of these disorders with parenteral hydroxycobalamin produces a variable response.

Defects in Methyl Cbl Synthesis. Cbl E and Cbl G (1, 9, 26) represent defects in methyl Cbl synthesis. Patients exhibit failure to thrive and vomiting. They have marked neurologic abnormalities that take the form of microcephaly, seizures, impaired development, and hypotonia. Megaloblastic anemia occurs in association with raised homocysteine levels, hypomethioninemia, and no methylmalonic aciduria.

One 21-year-old patient with the Cbl G mutant presented with gait disturbances and progressively impaired sensation, closely resembling the changes found in the neuropathy associated with cobalamin deficiency. These defects appear to reflect a mutation affecting the maintenance of cobalamin I in the reduced state (Cbl E) and in the cobalamin-binding domain of methionine synthase (Cbl G).

STANDARD TECHNIQUES FOR DIAGNOSIS OF COBALAMINE DEFICIENCY

Hematologic Parameters

The classical textbook features of Cbl deficiency include anemia with macrocytosis and a megaloblastic anemia. However, it is now appreciated that significant Cbl deficiency can occur leading to neurologic dysfunction in the absence of any of these parameters (7).

Serum Cobalamin Assay

In most laboratories the serum Cbl assay remains the standard method for diagnosing deficiency, defined as less than 150 pg/mL. However, significant deficiency may occur in the face of low normal, or only marginally reduced, levels of serum Cbl, especially in the elderly. Objective evidence of Cbl deficiency has been found in patients whose available serum Cbl ranges from 200 to 300 pg/mL and even on occasions more than 300 pg/mL.

Whether the radioimmunoassay used in most laboratories is as specific or sensitive as the bioassay using *Leishmanii donovani* remains controversial. The radioassay, by its nature, must include Cbl bound to TC I, which is biologically inactive. This gives a falsely high reading for the serum Cbl. Recent improvements in the stability, reproducibility, and efficiency of the microbiologic assay by using cryopreservation, a colistin sulfate-resistant organism and b-lactamase to hydrolyze interfering antibiotics have made it the assay of choice (34). It is suggested that measuring holo TC II is a better method of assessing early cobalamin deficiency (35). Measurement of the substrates of the two Cbl-dependent enzymes, MMA and Hcy, is a new and more accurate method of assessing the presence of intracellular cobalamin deficiency (14, 28).

Methylmalonic Acid

The factors controlling MMA levels in the plasma are not well understood. Normal variations in dietary intake do not affect the plasma levels. Since intestinal organisms can produce propionic acid, a source of MMA in the body, antibiotics may lower plasma MMA levels (7). MMA is excreted in the urine, which results in a good correlation between plasma and urine concentrations. However, plasma MMA levels rise in the presence of renal failure. Plasma MMA levels rise in cobalamin deficiency but not in folate deficiency. In cobalamin deficiency, the plasma levels rise from normal levels of 0.1 to 0.4 $\mu\text{mol/L}$ to 50 to 100 $\mu\text{mol/L}$ (36). These high levels may result in both MMA and propionate being incorporated into odd-carbon branched-chain fatty acids and 2-methylcitrate (36). MMA in urine or plasma is thus a sensitive measure of absolute and/or functional cobalamin deficiency, especially in the diagnosis of subclinical cobalamin deficiency in the elderly.

Plasma MMA levels appear to be more specific than homocysteine levels and are significantly better than serum cobalamin levels. Apparently normal individuals with normal serum cobalamin have had elevated MMA levels that fell following a single injection of cyanocobalamin. Furthermore, elevated MMA and homocysteine levels have been observed to predate the drop in serum cobalamin (36).

Homocysteine

Plasma homocysteine is derived in the main from dietary methionine, although the levels obtained are also affected by dietary cobalamin, folate, and pyridoxine, the vitamin cofactors associated with its metabolism (see above). Normal plasma homocysteine levels are higher in men than in women up to the menopause and increase with age, especially after the age of 60 (37). Erect posture also gives

significantly higher homocysteine levels than being prone, which probably reflects changes in plasma albumin binding (C. Cronin and colleagues, unpublished data). Renal excretion of homocysteine accounts for only 1% of the total homocysteine synthesized; nevertheless, plasma homocysteine rises in chronic renal failure.

Plasma homocysteine levels rise in (a) deficiency states of folate, cobalamin, and pyridoxine, (b) inborn errors of the enzymes associated with homocysteine metabolism, namely cystathionine synthetase, methylene reductase, and methionine synthase, and (c) defects associated with the synthesis of the cobalamin coenzymes required for normal function of methionine synthase (see also [Chapter 26](#), [Chapter 34](#) and [Chapter 61](#)). High plasma homocysteine levels have also been reported in hypothyroidism. Low levels occur in insulin-dependent diabetics without renal complications (C. Cronin and colleagues, unpublished data) and in Down's syndrome patients, who have an extra copy of the genes that produce cystathionine synthase ([36](#)). Some 7 to 9% of the normal population have raised plasma homocysteine levels due to genetic abnormalities associated with methylene reductase. The normal range for plasma homocysteine depends on the method used and the sex, age, and posture of the patient as described above; women have 6 to 12 $\mu\text{mol/L}$ and men 8 to 14 $\mu\text{mol/L}$ (subjects less than 60 years old).

Methionine loading tests (100 $\mu\text{g/kg}$ body weight) have been used to accentuate abnormalities of the homocysteine metabolic pathways. This technique is mainly used to detect patients with obligate heterozygous cystathionine b-synthase deficiency, since the K_m for this enzyme is relatively high. As the K_m for methionine synthase is low, methionine loading adds little to the standard plasma homocysteine level in diagnosing those with defective remethylation.

Other Metabolites

Cobalamin deficiency is also associated with elevated levels of 2-methyl citrate, *N*-methylglycine, *N*, *N*-dimethylglycine, and cystathionine ([14](#)). What place these metabolites will have in the routine diagnosis of deficiency or defective function has yet to be determined.

SUMMARY

Vitamin B₁₂ is an essential cofactor for two enzymes of internal metabolism.

Methylmalonyl-CoA mutase is involved in the conversion of propionic to succinic acid, which is required for fatty acid metabolism. High levels of MMA are associated with low levels of vitamin B₁₂ and are diagnostic of functional deficiency.

Methionine synthase controls two important processes in internal metabolism: nucleic acid synthesis and the methylation reactions of the body. Deficiency leads to two major clinical complications: megaloblastic anemia and cobalamin-associated neuropathy. Increased levels of a substrate (tHcy) of this enzyme have recently been shown to be associated with early atheromatous disease and may also induce birth defects such as

spina bifida, and hepatic steatosis.

The mechanisms by which cobalamin deficiency occurs and the pathogenesis of the complications induced by such deficiency are described above.

HISTORY OF DISCOVERY

Although a growth requirement for the *bios* fraction had been demonstrated in yeast, Boas first demonstrated the mammalian requirement for a factor, biotin, in rats fed egg white protein. The severe dermatitis, hair loss, and neuromuscular dysfunction was termed *egg-white injury* and was cured by a factor present in liver. The critical event in this egg-white injury of both humans and rats is the highly specific and very tight binding ($K_d = 10^{-15}$ M) of biotin by avidin, a glycoprotein found in egg white. Native avidin is resistant to intestinal proteolysis in both the free and biotin-combined forms. Thus, dietary avidin (e.g., in diets containing uncooked egg white) binds and prevents the

absorption of both dietary biotin and any biotin synthesized by intestinal bacteria.

STRUCTURE, CHEMISTRY, AND BIOCHEMISTRY OF BIOTIN

Structure

The structure of biotin ([Fig. 28.1](#)) was elucidated independently by Kogl and du Vigneaud in the early the 1940s ([1](#)). Eight stereoisomers exist, but only one (designated *d*-(+)-biotin or, simply, biotin) is found in nature and is enzymatically active. Biocytin (*e*-*N*-biotinyl-L-lysine) is about as active as biotin on a molar basis in mammalian growth studies.

Figure 28.1. Biotin metabolism. The specific systems leading to the sulfoxides have not been defined. *HS-CoA*, coenzyme A; *, site of attachment of carboxyl moiety.

Biotin is a bicyclic compound. One of the rings contains a ureido group (-N-CO-N-). The tetrahydrothiophene ring contains sulfur and has a valeric acid side chain. The Goldberg/Sternbach synthesis or modifications thereof is the method by which biotin is synthesized commercially ([1](#)). Additional stereospecific methods of synthesis have been published recently ([2](#), [3](#)).

Regulation

In mammals, biotin is an essential cofactor for four carboxylases, each of which catalyzes a critical step in intermediary metabolism—incorporation of bicarbonate as a carboxyl group into a substrate. All four use a similar catalytic mechanism. Attachment of biotin to the apocarboxylase ([Fig. 28.1](#)) is a condensation reaction catalyzed by holocarboxylase synthetase. An amide bond is formed between the carboxyl group of the valeric acid side chain of biotin and the *e*-amino group of a specific lysyl residue in the apocarboxylase; these apocarboxylase regions contain sequences of amino acids that tend to be highly conserved within and between species for the individual

carboxylases.

Regulation of intracellular mammalian carboxylase activity by biotin remains to be elucidated; however, the interaction of biotin synthesis and production of holoacetyl-CoA carboxylase in *Escherichia coli* has been studied extensively (4, 5). The biotin-protein ligase (specifically a holoacetyl-CoA carboxylase synthetase) catalyzes formation of the covalent bond between biotin and a specific lysine residue in the biotin carboxylase carrier protein (BCCP) of acetyl-CoA carboxylase. As with the four mammalian carboxylases, biotinylation of the apocarboxylase proceeds in two steps. First, the holocarboxylase synthetase reacts with biotin and ATP to form a complex between the synthetase and biotinyl-AMP, releasing pyrophosphate. If a suitable amount of apo-BCCP is present, the holocarboxylase is formed and AMP is released. If insufficient apo-BCCP is present, the holocarboxylase synthetase:biotinyl-AMP complex acts to repress further synthesis of biotin by binding to the promoter regions of the biotin operon ("bio"). These promoters control a cluster of genes encoding enzymes that catalyze biotin synthesis, including biotin synthetase, the enzyme complex that converts dethiobiotin to biotin. Biotinyl-AMP acts as a corepressor through its role in the holocarboxylase synthetase:biotinyl-AMP complex. Thus, the rate of biotin synthesis is responsive to both the supply of apo-BCCP and the supply of biotin as reflected in the biotinyl-AMP concentration.

Chemistry

In the carboxylase reaction, the carboxyl moiety is first attached to biotin at the ureido nitrogen opposite the side chain; then the carboxyl group is transferred to the substrate. The reaction is driven by hydrolysis of ATP to ADP and inorganic phosphate. Subsequent reactions in the pathways of the four mammalian carboxylases release CO₂ from the product of the carboxylase reaction. Thus, these reaction sequences rearrange the substrates into more useful intermediates but do not violate the classic observation that mammalian metabolism does not result in the *net* fixation of carbon dioxide.

The common mechanism for the carboxylase reaction begins with tautomerization of the ureido ring, enhancing the nucleophilicity at the two nitrogens in the ureido ring (6, 7). Because of steric hindrance at the 3'-N (same side of the molecule as the valeric acid side chain that joins biotin to the protein backbone of the carboxylase), the 1'-N uniquely reacts with a carbonyl phosphate that was previously formed by the reaction between bicarbonate and ATP. The product of this reaction is the 1'-N-carboxybiotinyl enzyme. This reactive carboxylate group then is incorporated into the substrate, typically at a carbon with incipient carbanion character.

Carboxylases

Three of the four biotin-dependent carboxylases are mitochondrial; the fourth (acetyl-CoA carboxylase, ACC) is found in both mitochondria and the cytosol. Allred and coworkers (1) have postulated that an inactive mitochondrial form of ACC (EC 6.4.1.2) serves as storage for biotin. ACC catalyzes the incorporation of bicarbonate into acetyl-CoA to form malonyl-CoA (Fig. 28.2). This three-carbon compound then serves

as a substrate for the fatty acid synthetase complex; the net result is elongation of the fatty acid substrate by two carbons and the loss of the third carbon as CO₂.

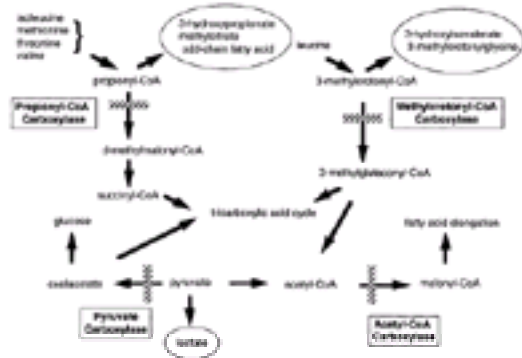

Figure 28.2. Pathways with biotin-dependent enzymes. Deficiencies (*hatched bar*) of PC, PCC, MCC, and ACC lead to increased blood concentrations and urinary excretion of characteristic organic acids denoted by *ovals*.

Pyruvate carboxylase (PC, EC 6.4.1.1) catalyzes the incorporation of bicarbonate into pyruvate to form oxaloacetate, an intermediate in the Krebs tricarboxylic acid cycle ([Fig. 28.2](#)). Thus, PC catalyzes an anaplerotic reaction. In gluconeogenic tissues (i.e., liver and kidney), oxaloacetate can be converted to glucose.

Methylcrotonyl-CoA carboxylase (MCC, EC 6.4.1.4) catalyzes an essential step in the degradation of the branched-chain amino acid leucine ([Fig. 28.2](#)). Deficient activity of this enzyme leads to metabolism of 3-methylcrotonyl-CoA to 3-hydroxyisovaleric acid and 3-methylcrotonylglycine by an alternate pathway ([1](#)). Thus, increased urinary excretion of these abnormal metabolites reflects deficient activity of MCC.

Propionyl-CoA carboxylase (PCC, EC 6.4.1.3) catalyzes the incorporation of bicarbonate into propionyl-CoA to form methylmalonyl-CoA, which undergoes isomerization to succinyl-CoA and enters the tricarboxylic acid cycle ([Fig. 28.2](#)). In a fashion analogous to MCC deficiency, deficiency of PCC leads to increased urinary excretion of 3-hydroxypropionic acid and 3-methylcitric acid ([1](#)).

In the normal turnover of cellular proteins, holocarboxylases are degraded to biocytin or biotin linked to an oligopeptide containing at most a few amino acid residues ([Fig. 28.1](#)). Because the amide bond between biotin and lysine is not hydrolyzed by cellular proteases, the specific hydrolase biotinidase (biotin amide hydrolase, EC 3.5.1.12) is required to release biotin for recycling.

Genetic deficiencies of holocarboxylase synthetase and biotinidase cause the two

distinct types of *multiple carboxylase deficiency* that were previously designated the neonatal and juvenile forms. Biotinidase deficiency is particularly relevant to understanding biotin deficiency because the clinical manifestations appear to result largely from a secondary biotin deficiency. The gene for human biotinidase has been cloned, sequenced, and characterized (8, 9).

Metabolism and Measurement

Instead of being incorporated into carboxylases after entering the pools of biotin and its intermediary metabolites, biotin may be metabolized. About half of biotin undergoes metabolism before excretion. Biotin, bisnorbiotin, and biotin sulfoxide (Fig. 28.1) are present in molar ratios of approximately 3:2:1 in human urine and plasma (1). Two additional minor metabolites, bisnorbiotin methylketone and biotin sulfone, have recently been identified in human urine. Biotin metabolism is induced in some individuals by anticonvulsants and during pregnancy, thereby increasing the ratio of biotin metabolites to biotin (10, 11).

A variety of assays have been proposed for measuring biotin at physiologic concentrations (i.e., 100 pmol/L to 100 nmol/L), and a limited number have been used to study biotin nutriture. For a more detailed review, see Mock (12). All published studies of biotin nutriture have used one of three basic types of biotin assays: (a) bioassays (most studies), (b) avidin-binding assays (several recent studies), or (c) fluorescent derivative assays (two published studies).

Bioassays generally have adequate sensitivity to measure biotin in blood and urine, especially with recent modifications using injected agar plates or metabolic radiometry. However, the bacterial bioassays (and perhaps the eukaryotic bioassays as well) suffer interference from unrelated substances and variable growth response to biotin analogues. Bioassays give conflicting results if biotin is bound to protein (12).

Avidin-binding assays generally measure the ability of biotin (a) to compete with radiolabeled biotin for binding to avidin (isotope dilution assays), (b) to bind to avidin coupled to a reporter and thus prevent the avidin from binding to a biotin linked to solid phase, or (c) to prevent inhibition of a biotinylated enzyme by avidin. A variety of novel reporter systems have recently been described (1). Avidin-binding assays generally detect all avidin-binding substances, although the relative detectabilities of biotin and analogues vary between analogues and between assays, depending on how the assay is conducted. Chromatographic separation of biotin analogues with subsequent avidin-binding assay of the chromatographic fractions appears to be both sensitive and chemically specific.

A problem in the area of biotin analytical technology that remains unaddressed is the disagreement among the various bioassays and avidin-binding assays concerning the true concentration of biotin in human plasma. Reported mean values range from approximately 500 pmol/L to more than 10,000 pmol/L.

ABSORPTION OF BIOTIN

Digestion of Protein-Bound Biotin

Neither the mechanisms of intestinal hydrolysis of protein-bound biotin nor the determinants of bioavailability have been clearly delineated. The content of free biotin and protein-bound biotin in foods is variable, but most biotin in meats and cereals appears to be protein bound. Wolf et al. (13) have postulated that biotinidase plays a critical role in releasing biotin from covalent binding to protein. In patients with biotinidase deficiency, doses of free biotin that do not greatly exceed the estimated dietary intake (e.g., 50–150 µg/day) appear adequate to prevent the symptoms of biotinidase deficiency, suggesting that biotinidase deficiency causes biotin deficiency through impaired intestinal digestion of protein-bound biotin or impaired renal salvage or both.

Intestinal Absorption

Based on the work of Said, Bowman, McCormick, and others (1), a biotin transporter has been demonstrated to be present in the intestinal brush border membrane. Transport is highly structurally specific, temperature dependent, and electroneutral. In the presence of an Na⁺ gradient, biotin transport occurs against a concentration gradient. However, at higher (pharmacologic) concentrations, diffusion predominates.

In rats, biotin transport is upregulated with maturation and by biotin deficiency. Although carrier-mediated transport of biotin is most active in the proximal small bowel of the rat, absorption of biotin from the proximal colon is still significant, supporting the potential nutritional significance of biotin synthesized by enteric flora. Clinical studies have also provided some evidence that biotin is absorbed from the human colon, but studies in swine indicate that absorption of biotin from the lower gut is much less efficient than from the upper intestine; further, biotin synthesized by enteric flora is probably not present at a location or in a form in which bacterial biotin contributes importantly to absorbed biotin (14, 15). Exit of biotin from the enterocyte (i.e., transport across the basolateral membrane) is also carrier mediated, but basolateral transport is independent of Na⁺, is electrogenic, and does not transport biotin against a concentration gradient.

TRANSPORT OF BIOTIN

Transport in Blood from the Intestine

Biotin is probably transported in blood from the site of absorption in the intestine to the peripheral tissues and the liver, but little has been definitively established concerning the mechanism(s) of transport (1). Wolf et al. (16) originally hypothesized that biotinidase might serve as a biotin-binding protein in plasma or perhaps even as a carrier protein for the transport of biotin into the cell. Based on protein precipitation or equilibrium dialysis after incubation with ³H-biotin, Chuahan and Dakshinamurti (17) concluded that biotinidase is the only protein in human serum that specifically binds

biotin. However, using ^3H -biotin, centrifugal ultrafiltration, and dialysis to assess reversible binding in plasma from the rabbit, pig, and human, Mock and coworkers (18) found that less than 10% of the total pool of free plus reversibly bound biotin is reversibly bound to plasma protein; the biotin binding observed could be explained by binding to human serum albumin. Using acid hydrolysis and ^3H -biotinyl-albumin, Mock and Malik (19) found additional biotin covalently bound to plasma protein. The percentages of free, reversibly bound, and covalently bound biotin in human serum are approximately 81%, 7%, and 12%, respectively.

The results of the two approaches discussed above apparently conflict (1). The importance of either type of biotin binding to the transport of biotin from the intestine to the peripheral tissues is not yet clear.

Transport into the Liver

The uptake of biotin by liver and peripheral tissues from mammals has been the subject of several investigations (1). Studies in a variety of cell lines indicate that uptake of free biotin is mediated both by diffusion and by a specialized carrier system that is dependent upon an Na^+ gradient and temperature. Transport is electroneutral and specific for a free carboxyl group, though not as strongly specific for structure as the intestinal transporter.

Additional studies demonstrated the importance of metabolic trapping, presumably as covalently bound biotin in holocarboxylase enzymes (20). After entering the hepatocyte, biotin diffuses into the mitochondria via a pH-dependent process (21).

Transport into the Central Nervous System

A variety of animal and human studies suggest that biotin is transported across the blood-brain barrier (1). The transporter is saturable and structurally specific for the terminal carboxylate group on the valerate side chain. Transport into the neuron also appears to involve a specific transport system as well as subsequent trapping of biotin by covalent binding to brain proteins, presumably carboxylase.

Renal Handling

Specific systems for the reabsorption of water-soluble vitamins from the glomerular filtrate may contribute importantly to conservation of water-soluble vitamins (22). Animal studies indicate that biotin is reclaimed from the glomerular filtrate against a concentration gradient by a saturable, Na^+ -dependent, structurally specific system. Subsequent egress of biotin from the tubular cells occurs via a basolateral membrane transport system that is not Na^+ dependent. Studies in patients with biotinidase deficiency suggest a possible role for biotinidase in the renal handling of biotin.

Placental Transport

Specific systems for transport of biotin from mother to fetus have recently been reported (23, 24 and 25). Studies using microvillus membrane vesicles and cultured trophoblasts detected a saturable transport system for biotin that is Na⁺ dependent and actively accumulates biotin within the placenta, with slower release into the fetal compartment. However, in the isolated, perfused, single cotyledon, net transport of biotin across the placenta was slow compared with placental accumulation. Little accumulation on the fetal side suggests that the overall placental transfer of biotin is most consistent with a passive process.

Transport into Human Milk

Using an avidin-binding assay, Mock and coworkers have concluded that more than 95% of the biotin is free in the skim fraction of human milk (26). The concentration of biotin in human milk varies substantially in some women (27) and exceeds the concentration in serum by one to two orders of magnitude, suggesting a transport system into milk. Bisnorbiotin accounts for approximately 50% and biotin sulfoxide about 10% of the total biotin plus metabolites in early and transitional human milk (28). With postpartum maturation, the biotin concentration increases, but the bisnorbiotin and biotin sulfoxide concentrations still account for 25 and 8%, respectively, at 5 weeks postpartum. Current studies provide no evidence for a predominant trapping mechanism or for a soluble biotin-binding protein.

BIOTIN DEFICIENCY

Circumstances Leading to Deficiency

The fact that normal humans have a requirement for biotin has been clearly documented in two situations: prolonged consumption of raw egg white and parenteral nutrition without biotin supplementation in patients with short gut syndrome and other causes of malabsorption (1). Biotin deficiency also has been clearly demonstrated in biotinidase deficiency. The mechanism by which biotinidase deficiency leads to biotin deficiency probably involves several processes: (a) gastrointestinal absorption of biotin may be decreased because deficiency of biotinidase in pancreatic secretions leads to inadequate release of protein-bound biotin; (b) salvage of biotin at the cellular level may be impaired during normal turnover of proteins to which biotin is linked covalently; and (c) renal loss of biocytin and biotin is probably abnormally increased.

The clinical findings and biochemical abnormalities caused by biotinidase deficiency are quite similar to those of biotin deficiency; the common findings include periorificial dermatitis, conjunctivitis, alopecia, ataxia, and developmental delay (1). These clinical similarities suggest the pathogenesis of biotinidase deficiency involves a secondary biotin deficiency. However, the reported signs and symptoms of biotin deficiency and biotinidase deficiency are not identical. Seizures, irreversible neurosensory hearing loss, and optic atrophy have been observed in biotinidase deficiency but have not been reported in human biotin deficiency.

Based on lymphocyte carboxylase activity and plasma biotin levels, Velazquez and coworkers have reported that biotin deficiency occurs in children with severe protein-energy malnutrition (1). These investigators have speculated that the effects of biotin deficiency may be responsible for part of the clinical syndrome of protein-energy malnutrition.

Accumulating data provide evidence that long-term anticonvulsant therapy in adults can lead to biotin depletion and that depletion at the tissue level can be severe enough to interfere with amino acid metabolism (1).

Biotin deficiency has also been reported or inferred in several other circumstances:

1. *Leiner's disease*, a severe form of seborrheic dermatitis that occurs in infancy: Although a number of studies have reported prompt resolution of the rash with biotin therapy (12), biotin was ineffective in the only double-blind therapeutic trial (29).
2. *Sudden infant death syndrome*: Biotin deficiency in the chick produces a fatal hypoglycemia dubbed "fatty liver-kidney syndrome"; impaired gluconeogenesis due to deficient activity of PC is the cause of the hypoglycemia. Johnson et al. (30) and Heard et al. (31) have proposed that biotin deficiency may cause sudden infant death syndrome (SIDS) by an analogous pathogenic mechanism. They supported their hypothesis by demonstrating that hepatic biotin is significantly lower at autopsy in SIDS infants than in infants dying from other causes. Additional studies (e.g., levels of hepatic PC, urinary organic acids, and blood glucose) are needed to confirm or refute this hypothesis.
3. *Pregnancy*: Concerns about the teratogenic effects of biotin deficiency led to studies of biotin status during human gestation. Some of these studies detected low plasma concentrations of biotin; others did not (1). Recent studies detected increased 3-hydroxyisovaleric acid in more than half of normal women by the third trimester of pregnancy, and urinary excretion of biotin was abnormally low in about 50% of the women studied (10).
4. *Dialysis*: Patients undergoing chronic hemodialysis have been reported to have reduced (32) or increased plasma concentrations of biotin (33). Yatzidis et al. (34) reported nine patients on chronic hemodialysis who developed either encephalopathy (four patients) or peripheral neuropathy (five patients); all responded to biotin therapy. The etiologic role of biotin in uremic neurologic disorders remains to be determined.
5. *Gastrointestinal diseases or alcoholism*: Reduced blood or liver concentrations of biotin or urinary excretion of biotin have been reported in alcoholism, gastric disease, and inflammatory bowel disease (1).
6. *Brittle nails*: Colombo et al. treated women with brittle fingernails with 2.5 mg biotin per day orally (35) and observed a 25% increase in nail thickness and improved morphology by electron microscopy.

Clinical Findings of Frank Deficiency

Whether caused by egg-white feeding or omission of biotin from total parenteral

nutrition, the clinical findings of frank biotin deficiency in adults, older children, and infants are similar. Typically, the findings appear gradually after weeks to several years of egg-white feeding or parenteral nutrition. Hair thinning and progression to loss of all hair including eyebrows and lashes have been reported. A scaly (seborrheic), red (erythematous) rash was present in most; in several, the rash was distributed around the eyes, nose, mouth, and perineal orifices. The appearance of the rash was similar to that of cutaneous candidiasis; typically, *Candida* could be cultured from the lesions. These cutaneous manifestations, in conjunction with an unusual distribution of facial fat, have been dubbed "biotin deficiency facies." Depression, lethargy, hallucinations, and paresthesias of the extremities were prominent neurologic symptoms in most adults. The most striking neurologic findings in infants were hypotonia, lethargy, and developmental delay.

Laboratory Findings of Biotin Deficiency

Although commonly used to assess biotin status in a variety of clinical populations, the putative indices of biotin status in humans had not been previously studied during progressive biotin deficiency. Mock and coworkers (36) induced progressive biotin deficiency by feeding egg white. Urinary excretion of biotin declined dramatically with time on the egg-white diet, reaching frankly abnormal values in 9 of 10 subjects by the 20th day of egg-white feeding. Biotin excretion declined in parallel, providing evidence for regulated catabolism of biotin. By day 14 of egg-white feeding, 3-hydroxyisovaleric acid excretion was abnormally high in all 10 subjects providing evidence that biotin depletion decreased the activity of MCC and altered leucine metabolism earlier in biotin deficiency than previously appreciated. Plasma concentrations of free biotin fell to abnormal values in half of the subjects, providing confirmation of the impression (37) that blood biotin concentration is not an early or sensitive indicator of impaired biotin status.

Odd-chain fatty acid accumulation, a marker of biotin deficiency (1), is thought to result from PCC deficiency (Fig. 28.2); the isolated genetic deficiency of PCC results in accumulation of odd-chain fatty acids in plasma, red blood cells, and liver. Apparently, accumulation of propionyl-CoA leads to substitution of propionyl-CoA moiety for acetyl-CoA in the ACC reaction and to the incorporation of a three- (rather than two) carbon moiety during fatty acid elongation.

Biochemical Pathogenesis

The mechanisms by which biotin deficiency produces specific signs and symptoms remain to be completely delineated. However, several studies have given new insights into the biochemical pathogenesis of biotin deficiency. The tacit assumption of most of these studies is that the clinical findings of biotin deficiency result directly or indirectly from deficient activities of the four biotin-dependent carboxylases.

Sander et al. (38) initially suggested that the central nervous system effects of biotinidase deficiency (hypotonia, seizures, ataxia, and delayed development) might be mediated through deficiency of brain PC and the attendant central nervous system lactic acidosis. Support for the central nervous system lactic acidosis hypothesis has come

from direct measurements of cerebral spinal fluid lactic acid in children with either biotinidase deficiency or isolated PC deficiency. The work of Suchy, Wolf, and Rizzo (39, 40) has provided evidence *against* an etiologic role for disturbances in brain fatty acid composition.

Several studies demonstrated abnormalities in metabolism of fatty acids in biotin deficiency and suggested that these abnormalities are important in the pathogenesis of the rash and hair loss. Significant abnormalities of the n-6 phospholipids are detectable in blood, liver, and heart, leading to speculation that n-6 abnormalities might result in abnormalities of the prostaglandins and related substances derived from n-6 fatty acids. Supplementation of n-6 polyunsaturated fatty acids (PUFA) prevented development of the cutaneous manifestations of biotin deficiency in a group of rats who were as biotin deficient (based on biochemical measurements) as a control biotin-deficient group that did not receive the supplemental n-6 fatty acids and that did develop the classic rash and hair loss; Mock (41) concluded that an abnormality in n-6 PUFA metabolism does play a pathogenic role in the cutaneous manifestations of biotin deficiency and that the effect of n-6 PUFA cannot be attributed to biotin sparing.

Other Effects of Deficiency

Subclinical biotin deficiency has been shown to be teratogenic in several species including chicken, turkey, mouse, rat, and hamster (1, 42, 43 and 44). Differences in teratogenic susceptibility among rodent species have been reported; a corresponding difference in biotin transport from mother to fetus has been proposed as the cause (45). Bain et al. (46) hypothesized that biotin deficiency affects bone growth via effects on the synthesis of prostaglandins derived from n-6 fatty acids. This effect on bone growth might be the mechanism for the teratogenic effects of biotin deficiency.

Diagnosis of Biotin Deficiency

Biotin deficiency can be diagnosed by demonstrating reduced urinary excretion of biotin, increased urinary excretion of the characteristic organic acids, and resolution of the clinical and laboratory abnormalities with biotin supplementation. Plasma or serum levels of biotin, whether measured by bioassay or avidin-binding assay, have not uniformly reflected biotin deficiency.

The clinical response to administration of biotin has been dramatic in all well-documented cases of biotin deficiency. Healing of the rash was striking within a few weeks, and growth of healthy hair generally occurred by 1 to 2 months. Hypotonia, lethargy, and depression generally resolved within 1 to 2 weeks, followed by accelerated mental and motor development in infants. Pharmacologic doses of biotin (e.g., 1–10 mg) have been used to treat most patients.

REQUIREMENTS AND ALLOWANCES

Data providing an accurate estimate of the dietary and parenteral biotin requirements for infants, children, and adults are lacking (47). Oral “safe and adequate intakes” for

various age groups of healthy individuals were presented in the 1989 Food and Nutrition report (47) (see also Appendix [Table II-A-2-a-3](#)). The 1998 report gives suggested “adequate intakes,” which are at lower levels than in the 1989 report (47a) (see also Appendix [Table II-A-2-c-1](#)). Oral and parenteral intake of biotin were suggested for preterm infants (48), and for parenteral intake in infants through adults (49).

DIETARY SOURCES OF BIOTIN

There is no published evidence that biotin can be synthesized by mammals; thus, higher animals must derive biotin from other sources. The ultimate source of biotin appears to be de novo synthesis by bacteria, primitive eucaryotic organisms such as yeast, molds, and algae, and some plant species.

The great majority of measurements of biotin content of foods have used bioassays. Despite the limitations due to interfering substances, protein binding, and lack of chemical specificity discussed above, there is reasonably good agreement among the published reports (50, 51, 52, 53 and 54), and some worthwhile generalizations can be made. Biotin is widely distributed in natural foodstuffs, but the absolute content of even the richest sources is low when compared with that of most other water-soluble vitamins. Foods relatively rich in biotin include egg yolk, liver, and some vegetables. Based on the data of Hardinge and Crooks (50), the average dietary biotin intake was estimated to be approximately 70 µg/day for the Swiss population. This result is in reasonable agreement with the estimated dietary intake in Canada of 60 µg/day (55) and Britain of 35 µg/day (56, 57).

TOXI CITY

Daily doses up to 200 mg orally and up to 20 mg intravenously have been given to treat biotin-responsive inborn errors of metabolism and acquired biotin deficiency; toxicity has not been reported.

ACKNOWLEDGMENTS

Many thanks to Nell Mock for the artwork and Gwyn Hobby for typing this manuscript.

HISTORY

Among specific nutritional deficiency diseases, scurvy has ranked with the highest in its toll of human suffering and death. The symptoms are rather characteristic and appear to be described as far back as the ancient civilizations of the Egyptians, Greeks, and Romans. The disease was rampant in the sea explorers of the 16th to 18th centuries, AD, in whom typical physical symptoms of bleeding and rotting gums, swollen and inflamed joints, dark blotches on the skin, and muscle weakness occurred within months of departure. Throughout this period, the British expeditions suffered greatly because of

scurvy. Of Admiral Anson's six ships circling the globe in 1740 to 1744, only the flagship returned, and 1051 men died. The carnage prompted the British Admiralty to seek the cure for scurvy, and in 1747, the Scottish surgeon James Lind performed an early clinical nutrition experiment on board ship. Six different diet supplements were given to six pairs of scorbutic sailors, and the results demonstrated the efficacy of oranges and lemons (and to a lesser extent apple cider) in curing scurvy. Lind published the results in his famous 1753 *Treatise of the Scurvy* wherein he also reasoned that scurvy was due to blocked perspiration resulting from damp salty sea air, resulting in “putrid humors” that had poisonous and noxious qualities when retained in the body. Captain James Cook in voyages from 1768 to 1775 first proved that long sea voyages did not necessarily result in scurvy. Throughout these voyages, he required that the crew eat local greens and grasses at every opportunity, maintain cleanliness, and practice fastidious personal hygiene. The British Admiralty was beset by inconsistent and conflicting accounts of scurvy cures, and it was not until 48 years after Lind's experiment that lemon or lime juice was made a part of routine British naval provisions.

The lessons of the Renaissance explorers were poorly learned by succeeding generations, however. Scurvy besieged 19th century populations on land, including much of Europe during the Great Potato Famine, armies of the Crimean and United States Civil War, arctic explorers, and California gold rush communities. In 1907, scurvy was produced experimentally in the guinea pig, and from 1928 to 1930, Albert Szent-György in Hungary and Glen King in the U.S. independently published their isolations of vitamin C or “hexuronic acid.” This pure substance alone prevented and cured scurvy in guinea pigs. It was later named ascorbic acid for its antiscorbutic properties. The molecular structure was determined and an effective laboratory synthesis was developed in 1933. The history of scurvy and vitamin C has been summarized in a well-annotated volume (1).

CHEMISTRY AND ANALYSIS

Ascorbic acid (AA) is the enolic form of an α -ketolactone. The molecular structure (Fig. 29.1) contains two ionizable enolic hydrogen atoms that give the compound its acidic character (pK_{a1} at carbon 3 = 4.17; pK_{a2} at carbon 2 = 11.57). The asymmetric carbon 5 atom allows two enantiomeric forms, of which the L form is naturally occurring. Ascorbic acid is a stable, odorless white solid, formula $C_6H_8O_6$ (176.13 g/mol), which is soluble in water, slightly soluble in alcohol, and insoluble in organic solvents. In aqueous solution, the compound is easily oxidized to the diketo form, dehydroascorbic acid (DHAA), and then further transformed to diketogulonic, oxalic, and threonic acids, as well as other minor products (Fig. 29.1). The oxidation of AA to DHAA is reversible, but catabolism beyond DHAA is irreversible and is enhanced by alkaline pH and metals, especially copper and iron. Hence, procedures for stabilizing the vitamin in biologic specimens require acidification and sometimes include addition of a reducing agent or metal chelator. Because DHAA is readily reduced in vivo, it possesses vitamin C (antiscorbutic) activity, whereas diketogulonic acid has no activity.

Figure 29.1. Metabolic pathway of ascorbic acid.

The chemical name for AA is 2,3-didehydro-L-threo-hexano-1, 4-lactone; other terms have included hexuronic acid, cevitamic acid, L-xyloascorbic acid, and vitamin C. Currently, vitamin C is used as the generic descriptor for all compounds exhibiting qualitatively the biologic activity of AA. Therefore, this term refers to both of the common biologically active forms, AA and DHAA.

A variety of analytical procedures for determining the amount of vitamin C in biologic specimens, foods, and pharmaceutical products have been described in which spectrophotometric, fluorometric, chromatographic, and electrochemical techniques are used (2, 3). Total vitamin C, AA, or DHAA can be determined depending on the particular assay technique selected. For example, AA may be determined by colorimetric techniques based on its ability to reduce chromogens such as 2,6-dichloroindophenol or an α,α -dipyridyl-iron complex. Methods that measure the total amount of vitamin C (AA + DHAA) involve oxidation of AA to DHAA and/or diketogulonic acid with copper, iodine, or ascorbate oxidase, followed by derivatization to form colored (e.g., hydrazones with 2,4-dinitrophenylhydrazine) or fluorescent (*o*-phenylenediamine) products. Total vitamin C content has also been determined as AA after reduction of sample DHAA with dithiothreitol or homocysteine. AA or DHAA can be determined by difference after measurements with and without sample pretreatment with exogenous oxidizing or reducing agents (2, 3 and 4). Recently, automated and microtiter plate spectrophotometric methods for determining plasma and leukocyte AA have been developed to increase assay speed and sensitivity (5, 6).

Although spectrophotometric methods are convenient, high-performance liquid chromatography (HPLC) methods generally provide better specificity and sensitivity. A variety of chromatographic conditions have been used, and AA or DHAA can be determined by the use of ultraviolet, electrochemical or fluorescent detection modes (2, 3, 7, 8). Isoascorbic (erythorbic) acid, the epimer of L-ascorbic acid, can also be determined by HPLC. Its presence in the diet (added as an antioxidant) may result in erroneously high plasma AA values determined by some non-HPLC analytical methods

(9).

BIOLOGIC ACTIVITY AND DIETARY INTAKE

AA and DHAA provide biologic vitamin C activity (antiscorbutic), whereas their immediate oxidation product diketogulonic acid and the AA epimer isoascorbic (erythorbic) acid do not. Erythorbic acid, however, is used as a food preservative because it possesses antioxidant properties similar to those of L-ascorbic acid. In this sense, the presence of erythorbic acid in biologic tissues or fluids provides some vitamin C-like activity, analogous to the role of AA as a biologic antioxidant.

Dietary intake surveys estimate U.S. per capita vitamin C intakes at approximately 95 and 107 mg/day for adult women and men (10), and 83 mg/day for children age 1 to 5 years (11). Approximately 90% of the vitamin C in Western diets comes from fruits and vegetables, with citrus fruits and their juices, green vegetables, tomatoes and tomato juice, and potatoes being major contributors (Table 29.1) (10, 12). The mean total vitamin C intake may be higher because of AA added in some processed foods as an antioxidant, and because of the consumption of vitamin C supplements by about 35% of the adult U.S. population (11). Consumption of five servings per day of fruits and vegetables as recommended by the USDA and the National Cancer Institute provides more than 200 mg/day of vitamin C.

Food	mg/100 g*
Black currants	200
Branche	21-113
Bruce's spruce	50-150
Cauliflower	50-60
Strawberries	40-60
Lemons	50-60
Cabbage	31-63
Peppers	40-70
Spruce, fresh	0-10
Spruce, frozen	0-44
Citrus fruit	20-40
Pineapple	20-40
Straw	15-40
Leafy, kidney	10-40
Potatoes	10-30
Spinach	10-30
Pineapple	0-20
Beans	10-20
Peas	2-10
Peas	10-15
Cauliflower	0-14
Apples	0-10
Lettuce	1-2
Corn's milk	1-2
Apple juice	100-200
Apple, dried	100-200

From Agricultural Research Service. Composition of Foods: raw processed and preserved. *Journal of Agricultural Research* 60: 60 and 6-11, 1935. Department of Agriculture, Research and Education Administration, 1964. 1968. (Data from Appendix IV, 2, of the *Handbook of Food Composition*.)

Table 29.1 Reported Vitamin C Contents of Selected Foods

Values for vitamin C content of food items listed in tables of food composition may represent either AA or total vitamin C, depending on the particular method of analysis. The DHAA content of fresh fruits and vegetables as a percentage of total vitamin C is on the order of 5 to 10%; storage and/or processing may increase the proportion to 30% or greater (10). The AA content of fresh fruits and vegetables may vary appreciably, even among different samples of the same item. The amount of available vitamin C in foods may be significantly reduced because of destruction that occurs during cooking and loss in cooking water. (See also Appendix [Table IV-A-21](#) for the vitamin C content of

common foods.)

METABOLISM

Absorption and Bioavailability

AA is absorbed in the human intestine through an energy-dependent active process that is saturable and dose dependent. Intestinal absorption of AA and its entry into cells are facilitated by conversion into DHAA, which is transported across cell membranes more quickly than AA (13). After its entry into the intestinal epithelium or tissue cells, DHAA is readily reduced to AA. At relatively low intakes (below 30 mg per day), AA is nearly completely absorbed, and 70 to 90% of the usual dietary intake of AA (30–180 mg/day) is absorbed (14, 15). However, absorption falls to about 50% with doses of 1 to 1.5 g and to 16% with a 12-g dose (14, 16). Single AA doses above 200 mg that contained ¹⁴C-labeled AA resulted in postabsorptive degradation of AA in the intestine to carbon dioxide, which was expired in the breath (17). The amount of label recovered in CO₂ increased from 1 to 30% with increasing amounts of AA ingested, indicating greater postabsorptive AA degradation with the larger doses. The presence of large amounts of unabsorbed AA in the intestine may account for the diarrhea and intestinal discomforts sometimes reported by persons ingesting large doses of AA. Maximal AA absorption is attained by ingestion of several spaced doses of less than 1 g throughout the day rather than ingestion of a single megadose. A saturable absorption mechanism also explains the greater bioavailability sometimes seen for sustained-release forms of AA compared with equivalent pure doses (18). The bioavailability of vitamin C in food and “natural form” supplements is not significantly different from that of pure synthetic AA, despite claims to the contrary by manufacturers of “natural form” vitamin C supplements (19, 20).

Distribution and Transport

As seen in Table 29.2, vitamin C content in body tissues and fluids varies widely, with the highest levels in pituitary, adrenals, leukocytes, eye lens, and brain, and the lowest levels in plasma and saliva (21, 22). Vitamin C concentrations also vary widely in different blood cell types (22, 23 and 24).

Specimen	Vitamin C (μmol/100 g wet) ^a
Pituitary gland	227–284
Adrenal glands	170–227
Leukocytes	40–800
Eye lens	142–176
Brain	74–85
Liver	57–91
Spleen and pancreas	57–85
Kidneys	28–85
Heart muscle	28–85
Semen (whole)	20–60
Lungs	40
Skeletal muscle	17
Testes	17
Cerebrospinal fluid	13–26
Thyroid	11
Plasma	1.7–8.5
Saliva	0.01–0.5

^a μmol/100 g wet × 0.176 = mg/100 g wet.

Table 29.2 Vitamin C Content of Human Tissues and Fluids

The total AA body pool in adults has been determined experimentally by feeding isotopically (^{13}C , ^{14}C , ^3H) labeled AA as a tracer (25, 26 and 27). Pharmacokinetic data from healthy men given doses of 1- ^{14}C -labeled AA along with steady-state AA intakes of 30 to 180 mg/day showed that the body half-life of AA was inversely related to intake and that the total body pool of AA increased to a maximum of about 20 mg/kg body weight or about 1500 mg for an average-sized man (25). The maximum body pool was reached at a plasma AA concentration of 57 $\mu\text{mol/L}$ (1.0 mg/dL), attained by 95% of the male population with an AA intake of 100 mg/day (25). In experimental vitamin C depletion studies with healthy male prisoners, clinical symptoms of scurvy appeared at a total body AA pool below 300 mg/day, and disappeared when larger body pools were present (27). In other studies, which did not involve direct isotopic techniques, the estimated AA body pool was 22 mg/kg body weight and 32 to 34 mg/kg fat-free weight (28).

The high concentrations of intracellular AA relative to the plasma are due to an energy-driven cellular transport process. The vitamin is actively transported into human leukocytes by a saturable, temperature-dependent process that exhibits stereospecific preference for L-form over D-form epimers and shows different transport kinetics depending on the cell type (13, 22, 29, 30). Evidence suggests that DHAA is the form of the vitamin that primarily crosses the membranes of intestinal epithelial cells, erythrocytes, and leukocytes, after which it is reduced intracellularly to the active reduced form (29, 31, 32). Both chemical and enzymatic reduction of intracellular DHAA has been reported, with glutathione being the principal source of reducing equivalents (32, 33). Accumulation of AA into isolated human neutrophils and lymphocytes is mediated by both high- and low-affinity transporters, and the vitamin is localized mostly to the cytosol (30, 34). As in plasma (35), intracellular vitamin C exists predominately in reduced form and is not protein bound (30, 34).

Homeostasis

The dose-dependent intestinal absorption of AA discussed above provides a mechanism whereby whole body status of AA is regulated. A second important mechanism involves renal action to conserve or to excrete unmetabolized AA. As the amount of plasma AA increases, the ability of the renal tubules to reabsorb AA reaches a maximum and the unresorbed excess AA is excreted in the urine. This point, called the renal threshold, occurs in humans at plasma AA levels of about 68 $\mu\text{mol/L}$ (1.2 mg/dL). Renal clearance of AA was found to depend on plasma concentrations, linearly between plasma levels of 57 and 227 $\mu\text{mol/L}$ (1.0 and 4.0 mg/dL) and sigmoidally over a larger range (36). Hence, renal regulation of AA conserves body AA stores during low AA intakes through renal tubular reabsorption and limits plasma AA levels by excretion of AA loads that exceed the renal threshold. Plasma AA concentration-time profiles were similar for subjects ingesting AA doses of 0.5, 1.0, or 2.0 g/day for 1 week, and the

percentage of the dose recovered in the urine decreased significantly with increasing dosage (36). This indicates that at high AA intakes, saturable intestinal absorption of AA results in a shift of the excess AA load toward the gastrointestinal route relative to urinary excretion. AA concentrations are regulated at the cellular level by controlled cellular transport (29) and enzymatic regeneration of cellular AA from DHAA (32, 33).

Turnover and Catabolism

In healthy nonsmoking men, the half-life of radioisotope-tracer AA was inversely related to the dosage, the average half-life being about 16 to 20 days (25). The half-life decreased from 40 to 8 days with increasing steady-state AA intakes from 30 to 180 mg/day, along with increased total AA turnover (14–134 mg/day) and increased AA body pool (11–22 mg/kg body weight) (25). In healthy prisoners depleted of AA, the whole body turnover of vitamin C, or catabolic rate, depended on the AA body pool size (27). The catabolic rate decreased from 45 mg/day at an initial body pool of 1500 mg to 9 mg/day at a pool size of 300 mg, below which, frank symptoms of scurvy appeared in all subjects. Overall, the body turnover of AA was about 3% of the existing body pool per day (27). At very low or zero intakes of AA, essentially no unmetabolized AA is excreted, yet an obligatory metabolic loss of several milligrams per day occurs. Intake of 8 to 10 mg/day of the vitamin is sufficient to compensate for obligatory catabolism and provide enough AA to satisfy critical functions and prevent overt scurvy symptoms.

In humans, AA is catabolized through oxidation to DHAA, hydrolysis of DHAA to diketogulonate, and decomposition of diketogulonate to a variety of compounds including oxalic and threonic acids, L-xylose, and ascorbate-2-sulfate (Fig. 29.1). The principal route of AA elimination is urinary excretion, with unmetabolized AA and all of the above-named metabolites being eliminated. Initial oxidation of AA to DHAA proceeds through a partially oxidized free radical intermediate, monodehydroascorbate (ascorbyl radical), which is unstable but can be detected by electron paramagnetic resonance spectroscopy. Metabolism of AA to exhaled CO₂ is a minor route of AA catabolism in humans consuming normal dietary intakes of the vitamin (17). Negligible amounts of AA or its metabolites are excreted in feces. The percentage of unmetabolized AA excreted in urine relative to catabolic products increases greatly with increasing dietary intake of AA. Oxalic acid constitutes a minor fraction (5–10%) of AA metabolites, but it seems to be an obligatory product in that it is found even at very low dietary AA intakes. With increasing AA intakes, conversion of AA to oxalate is limited (16, 37).

BIOCHEMICAL FUNCTIONS

The functions of AA are based primarily on its properties as a reversible biologic reductant. As such, it provides reducing equivalents for a variety of biochemical reactions, is essential as a cofactor for reactions requiring a reduced metal ion (Fe²⁺, Cu¹⁺), and serves as a protective antioxidant that operates in the aqueous phase and can be regenerated *in vivo* when oxidized. Few of the roles of AA have been established on a definitive molecular basis. Its roles in metal-catalyzed hydroxylations that use molecular oxygen are best defined (Fig. 29.2). In such cases, AA is believed to act to reduce the metal catalyst, allowing reactivation of the metal-enzyme complex,

and/or as a cosubstrate involved in reduction of molecular oxygen. The biochemical roles of AA have been reviewed (28, 38, 39).

Figure 29.2. Reactions that require ascorbic acid as a cofactor with metals for hydroxylations of proline (**A**) and dopamine (**B**). AA, Ascorbic acid; a-KG, a-ketoglutarate; noradrenaline (norepinephrine).

Collagen and Connective Tissue

One of the best established roles of AA is as a reductive cofactor for posttranslational hydroxylation of peptide-bound proline and lysine residues during formation of collagen (38, 40). The hydroxyproline and hydroxylysine units allow cross-linking to stabilize the triple helical structure of tropocollagen, an essential subunit of procollagen. The enzyme involved in proline hydroxylation, prolyl hydroxylase, requires molecular oxygen, AA, iron, and a-ketoglutarate (Fig. 29.2A). During the hydroxylation reaction, the enzyme-bound iron is oxidized to Fe^{3+} and AA is involved in reactivating the enzyme by reduction of iron back to the ferrous state. In an analogous reaction, AA participates as a cofactor in the hydroxylation of lysine residues catalyzed by copper-dependent lysyl hydroxylase.

Considerable evidence suggests AA involvement in collagen gene expression and related mRNA processing, but specific *in vivo* mechanisms have not been established (40, 41). AA also influences cellular procollagen secretion and the biosynthesis of other connective tissue components, including elastin, fibronectin, proteoglycans, bone matrix, and elastin-associated fibrillin (40). Although not all details of the processes are clearly resolved, the absolute requirement for AA in formation of mature connective tissue explains the primary physical symptoms of scurvy. The importance of AA for connective tissue formation during *in utero* development is illustrated by the vascular and skeletal abnormalities observed in the uterus and fetuses of ascorbate-requiring swine made vitamin C deficient (42).

Antioxidant Functions

AA is believed to be the most versatile and effective of the water-soluble dietary antioxidants. AA can readily donate electrons to quench a variety of reactive free radical and oxidant species and is easily returned to its reduced state by such ubiquitous electron donors as glutathione and NADPH (32, 33). The vitamin efficiently scavenges hydroxyl, peroxy, and superoxide radicals, as well as reactive peroxide, singlet oxygen, and hypochlorite species (43, 44). In addition, AA protects against plasma lipid and low-density lipoprotein (LDL) peroxidation (43, 45). AA appears to protect against lipid peroxidation by scavenging peroxy radicals in the aqueous phase before they can initiate lipid peroxidation and by regenerating the active form of vitamin E, the important lipophilic antioxidant.

The high levels of AA in the eye provide antioxidant protection against photolytically generated free radicals in various ocular fluids and tissues, including the lens, cornea, vitreous humor, and retina. Concentrations of AA in seminal fluid some 8- to 10-fold higher than blood levels are believed to protect against oxidative damage to sperm proteins. Oxidative stress has been associated with sperm agglutination and decreased male fertility (see discussion of eye disorders and fertility under "[Other Clinical and Therapeutic Aspects](#)").

The high AA levels in neutrophils provide cellular and host tissue protection during the respiratory burst in which reactive oxidants and free radicals are produced. Myeloperoxidase-derived hypochlorous acid is scavenged by AA, and lack of sufficient vitamin at sites of inflammation such as the rheumatoid joint may well facilitate proteolytic damage (30).

As an intracellular antioxidant, AA appears to be important in protecting DNA from oxidative damage linked to mutagenesis and the initiation of carcinogenesis. Oxidative damage to sperm DNA, as measured by the oxidatively modified DNA base 8-hydroxydeoxyguanosine, was increased in healthy men given an AA-deficient diet of 5 mg/day and was returned to baseline upon repletion with either 60 or 250 mg/day of AA (46). AA supplementation decreased gastric mucosal DNA damage in gastritis patients as measured by ³²P-postlabeling assay and lymphocyte chromosome damage induced by in vitro exposure to bleomycin (47).

Indirect Antioxidant Protection. AA can provide indirect antioxidant protection by supplying electrons to regenerate the active reduced form of other biologic antioxidants such as glutathione, tocopherol, and flavonoids (48). Studies with guinea pigs show that AA regenerates the important endogenous antioxidant glutathione from its oxidized form and that reduced glutathione can regenerate ascorbate from its oxidized form. Thus AA can ameliorate the consequences of induced glutathione deficiency, such as cataracts, and glutathione can delay or prevent the symptoms of scurvy (48). In healthy adult humans supplemented with AA, red cell glutathione rose nearly 50%, and a decrease in red cell lytic sensitivity indicated improved oxidant defense (49). These results indicate that ascorbate functions as a secondary antioxidant by maintaining reduced glutathione,

a primary cellular antioxidant.

Considerable in vitro evidence indicates that AA protects lipids indirectly by regenerating the active (reduced) form of tocopherol (50). However, studies in guinea pigs and humans have not shown a biologically significant “sparing” of vitamin E by AA in vivo, although some trends toward protection of human tissue tocopherol by higher AA intakes have been reported (51). Clearly, AA can regenerate some forms of oxidized tocopherol, and this likely occurs to some extent in vivo. However, this interaction may be difficult to demonstrate in vivo because oxidized tocopherol in the cell membrane and lipid-rich tissue is likely regenerated also by other biologic reductants, such as the lipid-soluble ubiquinol, and/or glutathione.

The synergistic antiproliferative effect of AA and flavonoids on carcinoma cells in culture has been attributed to the effect of AA in protecting the flavonoids against oxidation (52).

Neurotransmitter Synthesis and the Nervous System

The importance of AA in neurotransmitter synthesis and metabolism likely underlies the high concentrations and homeostatic control of AA found in adrenal and brain tissue and the relative resistance of these organs to AA depletion (28, 38, 53). AA is a required cofactor for the copper-containing dopamine- β -hydroxylase enzyme that catalyzes hydroxylation of the dopamine side chain to form norepinephrine (Fig. 29.2B). In guinea pigs, synthesis of biogenic amines has been shown to be AA dependent. AA is a cofactor for α -amidating monooxygenase enzymes in the biosynthesis of neuropeptides in the adrenals. AA also appears to be involved in the hydroxylation of tryptophan to form serotonin in the brain.

Activity of glutamatergic and dopaminergic neurons has been closely linked to changes in extracellular AA concentration in the brain. Aspects of neural activity modulated by AA concentrations include neurotransmitter membrane receptor synthesis and functions and neurotransmitter dynamics (53). Animal model and cell culture experiments indicate that AA is an important factor in the developing nervous system, particularly for the growth and maturation of glial cells and myelin.

Mixed-Function Oxygenase System

The microsomal drug-metabolizing system operates in liver microsomes and reticuloendothelial tissues to inactivate and metabolize a wide variety of substrates, such as endogenous hormones or xenobiotics (e.g., drugs and carcinogens). The systems operate with oxygenase enzymes, flavoproteins, cytochrome P450 protein, oxygen, and reducing agents such as NAD(P)H. The activity of the system is often affected by AA concentrations, although specific roles for the vitamin have not been elucidated (28). Results of animal studies indicate that AA depletion reduces the activity of system enzymes and the integrity of cytochrome P450 electron transport. Studies in animals and humans show that drug-metabolizing activity is reduced during AA deficiency and that stress (from steroid hormone activation) and/or use of drugs may alter AA metabolism and lower AA body status. Users of oral contraceptives have been shown to have reduced levels of plasma and leukocyte AA. Exposure of rats and guinea

pigs to polychlorinated biphenyls (PCBs) increased their requirement for AA and the activity of cytochrome P450 enzymes. The mRNA of these enzymes was increased when mutant ascorbate-requiring rats exposed to PCBs were supplemented with AA (41).

AA is involved in the synthesis of corticosteroids and aldosterone in the adrenal cortex, apparently supplying reducing electrons to mitochondrial P450 enzymes (54). The vitamin is also involved in the hepatic cytochrome P450–dependent microsomal hydroxylation of cholesterol in the conversion of cholesterol to bile acids. Studies with guinea pigs showed that marginal AA deficiency reduces the activity of this rate-limiting step in cholesterol degradation. Animal studies on the effect of increased AA intakes on lipid metabolism have been inconsistent; some indicate no direct effect, whereas another reports an increased rate of cholesterol conversion and decreased blood and liver lipid levels as the ascorbate dose increased (28).

Iron Absorption and Metabolism

AA is involved in the regulation of iron metabolism at a number of points. Ascorbate reduction of iron to the ferrous state is required in iron transfer and storage pathways involving transferrin and ferritin. AA deficiency in guinea pigs results in low serum iron concentrations, iron deficiency, and changes in genetic expression of iron-related proteins (55).

Measurement of iron absorption from single meals by use of isotopic iron tracers shows that dietary AA enhances intestinal absorption of nonheme iron. The mechanism of action is believed to involve the ability of AA to reduce intraluminal iron to the more absorbable ferrous state and/or to counteract the effect of dietary iron absorption inhibitors. However, controlled human studies in which the vitamin is added to meals over long periods have not shown significant improvement of body iron status, indicating that AA has less effect on iron bioavailability than has been predicted from tests with single meals (56).

AA can increase iron absorption and interact with iron to promote oxidative damage, raising concern that high supplemental intakes of AA, a common occurrence in developed countries, exacerbate iron overload and its related pathology. A review of studies assessing iron status during high AA intakes concluded that high intakes are not a significant factor in iron overload (57). Nevertheless, the strong prooxidant nature of the iron-ascorbate couple has been convincingly demonstrated in vitro (58), and reports suggesting a prooxidant effect of high ascorbate concentrations in premature babies (59) and children with cystic fibrosis (60) have recently appeared. In the former case, high levels of serum AA were suggested to inhibit the ferroxidase activity of ceruloplasmin and therefore exacerbate oxidative damage via increased ferrous iron (59). The relevance of possible prooxidant AA-iron interactions to human health warrants further study, especially in cases of iron overload and where free iron may be released into tissues because of inflammation or tissue trauma.

Animal and human studies indicate that AA also affects copper metabolism in a variety of ways, including inhibition of intestinal absorption and ceruloplasmin oxidase activity,

and labilization of ceruloplasmin-bound copper for cellular transport (61).

Other Functions

Carnitine Biosynthesis. Carnitine transports long-chain fatty acids across the mitochondrial membrane wherein β -oxidation provides energy to cells, especially for cardiac and skeletal muscle. Carnitine can be considered a conditionally essential nutrient for humans since we obtain carnitine from the diet and also biosynthesize carnitine from lysine and methionine. Ascorbate is required along with iron at two steps in the pathway of carnitine biosynthesis, in reactions similar to the hydroxylation of proline during collagen formation. Muscle carnitine concentrations are significantly decreased in scorbutic guinea pigs, suggesting that loss of carnitine-related β -oxidation energy may explain the fatigue and muscle weakness observed in human scurvy. Studies with guinea pigs and humans indicate that decreased tissue carnitine levels and increased urinary carnitine excretion in AA deficiency are due to defective renal reabsorption of carnitine rather than decreased carnitine synthesis (62, 62a). Increased free plasma carnitine in human AA deficiency was attributed to impaired carnitine transport into tissues because of a rise in d-butyrobetaine, the immediate biosynthetic precursor to carnitine (63). Although vitamin C deficiency appears to alter carnitine metabolism, the specific interactions and their relevance to functional carnitine status in humans is unclear.

Miscellaneous Functions. AA exerts vasodilatory and anticlotting effects by altering the production of prostacyclin and other prostaglandins (64). The apparent stimulation by AA of prostaglandin synthesis has been hypothesized as a mechanism to explain a variety of reported effects of the vitamin, such as antihistaminic and hypocholesterolemic actions, modified bronchial and vascular tone, immune and insulin responses, and collagen synthesis. Some recent evidence suggests that AA may protect neural and endothelial tissue and affect vascular tone via interactions with nitrite ions, nitric oxide, and/or nitrogen dioxide (65). In some studies, AA increased cellular levels of cyclic nucleotides (cAMP and cGMP), but the mechanism and physiologic significance of this effect is not clear (38). AA prevents uroporphyrin accumulation in hepatocyte cultures and in ascorbate-requiring rats by inhibiting the oxidation of uroporphyrinogen, suggesting a role for the vitamin in preventing uroporphyrin in humans (66). Vitamin C, as ascorbate-2-sulfate, has been suggested to serve as a sulfating agent, both of cholesterol as part of its catabolism and of mucopolysaccharides during formation of connective tissue. Evidence relating AA to immune function, risk of degenerative diseases, respiratory function, and other clinical conditions is discussed under "[Clinical and Therapeutic Aspects.](#)"

DEFICIENCY

Due to a lack of the enzyme required to convert L-gulonolactone to AA, humans are among the few species unable to synthesize AA from glucose. When dietary intake of AA is insufficient, humans exhibit a set of reproducible conditions termed *scurvy*. The scurvy symptoms listed in [Table 29.3](#) have been observed in both naturally occurring and experimentally induced scurvy (27). The mesenchymal symptoms result primarily from defects in connective tissue formation. A variety of hemorrhagic manifestations

occur, including bleeding into joints, the peritoneal cavity and/or pericardial sac, and the adrenals in severe cases. A decrease in the ability of the gingiva to resist inflammation and bleeding seems to be an early physical sign of AA deficiency. As seen in [Figure 29-3](#), even moderate (nonscorbutic) experimental AA depletion increased gingival bleeding in healthy men ([67](#)). In infants, AA deficiency may result in bone abnormalities, including impaired bone growth and disturbed ossification. Hemorrhagic symptoms may occur, such as retrobulbar and subperiosteal hemorrhages, epistaxis, hematuria, purpura, and resultant hypochromic anemia because of blood loss. The hemorrhagic manifestations of AA deficiency are presumed to be related to defective vascular tissue integrity, although no specific histologic defect has been identified. Adverse effects of AA deficiency on blood clotting are indicated by recent evidence that oxidative degradation of some blood coagulation factors is inversely related to plasma AA concentration ([68](#)).

Table 29.3 Clinical Manifestations of Vitamin C Deficiency

Figure 29.3. Blood and urine ascorbic acid levels and gingival bleeding indices in 11 healthy adult men receiving various ascorbic acid intakes between 5 and 605 mg/day as shown at *top*. *GI*, gingival index; *BI*, bleeding index ($\text{mg/dL} \times 56.8 = \mu\text{mol/L}$). (From Leggott PJ, Robertson PB, Rothman DL, et al. *J Periodontol* 1986;57:480–5, with

permission.)

A molecular basis for the weakness and fatigue associated with scurvy has not been established; alterations of iron or carnitine metabolism may be involved. Psychologic symptoms are likely related to altered neurotransmitter synthesis and metabolism. Some historically reported symptoms of scurvy may be attributable to coexisting nutrient deficiencies in thiamine, “wet beriberi” (edema), vitamin A (night blindness), vitamin D (rickets), and folic acid (megaloblastic anemia).

Prevalence

Clinical scurvy is rare in developed countries but is still occasionally seen in individuals with exceptionally poor diets (e.g., in alcoholism and drug abuse), peculiar or restricted diets, or diets with a near total lack of AA-containing foods. Most often, it is noted in elderly men who live alone and eat a diet frequently low in fruits and vegetables. Because breast milk provides adequate AA and infant formulas are fortified with AA, infantile scurvy is rarely seen.

Among U.S. population groups, the prevalence of low blood AA concentrations is higher in men than in women, higher in groups with lower socioeconomic status, and highest (about 20%) in poor elderly men (11). A greater proportion of low blood AA levels is observed in elderly persons who are institutionalized, housebound, or chronically sick (69). The trend to lower plasma and leukocyte AA levels observed in the elderly is not explained by differences in renal handling of AA (70). Although many factors related to aging have been postulated to explain lower AA levels in elderly individuals, no convincing evidence that any of these factors results in deficient AA status or an increased AA requirement in healthy elderly persons has been reported.

STATUS ASSESSMENT

Since no reliable functional tests of AA deficiency have been established, measurement of plasma and leukocyte AA levels remain the most practical and reliable tests for assessing human vitamin C status. Assessment of the total body AA pool provides a good integrated measure of status, but practical methods for making this determination have not been devised. Lack of increase in serum or urinary AA excretion after an oral vitamin C load can provide a useful test of AA tissue deficit in individuals, but this type of test is not practical for use in nutrition surveys (71).

Plasma and Leukocyte Tests

Plasma AA levels have generally been shown to correlate with dietary AA intake and with leukocyte AA in both epidemiologic and experimental studies (9, 24, 72, 73). The direct response of plasma and leukocyte AA levels to experimental changes in AA intake is shown in the top half of [Figure 29-3](#) for 11 healthy adult men housed in a

metabolic unit for 14 weeks (72). Plasma AA levels are most responsive to recent dietary intake, whereas leukocyte levels change more slowly but reflect AA tissue contents and the body pool more closely. Studies with monkeys and guinea pigs have confirmed that of a variety of blood AA measures, leukocyte AA levels correlate best with liver AA and AA body pool (24). Mixed leukocytes (e.g., the “buffy coat”) constitute a heterogeneous mixture of blood cells for which interpretation of results is not standardized (see “[Interpretive Guidelines](#)”). Plasma AA tests are preferred for large population studies because the test requires less blood, is easier to perform, and yields results that are interpreted easily and reliably.

The typical relationship between plasma AA and dietary vitamin C intake is shown in [Figure 29-4](#) for a healthy elderly population (74). The curve is similar to those published from a variety of other studies, both experimental and population based, in which steady-state plasma AA levels rise steeply from low vitamin C intakes below 20 mg/day and plateau between 68 and 102 $\mu\text{mol/L}$ (1.2–1.8 mg/dL) at intakes above 200 mg/day (16, 72, 74).

Figure 29.4. Plasma ascorbic acid versus total vitamin C intake (diet plus supplements) for elderly males ($N = 235$) and females ($N = 442$). Median plasma ascorbate values plotted at the median intakes for 12 percentiles of intake. (From Jacob RA, Otradovec CL, Russell RM, et al. *Am J Clin Nutr* 1988;48:1436–42, with permission.)

Other Tests

The pattern of changes in whole blood and erythrocyte AA levels after AA depletion in humans is qualitatively the same as for plasma levels, because of a relatively rapid exchange of the vitamin between plasma and red cells. Whole blood or erythrocyte AA levels are considered a less sensitive indicator of AA deficiency, however, because they do not change as much or fall as low as plasma levels during AA deficiency. In subjects nearly depleted of the vitamin, in whom scurvy symptoms exist or are imminent (AA body pool less than 300 mg), whole blood AA levels will fall to 17 $\mu\text{mol/L}$ (0.3 mg/dL) or

below, whereas plasma AA levels are less than 5.7 $\mu\text{mol/L}$ (0.1 mg/dL).

The rate of excretion of AA in urine is not linear with AA intake because of efficient renal reabsorption at low AA intakes and renal clearance at high intakes. Healthy adults ingesting a normal Western diet containing 40 to 100 mg/day of AA would be expected to excrete some 5 to 50 mg/day of unmetabolized AA. At plasma AA levels exceeding the renal reabsorption threshold, about 68 $\mu\text{mol/L}$ (1.2 mg/dL), excretion of AA increases abruptly with increased AA intake (Fig. 29.3). At AA intakes below 40 mg/day, urine AA excretion falls dramatically to less than 10 mg/day and to nearly undetectable levels in scurvy or in severe AA depletion. Hence, urinary AA content can be used to affirm a diagnosis of frank AA deficiency but is not useful for differentiating between subjects with normal or low but nonscorbutic AA status. Direct measurement of the AA body pool has been accomplished by radioisotope dilution techniques (25, 27), but no practical tests for the AA body pool have been developed. Salivary AA content does not appear to be a good measure of vitamin C status, as low or undetectable levels of salivary AA have been reported in nonscorbutic subjects, and salivary AA levels generally have not been found to correlate well with AA intake, plasma AA, or leukocyte AA levels (72).

Interpretive Guidelines

The reference ranges listed in Table 29.4 are general guidelines for interpreting biochemical AA measures. The guidelines for interpreting plasma AA levels are relatively well established. Few data on AA body pool measurements are available, however, and reported ranges of leukocyte AA vary greatly, in part because of the heterogeneous nature of blood cells and technical difficulties in their separation and analysis. Generally, the “deficiency” category represents frank vitamin C deficiency, in which clinical symptoms are either apparent or imminent. The “low” category represents a state of moderate risk for developing overt vitamin deficiency symptoms because of low AA intake and/or depleted body pool.

	Plasma ($\mu\text{mol/L}$) ¹	Body Pool (ng)	WBC (leukocytes) (mol/L) ² cell ($\mu\text{g}/10^6$ cells)	Mononuclear (leukocytes) (mol/L) cell ($\mu\text{g}/10^6$ cells)
Adequate	>12 [1-4]	>80	>14 [1-20]	>12 [1-20]
Low	7.4-12 [0.1-0.4]	30-80	5-14 [0-20]	1.4-12 [0-20]
Deficient	<7.4 [0.2]	<30	<5 [1-10]	<1.4 [1-20]
Normal range	21-84 [0.1-1.5]	300-1500 [10-22 mg/kg]	114-201 [20-52]	140-200 [25-40]

¹Age and sex may be important in subjects with vitamin C supplements.

²mol/L = 10⁶ - ng/L.

³mol/L cell = 10⁶ - $\mu\text{g}/10^6$ cells; leukocyte activity cell = mol/L leukocyte multiplied remainder cell. ⁴cell = 10⁶ L.

Table 29.4 Guidelines for Interpreting Biochemical Measures for Ascorbic Acid Status^a

Unlike plasma levels, interpretation of leukocyte AA levels is complicated by differing AA concentrations among the various cell types. Mononuclear cells have AA levels two to three times those of polymorphonuclear (PMN) cells. Other clinical and physiologic factors (e.g., infection, drugs, and glycemic state) affect leukocyte AA levels because of alterations in either cell populations or their AA uptake. Similarly, AA concentrations of the heterogeneous “buffy coat” may be affected by diverse factors unrelated to AA nutriture, especially in clinical conditions (24). For leukocyte assay, determination of AA in isolated fractions of mononuclear or PMN cells appears to be the best choice; data are insufficient to recommend one over the other.

The oxidized form of the vitamin, DHAA, is present in negligible amounts in the plasma of healthy subjects (35). In leukocytes, however, a dynamic relationship exists between AA and DHAA, especially in phagocytic cells in which AA is active as an antioxidant and free radical scavenger attendant to the respiratory burst and DHAA is rapidly converted back to AA. Reported levels of DHAA in human leukocytes range from zero to nearly half of the total cellular content of vitamin C, although the vitamin exists in isolated human neutrophils solely in the reduced form (30). How much of the reported leukocyte levels of DHAA truly exists in vivo and how much results from methodologic (oxidative) artifacts is not clear.

Effects of Gender, Smoking, and Age

Results from a nutrition survey of healthy elderly Boston area residents shown in [Figure 29-5](#) illustrate typical effects of gender (higher in women than men) and smoking (lower in smokers) on plasma AA concentrations (74). Women had higher plasma AA levels than men for all subgroups of age, smoking, or AA supplement use, even though dietary AA intakes were approximately the same. The gender-related differences in plasma AA concentrations are not explained by differences in renal handling of AA but are apparently due to such gender-related differences as lean body mass and hormonal influences (70). In nearly all studies, smokers show lower AA levels in plasma and leukocytes than nonsmokers, and lower dietary AA intake by smokers only partially explains the difference (24, 75). These findings suggest a higher AA dietary requirement for smokers, as discussed below. No significant relationship between age and plasma AA levels exists in the data presented in [Figure 29-5](#), although the mean values for men tend to decrease with age. The AA status of the elderly population is discussed above.

Figure 29.5. The 95% confidence intervals of the mean for plasma ascorbic acid in 677 healthy elderly by gender, age decade, cigarette smoking, and ascorbic acid supplement use (mg/dL \times 56.8 = μ mol/L). (From Jacob RA, Skala JH, Omaye ST, et al. Biochemical methods for assessing vitamin C status of the individual. In: Livingston GE, ed., Nutritional status assessment of the individual. Trumbull CT: Food & Nutrition Press, 1989;323–38, with permission.)

DIETARY REQUIREMENTS

Beyond the absolute requirement of 5 to 10 mg/day to prevent scurvy, the human dietary requirement for vitamin C remains controversial. Current worldwide recommendations for vitamin C intake vary from 30 to 100 mg/day. The increases in the allowances over that required to prevent scurvy are based primarily on providing a total body pool of ascorbate (e.g., 900–1500 mg) that will ensure against scorbutic symptoms even after weeks of low ascorbate intake or periods of physiologic or exogenous stress that may increase the vitamin turnover or requirement. Given an AA turnover of about 3% of the body pool per day and development of the first scorbutic symptoms and/or reduction of total AA body pool to 300 mg or less in 24 to 30 days for both men and women, the RDA (recommended dietary allowance) in the United States was set in 1989 at 60 mg/day for adult men and women (see Appendix [Table II-A-2-b-2](#)) (75). To cover 95% of the population, the 60 mg/day value is 2 SD above the mean intake estimated to provide adequate vitamin C reserves. The 60 mg/day intake precludes appearance of scorbutic symptoms for at least 4 weeks, even in the face of deficient AA intakes and/or increased use and needs and also provides plasma and leukocyte AA levels above the “at risk” or low levels listed in [Table 29.4](#) for most of the population. An AA intake of 60 mg/day is easily achieved in normal Western diets; median intakes of vitamin C in the U.S. in 1989–91 were above the RDA for all major population subgroups (76). The United Kingdom (Appendix [Table II-A-4-d](#)) and World Health Organization (Appendix [Table II-A-8-a](#)) value of 30 mg/day is deemed adequate for the population because it is about three times that needed to prevent scurvy.

Special Requirements

The lower plasma and leukocyte AA levels found in *smokers* (compared with nonsmokers) are explained only in part by their lower AA intakes. Radioisotope-labeled AA dilution studies showed that the metabolic turnover of AA in smokers averaged about twice that of nonsmokers (70.0 vs. 35.7 mg/day) (26). The reason for this difference has not been established, although increased AA catabolism caused by the oxidative stress of smoking has been suggested. The lower levels of AA and decreased AA half-life in smokers puts them at comparatively greater risk for development of AA deficiency. Hence the RDA in the United States is set at 100 mg/day for smokers, 40 mg higher than that for nonsmokers (75).

Despite frequently observed low blood AA levels as well as possible increased needs because of sickness and therapeutic drug use, no increase in the vitamin C allowance for the *elderly* has been established because convincing evidence of an increased requirement or AA turnover related to aging alone has not been reported (see discussion above of elderly AA status under “[Deficiency](#)”). As discussed above, additional dietary AA may significantly enhance nonheme iron absorption. This effect may be important in vegetarians or individuals with limited heme iron intakes, but the uncertain benefit of this effect to most omnivorous individuals does not justify increasing recommended AA intakes on a population basis.

Plasma AA levels of women decrease during *pregnancy*, primarily because of hemodilution. However, the plasma AA levels of the fetus and neonate are some 50% higher than those of the mother, indicating active transplacental transport and a relatively higher body pool of the vitamin. Based solely on the weight of a near-term fetus, the increased maternal requirement for AA would be about 3 to 4 mg/day, although AA turnover in the fetus is believed to be greater than that for adults. The RDA therefore includes an additional intake of 10 mg/day for pregnant women to compensate for AA losses during pregnancy and to maintain an adequate body pool (75).

Human breast milk contains 170 to 568 $\mu\text{mol/L}$ (3–10 mg/dL) of AA, and average milk volumes are 750 mL/day (first 6 months) and 600 mL/day (7–12 months). To allow for variation in AA level and milk production, the RDA for lactating women includes an additional increment of 35 mg/day during the first 6 months of *lactation* and 30 mg/day thereafter (75).

On the basis of a complete lack of reports of scorbutic symptoms in breast-fed *infants* receiving 7 to 12 mg/day of AA and in formula-fed infants receiving about 7 mg/day, an intake of 30 mg/day is recommended to provide adequate vitamin C reserves plus a margin of safety in 95% of the population of infants during the first 6 months of life (75). Beyond 6 months, the requirements gradually increase to the adult level.

Evidence for Benefits of Higher Intakes

A great deal of evidence, covered briefly below, suggests that AA intake beyond that required to prevent scurvy may reduce the risk of developing chronic diseases such as cancer, coronary heart disease, age-related eye diseases, and neurodegenerative diseases. These results raise questions as to whether the goal of recommendations for

AA intake should be plasma and/or tissue ascorbate saturation rather than prevention of scurvy symptoms. For example, authors of a recent pharmacokinetic study of AA intakes from 30 to 2500 mg/day in healthy men recommended an increase in the RDA to 200 mg/day, based partly on determination of AA plasma saturation (16). However, because body ascorbate accumulation is limited by homeostatic mechanisms including saturable absorption and renal excretion, ascorbate intakes required to maximize the body pool are only 100 to 150 mg/day in healthy nonsmoking adult men and about 150 and 80 mg/day for healthy elderly men and women, respectively (47).

The limitation on increasing the body ascorbate pool by higher intakes is one reason why recommended intakes for the vitamin have not been increased significantly. Otherwise, much of the evidence suggesting health benefits for higher intakes of AA is based on in vitro and animal studies whose results may or may not be relevant to humans and epidemiologic studies that show *associations* of the vitamin with reduced disease risk but cannot sort out what factors may be the responsible agents. Increasing evidence indicates that a wide variety of dietary substances besides AA contributes to reduced disease risk. The evidence that higher AA intakes alone provide health benefits to humans is mixed. While higher AA intakes may be recommended for certain groups such as smokers and those under a variety of stresses, the current data suggesting health benefits for consumption of higher doses are controversial and not widely accepted as a justification for recommending higher intakes as a public health measure.

CLINICAL AND THERAPEUTIC ASPECTS

Over the past three decades, a great deal of evidence suggesting health benefits for AA intake beyond that needed to prevent scurvy has been reported. While much of the evidence derives from in vitro, animal, and limited human studies, the few controlled human intervention trials have provided mixed results. A brief review of proposed extrasorbatic and clinical roles follows. The reader is referred to other sources for expanded and detailed coverage (28, 77, 78, 79, 80, 81 and 82).

Immune Function

Various immune-related functions are altered by ascorbate nutriture, including neutrophil chemotaxis, lymphocyte proliferation, antimicrobial and natural killer cell activities. The vitamin also affects many immune system modulators such as blood histamine, serum complement, prostacyclin, prostaglandins, and B- and T-cell cyclic nucleotides (83, 84, 85 and 86).

Results from studies of the effects of AA supplements on immune functions have not been consistent, perhaps because of methodologic problems in assessing immunocompetence and extrapolating the results of animal model and isolated cell studies to steady-state immune function in humans. Many studies suggest that the vitamin has beneficial effects, while other studies show no effects, or negative effects. Because of active transport of AA into leukocytes, attempting to increase leukocyte AA levels via increased dietary intake is questionable. For example, in a double-blind study of 24 healthy free-living women, ingestion of 1 or 4 g of AA daily produced increases in serum AA levels relative to the placebo group, but no differences were evident in

leukocyte AA levels or leukocyte function (87).

AA inactivates or inhibits a wide range of viruses in vitro, including HIV (85), yet no clinical efficacy has been demonstrated. A review of 21 controlled human trials of megadose ascorbate intake and the common cold showed no consistent effect on reducing the incidence of colds, although the duration of episodes and severity of symptoms was reduced by an average of 23% (85). The basis for the reported decreases in severity of colds may lie in the antihistaminic action of the vitamin and/or its ability to reduce inflammation associated with reactive oxidants produced by phagocytic leukocytes. Results from a study of healthy adults supplemented with AA indicated that the vitamin may enhance neutrophil chemotaxis indirectly by reducing the immunosuppressive effects of histamine in vivo (86).

Controlled experimental depletion of ascorbate in healthy men, short of scurvy, decreased delayed skin hypersensitivity responsiveness but had no effect on lymphocyte proliferation capability (88). AA supplementation reduced the incidence of upper respiratory tract infection in marathon runners, suggesting similar benefits for the sedentary; however, interpretation of the study results has been criticized (79). As for many questions relating to the health benefits of vitamin C, claims of improved immunocompetence with high vitamin intake are controversial.

Cancer

Evidence suggesting a role for AA in cancer prevention is derived primarily from cell culture, animal model, and human epidemiologic studies (79, 89, 90, 91, 92 and 93). Possible anticarcinogenic effects of AA likely involve its ability to block carcinogenic processes through antioxidant activity, to detoxify carcinogens, and/or to enhance immunocompetence. AA has been shown to prevent formation of carcinogenic substances, such as nitrosamines, in foods and in the gastrointestinal tract. The vitamin has also been reported to detoxify chemical mutagens and carcinogens, including anthracene, benzpyrene, organochlorine pesticides, and heavy metals. As a free-radical scavenger, the vitamin is believed to be important in preventing oxidative damage to proteins, DNA, and cell membranes. Oxidative damage to human sperm DNA, as determined by levels of 8-hydroxy-2 ϕ -deoxyguanosine, was increased in men consuming low dietary intakes of AA and was inversely related to semen AA levels (46). Lymphocytes can effectively destroy some types of cancer cells, and certain immune functions such as chemotaxis and natural killer cell activity may be augmented by AA.

Evidence that AA provides an antitumorigenic effect in animals exposed to carcinogens is seen in many but not all animal studies (mice, rat, and hamster). Some protective effects of AA have also been seen in tumor cell transplant and cell culture experiments, but results have been inconsistent. Some experimental studies have indicated that AA may enhance carcinogenesis and tumor formation (92).

Epidemiologic studies show strong associations of AA nutriture with reduced risk for cancers of the oral cavity, esophagus, stomach, and pancreas, somewhat less strong evidence for protection against cancers of the lung, cervix, rectum, and breast, and weak or no evidence for protection against cancers of the colon, bladder, ovaries, and

prostate (90, 91). However, associations of AA-containing foods and decreased cancer occurrence cannot be attributed to the actions of AA alone, as numerous other putative anticarcinogenic micronutrients and dietary/lifestyle factors may be involved.

AA is actively secreted into the gastric juice, where it is postulated to reduce cancer risk by reduction of carcinogenic nitrosamines or prevention of oxidative damage in the gastric mucosa (93, 94). Increased oxidative damage to the gastric mucosa has been reported in patients with *Helicobacter pylori*-associated gastritis, a condition that predisposes to gastric cancer (94). The evidence suggests that increasing gastric juice AA concentrations by eradication of *H. pylori* and/or by AA supplementation may reduce the risk of developing gastric cancer.

Evidence for a chemopreventive effect of AA from controlled intervention trials is also limited by study design factors, such as study of multiple nutrients, high-risk populations, small numbers of subjects, and measurement of surrogate cancer markers over relatively short time periods. To date, the few controlled clinical intervention trials have generally shown no benefit of AA supplementation toward reduced cancer risk. Whereas experimental and epidemiologic evidence suggests a protective effect of AA nutriture on esophageal and gastric cancer (93), results from the 6-year Linxian, China, micronutrient intervention trial showed no benefit from a vitamin C–molybdenum supplement in a population having low AA status and a high rate of esophageal and stomach cancer (95). Overall, the present data do not provide strong support for the claim that high AA intakes protect against human cancer.

Studies reporting a therapeutic use of AA for treatment of cancer have been neither abundant nor consistent. Prolongation of survival, even cures, of cancer patients by AA megadosing has sometimes been claimed but has not been corroborated by controlled studies. Current data suggest no utility for AA as a cancer treatment agent.

Heart Disease

AA has been reported to affect a variety of factors associated with heart disease risk, including vascular tissue integrity, vascular tone, lipid metabolism, and blood pressure (96, 97 and 98). The elasticity and structural integrity of the vascular matrix depends on ascorbate as an essential cofactor for molecular cross-linking of collagen; hence the connective tissue–related defects found in scurvy likely result from aberrant cross-linking. AA has beneficial effects on the human cardiovascular system beyond collagen formation. The vitamin inhibits plasma LDL oxidation, an *in vivo* event linked with initiation of atherosclerosis in the vascular intima (45). Ascorbate also exerts vasodilatory and anticlotting effects by altering the production of prostacyclin and other prostaglandins (64).

Human studies have shown mixed results as to the efficacy of AA in reducing heart disease risk and occurrence. Increased vitamin C intake has been linked with an improved blood lipid profile of total and HDL cholesterol, and with decreases in blood pressure (96, 97). However, treatment of elderly hypertensives for 6 weeks with 500 mg/day of AA provided no significant improvement in blood pressure compared with placebo (99). While *in vitro* studies suggest that ascorbate is an effective antioxidant

against plasma lipid and LDL oxidation, results from the Nurses and Health Professionals prospective cohort studies showed that consumption of vitamin E, but not vitamin C, was associated with reduced coronary disease (45, 97). Furthermore, a 20-year follow-up cohort study of elderly persons in Britain showed that AA status was strongly associated with decreased risk of subsequent stroke but not of coronary heart disease (100). A review summarizes evidence linking vitamin C to reduced heart disease risk as largely circumstantial but suggesting an association (96). More recent reviews state that limited results from controlled intervention trials of antioxidant vitamins, including vitamin C, do not presently support the hypothesis of heart disease protection suggested by experimental and epidemiologic evidence and that the hypothesis is promising but unproven until corroborated by results from randomized trials designed specifically to answer this question (101, 102).

Other Clinical and Therapeutic Aspects

Evidence linking AA nutriture to a variety of other physiologic functions and disease conditions is briefly reviewed below. The cited references are recommended for comprehensive and detailed coverage (28, 77, 79, 80, 81 and 82). As for the vitamin's links with degenerative diseases and immunocompetence, the evidence is not sufficiently convincing to recommend vitamin-based therapies or widespread increases in AA dietary intakes as prophylactic measures.

Improvement in a variety of *pulmonary functions* has been related to increased AA nutriture, possibly because of the vitamin's actions in degrading histamine, in attenuating free radical-related inflammation, and in modulating smooth muscle contractility via prostaglandin syntheses (103, 104 and 105). Human studies have found AA-related improvements in forced expiratory volume, forced vital capacity, acute respiratory infections, and bronchial reactivity. Clinical studies relating AA status to the occurrence of asthma have provided conflicting results, however.

High AA levels in the humors and tissues of the eye protect against damage from photolytically generated free radicals that may result in *cataracts and macular degeneration*. Some human studies show that AA nutriture is directly associated with reduced risk of age-related eye diseases, cataracts, and macular degeneration; however, the evidence linking ascorbate alone to reduced eye disease is neither consistent nor conclusive. In recent studies, dietary carotenoids, vitamin E, or a combination of antioxidants showed stronger associations with reduced risk for these eye disorders than did AA alone (106, 107 and 108). In contrast to evidence that AA protects against cataract formation, a variety of studies suggest that AA can facilitate lens opacities via the Maillard reaction or by the actions of AA breakdown products (109).

Ascorbate has been suggested to play various roles in *glucose metabolism and diabetes* (110). The metabolism and cellular transport of ascorbate is disturbed in animals made hyperglycemic and in diabetics, possibly because of the structural similarity of the glucose molecule to ascorbate. Low serum ascorbate levels often seen in diabetics are not explained by decreased dietary intake of the vitamin nor by increased urinary ascorbate loss (in subjects without renal pathology). Increased in vivo

destruction of antioxidants because of free radical stress may provide an alternative explanation, as increased oxidative stress and decreased serum antioxidant capacity have been hypothesized as factors in the complications of diabetes. In human studies, AA nutriture has been associated with improvement in some aspects of glycemic control and vascular health and with decreased protein glycosylation and erythrocyte sorbitol (a glucose metabolite linked to diabetic complications). However, effects of AA supplementation on serum glucose and glycosylated hemoglobin (a time-integrated measure of blood glucose levels) have been inconsistent. Megadose supplements (2 g/day) of AA given to healthy adults delayed the insulin response to a glucose challenge, possibly by competitive inhibition by AA of glucose uptake into pancreatic β cells ([111](#)).

AA nutriture has been postulated to affect *fertility* via roles in cellular oxidant defense and hormone and collagen production ([112](#)). Some evidence suggests that the high levels of AA in the brain are important for protection against iron-related oxidant damage linked to *senile dementias and Parkinson's disease*. On the other hand, AA also exerts an in vitro prooxidant effect in brain tissue under certain conditions. AA is important to *wound healing*, presumably because of its role in biosynthesis of mature cross-linked collagen, and in maintaining healthy gingival tissue ([Fig. 29.3](#)) ([67](#)). AA has been shown to ameliorate *heavy metal toxicity* effects, in some cases because of reductive action that decreases metal absorption or converts metals to less toxic forms. Supplements of AA have been reported to alleviate pain and provide clinical benefit to patients suffering from acute *pancreatitis* and from some *bone diseases*, including osteoarthritis, bone metastases, Paget's disease, and osteogenesis imperfecta. Low plasma concentrations of the vitamin found in critically ill patients suggest compromised antioxidant protection, wound healing, and recovery in these patients. Other conditions linked to AA status include anemia, mental depression, idiopathic thrombocytopenic purpura, gastrointestinal ulcers and hemorrhage, menorrhagia, habitual abortion, premature birth, and premature rupture of fetal membranes ([28](#), [77](#), [82](#)).

PHARMACOLOGIC INTAKES

Possible harmful effects of pharmacologic intakes of AA in the range of 1 to 15 g/day have been suggested; however, literature reviews of controlled studies involving supplementation with large doses of AA show no related toxicity ([81](#), [82](#), [113](#), [114](#)). The paucity of reported AA-related harmful effects in a U.S. population in which some 1/3 of individuals consumes supplementary AA suggests that the vitamin is nontoxic for healthy adults even in large amounts. Homeostatic mechanisms—saturation of absorption at 2 to 3 g/day intake and renal clearance of excess unmetabolized vitamin—probably play the most important roles in preventing AA toxicity. Nausea and diarrhea that sometimes accompany megadose intakes are ascribed to osmotic effects of unabsorbed vitamin passing through the intestine.

The fact that oxalic acid is a metabolite of AA catabolism prompts concerns of hyperoxaluria and contributions to kidney stones, although excess AA is mostly excreted into the urine unchanged, and the amount metabolized to oxalate is limited regardless of intake. Urinary oxalate and urate excretion were higher in healthy volunteers receiving 1 g/day of AA than with lower doses ([16](#)). However, most studies

show that increased AA intakes do not significantly increase body oxalate concentrations, and reports of stone formation linked directly to excess AA intake are limited to rare cases of individuals with renal disease (82, 115). Therefore, patients with kidney stones or renal disease are advised to avoid excess intake of AA.

The possible role of high dietary AA in facilitating intestinal iron absorption, exacerbating iron overload, and interacting with iron to promote in vivo oxidative damage warrants further study as discussed above in the “Biochemical Functions” section. Hemolysis has been reported in patients with glucose-6-phosphate dehydrogenase deficiency receiving high-dose AA therapy (82). The proposed toxic effects of high-dose AA ingestion, such as antagonism toward copper absorption and metabolism of vitamins B₆ and B₁₂, and systemic conditioning, are unconfirmed and appear to be unimportant (37, 61).

The reductive action of large amounts of AA in urine and feces can interfere with certain laboratory diagnostic tests such as those for glycosuria and fecal occult blood. A variety of blood tests based on redox chemistries, (e.g., cholesterol, glucose, uric acid) are biased by high plasma AA levels that result from supplement consumption (116). Large doses of AA may interfere with heparin or coumarin anticoagulant therapy.

Cobalt

Molybdenum

Manganese

Chapter References

Selected Readings

Nutritional disorders result from an imbalance between the body's requirements for nutrients and energy sources and the supply of these substrates of metabolism. This imbalance may take the form of either deficiency or excess and may be attributable to an inappropriate intake or to defective utilization or, frequently, a combination of both.

Despite our extensive understanding of human nutritional requirements for maintenance of health, malnutrition continues to be one of the main causes of morbidity and mortality

in developing countries, especially in young children. In technologically advanced societies, undernutrition due to dietary restriction no longer constitutes a major hazard to health, but it continues to occur in hospitalized patients and in other especially vulnerable groups. The special nutritional needs in patients receiving total parenteral nutrition (TPN) and chronic renal dialysis are now much better recognized than in previous years. However, deficiency states continue to arise in patients with long-term alcohol or drug abuse problems and in food fadism. Secondary undernutrition resulting from malabsorption, failure in transport, storage, or cellular utilization, or excessive losses requires constant vigilance in clinical practice. The improper usage of nutrient supplements has led to numerous instances of vitamin and element toxicity, often because of ignorance on the part of the user or inadequate or improper information by the supplier.

This chapter is confined to a consideration of clinical manifestations of nutritional disorders related to vitamins and essential trace elements. Disorders of protein and energy are considered elsewhere. A number of vitamin-dependency states have been identified and their symptomatology relates to the metabolic abnormalities produced by the respective apoenzyme disorders and not to the vitamin per se. Consequently, they are considered elsewhere under the appropriate vitamin.

The clinical manifestations of vitamin and essential element disorders consist of the relevant symptoms expressed by the patient and the signs observed by the physician on general physical examination. The present intention is to provide a comprehensive, yet reasonably brief, resumé of clinical nutrition for the physician practicing medicine within a highly specialized context. The particular clinical circumstances within which the various nutritional disorders tend to arise are indicated to help prevent their being missed as so often happens when they are “out of sight out of mind.”

VITAMINS

Vitamin A (Retinol)

Deficiency

The symptoms and signs of vitamin A deficiency have been studied in greater detail than those of any other nutritional deficiency disorder (1, 2). The eye is primarily involved and the condition, given the general name of xerophthalmia, predominantly affects young children. In a cooperative subject impaired dark adaptation of the retinal rods can be detected by instrumental means, scotometry or electroretinography. In young children night blindness can be elicited by a careful history and some simple tests in a poorly illuminated room (3). Photopic and color vision, mediated by the retinal cones, is usually unaffected.

Dryness (xerosis) and unwettability of the bulbar conjunctiva follow. Conjunctival impression cytology is abnormal at this stage. Bitot's spot is advanced conjunctival epithelial cell keratinization, a heaping up of desquamated cells most commonly seen in the interpalpebral fissure on the temporal aspect of the conjunctiva (Fig. 30.1A). In older

children and adults, Bitot's spots may be stigmata of past deficiency or may be entirely unrelated to vitamin A deficiency, when local trauma may be responsible. Corneal involvement, starting as a superficial punctate keratopathy (4) and proceeding to xerosis (Fig. 30.1B) and varying degrees of "ulceration" and liquefaction (keratomalacia) (Fig. 30.1C), frequently results in blindness. Punctate degenerative changes in the retina (xerophthalmic fundus) are a rare sign of chronic deficiency usually seen in older children (5). Corneal scars may have many causes, but those that are bilateral in the lower and outer part of the cornea of a person with a history of past malnutrition and/or measles often signal earlier vitamin A deficiency. They may appear as fine nebulae or denser leukomata, or there may be total scarring of a shrunken globe (phthisis bulbi) or corneal ectasia or anterior staphyloma.

Figure 30.1. **A.** Vitamin A deficiency. Bitot's spot in temporal interpalpebral fissure. **B.** Vitamin A deficiency. Conjunctival and corneal xerosis. **C.** Vitamin A deficiency. Keratomalacia. **D.** Riboflavin deficiency. Cheilosis and angular stomatitis. **E.** Riboflavin deficiency. Magenta tongue. **F.** Niacin deficiency. Symmetric dermatosis of pellagra. **G.** Fluorosis. Early stage with brown mottling that is most marked on upper central incisors. **H.** Zinc deficiency. Typical dermatosis associated with alcoholic cirrhosis in this patient. (From Ilchyshyn A, Mendelsohn Z. Br Med J 1982;284:1676.)

Extraocular manifestations include perifollicular hyperkeratosis, a heaping up of hyperkeratinized skin epithelium around hair follicles. This condition is most commonly seen on the outer aspects of the upper arms and the thighs. It is also seen in starvation and has been attributed to B complex vitamin or essential fatty acid deficiency. Other changes, which include impaired taste, anorexia, vestibular disturbance, bone changes with pressure on cranial nerves, increased intracranial pressure, congenital malformations and infertility, have been best demonstrated in animals (6) (see also Chapter 17).

In recent years, clinical and community trials of vitamin A supplementation of young children have demonstrated a significant decrease in all-cause mortality and morbidity

(6a) (see also [Chapter 97](#)).

Toxicity (Hypervitaminosis A)

Acute toxicity is more common in children. Most of the features relate to a rise in intracranial pressure: nausea, vomiting, headache, vertigo, irritability, stupor, fontanel bulging (in infants), papilledema and pseudotumor cerebri (mimicking brain tumor) (7). There is also pyrexia and peeling of the skin.

Chronic poisoning produces a bizarre clinical picture that is often misdiagnosed because of failure to consider excessive vitamin A intake (7). It is characterized by anorexia, weight loss, headache, blurred vision, diplopia, dry and scaling pruritic skin, alopecia, coarsening of the hair, hepatomegaly, splenomegaly, anemia, subperiosteal new bone growth, cortical thickening (especially bones of hands and feet and long bones of the legs), and gingival discoloration.

X-ray appearance may assist in making a correct diagnosis ([Fig. 30.3](#), [Fig. 30.4](#)). Cranial sutures are widened in the young child. Dense lines that appear at the metaphyses of all long bones represent cortical hyperostoses. These cortical thickenings usually stop short of the ends of the shafts. Premature fusion of hypertrophied epiphyseal ossification centers with their shafts is most often seen at the distal ends of the femurs. There may also be metaphyseal cupping and splaying of the affected end of the shaft. Cortical hyperostosis of the ribs may also occur.

Figure 30.3. A. and B. Frontal and lateral projections of skull of a 2-year-old girl with hypervitaminosis A showing wide sagittal and coronal sutures. (From Watson RC, Grossman H, Meyers MA. Radiologic findings in nutritional disturbances. In: Shils ME, Olson JA, Shike M. Modern nutrition in health and disease. 8th ed. Philadelphia: Lea & Febiger, 1994, with permission.)

Figure 30.4. Same patient as in [Figure 30.3](#). **A.** Dense line occurs at the distal end of radius and ulna. No subperiosteal new bone is present. **B.** Three weeks later, periosteal new bone is seen on the lateral aspect of the ulna. (From Watson RC, Grossman H, Meyers MA. Radiologic findings in nutritional disturbances. In: Shils ME, Olson JA, Shike M. Modern nutrition in health and disease. 8th ed. Philadelphia: Lea & Febiger, 1994, with permission.)

Vitamin A and other retinoids are powerful teratogens in both pregnant experimental animals and women ([7](#)). Birth defects have been reported in the offspring of women receiving 13-cis-retinoic acid (isotretinoin) during pregnancy ([8](#)). An increased risk of birth defects is present in infants of women taking more than 10,000 IU of supplementary preformed vitamin A per day before the 7th week of gestation ([9](#)); other reports indicate that birth defects are likely to occur at levels several times higher.

Hypercarotenosis

Excessive intake of carotenoids can cause hypercarotenosis. Yellow or orange discoloration of the skin (xanthosis cutis, carotenoderma) affects areas where sebum secretion is greatest—nasolabial folds, forehead, axillae, and groin—and keratinized surfaces such as the palms and soles. The sclerae and buccal membranes are not affected, which distinguishes it from jaundice, in which they are stained (see [Chapter 33](#)).

Vitamin D (Calciferol)

Deficiency

Vitamin D deficiency is manifested as rickets in children and osteomalacia in adults. Those forms not due to primary nutrient deficiency—previously termed *metabolic rickets*—also exhibit signs and symptoms of the underlying disease and hypocalcemia.

Rickets. The rachitic infant is restless and sleeps poorly. Consequently, the occipital

hair is denuded. Craniotabes, softening of the bones of the skull and their ready depression on palpation, is often the earliest sign, but it must be present away from the suture lines to be diagnostic of rickets. Frontal bossing occurs and the fontanelles close late. Sitting, crawling, and walking are all delayed. If the disease is active when these activities occur, weight bearing results in bowing of the arms ([Fig. 30.2A](#)), knock-knees (genu valgum), or outward bowing (genu varum).

Figure 30.2. **A.** Rickets. An infant with nutritional rickets at the crawling stage, demonstrating the role of pressure in causing bowing of the bones, in this case of the arms. **B.** Vitamin K deficiency. Hemorrhagic disease of the newborn secondary to vitamin K deficiency. Hemorrhage around the genitalia is a common site. **C.** Pellagra. Casal's necklace, a broad band or collar of dermatosis, induced by exposure to sunlight, is a classic sign of pellagra. The patient was an elderly female in Tanzania. **D.** Biotin deficiency. Adult on prolonged parenteral nutrition devoid of biotin with alopecia, dermatitis, and conjunctivitis (*left*). Slit lamp examination revealed corneal lesions. All were corrected by inclusion of 60 μg of biotin daily (*right*). (From McClain et al. JAMA, 1982;247:3116, with permission.) **E.** Scurvy. "Swan neck" or "corkscrew" deformities of the hairs characteristic of the early stages of adult scurvy. **F.** Scurvy. In adult scurvy, petechiae are characteristically perifollicular and usually precede larger extravasations, termed *ecchymoses*. The thighs and shins are common sites. **G.** Hypocalcemia. The characteristic contraction of the hands (tetany) in this marasmic infant is associated with the presence of marked hypocalcemia often secondary to magnesium depletion. **H.** Zinc deficiency. Lesions on pressure areas on the back of the hands in a child on prolonged parenteral nutrition who had rapidly depleted zinc stores through loss of large volumes of intestinal contents following an intestinal fistula. Similar lesions occurred on the elbows and knees. Sterile pustules were present on the palms, and lesions were present about the mouth. All responded to increased zinc administration. (Courtesy of M. E. Shils.)

The characteristic x-ray appearance usually precedes clinical signs ([Fig. 30.5](#)). The diaphyseal ends of the bones, most characteristically the lower ends of the radius and ulna, lose their sharp, clear outline, become cup shaped, and show a spotty or fringelike

rarefaction. Due to failure of calcification the distance between the radius and ulna and the metacarpals appears increased. Shadows cast by the shaft decrease in density, and the network formed by laminae becomes coarse. As healing begins, a thin white line of calcification appears in the epiphysis, becoming thicker and denser as calcification proceeds. Lime salts are deposited beneath the periosteum, the shaft casts a denser shadow, and the lamellae disappear. Bone morphology is also discussed in [Chapter 83](#).

Figure 30.5. A 10-month-old boy during various stages of rickets. **A.** Noncalcified provisional zone and fraying of the distal humerus are evident. Strands of calcified osteoid project from the sides of the bone. **B.** Cupping, spread metaphysis, fraying, and cortical spurs occur. Transverse linear recalcified density develops in rachitic metaphysis. A fracture is present in the midshaft of the radius. Greenstick fractures are common in the long bones. **C.** Metaphyseal spongiosum recalcifies and fuses with that of the provisional zone of calcification. Diffuse layer of recalcified cortex is present. (From Watson RC, Grossman H, Meyers MA. Radiologic findings in nutritional disturbances. In: Shils ME, Olson JA, Shike M. Modern nutrition in health and disease. 8th ed. Philadelphia: Lea & Febiger, 1994, with permission.)

The rachitic rosary, caused by enlargement of the costochondral junctions of the ribs, is said to be smoother than that due to scurvy (see discussion of [vitamin C](#)). The chest may be deformed to give Harrison's sulcus or groove, which consists of a bilateral indentation of the lateral parts of the lower ribs (see also [Chapter 18](#)). Other deformities of the chest, such as depression (funnel chest or pectus excavatum) of the sternum, are now considered to be congenital and not rachitic in origin.

Occasionally, stridor and intermittent sudden airway obstruction due to laryngospasm may present in infancy as a result of hypocalcemia accompanying biochemical and x-ray evidence of rickets but without the classical bony physical signs. A few instances of congenital cataract appear to be due to vitamin D deficiency in the mother ([10](#)).

Osteomalacia. The main features of osteomalacia are bone pains and tenderness, skeletal deformity, and weakness of the proximal muscles. In severe cases, all the

bones are painful and tender, often enough to disturb sleep. Tenderness may be particularly marked over Looser's zones (Milkman lines), usually occurring in the long bones, pelvis, ribs, and around the scapulae in a bilaterally symmetric pattern. These radiotranslucent zones are sometimes termed "pseudofractures." True fractures of the softened bones are common. The proximal muscle weakness, the cause of which is uncertain, is more marked in some forms of osteomalacia than in others. Osteomalacia usually results in a waddling gait and difficulty going up and down stairs. In the elderly it may simulate paraplegia; in younger persons it may simulate muscular dystrophy. Immigrant women to Europe and North America from Asia and the Middle East are especially susceptible.

Toxicity (Hypervitaminosis D)

Some of the symptoms and signs are related to hypercalcemia and are common to all causes of that condition. Anorexia, nausea, vomiting, and constipation are usually present. Weakness, hypotonia, stupor, and hypertension are less common. Polyuria and polydipsia are caused by hypercalciuria. Renal colic due to stone formation may result.

X-ray of the skeleton may assist diagnosis. There is increased epiphyseal bone density due to excessive calcium deposition.

Vitamin D excess has been reported to take two forms: mild and severe. In the mild form the patient is usually 3 to 6 months of age, and the symptoms and signs are those already described. In the severe form, also seen in infants, in addition to the manifestations of hypercalcemia, there is mental retardation, stenosis of the aorta and the pulmonary arteries, and a characteristic facial appearance termed *elfin facies* ([11](#)).

Vitamin E (Tocopherol)

Deficiency

In recent years clinical disease responsive to vitamin E has attracted considerable attention. Low-birth-weight infants are particularly susceptible, especially if fed formulas high in polyunsaturated fatty acids after occurrence of hemolytic anemia; the condition is made worse by iron supplements ([12](#), [13](#)). Defective vitamin E status of premature infants may also contribute to their greater susceptibility to platelet dysfunction, intraventricular hemorrhage, retinopathy of prematurity, and bronchopulmonary dysplasia. Lipofuscin deposition within muscle cells has been reported to account for the brown bowel syndrome ([14](#)).

Recently, the molecular basis has been discovered of two conditions in which vitamin E deficiency has long been known to figure prominently ([15](#)). In *spinocerebellar ataxias* of the Friedreich's ataxia type there is a defect in the α -tocopherol-transfer protein (α -TTP), and in *abeta lipoproteinemia* (Bassen-Kornzweig syndrome, acanthocytosis) there are mutations in the gene coding for one subunit of the microsomal triglyceride-transfer protein. Friedreich's ataxia presents in childhood with progressive ataxia of gait, dysarthria, areflexia, extensor plantar signs, and impaired vibratory and positional

sense. In abeta-lipoproteinemia there is steatorrhea, acanthocytes (erythrocytes with spiny projections of the membrane), retinitis pigmentosa–like changes in the retina, ataxia, and mental retardation. (See also [Chapter 19](#).)

Toxicity

In the early 1980s, use of an intravenous vitamin E product (E-Ferol), a drug that had not been approved by the United States Food and Drug Administration (FDA), led to pulmonary deterioration, thrombocytopenia, liver and renal failure, and a high mortality in newborn premature infants ([16](#)). Its toxicity may have been related to non–vitamin E constituents of the formulation ([16a](#)). Reports that low-birth-weight infants receiving pharmacologic doses of vitamin E had a high incidence of sepsis and necrotizing enterocolitis ([17](#)) have not been confirmed (see also [Chapter 19](#) concerning safety).

Vitamin K

Deficiency (Hypoprothrombinemia)

Understanding of the pathogenesis of vitamin K deficiency in the neonate has increased considerably. Hemorrhagic disease of the newborn (HDN) is usually classified into three syndromes: early, classic, and late ([18](#)). The early form presents within 0 to 24 hours of birth and the most common bleeding sites are cephalohematoma, within the gut (producing melena neonatorum), and around the genitalia ([Fig. 30.2B](#)). Classical HDN presents on day 1 to 7, and the bleeding is usually gastrointestinal, dermal, nasal, or from circumcision. The peak incidence of late HDN is from the 3rd to 6th week, and intracranial hemorrhage (rare in classical HDN) accounts for about 50% of the bleeding episodes at presentation. Late HDN may occur over weeks 2 to 12 and also commonly affects the skin and gastrointestinal tract.

In the adult, bleeding from this cause is most common in chronic liver disease, obstructive jaundice, and in patients receiving anticoagulants, prolonged antibiotic therapy, or certain cephalosporin antibiotics, such as moxalactam disodium.

Rare instances of deficiency have been attributed to dietary restriction ([19](#)) or inadequate TPN ([20](#)). Large doses of vitamin E may induce deficiency of vitamin K ([21](#)).

Toxicity

Kernicterus (bilirubin encephalopathy) has occurred in low-birth-weight infants receiving large doses of menadione (75 mg) or its water-soluble derivatives; it has not occurred when vitamin K itself has been given. Lethargy, hypotonia, and loss of sucking reflex are followed by opisthotonos, generalized spasticity, and frequently death from pulmonary complications. Survivors may develop the postkernicterus syndrome: high-frequency nerve deafness, athetoid cerebral palsy, and dental enamel dysplasia.

Thiamin (Vitamin B₁, Aneurin)

Deficiency

Beriberi in the adult occurs in two distinct forms, wet and dry beriberi, in which the cardiovascular and the nervous systems, respectively, are affected. Both may be involved in the same patient, but one or the other tends to predominate. Infantile beriberi is described separately (see also [Chapter 21](#)).

Cardiovascular beriberi usually manifests as chronic high-output right- and left-sided heart failure with tachycardia, rapid circulation time, elevated peripheral venous pressure, sodium retention, and edema ([22](#)). A much less common acute fulminating form of heart failure (sometimes called “shoshin”) is characterized by severe metabolic lactic acidosis, intense dyspnea, thirst, anxiety, and cardiovascular collapse. Signs also include stocking-glove cyanosis, extreme tachycardia, cardiomegaly, hepatomegaly, and neck vein distension. Edema is usually absent ([23](#)). This highly fatal form is not uncommon as a cause of sudden death in young migrant laborers in the Orient subsisting on rice.

Beriberi of the Nervous System ([24](#)). *Cerebral Beriberi (Wernicke-Korsakoff Syndrome).* Cerebral beriberi in its most severe form, mental confusion, accompanied by ophthalmoplegia due to paralysis of the 6th cranial nerve, leads to coma. Korsakoff's psychosis consists of loss of memory for distant events, inability to form new ones, and loss of insight and initiative. The patient is alert and can converse, think, and solve problems. Response to thiamin is complete in only 25% of cases and partial in 50%. Ethanol is thought to have a direct part in neurotoxicity ([25](#), [26](#)). Wernicke encephalopathy is most likely to occur in chronic alcoholics given carbohydrates without adequate thiamin replacement or in nonalcoholic depleted patients given infusions high in glucose without adequate thiamin. It is reported as a complication of vertical-banded gastroplasty for morbid obesity ([27](#)). (See [Chapter 95](#).)

Peripheral Neuropathy The most characteristic features of peripheral neuropathy are symmetric footdrop, associated with marked tenderness of the calf muscles, and a mild disturbance of sensation over the outer aspects of the legs and thighs and in patches over the abdomen, chest, and forearms. Ataxia with loss of position and vibration sense, burning paresthesias in the feet, and amblyopia are less common.

Infantile Beriberi. Early manifestations of infantile beriberi are anorexia, vomiting, pallor, restlessness, and insomnia. The disease progresses typically to (a) an acute cardiac form in infants 2 to 4 months of age, (b) a subacute aphonic form in those 5 to 7 months old, and (c) a chronic, pseudomeningeal form in those between 8 and 10 months of age. The acute form presents with dyspnea, cyanosis, a rapid thready pulse, and other signs of acute heart failure. In the subacute form, aphonia or a characteristic hoarse cry, dysphagia, vomiting, and convulsions predominate. The chronic form is characterized by neck retraction, opisthotonos, edema, oliguria, constipation, and

meteorism (28).

Subacute Necrotizing Encephalomyopathy (SNE, Leigh's Disease). SNE may be related to a defect in thiamin metabolism. About 100 cases have been reported (29). Onset is usually before 1 year of age. Hypoventilation and apnea, cranial neuropathies, and hypotonia are the most common features.

Possible Toxicity

Large doses of thiamin have been given to alcoholics as a part of their therapy. A survey of the U.S. literature revealed a significant number of reports of adverse effects in the late 1930s to early 1940s. From 1943 to 1973 there were six reports of sensitization of an anaphylactic nature, with nothing similar until 1992. At that time a case was reported of an alcoholic with a high blood alcohol level given 100 mg of thiamin-HCl intravenously, which was associated with onset of nausea, anxiety, arrhythmia, moderate hypotension, and wheezing; improvement occurred with epinephrine, antihistamines, and steroids (30). In contrast, 9 deaths were reported in the European literature between 1965 and 1985. Of note is the absence of reports of anaphylactic reactions with multivitamins containing thiamin used in TPN solutions.

Riboflavin

Deficiency

The skin and mucous membranes are affected in what is known as the oroculogenital syndrome. Areas of skin involved are usually those containing many sebaceous glands: mainly the nasolabial folds, alae nasi, external ears, eyelids, scrotum in the male, and labia majora in the female. They become reddened, scaly, greasy, painful, and pruritic. Plugs of inspissated sebum may accumulate in the hair follicles and give the appearance known as dyssebacia, or sharkskin (Fig. 30.6).

Figure 30.6. Dyssebacia associated with riboflavin deficiency.

At the angles of the mouth there are painful fissures known as angular stomatitis when active (see [Fig. 30.1B](#) and [Fig. 30.1D](#)). When chronic, these fissures give rise to one form of rhagades. Vertical fissures of the vermilion surfaces of the lips constitute cheilosis. These and the angular lesions may become infected with *Candida albicans*, giving rise to the appearance known as perleche. The tongue may be painful, swollen, and magenta colored ([Fig. 30.1E](#)). These mucocutaneous changes may also be seen in other nutrient deficiencies or in elderly edentulous individuals with chronically moist angles. Because deficiency is often multiple, it is rarely possible in clinical practice to demonstrate the precise cause.

Other signs that have been described include photophobia, lacrimation, and conjunctival injection. Corneal neovascularization, so common in experimental animals, is rarely seen in man. The hemopoietic and nervous systems are occasionally affected. A normocytic normochromic anemia, reticulocytopenia, leukopenia, thrombocytopenia from marrow hypoplasia, and peripheral neuropathies with hyperesthesia, altered temperature sensation, and pain have been reported ([31](#)).

Niacin

Deficiency

Pellagra affects primarily the skin, gastrointestinal tract, and nervous system. Dermatitis is usually the earliest and most prominent manifestation. It is symmetric and appears on parts exposed to sunlight or trauma. Erythema progresses to keratosis and scaling with pigmentation. The back of the hands, wrists, forearms, face, and neck (Casal's necklace) are typically affected ([Fig. 30.1F](#) and [Fig. 30.2C](#)). The skin and mucous membrane changes of riboflavin deficiency are also commonly present (see above).

The tongue often has a "raw beef" appearance, is bright red, swollen, and painful. Symptoms of gastritis, bouts of diarrhea, and signs of malabsorption suggest similar changes in the gastrointestinal tract.

Nervous system involvement is suggested in the early stages by periods of depression with insomnia, headaches, and dizziness. Later, tremulous movement or rigidity of the limbs occurs with loss of tendon reflexes, numbness, and paresis of the extremities, ultimately incapacitating the patient. In profound deficiency, an encephalopathy has been described that resembles that of acute cerebral beriberi (see section on [thiamin](#)) but responds to some extent to niacin. Mental disturbance is so prominent in some patients that there is a real danger that the true diagnosis might be missed and the patient be incarcerated in a mental institution.

Toxicity

Side effects of megadoses (e.g., 3 g/day) include vasodilatation, flushing, pruritus,

blistering of the skin with brown pigmentation, nausea, vomiting, and headache (32).

Pyridoxine (Vitamin B₆)

Deficiency

Pyridoxine deficiency is rarely severe enough to produce signs or symptoms. Volunteers receiving a deficient diet and a pyridoxine antagonist became irritable and depressed. Seborrheic dermatosis affected the nasolabial folds, cheeks, neck, and perineum. Several subjects also developed glossitis, angular stomatitis, blepharitis, and a peripheral neuropathy.

An uncommon form of sideroblastic anemia, often severe, has been reported to respond in some instances to pyridoxine, but most cases appear to be due to dependency rather than deficiency (33). Some years ago convulsions occurred in infants fed a milk formula in which the pyridoxine had been destroyed during processing (34).

Toxicity

A sensory neuropathy has been attributed to the abuse of pyridoxine in megadoses (35). Seven adults developed gradually progressive sensory ataxia and profound lower limb impairment of position and vibration sense. Touch, temperature, and pain perception were less affected. The motor and central nervous systems were unaffected. One review suggested that an impurity in the pharmacologic product might have been responsible (36).

Two patients with encephalitis suffered intensification of symptoms after dosing with pyridoxine and improved after its discontinuation (37).

Biotin

Deficiency

Biotin deficiency has occasionally been induced in patients who consumed large amounts of raw egg white over a prolonged period. Egg white contains avidin, which antagonizes the action of biotin. The skin of the face and hands becomes dry, shining, and scaling. The oral mucosa and tongue are swollen, magenta, and painful.

The most clear-cut cases of biotin deficiency occurred in children and adults maintained on long-term TPN in the early days before biotin was included in commercial vitamin formulations. An infant with short gut syndrome received TPN from 5 months of age. Five months later the infant lost all body hair and developed a waxy pallor, irritability, lethargy, mild hypotonia, and an erythematous rash. Biotin deficiency was confirmed biochemically, and all signs were reversed by supplementation (38). Two adult patients receiving home parenteral nutrition after extensive gut resection developed hair loss that was reversed by 200 µg biotin given intravenously daily (39). Another adult with

alopecia, rash, and metabolic acidosis responded to 60 µg of biotin added to parenteral fluids (30.2D) (see also [Chapter 28](#)).

Vitamin B₁₂ (Cobalamin)

Deficiency

Deficiency may be primary or secondary, as in pernicious anemia.

Pernicious Anemia. Pernicious anemia usually manifests after middle age. There is a slight female preponderance. It may be associated with signs of other autoimmune diseases. The most common complaints—those associated with anemia—ordinarily do not arise until the anemia is well advanced. Neurologic changes may long precede the hematologic changes. The tongue may be red, smooth, shining, and painful. Anorexia, weight loss, indigestion, and episodic diarrhea are all usually present (see [Chapter 27](#) and [Chapter 88](#)).

The typical patient has prematurely gray hair and blue eyes. A few patients have widespread brownish pigmentation affecting nail beds and skin creases but sparing the mucous membranes (in contrast to Addison's disease). In advanced cases there is usually pyrexia, enlargement of the liver and spleen, and occasionally bruising due to thrombocytopenia. Older patients may present with congestive cardiac failure.

A distal sensory neuropathy with “glove and stocking” sensory loss, paresthesias, and areflexia may occur in isolation or more commonly together with a myelopathy known as subacute combined degeneration of the cord. In this condition the initial symptom is symmetric paresthesias of the feet or, occasionally, of the hands. A combination of weakness and loss of postural sense makes walking increasingly difficult. Psychiatric disturbances, especially mild dementia, may be the presenting or only feature. Visual loss from optic atrophy is not uncommon.

Congenital lack of intrinsic factor presents before the age of 2 years with irritability, vomiting, diarrhea, weight loss, and anemia. It was reported that an infant exclusively breast fed by a mother with latent pernicious anemia developed megaloblastic anemia and neurologic abnormalities ([40](#)).

Primary Dietary Deficiency. When dietary lack or malabsorption is the cause of deficiency, anemia is usually the most prominent feature, but glossitis, optic atrophy, and subacute combined degeneration of the cord have also been described. Hyperpigmentation of the skin of the forearms has been reported. Megaloblastic anemia developed in an infant exclusively breast fed by a vegan mother ([41](#)).

Folic Acid

Deficiency

The anemia of folic acid deficiency has morphologic features similar to those of vitamin B₁₂ deficiency (see [Chapter 26](#) and [Chapter 88](#)), but it develops much more rapidly. Subacute combined degeneration of the cord does not occur, but about 20% of patients may have peripheral neuropathy. The tongue may be red and painful in the acute stage. In chronic deficiency, the tongue papillae atrophy, leaving a shiny, smooth surface. Hyperpigmentation of the skin similar to that occasionally seen in vitamin B₁₂ deficiency has been noted.

Folic acid therapy before conception is now accepted as protective against neural tube defects in infants of families in which these abnormalities have previously arisen ([42](#)). Inadequate one-carbon metabolism in conditions associated with genetic mutations and hyperhomocysteinemia is described in [Chapter 26](#), [Chapter 27](#) and [Chapter 34](#)).

Folate deficiency has been described in TPN with certain amino acid mixtures in the absence of supplementary folic acid ([43](#)). There is a single report of an infant, exclusively breast fed by a mother taking estrogen-progestogen contraceptive pills, who developed megaloblastic anemia responsive to folic acid ([44](#)).

Pantothenic Acid

Deficiency

Researchers reported “burning feet syndrome” in adult volunteers on a deficient diet and claimed that this condition responded to pantothenic acid. In clinical practice this distressing condition has rarely responded to this treatment, and there is at present no certain clinical manifestation of pantothenic acid deficiency.

Vitamin C (Ascorbic Acid)

Deficiency

Scurvy tends to affect either the very young or the elderly. The clinical picture differs in these two groups.

Infantile Scurvy (Barlow's Disease). The onset of infantile scurvy, usually in the second half of the 1st year of life, is preceded by a period of fretfulness, pallor, and loss of appetite. Localizing signs are tenderness and swelling, most marked at the knees or ankles. These signs result from characteristic bone changes demonstrable by radiograph ([Fig. 30.7](#), [Fig. 30.8](#) and [Fig. 30.9](#)).

Figure 30.7. A 27-month-old boy with scurvy. Frontal **(A)** and lateral **(B)** chest roentgenograms demonstrate bony swelling at the costochondral junctions of the ribs. (From Watson RC, Grossman H, Meyers MA. Radiologic findings in nutritional disturbances. In: Shils ME, Olson JA, Shike M. Modern nutrition in health and disease. 8th ed. Philadelphia: Lea & Febiger, 1994, with permission.)

Figure 30.8. A 10-month-old boy with scurvy. A thick white line occurs at the metaphyses of the long bones of the knees. Linear breaks are present in the bones proximal and parallel to the white lines of the distal femur. Spurs are present and best seen at the ends of the femurs and medial aspect of the right tibia. The ossification centers have central rarefaction with heavy ring shadows on the margins. Periosteal new bone is along the medial aspects of the tibias. (From Watson RC, Grossman H, Meyers MA. Radiologic findings in nutritional disturbances. In: Shils ME, Olson JA, Shike M. Modern nutrition in health and disease. 8th ed. Philadelphia: Lea & Febiger, 1994, with permission.)

Figure 30.9. A 12-month-old boy with healing scurvy. **A.** Fracture of the provisional zone of the calcification of the distal femur with early calcification is apparent. Displacement of the soft tissues is due to hematoma that has not begun to calcify. **B.** Extensive calcification of elevated periosteum occurs after 2 weeks of vitamin C therapy. (From Watson RC, Grossman H, Meyers MA. Radiologic findings in nutritional disturbances. In: Shils ME, Olson JA, Shike M. Modern nutrition in health and disease. 8th ed. Philadelphia: Lea & Febiger, 1994, with permission.)

The earliest x-ray changes appear at the sites of most active growth; the sternal end of the ribs, distal end of the femur, proximal end of the humerus, both ends of the tibia and fibula, and distal ends of the radius and ulna. A zone of rarefaction immediately shaftward of the zone of provisional calcification gives rise to the “corner fracture” sign. Atrophy of trabecular structure and blurring of trabecular markings cause a “ground glass” appearance. Widening of the zone of provisional calcification causes a dense shadow at the end of the shaft which is also seen at the periphery of the centers of ossification. This ringlike appearance is seen best at the knee and is very characteristic of scurvy. As the deficiency proceeds, fractures may occur in areas of extending rarefaction. The overlying zone of provisional calcification may be comminuted with the shaft, and spur formation may occur. Epiphyses may separate and be displaced. Temporary healing often modifies the radiologic appearance. With treatment, even the grossest deformities resolve, although radiologic evidence may persist for several years.

Enlargement of the costochondral junctions produces the scorbutic rosary, which has a sharper feel than that due to rickets (see section on [vitamin D](#)). The infant often adopts the “pithed frog” position of maximum comfort, with the legs flexed at the knees and the hips partially flexed and externally rotated. The arms are less commonly involved. Hemorrhage and spongy changes in the gums are confined to the sites of teeth that have recently erupted or are about to do so. Bleeding may occur anywhere in the skin (the orbit is a frequent site) or from mucous membranes, including the renal tract. In infancy, intracranial hemorrhages are rapidly progressive if treatment is delayed, and death may occur. Petechiae and ecchymoses, usually found in the region of the bone lesions, are less common than in the adult. Microcytic hypochromic anemia is common, a normochromic normocytic picture less so. Older children may develop characteristic

perifollicular hemorrhages and hair changes seen in the adult.

Adult Scurvy. Early symptoms of adult scurvy are weakness, easy fatigue, and listlessness, followed by shortness of breath and aching bones, joints, and muscles, especially at night. These symptoms are followed by characteristic changes in the skin (45). Acne, indistinguishable from that of adolescence, precedes defects in the hairs of the body. These defects consist of broken and coiled hairs and a “swan-neck” deformity resulting from their being flat instead of round in cross section (Fig. 30.2E). A salient feature of scurvy in the adult is perifollicular hemorrhages and perifollicular hyperkeratosis, most commonly affecting the anterior aspects of the thorax, forearms, thighs, and legs and the anterior abdominal wall (Fig. 30.2F).

Frank bleeding is a late feature of scurvy. The classic gum changes are only associated with natural teeth or buried roots and are enhanced by poor dental hygiene and advanced caries. The interdental papillae become swollen and purple and bleed with trauma. In advanced scurvy, the gums are spongy and friable, bleeding freely. Secondary infection leads to loosening of the teeth and to gangrene. Patients who are edentulous or whose teeth are in good repair have little or no evidence of scorbutic gingivitis. Hemorrhage commonly occurs deep in muscles and into joints as well as over large areas of the skin in the form of ecchymoses (Fig. 30.10). Multiple splinter hemorrhages may form a crescent near the distal ends of the nails. Old scars break down, and new wounds fail to heal. Bleeding into viscera or the brain leads to convulsions and shock; death may occur abruptly.

Figure 30.10. Perifollicular hemorrhages of the legs in adult scurvy.

ESSENTIAL FATTY ACIDS (EFAS)

Although EFAs are not vitamins in the ordinary sense, it is convenient to consider symptoms of deficiency of these fatty acids here.

w-6 EFA Deficiency

Growth retardation, sparse hair growth, branlike desquamation of the skin of the trunk, poor wound healing, and increased susceptibility to infection have been observed in infants receiving a formula deficient in essential fat or in children and adults receiving long-term, lipid-free parenteral nutrition (46).

Sometimes there is only dry, flaky skin, but more advanced deficiency results in scaling, eczematoid dermatosis, usually starting on the nasolabial folds and eyebrows and spreading across the face and neck (Fig. 30.11). Anemia and enlarged fatty liver have also been reported.

Figure 30.11. Dermatitis of essential fatty acid deficiency associated with total parenteral nutrition. (Courtesy of Dr. R. E. Hodges.)

w-3 EFA Deficiency

The first human report of w-3 EFA deficiency was of a 7-year-old girl with extensive gut resection who received TPN rich in w-6 but very low in w-3 fatty acids. Neurologic changes included paresthesias, weakness, inability to walk, pain in the legs, and blurred vision (47). These are reported to have responded to change of treatment, but it is possible that other deficiencies, including that of vitamin E, might have been responsible. Other possible cases have since been reported, and the subject has been reviewed (48). It now appears that the symptoms of the two kinds of fatty acid deficiency are quite distinct.

MINERALS

Calcium

Hypocalcemia

Symptoms and signs of underlying disorders are present in hypocalcemia. True hypocalcemia (i.e., subnormal ionized calcium) in clinical conditions is rarely caused by inadequate calcium ingestion but rather by disorders of calcium metabolism or use. It affects the nervous system with depression and psychosis, progressing to dementia or encephalopathy. The most characteristic syndrome is tetany, consisting of (a) paresthesias about the lips, tongue, fingers, and feet; (b) carpopedal spasm, resulting in “obstetrician's hand,” or Trousseau's sign, a deformity that may be painful and prolonged ([Fig. 30.2G](#)); (c) generalized muscle aching; and (d) spasm of the facial muscles. At the earlier stage of latent tetany, neuromuscular irritability may be elicited by provocative tests. Chvostek's sign is contraction of the facial muscles on light tapping of the facial nerve. Trousseau's sign is carpopedal spasm induced by restriction of the blood supply to a limb by a tourniquet or elevation above systolic pressure with a blood pressure cuff applied for 3 minutes or less. Rarely, cataract is the earliest feature.

In about 80% of very low birth weight infants, osteopenia can be diagnosed radiologically, and rickets is much less common ([49](#)). In the neonate and older infant, tetany may manifest as rhythmic, focal myoclonic jerks, sometimes followed by convulsions, cyanosis, and heart failure. Muscular spasms and laryngismus stridulus may occur in young children.

Osteoporosis

Calcium insufficiency plays an ill-defined role in this condition of loss of bone mass (see [Chapter 83](#) and [Chapter 85](#)). It is common in the elderly, especially in postmenopausal white women. There is bone deformity, localized pain, and fractures. Osteomalacia may coexist. The most common deformity is loss of height caused by vertebral collapse, which accounts for most of the pain. Fractures of the neck of the femur and Colles' fracture above the wrist are most commonly precipitated by trauma, which may be trivial, in elderly persons with osteoporosis.

Calcium-Deficiency Rickets

Reports from South Africa suggested that true rickets can be produced by dietary calcium deficiency in the presence of normal vitamin D status ([50](#)). The histologic changes of rickets were confirmed by biopsy and responded to calcium therapy alone ([51](#)).

Hypercalcemia

Hypercalcemia has a variety of causes and produces a symptom complex that is, to some extent, characteristic. Gastrointestinal symptoms include anorexia, nausea, vomiting, constipation, abdominal pain, and ileus. Renal system involvement produces

polyuria, nocturia, polydipsia, stone formation, and sometimes hypertension and signs and symptoms of uremia. Muscle weakness and myopathy occur. More advanced disease, which causes psychosis, delirium, stupor, and coma, may be fatal.

Phosphorus

Hypophosphatemia

Hypophosphatemia is defined as lowered inorganic phosphate level (<0.71 mmol/L, or 2.2 mg/dL) with or without a significant decrease in the total body phosphate in relation to total body nitrogen. The latter situation usually occurs in any situation stimulating anaerobic glycolysis, such as infusion of hypertonic glucose continuously without adequate phosphate replacement; this results in a shift of serum inorganic phosphate into cells and a fall in serum phosphate levels. The markedly depressed serum phosphate (usually <0.30 mmol/L, or 0.93 mg/dL) is associated in 3 to 4 days with circumoral and extremity paresthesias and red cell fragility and hemolysis.

Total Body Phosphate Depletion

Total body phosphate depletion occurs with total body nitrogen loss as the result of various diseases that lead to excessive loss of both in the stool (e.g., malabsorption, vitamin D deficiency) or in the urine (e.g., hyperparathyroidism, congenital or drug-induced renal tubular acidosis, severe potassium depletion). In the management of advanced renal disease, administration of phosphate-binding gels intended to reduce phosphate absorption in association with restricted phosphate in the diet may lead to symptomatic phosphate deficiency (52, 53) (Table 30.1) (see also Chapter 8).

Organ System Affected	Manifestation
Constitutional	Anorexia, malaise, debility, lethargy
Neuropsychiatric	Altered sensorium, confusion, seizures, coma, decreased motor and sensory nerve conduction
Hematologic	Erythrocyte deformity, hemolysis, impaired phagocytosis, thrombocytopenia, hemorrhage
Metabolic	Insulin resistance and glucose intolerance
Gastrointestinal	Dysphagia, ileus, impaired liver function
Musculoskeletal	Rickets (osteomalacia), arthralgia, muscle weakness, rhabdomyolysis
Renal	Glycosuria, magnesuria, renal tubular acidosis

From *Bonner TM, Shike M: Annu Rev Nutr 1988;8:121-48.*

Table 30.1 Manifestations of Phosphate Depletion and/or Hypophosphatemia

Potassium

Deficiency

Potassium deficiency is usually due to excessive losses in urine or stool, less commonly to decreased intake, as in starvation or failure to give potassium in intravenous solutions, and losses in sweat as in cystic fibrosis.

Severe hypokalemia (serum K <3 mmol/L, or <3 mEq/L) may cause muscle weakness leading to respiratory failure, paralytic ileus, hypotension, and tetany. Potassium nephropathy results in polyuria with secondary polydipsia. Cardiac effects are particularly likely in patients receiving digitalis. The electrocardiogram (ECG) is characteristic with S-T segment depression, increased U wave amplitude, and T wave amplitude less than that of U wave in the same lead. Premature ventricular and atrial contractions and ventricular and atrial tachyarrhythmias occur.

Toxicity (Hyperkalemia)

Acute oliguric states are often responsible for hyperkalemia, but excessive ingestion or infusion may produce symptoms even in the presence of normal renal function.

Cardiac toxicity, of serious import, starts with shortening of the Q-T interval of the ECG and tall, peaked T waves. Progressive toxicity with serum K levels above 6.5 mmol/L (>6.5 mEq/L) causes nodal and ventricular arrhythmias, widening of the QRS complex, PR interval prolongation and disappearance of the P wave, and finally degeneration of the QRS complex with ventricular asystole or fibrillation and death.

Magnesium

Deficiency

In depletion studies in humans as well as in clinical practice, when hypomagnesemia (defined as serum Mg <1.5 mEq/L, <1.9 mg/dL) progresses below 1.0 mEq/L, it is often accompanied by hypocalcemia and hypokalemia.

The symptoms and signs of both experimental and clinical deficiency are primarily neuromuscular: Trousseau and Chvostek signs, muscle fasciculations, tremor, muscle spasm, personality changes, anorexia, nausea, and vomiting. Recently, low dietary intake of magnesium was associated with impaired lung function and wheezing (54). Convulsions or coma in infancy is not infrequently associated with magnesium deficiency.

Magnesium depletion has been associated with malabsorption syndromes, renal tubular abnormalities, endocrine dysfunction, and genetic and familial conditions (55). In some clinical situations, serum magnesium may be within normal limits despite evidence of cellular or tissue depletion (see also [Chapter 9](#)).

Toxicity (Hypermagnesemia)

Elevated serum magnesium levels (>2.1 mEq/L, >2.5 mg/dL) are not uncommon in patients with renal failure who are receiving magnesium-containing drugs and in children with chronic constipation treated with magnesium sulfate enemas. With higher levels, deep tendon reflexes disappear and ECG abnormalities (prolonged PR interval, widening of QRS complex, and increased T wave amplitude) occur. Hypertension, respiratory depression, narcosis, and ultimately cardiac arrest may occur with very high blood magnesium levels (see [Chapter 9](#)).

Iodide (Iodine)

Deficiency

Enlargement of the thyroid gland is the most common clinical sign of iodide deficiency. When it is due to iodine lack, this condition is termed simple, colloid, endemic, or euthyroid goiter. It is more common in women and is often noted at the onset of puberty, during pregnancy, or at the menopause. Early on, the enlargement is soft, symmetric, and smooth; later, multiple nodules and cysts may appear. Most patients are euthyroid, a few have hyperthyroidism, and rarely hypothyroidism occurs.

Severe endemic goiter is often accompanied by cretinism. Endemic cretinism occurs in two distinct forms, the myxedematous and the neurologic, which may coexist ([56](#)). In most areas of the world, the neurologic form is by far the more common. The clinical manifestations of the two conditions are listed in [Table 30.2](#) (see also [Chapter 13](#)).

Feature	Myxedematous Cretin	Neurologic Cretin
Mental retardation	Present, often severe	Present, often severe
Deaf-muteness	Absent	Usually present
Central epilepsy	Absent	Often present
Stature	Severe growth retardation	Usually normal, occasionally slight growth retardation
General features	Coarse dry skin, protrudent abdomen with umbilical hernia, large tongue	No physical signs of hypothyroidism
Reflexes	Delayed relaxation	Excessively brisk
ECG	Small-voltage QRS complexes and other abnormalities of hypothyroidism	Normal
Skull x-rays	Epiphyseal dysgenesis	Normal
Effect of thyroid hormones	Improvement	No effect

From [Hazzal BS, Hay ID. Clin Endocrinol 1979;11:445-60](#)

Table 30.2 Comparative Clinical Features in Myxoedematous and Neurologic Cretinism

Toxicity

Prolonged excessive intake of iodine leads eventually to iodide goiter and myxedema, especially in patients with preexisting Hashimoto's thyroiditis.

Iron

Deficiency

Iron deficiency has its major impact on many systems via reduction in tissue oxygenation due to decreased hemoglobin concentration. The clinical picture depends on the rapidity of development of anemia and on its severity (see [Chapter 10](#) and [Chapter 88](#)).

The typical microcytic hypochromic anemia of insidious onset manifests as increasing fatigue and slight pallor, best seen in the mucous membranes. Later, cardiorespiratory signs and symptoms include exertional dyspnea, tachycardia, palpitations, angina, claudication, night cramps, increased arterial and capillary pulsation, cardiac bruits, reversible cardiac enlargement and, if cardiac failure occurs, basal crepitations, peripheral edema, and ascites. Neuromuscular involvement is evidenced by headache, tinnitus, vertigo, cramps, faintness, increased cold sensitivity, and retinal hemorrhage. Gastrointestinal symptoms include anorexia, nausea, constipation, and diarrhea. Low-grade fever, menstrual irregularity, urinary frequency, and loss of libido may occur.

Iron deficiency per se has certain characteristics not usually associated with other forms of anemia. A nonspecific glossitis with almost complete loss of filiform papillae is common. Angular stomatitis is less frequent. Spoon-shaped nails (koilonychia) are characteristic of longstanding iron deficiency. The Patterson-Kelly (Plummer-Vinson) syndrome is the association of iron deficiency anemia, glossitis, dysphagia, and achlorhydria, usually seen in middle-aged women, but much less commonly than was formerly the case. In severe cases, postcricoid webs and malignant change in this region may occur. Signs of deficiency of some B group vitamins are also often present. Pica (geophagia) is an occasional feature. Even mild iron deficiency is considered important in decreased work efficiency ([58](#)). In infants and young children, certain aspects of learning ability are impaired.

Toxicity

Acute poisoning causes vomiting, upper abdominal pain, pallor, cyanosis, diarrhea, drowsiness, and shock. Death may occur in children mistaking iron tablets for sweets.

Chronic toxicity (hemochromatosis, iron overload) affects many tissues (see [Chapter 10](#)). Diabetes, often the presenting feature, eventually develops in about 80% of patients. The skin is a characteristic slate-gray color. The liver becomes enlarged and then cirrhotic, and hepatoma may develop. Cardiomyopathy leads to heart failure in about 50% of patients. Pituitary failure may cause testicular atrophy and loss of libido. Focal hemosiderosis damages the lungs and kidneys.

Copper

Deficiency

The principal features of copper deficiency are a hypochromic anemia unresponsive to iron therapy, neutropenia, and osteoporosis. Early radiologic findings are osteoporosis of the metaphyses and epiphyses and retarded bone age. Typical findings are increased density of the provisional zone of calcification and cupping with sickle-shaped spurs in the metaphyseal region. Other skeletal abnormalities include periosteal layering and submetaphyseal and rib fractures ([Fig. 30.12](#)).

Figure 30.12. Bone changes due to copper deficiency. (From Bennani-Smires C, Medina J, Young LW. *Am J Dis Child* 1980;134:1155.)

Premature infants are especially vulnerable and have shown the following signs: pallor, decreased pigmentation of the skin and hair, prominent superficial veins, skin lesions resembling seborrheic dermatitis, failure to thrive, diarrhea, and hepatosplenomegaly. Some have features suggesting central nervous system damage, including hypotonia, apathy, psychomotor retardation, apparent lack of visual responses, and apneic episodes.

The most extreme form is seen in Menkes' steely hair disease ([59](#)), a complex X-linked disease of male infants in which there is both failure to absorb copper and then failure to form functional cuproproteins. Interference with cross-linking of elastin and collagen can be held responsible for many of the features: premature rupture of the membranes leading to premature birth, lax skin and joints, elongation and dilatation of major arteries resulting in rupture and hemorrhage, subintimal thickening with partial occlusion of major arteries, hernias, and diverticula of bladder and ureters causing recurrent infection or rupture. Osteoporosis, flaring of metaphyseal edges, and Wormian bones in cranial sutures may all be secondary to collagen abnormalities. Lack of pigmentation of the skin

and hair and abnormal spiral twisting (pili torti) and fragility of hair add to the characteristic appearance of affected babies. Neurologic development rarely progresses beyond 6 to 8 weeks, and even these functions are lost during the ensuing months. Ataxia is striking in mild cases.

Toxicity

In Wilson's disease (hepatolenticular degeneration) accumulation of copper in the liver leads to cirrhosis and signs of liver failure. Deposits in the brain result in tremors, choreoathetoid movements, rigidity, dysarthria, and eventually dementia. Anemia and signs of renal failure are common. Characteristic changes in the eye are the Kayser-Fleischer ring, a brown or green ring near the limbus of the cornea, and a "sunflower" cataract. Childhood cirrhosis has been common on the Indian subcontinent and is reported to occur in Indian children living elsewhere (60). It has been attributed to copper accumulation in the liver. The suggestion that the source of the copper is milk contaminated by boiling and storage in brass and copper pots has not been confirmed (61).

Acute poisoning has resulted from ingestion of solutions of copper salts or contaminated water supplies or dialysis fluid. In severe cases, evidence of hepatic or renal failure (or both) is found.

Zinc

Deficiency

The first report of human zinc deficiency was from Iran, consisting of a syndrome of dwarfism, hypogonadism, anemia, hepatosplenomegaly, rough dry skin, and lethargy associated with geophagia (62). In a similar picture in Egypt, parasitism appears to play an important role (63). Hypogeusia (impaired taste) and growth retardation in otherwise healthy children have been found to respond to zinc supplementation in parts of North America (64).

Clinical cases of zinc deficiency have been reported with various manifestations, depending on the severity of depletion and other factors. In addition to those mentioned above they include dermatoses, immune deficiencies, glossitis, photophobia, lack of dark adaptation, and delayed wound healing. Precipitating factors include short bowel syndrome, alcoholism with pancreatic and liver disease (Fig. 30.1H), sickle cell anemia, certain chelating medications, the acrodermatitis enteropathica genotype, intestinal losses via fistula, and inadequate amounts of zinc in parenteral nutrition fluids (see Chapter 11).

TPN with inadequate zinc supplementation has occasionally caused an acute deficiency syndrome consisting of diarrhea, mental depression, alopecia, and dermatosis, usually around the orbits, nose, and mouth (65) (Fig. 30.1H). Loss of zinc through an intestinal fistula was responsible for development of skin lesions about the mouth, palms (sterile pustules), and pressure points on hands and elbows in a 6-year-old child with

non-Hodgkin's lymphoma ([Fig. 30.2H](#)); they responded rapidly to additional zinc.

Acrodermatitis enteropathica, an autosomal recessive disorder manifested in artificially fed infants, caused by a defect in zinc absorption, is characterized by extensive dermatitis, growth retardation, diarrhea, hair loss, and paronychia (see [Chapter 11](#)). The skin changes somewhat resemble those seen in kwashiorkor ([66](#)), but the skin changes of zinc deficiency have a typical appearance: the distribution is often acro-orificial, commonly also involving the flexures and friction areas, and may become generalized. Eczematoid, psoriaform, vesiculobullous, and pustular lesions may be present. The earliest skin lesions are bright reddish, nonscaly macules and patches.

Toxicity

Ingestion of large amounts of zinc, usually from an acid food or drink from a galvanized container, has caused vomiting and diarrhea. Excessive zinc intake, as in large daily doses (30–150 mg) for several weeks, interferes with copper absorption and leads to copper deficiency. Severe lethargy in dialysis patients has been attributed to excessive zinc in dialysis fluids. Accidental intravenous administration of 1.5 g has proven fatal.

Fluoride

Deficiency

Fluorine has not yet been proved an essential element for man, but it has a role in bone mineralization and hardening of tooth enamel. Areas with a low fluorine content in the water supply have high rates of dental caries. Fluoridation of the water or use of supplemented tooth paste is associated with a significant fall in dental caries rates (see also [Chapter 16](#)).

Toxicity (Fluorosis)

Fluorosis is associated with high levels (>10 ppm) in the drinking water. It is most evident in permanent teeth that develop during high fluorine intake. Deciduous teeth are affected only at very high levels. The earliest changes, chalky white, irregularly distributed patches on the surface of the enamel, become infiltrated by yellow or brown staining, giving rise to the characteristic “mottled” appearance ([Fig. 30.1 G](#)). More severe fluorosis also causes pitting of the enamel.

Chronic ingestion of very large amounts of fluoride (>5 mg/day) for years may lead to crippling skeletal fluorosis progressing from occasional stiffness or joint pain to chronic pain and osteoporosis of long bones. This rare condition in the United States is associated with drinking high-fluoride well water ([66a](#)).

Selenium

Deficiency

Two syndromes have been described from China in which selenium deficiency is believed important. The first is Keshan disease, named for its place of origin, which consists of a highly fatal cardiomyopathy affecting mainly young children and women of childbearing age. Good response to selenium supplementation has been reported (67). The other, known as Kashin-Beck disease, features osteoarthritis during preadolescence or adolescence that results in dwarfing and joint deformities from cartilage abnormalities (68) (see [Chapter 14](#)).

In the United States, some patients have been reported to develop selenium deficiency on TPN with no added selenium (69). Features have included a severe cardiomyopathy, muscle pain and tenderness, dyschromotrichia, white fingernail beds, and macrocytosis.

Toxicity

Endemic selenosis, long recognized in animals, has been suspected in some human communities, most convincingly from China (70). The most frequently observed signs were loss of hair and nails. Skin lesions and polyneuritis were less certainly attributed to selenium toxicity.

Alopecia and nail changes occurred in New York City from consumption of a “health store” supplement containing excessive amounts of selenium (71). In eight reported cases of criminal poisoning, four were fatal (72). Symptoms and signs were distinctive: metallic taste, odor of garlic caused by methylation of selenium, mucosal irritation, gastroenteritis, paronychia, and red pigmentation of nails, hair, and teeth.

Chromium

Deficiency

A patient receiving total parenteral nutrition for more than 5 years unexpectedly developed 15% weight loss, peripheral neuropathy, and glucose intolerance after 3.5 years of nutritional support (73). These conditions were all reversed with chromium therapy. Two further cases have been reported, both with weight loss and hyperglycemia that responded to chromium (74, 75). In some parts of the world, protein-energy malnutrition appears to be complicated by chromium deficiency (76).

Toxicity

Toxicity usually results from direct contact or inhalation in industry. Chrome ulcers on the hands or perforation of the nasal septum may result. Lung cancer can occur, but only with hexavalent compounds.

Cobalt

There is little evidence of a role for cobalt in human nutrition other than as part of the vitamin B₁₂ molecule.

Toxicity

Cobalt at one time was recommended for treatment of anemia of nephritis and infection in addition to the usual hemopoietic agents. In this context, it was reported to cause goiter, myxedema, and congestive heart failure in five patients (77). A cardiomyopathy with a high mortality has been described after industrial exposure, during maintenance dialysis, and after drinking beer that was contaminated with cobalt during processing (78).

Molybdenum

Deficiency

An autosomal recessive molybdenum cofactor deficiency resulting in deficiencies of xanthine oxidase and sulfite oxidase was reported in more than 20 patients in the past decade (79). There is severe brain damage, convulsions are frequent, and about half the patients failed to survive beyond early infancy.

Only one clear-cut case related to prolonged TPN has been reported to date (80), involving tachycardia, tachypnea, headache, night blindness, central scotomas, nausea, vomiting, lethargy, disorientation, and coma. These signs and symptoms were reversed by 300 µg/day of molybdenum, and the urinary excretion of abnormal amounts of methionine metabolites was dramatically decreased.

Toxicity

Elevated blood levels of molybdenum were associated with a goutlike syndrome in Armenia in 1961 (81). Other symptoms and signs mentioned suggested some involvement of liver, gastrointestinal tract, and kidney. The pathogenesis was unclear.

Manganese

Deficiency

One unsubstantiated case of human deficiency was reported to have occurred when manganese was inadvertently omitted from an experimental diet fed to a volunteer. Clinical signs included weight loss, transient dermatitis, nausea and vomiting, changes in hair color, and slow growth of hair (82).

Toxicity

Manganese toxicity is usually reported in those who mine or refine ore. Prolonged exposure has caused neurologic changes resembling those of parkinsonism or Wilson's disease. In an area in Greece, well water with a high manganese content may be responsible for occurrence of a parkinsonian syndrome (83). Recently, it has been reported that manganese accumulates in the basal ganglia of patients with cirrhosis of the liver, and it is suggested that this may be associated with the occurrence of encephalopathy in these patients (84). Toxicity has been reported in children given 0.8 to 1.0 mmol of manganese ion per kilogram body weight in long-term TPN (85). This level is about 50 times greater than the recommendations in [Chapter 101](#).

HISTORICAL INTRODUCTION

Carnitine was first discovered in muscle extracts independently by Gulewitsch and Krimberg and by Kutscher in 1905, and the correct structure was assigned in 1927 by Tomita and Sendju (1). Between 1948 and 1952, Fraenkel and colleagues demonstrated the essential nature of this compound for the mealworm, *Tenebrio molitor*, and assigned the term *vitamin B_T* to carnitine (1). A function for carnitine in fatty acid oxidation was first discovered independently by Bremer and by Fritz and Yue between 1962 and 1963 (2). The origin of the methyl groups of carnitine was identified by Wolf and Berger and Bremer in 1961 (2), and the origin of the carbon chain of carnitine from the essential amino acid lysine was first reported by Tanphaichitr and colleagues (3) in 1971. Clinical syndromes associated with carnitine deficiency were first reported by Engel and colleagues in 1973 (4) and 1975 (5), and carnitine deficiency was associated specifically with a defect in carnitine transport by Treem et al. in 1988 (6).

CHEMISTRY AND NOMENCLATURE

Carnitine (β-hydroxy-γ-*N,N,N*-trimethylaminobutyric acid) is a zwitterionic quaternary amine (Fig. 31.1) with molecular weight 161.2 g/mol (inner salt). Only the L isomer is biologically active. L-Carnitine participates in transesterification reactions (Fig. 31.1) in which short-chain organic acids or medium- or long-chain fatty acids are transferred

from coenzyme A to the hydroxyl group of carnitine. These reversible reactions are catalyzed by a group of enzymes termed *carnitine acyltransferases*. Thus, carnitine exists in biologic systems in both nonesterified and esterified forms. Under normal conditions, the predominant ester of carnitine in cells and biologic fluids is acetylcarnitine.

Figure 31.1. Carnitine structure and metabolic interconversions.

FUNCTIONS

Mitochondrial Long-Chain Fatty Acid Oxidation

Long-chain fatty acids enter mitochondria only as acylcarnitine esters ([Fig. 31.2](#)). Carnitine palmitoyltransferase I (EC 2.3.1.21) on the inner surface of the outer mitochondrial membrane catalyzes transesterification of long-chain fatty acids from coenzyme A to carnitine. The acylcarnitine esters traverse the inner mitochondrial membrane via a carnitine-acylcarnitine translocase, and the acyl moieties are transesterified to intramitochondrial coenzyme A by the action of carnitine palmitoyltransferase II, located on the matrix surface of the inner mitochondrial membrane. Thus, carnitine is essential for mitochondrial use of long-chain fatty acids for energy production.

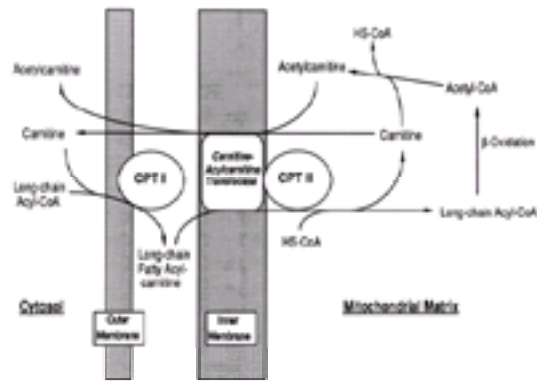

Figure 31.2. Carnitine function in facilitation of mitochondrial long-chain fatty acid oxidation and modulation of intramitochondrial acyl-CoA:CoA ratio.

Modulation of Acylcoenzyme A:Coenzyme A Ratio

Coenzyme A is a required cofactor in many cellular reactions. If nonesterified coenzyme A is not available in a cellular compartment (e.g., cytosol, mitochondria, peroxisomes) because it is completely esterified, the flux through pathways that require this cofactor will diminish. Carnitine is a reservoir for excess acyl residues, generated, for example, by high rates of β -oxidation in mitochondria, in which the acyl residue is transesterified from coenzyme A to carnitine, thus freeing coenzyme A to participate in other cellular reactions (Fig. 31.2). The acylcarnitine ester formed in this process may remain in the organelle or cell of origin for use when needed, or may be exported out of the cell for use by other cells or tissues or for excretion. Because acetyl-CoA is a major product of cellular metabolism (e.g., β -oxidation of fatty acids, oxidation of pyruvate), the primary enzyme involved in this function is carnitine acetyltransferase (EC 2.3.1.7).

This function has important implications for cellular energy metabolism. For example, carnitine facilitates oxidation of glucose in working hearts by relieving inhibition of pyruvate dehydrogenase by fatty acids (7). The mechanism involves removal of acetyl groups generated from fatty acid β -oxidation by transesterification from acetyl-CoA to carnitine, thus freeing coenzyme A to participate in the pyruvate dehydrogenase reaction sequence.

The role of carnitine in modulation of the acyl-CoA:CoA ratio also is important in long-chain fatty acid use for membrane remodeling (8). Carnitine acts as a reservoir for long-chain fatty acids destined for incorporation into membrane phospholipids, as, for example, during repair after oxidative insult. This role for carnitine, facilitated by extramitochondrial carnitine palmitoyltransferase activity, has been demonstrated in erythrocytes but presumably occurs in nucleated cells as well (8).

The ability of carnitine to act as a reservoir for activated acyl residues is important in abnormal cellular metabolism, in particular, in genetic diseases associated with defects

in organic and fatty acid metabolism. For example, in propionyl-CoA carboxylase deficiency, propionyl-CoA is an end-product that, if not cleared, would starve the cellular energy-producing machinery of nonesterified coenzyme A. In patients with this disease, large amounts of propionylcarnitine are excreted, indicating that cells and tissues adapt to the demand for nonesterified coenzyme A by transesterification of excess propionyl residues to carnitine (9). Pharmacologic amounts of carnitine are often prescribed for treatment of this disease.

Other Actions in Cellular Metabolism

Carnitine and its esters may have other functions in mammalian cells. Pharmacologic administration of carnitine reduces the mortality and metabolic consequences of acute ammonium intoxication in mice (10). The mechanism for this effect may have two components: L-carnitine administration normalizes the redox state of the brain (perhaps by increasing the availability of β -hydroxybutyrate to the brain), and it increases the rate of urea synthesis in the liver. At least part of the protective effect of carnitine is associated with flux through the carnitine acyltransferases, as analogues of carnitine that are competitive inhibitors of carnitine acyltransferases enhance toxicity of acute ammonium administration (11). It has been proposed that carnitine increases urea synthesis in the liver by facilitating fatty acid entry into mitochondria, leading to increased flux through the β -oxidation pathway, an increase of intramitochondrial reducing equivalents, and enhanced ATP production (10).

Propionyl-L-carnitine protects the ischemic heart from reperfusion injury, perhaps by scavenging free radicals or by preventing their formation by chelating iron necessary for generation of hydroxyl radicals (12). Propionyl-L-carnitine also improves contractile function of rat hearts, presumably by increasing the supply of four-carbon intermediates, thus increasing the flux through the citric acid cycle (13). The same effects were not achieved by propionate or carnitine alone. These mechanisms may be responsible for beneficial effects of propionyl-L-carnitine on ischemia-induced myocardial dysfunction in humans with angina pectoris (14).

L-Carnitine regulates the transcriptional response to triiodothyronine of genes for malic enzyme (EC 1.1.1.40) and fatty acid synthase (EC 2.3.1.85) in chick embryo hepatocytes (15). Acetyl-L-carnitine corrected the impaired mitochondrial DNA expression in brain and heart of senescent rats, restoring these rates to those seen in normal adult rats (16). This treatment had no effect on the rates of mitochondrial DNA expression in normal adult (nonsenescent) rats. Pharmacologic treatment with acetyl-L-carnitine improved the ability of patients with Alzheimer's disease to handle tasks requiring attention and concentration (17). Acetyl-L-carnitine may improve the mental ability of these patients by inhibiting apoptosis of nerve cells in the brain. In this regard, acetyl-L-carnitine inhibited apoptosis induced by serum deprivation in a teratocarcinoma cell line (18). The latter effect was shown not to involve the putative antioxidant effects (19) of acetyl-L-carnitine.

L-Carnitine greatly increased the survival rate of rats treated with *Escherichia coli* lipopolysaccharide, independent of any changes in activity of enzymes that metabolize fatty acids, coenzyme A, or carnitine derivatives in liver (20). Circulating cytokine

(interleukin-1b, interleukin-6, and tumor necrosis factor-a) concentrations were reduced by carnitine treatment in this model as well as in a methylcholanthrene-induced sarcoma model of cachexia in rats (21). L-Carnitine prevented cardiac toxicity associated with interleukin-2 cancer immunotherapy (22).

Carnitine (either the L or D isomer) and to a lesser extent g-butyrobetaine inhibit clustering of erythrocytes by fibrinogen or clusterin (23). The mechanism involves binding of carnitine to sulfhydryl groups on the erythrocyte membrane but not to fibrinogen or clusterin. The possible physiologic significance of these findings is unknown. Further investigation of these observations may identify new general roles for carnitine in cellular metabolism.

Proteins Associated with Carnitine Function

Carnitine Palmitoyltransferase

Two major forms of carnitine palmitoyltransferase have been identified, carnitine palmitoyltransferase I (CPT I) and carnitine palmitoyltransferase II (CPT II). CPT I is located on the inner surface of the outer mitochondrial membrane, whereas CPT II is found on the matrix surface of the inner mitochondrial membrane. CPT I, but not CPT II, is potently inhibited by malonyl-CoA. This reversible inhibition is a primary metabolic regulator that partitions fatty acids to mitochondrial oxidation or to triglyceride formation. There are at least two isoenzymes of CPT I, a “liver” isozyme of approximately 88 kDa, and a “muscle” isozyme of approximately 82 kDa (24). These isozymes differ in their affinities for carnitine and malonyl-CoA.

CPT II is synthesized as a 74-kDa proenzyme. The N-terminal 25 residues are cleaved following import into mitochondria, resulting in a mature protein of 71 kDa. CPT I and CPT II are distinct enzymes, coded by different genes (24). Moreover, the liver and muscle variants of CPT I also arise from separate genes.

Carnitine palmitoyltransferase activity is found extramitochondrially, in peroxisomes and endoplasmic reticulum. The activity present in peroxisomes is generally attributed to carnitine octanoyltransferase (see below) present in this organelle. Carnitine palmitoyltransferase activity in endoplasmic reticulum has been observed (e.g., in erythrocytes [8]) but has not been well characterized.

Carnitine Acetyltransferase (CAT)

CAT catalyzes reversible transesterification of short-chain organic acids (two to eight carbons, with maximal activity directed to acetyl and propionyl residues) between coenzyme A and carnitine. CAT is found in soluble form in mitochondria and peroxisomes and membrane-associated in endoplasmic reticulum (25). The enzyme has been purified from different tissues of various species. Reported molecular masses range from 51 to 75 kDa. On the basis of enzyme kinetics and specificity, it is generally accepted that carnitine acetyltransferase in the various subcellular compartments provides for efficient synthesis, use, and/or disposal of short-chain organic acids

generated by mitochondrial or peroxisomal metabolism of both physiologic and xenobiotic compounds.

Carnitine Octanoyltransferase (COT)

COT is a broad-specificity enzyme with highest affinity for medium-chain fatty acids (highest activity with hexanoyl-CoA as substrate). It is found mostly in peroxisomes, and its activity in liver is increased by peroxisomal proliferating agents. Peroxisomes generally oxidize very long chain fatty acids that are not metabolized in mitochondria. Chain-shortened products, primarily medium-chain fatty esters of coenzyme A, are transesterified to carnitine and are subsequently oxidized in mitochondria. Peroxisomal COT has a molecular mass of approximately 62 kDa and is immunologically distinct from mitochondrial carnitine palmitoyltransferases and carnitine acetyltransferase (26). Like mitochondrial CPT I, it is inhibited by malonyl-CoA. COT accounts for the carnitine palmitoyltransferase activity observed in peroxisomal preparations.

COT activity is also found in rough and smooth endoplasmic reticulum. This 53-kDa protein is immunologically distinct from peroxisomal COT (27). Like mitochondrial CPT I, crude (membrane-bound) microsomal COT is inhibited by malonyl-CoA, but after solubilization with detergents, inhibition by malonyl-CoA is lost. Microsomal COT probably accounts for the carnitine palmitoyltransferase activity in endoplasmic reticulum. Like peroxisomal CAT and COT, reversible reaction kinetics of this enzyme favor formation of acylcarnitine esters at normal intracellular concentrations of its substrates (27).

Carnitine-Acylcarnitine Translocase

Entry of long-chain fatty acylcarnitine esters into mitochondria occurs by rapid-exchange diffusion (28), facilitated by a 32.5-kDa carnitine-acylcarnitine translocase in the inner mitochondrial membrane. This protein has been purified and functionally reconstituted into liposomes (29). It is inhibited by sulfhydryl-reactive reagents and some analogues of carnitine (e.g., sulfobetaines). The translocase has several other important functions in addition to its role in facilitating entry of long-chain fatty acylcarnitine esters into mitochondria. It facilitates entry into mitochondria of short- and medium-chain acylcarnitine esters formed in peroxisomes from oxidation of very long chain fatty acids. It also facilitates removal of short-chain acylcarnitine esters from mitochondria, freeing coenzyme A to recycle through the various pathways in the mitochondrial matrix.

BIOSYNTHESIS

Pathway

Carnitine ultimately derives from the essential amino acids lysine and methionine (Fig. 31.3). Lysine provides the carbon chain and nitrogen atom of carnitine, whereas three methionine molecules provide the methyl groups for one molecule of carnitine (30). Methylation of the epsilon amino group of lysine is catalyzed by one or more protein:lysine methyltransferases. Lysine residues destined for carnitine synthesis must

be peptide linked; there is no evidence that free lysine is enzymatically methylated in mammals. *e-N*-Trimethyllysine is released for carnitine synthesis via normal mechanisms of protein hydrolysis. In the pathway to carnitine synthesis, *e-N*-trimethyllysine undergoes four sequential enzymatic reactions: hydroxylation at position two of the carbon chain, catalyzed by *e-N*-trimethyllysine hydroxylase (EC 1.14.11.8); aldol cleavage between carbons two and three of the carbon chain, catalyzed by serine hydroxymethyltransferase (EC 2.1.2.1); oxidation of the resulting aldehyde by any of several NAD⁺-requiring aldehyde dehydrogenases; and a second hydroxylation, catalyzed by *g*-butyrobetaine hydroxylase (EC 1.14.11.1).

Figure 31.3. Pathway of carnitine biosynthesis in mammals. (Modified from reference 33: Rebouche CJ. Am J Clin Nutr 1991;54(Suppl): 1147S–52S, with permission.)

All enzymes in the pathway except *g*-butyrobetaine hydroxylase are ubiquitous in mammalian tissues. The last enzyme in the pathway is not found in cardiac and skeletal muscle (30). *g*-Butyrobetaine hydroxylase activity is highest in liver and testes, and in some species, including humans, it is abundant in kidney.

Rate and Regulation

The normal rate of carnitine synthesis in humans is approximately 1.2 $\mu\text{mol} \cdot \text{kg body weight}^{-1} \cdot \text{day}^{-1}$ (31). This estimate is obtained from normal rates of urinary carnitine excretion by strict vegetarians, who obtain very little carnitine (generally less than 0.1 $\mu\text{mol} \cdot \text{kg body weight}^{-1} \cdot \text{day}^{-1}$) from dietary sources. Direct measurement of the rate of carnitine synthesis by, for example, isotope incorporation from labeled precursors, is not technically feasible (31).

The rate of carnitine synthesis in mammals is regulated by the availability of *e-N*-trimethyllysine, which in turn is determined by the extent of peptide-linked lysine methylation and by the rate of protein turnover. *e-N*-Trimethyllysine destined for carnitine synthesis probably is derived from the general protein pool and not from any single or small group of proteins. Provision of excess lysine in the diet may increase

carnitine synthesis modestly (32), but the evidence is indirect, and the mechanism (e.g., increased flux through protein synthesis, methylation, and turnover; or stimulation of a putative vestigial capability to methylate free lysine) has not been identified.

DIETARY SOURCES, ABSORPTION, AND METABOLISM

Carnitine is generally abundant in food products of animal origin (Table 31.1). Fruits, vegetables, grains, and other plant-derived foods contain relatively little carnitine. Thus, a normal omnivorous diet provides approximately 2 to 12 $\mu\text{mol} \cdot \text{kg body weight}^{-1} \cdot \text{day}^{-1}$ of carnitine, whereas a strict vegetarian diet contains about 0.1 $\mu\text{mol} \cdot \text{kg body weight}^{-1} \cdot \text{day}^{-1}$ (31). Carnitine is available commercially as a diet supplement. Carnitine consumed orally in large quantities (about 5 g/day by an adult) may cause diarrhea or fish odor syndrome. No other toxic properties have been identified.

Food Item	Carnitine Content*	Food Item	Carnitine Content
Meat products			
Beef (lean)	540 ± 100 (2)	Strawberries	0.0055
Ground beef	580 ± 33 (2)	Apples	0.0007

Adapted from Robinson (1), (2) and (3). *Data are mean (SD) values. ND, not detectable. Values for meat products are mean (SD) values of determinations in unadiposated (lean) tissue. Values are given in $\mu\text{mol} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ based on a 70-kg adult. Values represent only the carnitine in the food item, not the carnitine in the body.

Table 31.1 Carnitine Content of Selected Foods

Approximately 63 to 75% of carnitine is absorbed from the normal omnivorous diet (34). The remainder is degraded by bacteria in the large intestine. The percentage of carnitine absorbed from supplements may be much lower; for example, from a 2-g daily supplement, approximately 20% is absorbed (35). Principal organic degradation products of carnitine are trimethylamine (excreted in urine as trimethylamine oxide) and g-butyrobetaine (excreted primarily in feces). Carnitine is not degraded by enzymes of animal origin (31).

Carnitine is concentrated in most tissues of the body. In humans, the intracellular concentrations of carnitine in skeletal muscle and liver are approximately 90 and 75 times higher, respectively, than that in extracellular fluid. Approximately 97% of all carnitine in the body is in skeletal muscle. Carnitine homeostasis is maintained by a low rate of carnitine synthesis and efficient reabsorption of carnitine by the kidney. Approximately 95% of filtered carnitine is reabsorbed in normal humans. Genetic diseases associated with reduced carnitine reabsorption efficiency (e.g., medium-chain

acyl-CoA dehydrogenase deficiency) are characterized by carnitine depletion in skeletal muscle and extracellular fluid.

NUTRIENT-NUTRIENT AND DRUG-NUTRIENT INTERACTIONS

Carnitine status and/or metabolism are affected by several nutrients and drugs. For example, rates of carnitine excretion by humans supplemented with choline are lower than corresponding rates of unsupplemented individuals (36). Experimental vitamin C deficiency in guinea pigs is associated with decreased plasma carnitine levels and increased rate of urinary carnitine excretion (37).

Valproic acid and pivalic acid-containing prodrugs (antibiotics) negatively affect carnitine status in humans (38). Valproic acid administration lowers circulating carnitine concentrations in some patients. The mechanism for this effect has not been identified. Pivalic acid is conjugated to some antibiotics to improve their rates of absorption. In the intestinal mucosa, pivalic acid is cleaved by nonspecific esterases. Pivalic acid is conjugated to carnitine and is quantitatively excreted in urine as pivaloylcarnitine. Prolonged treatment with these antibiotics leads to depletion of the circulating carnitine pool and presumably tissue carnitine pools as well.

DEFICIENCY AND DEPLETION

Distribution and Diet

Carnitine has been described as a “conditionally essential” nutrient for some segments of the human population. Infants (both term and preterm) fed formulas lacking carnitine have very low circulating carnitine concentrations (31). Schmidt-Sommerfeld and Penn (39) estimated that the amount of carnitine in skeletal muscle of very premature infants, indexed to whole-body weight, is about 10 times less than that in adults. A number of investigators have observed various biochemical differences, with or without a lipid challenge, in preterm infants provided exogenous carnitine compared with those with no exogenous carnitine administration (31). Results of these studies have not provided clear evidence for a requirement for carnitine by preterm infants.

Fomon and Ziegler (40) summarized energy intake and growth of 204 normal term infants participating in designed growth studies and fed milk-based (70–230 $\mu\text{mol/L}$ carnitine concentration) or soy protein-based (<2 $\mu\text{mol/L}$ carnitine concentration) formulas from 8 to 111 days of age. They found no differences, with respect to formula fed, in energy intake, weight gain, or growth in length from 8 to 41 days, 42 to 111 days, or 8 to 111 days, in either male or female infants. In other studies, term infants fed soy protein-based formulas without added carnitine had lower serum carnitine concentrations, higher serum-free fatty acid concentrations, and higher rates of excretion of medium-chain dicarboxylic acids than did infants whose formulas were supplemented with carnitine. But growth (length and weight gain) was not different for infants consuming the unsupplemented and carnitine-supplemented soy protein-based formulas (31). Thus, it is reasonable to conclude that infants who do not acquire carnitine from their diet are not deficient in carnitine but that the demands of growth

create a condition of carnitine depletion in these infants.

There is no evidence that carnitine deficiency occurs in the general population (children and adults) of strict vegetarians, whose diet generally provides a very minimal amount of carnitine. Strict vegetarian children have plasma carnitine concentrations about 70% of those in age- and sex-matched omnivores (31). Likewise, in strict vegetarian adults, plasma carnitine concentrations are about 10% lower than those in corresponding omnivores (31).

Genetic Disorders

Primary carnitine deficiency due to a genetic disorder in carnitine transport has been identified (6). Features of this disease include progressive cardiomyopathy, skeletal muscle weakness, and episodes of fasting hypoglycemia (41). The disease most often presents in the first 5 years of life. Circulating and skeletal muscle carnitine concentrations in affected individuals are generally less than 10 and 20%, respectively, of normal. No primary carnitine deficiency due to a defect in carnitine biosynthesis has been identified.

Carnitine deficiency or depletion occurs secondary to a large number of genetic and acquired disorders and conditions (see Chapter 62, this volume; and ref. 42). At least two basic mechanisms are responsible for these effects on carnitine status. In some disorders, the efficiency of carnitine reabsorption is impaired (e.g., medium-chain acyl-CoA dehydrogenase deficiency). In others, abnormal amounts of short-chain organic acids are produced, which are removed from the body by urinary excretion as acylcarnitine esters (e.g., propionylcarnitine in propionyl-CoA carboxylase deficiency). In these disorders, the rate of excretion of carnitine as short-chain acylcarnitine esters exceeds the combined rates of endogenous synthesis and dietary carnitine intake, leading to a state of carnitine depletion.

EVALUATION OF STATUS

Carnitine status most often is reported as a function of circulating carnitine concentration, and the ratio of esterified to nonesterified carnitine. In general, plasma-free carnitine concentration of 20 $\mu\text{mol/L}$ or less, or total carnitine concentration of 30 $\mu\text{mol/L}$ or less, is considered abnormally low. However, these values only demarcate the lower range of normal plasma carnitine concentrations; they do not reflect points at which functional carnitine deficiency is observed. A ratio of esterified to free carnitine of 0.4 or greater in plasma or serum (but not urine) is considered indicative of abnormal carnitine metabolism. This ratio is elevated primarily when mitochondrial energy metabolism is impaired, resulting in increased load of short-chain organic acids esterified to coenzyme A, which are transesterified to carnitine for export from tissues into the circulation. Thus, in genetic disorders of fatty acid and organic acid oxidation (see Chapter 62, this volume), the ratio of esterified to free carnitine in the circulation often is elevated. This elevated ratio is associated with carnitine depletion caused by either hyperexcretion of acylcarnitine esters or decreased ability of the kidneys to reabsorb carnitine and its esters. Rates of carnitine excretion in urine do not provide a particularly useful measure of carnitine status, because these rates vary

considerably with dietary carnitine intake and other physiologic parameters. No validated tests or measures of functional carnitine deficiency are available to assess carnitine status in humans.

Carnitine concentration in body fluids and tissues is measured most accurately and efficiently by the radioenzymatic technique described by Cederblad and Lindstedt (43). Qualitative and quantitative methods are available for analysis of individual acylcarnitine esters and acylcarnitine ester profiles. These include liquid chromatography/mass spectrometry (44), radioisotope exchange/liquid chromatography (45), and derivatization/liquid chromatography (46). These methods are useful for detection and/or quantification of specific acylcarnitine esters that are diagnostic for various metabolic disorders.

REQUIREMENTS AND RECOMMENDED INTAKES FOR HUMANS

Carnitine is not a required nutrient for children and adults. Supplementation of formulas for infants (particularly premature infants) is recommended at a level normally found in human milk (28–95 $\mu\text{mol/L}$). These recommendations are based on observations of very low plasma and tissue carnitine concentrations and other biochemical differences observed in infants not fed exogenous carnitine (31). Exogenous carnitine is recommended for treatment in some genetic and acquired disorders (e.g., anticonvulsant polytherapy that includes valproic acid in children), but for these purposes, use of exogenous carnitine is pharmacologic rather than nutritional.

Choline is a quaternary amine that is widely distributed in foods (1) and is essential for normal function of all cells. Choline ensures the structural integrity and signaling functions of cell membranes; it is the major source of methyl groups in the diet; it directly affects cholinergic neurotransmission; and it is required for lipid transport/metabolism (reviewed in [1]). Most choline in the body is found in phospholipids such as phosphatidylcholine and sphingomyelin. Phosphatidylcholine is the predominant phospholipid (>50%) in most mammalian membranes. Though representing a smaller proportion of the total choline pool, important metabolites of choline include platelet-activating factor, acetylcholine, choline plasmalogens, lysophosphatidylcholine, phosphocholine, glycerophosphocholine, and betaine.

First discovered by Strecker in 1862, choline was chemically synthesized in 1866 (2). It was known to be a component of phospholipids, but the pathway for its biosynthesis was first described in 1941 by duVigneaud (3). The route for its incorporation into phosphatidylcholine (lecithin) was not elucidated until 1956 (4). The importance of choline as a nutrient was first appreciated during the pioneering work on insulin (5). Depancreatized dogs maintained on insulin developed fatty infiltration of the liver and died. Administration of raw pancreas prevented hepatic damage; the active component was the choline moiety of pancreatic phosphatidylcholine. In 1935, the association between a low-choline diet and fatty infiltration of the liver in rats was recognized (6). The term *lipotropic* was coined to describe choline and other substances that prevented deposition of fat in the liver. Subsequently, researchers suggested that the liver disease associated with alcoholism might respond to choline therapy. However, few data

supported this hypothesis until recently, when Lieber showed that phosphatidylcholine supplementation prevented fibrosis and fatty liver caused by ethanol ingestion in baboons (7).

In 1975, several laboratories reported that administration of choline accelerated synthesis and release of acetylcholine by neurons (reviewed in [8]). A revival of interest in choline ensued, resulting in a plethora of publications characterizing the metabolism, physiologic effects, and pharmacology of choline.

Our understanding of choline phospholipid-mediated signal transduction has vastly improved during the last decade. Breakdown products of choline phospholipids can amplify external signals or can terminate the signaling process by generating inhibitory second messengers (9). These signals are a matter of life and death for cells. Recently we found that choline deficiency activates an internal program for cell suicide called apoptosis (10). Apoptosis is involved in normal cell turnover, hormone-induced tissue atrophy, embryogenesis, and elimination of cancer cells.

Choline has not been considered an essential nutrient for humans because an endogenous pathway exists for de novo biosynthesis of choline (11). However, the presence of a pathway for endogenous synthesis does not make a nutrient dispensable; vitamin D is an excellent example. In the last few years, several investigators have identified choline-deficiency syndromes in humans (12, 13, 14, 15 and 16). This review discusses the expected biochemical and physiologic uses for choline and the expected effects of choline deficiency.

DIETARY SOURCES OF CHOLINE

Many foods eaten by humans contain significant amounts of choline and esters of choline (Table 32.1). Some of this choline is added during food processing (especially when preparing infant formula (17)). Average dietary intake of choline and choline esters in the adult human is estimated to be 7 to 10 mmol/day (18). When humans were switched from a diet of normal foods to a defined diet containing 5 mmol/day, plasma choline and phosphatidylcholine concentrations decreased in most subjects (13). Evidently, the average dietary intake of choline exceeds 5 mmol/day in adults. Human milk is rich in choline and choline esters (19, 20). Assuming that a newborn infant drinks 800 mL milk/day, daily choline intake (all forms) would be approximately 1.2 mmol/day. Per kilogram body weight, this intake is two to three times that ingested by the adult human.

Food	Concentration (µmol/kg) ^a		
	Choline	Phosphatidylcholine	Sphingomyelin
Apple	27	280	15
Banana	240	37	20
Beef liver	5831	43500	1850
Beef steak	75	6030	500

Adapted from Jones SM. Biological consequences of choline deficiency in humans. In: Sturman J, ed. Choline Metabolism and Brain Function. New York: Raven Press, 1998:16-26.

^aCholine, phosphatidylcholine and sphingomyelin were measured using a gas chromatography/mass spectrometry assay on foods prepared in the form that they would normally be consumed.

Table 32.1 Choline Content of Some Common Foods

Where does all of this choline in milk come from? Mammary epithelial cells are capable of concentrative uptake of choline from maternal blood (21)(Fig. 32.1). There are two uptake processes: one is saturable and obeys Michaelis-Menten kinetics; the other is nonsaturable and linear. Mammary epithelial cells can synthesize choline de novo (22) via phosphatidylethanolamine *N*-methyltransferase activity; this is the only pathway for synthesis of the choline moiety.

Figure 32.1. Forms of choline in milk and infant formulas. Human and bovine milks and infant formulas were analyzed for choline content by GC/mass spectrometry. Data are expressed as mean concentration (µmol/L) in human milk (*N* = 33), bovine milk (*N* = 3), and infant formulas (*N* = 3). Commercial powdered formulas are either bovine-derived (BD) or soy-derived (SD). Abbreviations: GPCho, glycerophosphocholine; PCho, phosphocholine; PtdCho, phosphatidylcholine; SM, sphingomyelin. Variability of data is indicated as SEM within the stacked bar for the data. Error bars are not shown when they essentially coincided with the compound division line. (From Holmes-McNary M, Cheng WL, Mar MH, et al. Am J Clin Nutr 1996;64:572–6, with permission.)

Rat pups denied access to milk have lower serum choline concentrations than do their milk-fed litter mates (23). Thus, dietary intake of choline contributes to the maintenance of high serum choline concentrations in the neonate. In the rat, supplemental choline is concentrated into the dam's milk (24). In lactating women eating a low-choline diet, milk choline content is lower than in those eating a more adequate diet (25). Dietary variation causes a 4-fold change (comparing choline-deficient and choline-supplemented diets) in milk phosphocholine content (19, 20).

Human milk, commercially available infant formulas, bovine milk, and rat milk contain approximately 1 to 2 $\mu\text{mol/L}$ choline and choline esters (20). The free choline content of human milk is very high at the start of lactation and diminishes to approximate that in commercial formulas by 30 days postpartum (19). Human milk has significantly higher phosphocholine concentration and the same or lower glycerophosphocholine concentration than either bovine milk or bovine-derived infant formulas; phosphatidylcholine and sphingomyelin concentrations are similar. Soy-derived infant formulas have lower glycerophosphocholine and sphingomyelin concentrations and higher phosphatidylcholine concentrations than do either human milk or bovine milk-derived formulas.

METABOLISM

Intestinal Absorption

The extent to which dietary choline is bioavailable depends upon the efficiency of its absorption from the intestine. In adults, some ingested choline is metabolized before it can be absorbed from the gut. Gut bacteria degrade it to form betaine and to make methylamines (26). The free choline surviving these fates is absorbed all along the small intestine (reviewed in [1]). At this time, no other component of the diet has been identified as competing with choline for transport by intestinal carriers. Both pancreatic secretions and intestinal mucosal cells contain enzymes (phospholipases A₁, A₂, and B) capable of hydrolyzing dietary phosphatidylcholine. The free choline that is formed enters the portal circulation of the liver (27).

In infants, there are differences in the bioavailability of the water-soluble, choline-derived compounds (choline, phosphocholine, and glycerophosphocholine) and the lipid-soluble compounds (phosphatidylcholine and sphingomyelin) present in milk (28). Liver tissue metabolizes the glycerophosphocholine ingested in milk differently than it does either choline or phosphocholine. In addition, phosphatidylcholine-derived label is metabolized very differently from other choline esters, with most remaining as phosphatidylcholine in liver and probably being incorporated into liver membranes. The various dietary sources of choline available in milk are, therefore, used differently by the liver in the rat pup. While the data obtained from the rat pup model cannot be directly extrapolated to the human infant, these variations in bioavailability and use should be considered when milk substitutes are developed. Human milk serves as a useful model

for safe and effective provision of choline to the neonate from milk substitutes.

Increased Availability of Choline to Tissues during the Perinatal Period

During development, there is a progressive decline in blood choline concentration that begins in utero. In fact, plasma or serum choline concentrations are 6- to 7-fold higher in the fetus and neonate than they are in the adult (1). This decline in serum choline concentration occurs during the first weeks of life (29). High levels of choline circulating in the neonate presumably ensure enhanced availability of choline to tissues. Neonatal rat brain efficiently extracts choline from blood (30), and increased serum choline in the neonatal rat is associated with a 2-fold higher choline concentration in neonatal brain than is present later in life. Supplementing choline during the perinatal period further increases choline metabolite concentrations in blood and brain (31).

Large amounts of choline are delivered to the fetus across the placenta, where choline transport systems pump it against a concentration gradient (32). The placenta is one of the few nonneuronal tissues to store large amounts of choline as acetylcholine (33). Perhaps this is a special reserve storage pool that ensures delivery of choline to the fetus.

Uptake of Choline by Tissues

All tissues accumulate choline by diffusion and mediated transport, but uptake by liver, kidney, mammary gland, placenta, and brain are of special importance (reviewed in [1]). A specific carrier mechanism transports free choline across the blood-brain barrier at a rate proportional to serum choline concentration, and in the neonate, this choline transporter has especially high capacity (30). Hepatectomy increases the half-life of choline and the blood choline concentration. The rate at which liver takes up choline suffices to explain the rapid disappearance of choline injected systemically. The kidney also accumulates choline (34). Some of this choline appears in the urine unchanged, but most is oxidized within the kidney to form betaine (35). Betaine serves as an important intracellular osmoprotectant within kidney (36). Mean free choline concentrations in the plasma of azotemic humans are several times greater than those in normal controls. Hemodialysis rapidly removes choline from the plasma (37). Renal transplantation in humans lowers plasma choline from 30 $\mu\text{mol/L}$ in the azotemic patient to 15 $\mu\text{mol/L}$ within 1 day (38).

Tissue Distribution and Transformation

Only a small fraction of dietary choline is acetylated, catalyzed by the activity of choline acetyltransferase (reviewed in [8]). This enzyme is highly concentrated in the terminals of cholinergic neurons but is also present in the placenta. The availability of choline and acetyl-CoA influences choline acetyltransferase activity. In the brain, it is unlikely that choline acetyltransferase is saturated with either of its substrates, so choline (and possibly acetyl-CoA) availability determines the rate of acetylcholine synthesis. Increased brain acetylcholine synthesis is associated with an augmented release into the synapse of this neurotransmitter. Choline taken up by brain may first enter a storage pool (perhaps the phosphatidylcholine in membranes) before being converted to

acetylcholine. The choline-phospholipids in cholinergic neurons are a large precursor pool of choline available for use in acetylcholine synthesis. This may be especially important in neurons with increased demands for choline to sustain acetylcholine release (e.g., when particular cholinergic neurons fire frequently, or when the supply of choline from the extracellular fluid is inadequate) (39). Human nerve cells in culture use choline from phosphatidylcholine as a source of choline for acetylcholine synthesis (40, 41).

Methyl Group Transfer

The methyl groups of choline can be made available from one-carbon metabolism, upon conversion to betaine (reviewed in [1]). This process requires two steps. First, choline is oxidized to betaine aldehyde by the enzyme choline dehydrogenase, which is present in the inner mitochondrial membrane (42). The oxidation of betaine aldehyde, catalyzed by betaine aldehyde dehydrogenase or by a nonspecific aldehyde dehydrogenase, takes place in both mitochondria and the cytosol. Liver and kidney are the major sites for choline oxidation. In kidney, betaine serves as an osmolyte (43). Betaine:homocysteine methyltransferase catalyzes the methylation of homocysteine, using betaine as the methyl donor. Betaine cannot be reduced back to choline. Thus, the oxidation pathway diminishes the availability of choline to tissues as it scavenges some methyl groups.

Phosphatidylcholine Biosynthesis

Elegant regulatory mechanisms control phosphatidylcholine biosynthesis and hydrolysis, many of which have been elucidated during the last decade (44). Synthesis occurs by two pathways. In the first, choline is phosphorylated, then converted to cytidine diphosphocholine (CDP-choline). This high-energy intermediate, in combination with diacylglycerol, forms phosphatidylcholine and cytidine monophosphate. In the alternative pathway, phosphatidylethanolamine is sequentially methylated to form phosphatidylcholine, using S-adenosylmethionine as the methyl donor.

Choline kinase, the first enzyme in the CDP-choline pathway, has been purified, and its properties have been reviewed elsewhere (45, 46). It is a cytosolic enzyme that also catalyzes the phosphorylation of ethanolamine. There are three isoforms of choline kinase in liver (45).

The second step in the pathway, catalyzed by CTP:phosphocholine cytidyltransferase, is the rate-limiting (47) and regulated step of phosphatidylcholine biosynthesis (48). Deficient activity of this enzyme in the lungs of prematurely born human infants contributes to the respiratory distress syndrome (49). Cytidyltransferase is present in the cytosol and probably within the nucleus (50) as an inactive dimer of two 42-kDa subunits; in the endoplasmic reticulum, the Golgi apparatus, and the nuclear envelope it is in an active membrane-bound form (48, 51). The presence of significant cytidyltransferase activity in the nuclear membranes is remarkable because phosphatidylcholine synthesis was previously thought to occur exclusively in the endoplasmic reticulum and Golgi apparatus.

The state of phosphorylation of cytidyltransferase, as well as membrane

phosphatidylcholine and diacylglycerol content, regulates the reversible translocation of the enzyme between cytosol and membranes (48). When cytidylyltransferase is phosphorylated by a cAMP-dependent protein kinase it translocates from membranes into the cytosol and becomes inactivated. This process reverses when the enzyme is dephosphorylated by protein phosphatase (50). The phosphatidylcholine content of the membrane also regulates the amount of enzyme bound to membranes. Cytidylyltransferases bind to membranes more avidly when their phosphatidylcholine content decreases, whereas the reverse occurs when membrane phosphatidylcholine content increases (51, 52). This may explain why cytidylyltransferase activity increases in choline-deficient hepatocytes (53).

Diacylglycerol also regulates cytidylyltransferase. Treatments that increase intracellular diacylglycerol levels (exposure to oleate [54] or that mimic the actions of diacylglycerol (exposure to phorbol ester [55]) activate cytidylyltransferase. Fatty acids and diacylglycerol may be acting indirectly on cytidylyltransferase by modulating protein kinase C and protein phosphatase activities (50).

The third enzyme in the CDP-choline pathway (CDP-choline:1,2-diacylglycerol choline-phosphotransferase) is present in the membranes of the endoplasmic reticulum. Its properties were reviewed recently (56). Because it is not the rate-limiting enzyme in the pathway, CDP-choline does not accumulate in significant concentrations within cells. The efficacy of CDP-choline as a treatment for ischemia and memory disorders is currently being tested in clinical trials (57, 58 and 59).

An alternative pathway for phosphatidylcholine biosynthesis (via methylation of phosphatidylethanolamine by phosphatidylethanolamine *N*-methyltransferase) is most active in liver but occurs in many other tissues, including brain (60, 61) and the mammary gland (22). This is the major (perhaps only) pathway for *de novo* synthesis of the choline moiety in adult mammals. However, plants (62) and perhaps embryonic neurons (from chicken or rat) (63) are capable of methylating phosphoethanolamine to form phosphocholine. The properties of phosphatidylethanolamine-*N*-methyltransferase were reviewed recently (64).

There are no accurate estimates of the activity of phosphatidylethanolamine-*N*-methyltransferase *in vivo*; the enzyme is membrane bound, and at least two isoforms exist (65). In adult liver, the availability of phosphatidylethanolamine, the *S*-adenosylmethionine:*S*-adenosylhomocysteine concentration ratio, and the composition of the boundary lipids that surround phosphatidylethanolamine-*N*-methyltransferase regulate its activity. *S*-Adenosylhomocysteine, a product of the reactions, inhibits the methyltransferase. The availability of *S*-adenosylmethionine in the liver of choline-deficient animals limits the activity of this pathway.

Interactions among Choline, Homocysteine, and Folate

The demand for choline as a methyl donor is probably the major factor that determines how rapidly a choline-deficient diet will induce pathology. The metabolism of choline, methionine, and methylfolate is closely interrelated (Fig. 32.2). The pathways intersect

at the formation of methionine from homocysteine. Betaine:homocysteine methyltransferase catalyzes the methylation of homocysteine, using the choline metabolite betaine as the methyl donor (66). In an alternative pathway, 5-methyltetrahydrofolate:homocysteine methyltransferase regenerates methionine, using a methyl group derived de novo from the 1-carbon pool (66). Perturbing the metabolism of one of the methyl donors results in compensatory changes in the other methyl donors because of the intermingling of these metabolic pathways (67, 68). Rats ingesting a choline-deficient diet showed diminished tissue concentrations of methionine and S-adenosylmethionine (69) and diminished total folate (68).

Figure 32.2. Metabolism of choline. The three major metabolic uses for choline are as a precursor for phosphatidylcholine biosynthesis, as a methyl donor, and as a precursor for acetylcholine biosynthesis. (From Cheng W-L, Holmes-McNary MQ, Mar M-H, et al. *J Nutr Biochem* 1996;7:457–64, with permission.)

Methotrexate, which is widely used in the treatment of cancer, psoriasis, and rheumatoid arthritis, limits the availability of methyl groups by competitively inhibiting dihydrofolate reductase, a key enzyme in intracellular folate metabolism. Rats treated with methotrexate have diminished pools of all choline metabolites in liver (70). Choline supplementation reverses the fatty liver caused by methotrexate administration (71, 72 and 73).

The interrelationship between choline and folate is especially interesting because multiple studies in humans have demonstrated that individuals with diminished folate status are much more likely to have babies with neural tube defects (74), and the progeny of pregnant mice with folate deficiency show increased rates of exencephaly (75). Also, the intermingling of choline and homocysteine metabolism is important because increased plasma homocysteine concentration is an independent risk factor for cardiovascular disease (76).

BIOCHEMICAL AND PHYSIOLOGIC CONSEQUENCES OF CHOLINE

DEFICIENCY

Chronic ingestion of a diet deficient in choline has major consequences, including hepatic, renal, pancreatic, memory, and growth disorders (reviewed in [1]). In most animals (except ruminants), choline deficiency results in liver dysfunction. Large amounts of lipid (mainly triglycerides) can accumulate in liver, eventually filling the entire hepatocyte. Fatty infiltration of the liver starts in the central area of the lobule and spreads peripherally. This process differs from that occurring in kwashiorkor or essential amino acid deficiency, in which fatty infiltration usually begins in the portal area of the lobule. Lipid accumulation within hepatocytes begins within hours after rats are started on a choline-deficient diet, peaks within the first 6 months (at >2000 mg/liver; control rats, 28 mg/liver), and then diminishes as the liver becomes fibrotic. Fatty liver occurs because triacylglycerol must be packaged as very low density lipoprotein (VLDL) to be exported from liver. Phosphatidylcholine is an essential component of VLDL (77, 78); other phospholipids cannot substitute. Methionine can substitute for choline only as long as phosphatidylethanolamine-*N*-methyltransferase (see above discussion) was fully active. Secretion of high-density lipoprotein (HDL) from hepatocytes does not require synthesis of new phosphatidylcholine molecules (79). Choline-deficient humans have diminished plasma low density lipoprotein cholesterol (LDL; derived from VLDL) (13). This observation is consistent with the hypothesis that in humans, as in other species, choline is required for VLDL secretion.

Renal function is also compromised by choline deficiency (reviewed in [1]), with abnormal concentrating ability, free water reabsorption, sodium excretion, glomerular filtration rate, and renal plasma flow. Gross renal hemorrhage also results. Infertility, growth impairment, bony abnormalities, decreased hematopoiesis, and hypertension have also been reported to be associated with diets low in choline (1).

CHOLINE AND THE DEVELOPING BRAIN

Nature has developed a number of mechanisms to ensure that a developing animal gets adequate amounts of choline. As discussed above, the placenta regulates transport of choline to the fetus. In this regard, the choline concentration in amniotic fluid is 10 times that in maternal blood (Zeisel, unpublished observations). The capacity of brain to extract choline from blood is greatest during the neonatal period. Neonatal rat brain has a novel phosphatidylethanolamine-*N*-methyltransferase that is extremely active (80); this enzyme is not present in adult brain. Furthermore, in the brains of newborn rats, *S*-adenosylmethionine concentrations are 40 to 50 nmol/g of tissue (81), which probably allows the neonatal phosphatidylethanolamine-*N*-methyltransferase to maintain high activity. As mentioned above, human and rat milk provide large amounts of choline to the neonate. These multiple mechanisms to ensure availability of choline to the fetus and neonate support the view that choline supply is crucial during this period.

There are two sensitive periods in the development of rat brain during which treatment with choline results in long-lasting enhancement of spatial memory. The first occurs during embryonic days 12 to 17; the other during postnatal days 16 to 30 (82, 83 and 84). These two sensitive periods for responsiveness to supplemental choline correlate with the formation of cholinergic neurons (neurogenesis; prenatal) and nerve-nerve

connections (synaptogenesis; postnatal) in the memory area of brain (hippocampus and basal forebrain), respectively. Choline supplementation during these critical periods elicits major improvement in memory performance at all stages of training on a 12-arm radial maze. The choline-induced spatial memory facilitation correlates with altered distribution and morphology of neurons involved in memory storage within brain (septal neurons) (83). A dam eating 50 g/day ingests 0.5 mmol of choline/day. The choline-supplemented dams in these memory studies consumed an additional 1 mmol/day of choline in drinking water. The progeny appeared normal in weight and showed no symptoms of choline deficiency. Note that the improvement in memory is detected months after the short exposure to choline. These effects of perinatal choline treatment on memory appear to be permanent, as both working and reference memory performance continued to show facilitation relative to controls even at 26 months of age (W. Meck, personal communication).

How a choline supplement supplied to the dam yields a permanent memory change in the offspring has not been elucidated. Our initial hypothesis was that the effects of neonatal choline supplementation on memory are mediated by increased brain choline levels with subsequent increased acetylcholine release. However, the amount of choline that accumulates in fetal brain after treatment of the pregnant dam is not enough to enhance acetylcholine release (31). Rather, supplementing choline to dams results in significantly greater accumulation of phosphorylcholine and betaine in fetal brain than in fetuses of controls (31). This leaves open the possibility that changes in these metabolites mediate these long-term effects on brain and behavior.

Whether these findings in rats also apply to humans is not known. Of course human and rat brains mature at different rates, with the rat brain comparatively more mature at birth than is the human brain. In humans, synaptogenesis may continue for months after birth. Should there be a recommended intake for choline in pregnant women? Are we varying the availability of choline when we feed infant formulas instead of milk? Does the form and amount of choline ingested contribute to variations in memory observed between humans? All these questions are worthy of additional research.

CARCINOGENESIS

Choline deficiency, alone among those of single nutrients, causes development of hepatocarcinomas in the absence of any known carcinogen (85). Choline-deficient rats not only have a higher incidence of spontaneous hepatocarcinoma but also are markedly sensitized to the effects of administered carcinogens (85). Choline deficiency is therefore considered to have both cancer-initiating and cancer-promoting activities.

Several mechanisms have been suggested to explain the cancer-promoting effect of a choline-devoid diet (86). These include (a) hepatic damage and regeneration, causing greater sensitivity to chemical carcinogens, (b) hypomethylation of DNA, causing abnormal repair of DNA, and (c) increased lipid peroxidation, which could be a source of free radicals that could modify DNA. As discussed below, we have proposed that choline deficiency perturbs protein kinase C (PKC; serine/threonine kinase) signal transduction and perturbs regulation of apoptosis, thereby promoting carcinogenesis.

FUNCTIONS

How Might Choline Influence Organ Function and Development

Cholinergic Neurons

Choline's relationships to acetylcholine synthesis have been thoroughly reviewed elsewhere (8). "Autocannibalism" of membrane phospholipid to supply choline for acetylcholine synthesis may explain the extensive degeneration of cholinergic neurons (which project to the brain cortex and hippocampus) in Alzheimer's disease (87). Abnormal phospholipid metabolism in this disease (88) results in reduced levels in brain (at autopsy) of phosphatidylcholine, phosphatidylethanolamine, choline, and ethanolamine and increased levels of glycerophosphocholine and glycerophosphoethanolamine.

Signal Transduction

Our understanding of choline phospholipid-mediated signal transduction has been vastly improved during the last decade. Stimulation of membrane-associated receptors activates neighboring phospholipases, resulting in formation of breakdown products that are signaling molecules per se (i.e., they stimulate or inhibit the activity of target macromolecules) or are converted into signaling molecules by specific enzymes. Much signaling research has focused on minor phospholipid components of membranes, particularly phosphatidylinositol derivatives (extensively reviewed elsewhere [89, 90]). However, choline phospholipids, especially phosphatidylcholine and sphingomyelin, are concerted biologically active molecules that can amplify external signals or terminate the signaling process by generating inhibitory second messengers (9).

In these signaling processes, activation of receptors at the plasma membrane leads to altered conformation of the receptor so that it can activate a guanosine triphosphate (GTP)-binding protein (G-protein). Activation of the G-protein results in the subsequent activation of phospholipase C activity within the plasma membrane. The phospholipases C are a family of phosphodiesterases that hydrolyze the glycerophosphate bond of intact phospholipids to generate 1,2-*sn*-diacylglycerol and an aqueous soluble head group.

The action of phospholipase C triggers the next event in the signal cascade, the activation of PKC. Products generated by phospholipid hydrolysis include diacylglycerol, which is both a messenger molecule and an intermediate in lipid metabolism. Normally, PKC is folded so that an endogenous "pseudosubstrate" region on the protein is bound to the catalytic site, thereby inhibiting activity. Diacylglycerol causes a conformational change in PKC, causing flexing at a hinge region, which withdraws the pseudosubstrate and unblocks the PKC catalytic site. The appearance of diacylglycerol in membranes is usually transient, so that PKC is activated only for a short time after a receptor has been stimulated.

There is also evidence that receptors with intrinsic tyrosine kinase activity (e.g., EGF or PDGF receptors) stimulate phosphatidylcholine hydrolysis (91). Sustained activation of PKC is essential for triggering cell differentiation and proliferation (92). Other products of phosphatidylcholine hydrolysis, such as phosphatidic acid, lyso-phosphatidylcholine, and free fatty acids also are second messengers (91, 93). Phosphatidic acid can also act as a mitogen (94). Lysophosphatidylcholine stimulates PKC activity (92) but is a membranolytic detergent with potential toxic effects. Lysophosphatidylcholine generation is important in chemotaxis, relaxation of smooth muscle, and activation of T lymphocytes (92). That modulation of PKC isozymes by phosphatidylcholine may be isoform specific (95).

As discussed above, choline deficiency causes massive fatty liver in which 1,2-*sn*-diacylglycerol accumulates (96). In plasma membranes from livers of choline-deficient rats, diacylglycerol reaches levels higher than those occurring after stimulation of a receptor linked to phospholipase C activation (e.g., vasopressin receptor). This results in a stable activation of PKC and/or an increase in the total PKC pool in the cell (96, 97).

Characterization of events that occur downstream from PKC is just beginning. Serine-threonine kinases and tyrosine kinases catalyze phosphorylation of target proteins distal to PKC. Phosphorylation alters the biochemical properties of these substrates, resulting in a range of cellular responses. These phosphorylation cascades enhance amplification of the original signal. PKC signals impinge on several known intracellular control circuits (98), including receptors for insulin, epidermal growth factor, and many proteins involved in control of gene expression (99, 100). Accumulation of diacylglycerol and subsequent activation of PKC within liver during choline deficiency may contribute to the development of hepatic cancer in these animals (96, 97).

Although choline sphingolipids are ubiquitous components of mammalian cells, they have only recently been shown necessary for cellular survival and growth (101). Hydrolysis of sphingomyelin generates messengers that terminate the PKC signaling cascade. Sphingomyelin, sphingomyelinase, and ceramidase, which produces sphingosine and fatty acid from ceramide, are present in the outer leaflet of the plasma membrane. Ceramide is a potent inhibitor of cell growth as well as a promoter of cell differentiation. Its metabolite sphingosine is a potent inhibitor of PKC that acts by blocking diacylglycerol-mediated activation (102). Sphingosine concentrations in cells are in the micromolar range, perhaps high enough to inhibit PKC (103). Sphingosylphosphocholine (lysosphingomyelin) has recently been described as a potent mitogen (104).

Apoptosis

Apoptosis is a regulated form of cell suicide that is involved in such physiologic conditions as normal cell turnover, hormone-induced tissue atrophy, and embryogenesis (105). Cells undergoing apoptosis show internucleosomal DNA fragmentation and characteristic morphologic changes such as marked decrease in cell volume, nuclear condensation, nuclear fragmentation, and formation of apoptotic bodies consisting of

membrane-enclosed pieces of condensed chromatin and well-preserved organelles (106, 107). Another characteristic change often occurring in apoptosis results from endonuclease activity that cleaves transcriptionally active nuclear DNA (106) (but not mitochondrial DNA) into 200-bp internucleosomal fragments that form a ladder on gel electrophoresis.

DNA strand breaks are an early consequence of choline deficiency (108, 109). DNA damage is important in the induction of morphologic changes associated with apoptosis (106). Rat hepatocytes maintained in a choline-deficient medium undergo apoptosis (10), and choline deficiency is a potent apoptosis inducer in neuronal cells as well. In PC12 cells (a neuronal cell line derived from a rat pheochromocytoma), choline deficiency could initiate apoptotic death, with characteristic DNA strand breaks and apoptotic body formation (109a). If choline availability modulates apoptosis in nerve cells, might it also alter the amount of apoptosis occurring in developing fetal brain? Could this explain why maternal intake of choline modulates the structure and function of their offspring's brains? In this regard, the amount of apoptosis in fetal brain inversely correlates with maternal choline intake (Holmes-McNary, unpublished observations). Thus, the behavioral effects of dietary choline could be due to changes in the relative survival of different groups of hippocampal cells at a critical period in brain development.

The process of carcinogenesis involves an initiating event that induces genetic damage, followed by survival and progression of selected clones of the mutant cells able to form tumors. Little is understood about the mechanisms that drive initiated cells to progress to carcinomas. As discussed above, something peculiar to the choline-deficient environment enhances tumor progression. Hepatocytes adapt and survive in a low-choline medium by becoming resistant to choline deficiency-induced apoptosis (110). Adapted hepatocytes may be resistant to choline deficiency-induced apoptosis because they have developed a defect in the apoptosis pathway involved. Perhaps prolonged choline deficiency creates a selective pressure that favors survival of cells with such defects. Adaptation to a choline-deficient environment is associated with cell transformation (increase in anchorage-independent growth and tumorigenic potential) (110). Thus, mutations that permit tumorigenesis may escape elimination because apoptosis is defective in adapted cells.

Is the apoptosis induced by choline deficiency due to a lack of choline moieties or to a methyl-group deficiency? Choline deficiency and methyl deficiency are often considered the same phenomenon, in which choline deficiency decreases methyl-group availability (85, 111). Methyl supplementation with betaine, methionine, folate, or vitamin B₁₂, however, did not prevent apoptotic death induced by choline-deficiency in hepatocytes (112). Thus, there are specific and important functions for choline that are not met when alternative methyl donors are substituted.

CHOLINE DEFICIENCY IN HUMANS

Humans require choline to sustain normal life. Is a dietary source of choline required? As discussed above, normal diets deliver sufficient choline. When healthy humans were fed a choline-deficient diet for 3 weeks, however, they developed biochemical changes consistent with choline deficiency (13). These changes included diminished plasma

choline and phosphatidylcholine concentrations, as well as diminished erythrocyte membrane phosphatidylcholine concentrations. Serum alanine transaminase (ALT) activity, a measure of hepatocyte damage, increased significantly during choline deficiency.

Hepatic complications associated with total parenteral nutrition (TPN), which include fatty infiltration of the liver and hepatocellular damage, have been reported by many clinical groups. Frequently, TPN must be terminated because of the severity of the associated liver disease. Some liver disease associated with TPN is related to choline deficiency. Amino acid–glucose solutions used in TPN of humans contain no choline (14, 113). The lipid emulsions used to deliver extra calories and essential fatty acids during parenteral nutrition contain choline in the form of phosphatidylcholine (20% emulsion contains 13.2 mmol/L). Humans treated with parenteral nutrition required 1 to 1.7 mmol of choline-containing phospholipid/day during the first week of parenteral nutrition therapy to maintain plasma choline levels (14). Plasma choline concentrations decreased in parenteral nutrition patients at the same time that liver dysfunction was detected (114).

Clinical trials support the requirement for supplemental choline during TPN (15, 16). Patients were treated with TPN (average duration 7 years) including 4 kcal/kg/day as 20% Intralipid (delivering approximately 50 $\mu\text{mol/kg/day}$ choline as phosphatidylcholine). These patients had low plasma choline concentrations (average, 6.3 $\mu\text{mol/L}$). In a double-blind protocol, investigators administered either 20 g lecithin (30% phosphatidylcholine; delivering approximately 300 μmol choline moiety/kg/day) or placebo (soybean oil) orally twice a day for 6 weeks. At the end of this experimental period, plasma choline had risen by more than 50% in the lecithin group, while in the placebo group it had decreased by 25%. Fatty liver was defined by computed tomography. In the treated group, liver density increased (fat decreased) by approximately 30% ($P < .05$); in the placebo group, liver density increased by only 8% (nonsignificant). Thus, choline seems to be an essential nutrient during long-term TPN.

PREGNANT ANIMALS DEplete THEIR CHOLINE RESERVES

Transport of choline from mother to fetus depletes maternal stores of choline and degrades tissue choline content (the choline concentration of maternal liver falls from a mean of 130 $\mu\text{mol/L}$ in adult nonpregnant rats to 38 $\mu\text{mol/L}$ in late pregnancy [115]). Pregnant rats eating a standard rat diet (AIN-76A diet) with and without choline for 6 days (days 12–18 gestation) were compared with nonmated female and male rats eating the same diets (116). Nonmated female rats eating the control diet had higher hepatic choline metabolite concentrations than did male rats (choline, 98% higher; betaine, 96% higher; phosphocholine, 55% higher) or pregnant rats (betaine, 42% higher; phosphocholine, 47% higher). Nonmated females eating a choline-deficient diet showed only a modest decrease (33%) in the labile choline metabolite phosphocholine in liver, compared with similar rats eating a control diet. Phosphocholine concentration in liver is the most reliable marker for changes in choline status. It was most sensitive to modest dietary choline deficiency in male adult rats, decreasing to 10 to 20% of control values after a short period of consuming a deficient diet (70). Pregnant rats had significantly greater diminution of hepatic phosphocholine (83% decrease) when fed a

choline-deficient diet than did nonmated females (116). The depletion of choline stores evident in pregnant rats indicates that demand for choline exceeds the capacity of the combination of dietary intake and de novo synthesis during pregnancy. Even though female rats are more resistant to choline deficiency than are male rats, pregnancy renders them more vulnerable to deficiency than males are. Decreased demands for methylation and an enhanced capacity to form the choline moiety de novo may explain the relative resistance of nonmated females to choline deficiency. A major sink for methyl groups is formation of creatinine. In males this demand is much higher (because of greater muscle mass) than in females (117); therefore, females may use less choline (betaine) as a methyl donor. Phosphatidylethanolamine-*N*-methyltransferase activity in some tissues is influenced by sex hormones (118). Females have 10% (119) to 50% (120) greater phosphatidylethanolamine-*N*-methyltransferase activity in liver than do males. In addition, young women incorporate methylmethionine into phosphatidylcholine significantly faster than do postmenopausal women (121).

LACTATION EXACERBATES THE CHOLINE DEPLETION THAT STARTS IN PREGNANCY

Most of the choline moiety in human milk (2 mmol/L) is derived from maternal plasma. Thus, transport of choline from mother to infant via the mammary gland constitutes an appreciable drain on maternal choline stores and makes the lactating female even more vulnerable to the effects of choline deficiency. After eating a defined control diet for 25 days (gestation day 12 to postpartum day 15), lactating rats had lower hepatic choline metabolite concentrations (phosphocholine, 67%; phosphatidylcholine, 73%; and betaine, 37%) than similarly fed, nonmated females (116). These lactating rats clearly were highly sensitive to choline deficiency, inasmuch as their liver phosphocholine decreased 88% during the 25-day feeding period compared with a 12% decrease in nonmated females (116).

SUMMARY

Choline is crucial for sustaining life. It modulates the basic signaling processes within cells, is a structural element in membranes, and is vital during critical periods in brain development. Choline metabolism is closely interrelated with the metabolism of methionine and folate. Although the normal human diet provides sufficient choline to sustain healthy organ function, populations vulnerable to choline deficiency exist, including the growing infant, the pregnant or lactating woman, the cirrhotic patient, and the patient fed by TPN. Studies of choline requirements in these groups need to be pursued vigorously.

The 1998 Reference Dietary Intakes of the Food and Nutrition Board Institute of Medicine include suggested “adequate intake” levels for healthy individuals of various age groups (123) (see also Appendix [Table II-A-2-c-1](#) and [Table II-A-2-c-4](#)).

[Selected Readings](#)

The carotenoids consist of more than 600 compounds, exclusive of isomers, all of which are polyisoprenoids, possess an extensive system of conjugated double bonds, usually contain 40 carbon atoms, commonly show internal symmetry, and often have one or two cyclic structures at the ends of their conjugated chains. They are found in some species of most types of living organisms, including animals, plants, and microorganisms. They are required for survival in a few, but not many, life forms. They and their metabolites perform many useful functions in nature, including their involvement as accessory light-gathering pigments and as protective agents in photosynthesis, their conversion to vitamin A in animals and in some microorganisms, and the involvement of a metabolite in leaf abscission. They are prominent in the coloration of birds and other organisms, which is often related to mating cycles, and in flowers, possibly as an attractant for insects that enhance pollination. They are colorful, yielding a spectrum of compounds from yellow to red. Besides their above-cited functions, they delight the eye and raise

human spirits.

This treatment of carotenoids, however, appropriately for a treatise devoted largely to human nutrition, focuses on their physiology and metabolism in animals and humans and on their potentially beneficial and adverse effects in human disease. Because they are easily extracted, brightly colored compounds, they have interested chemists and biologists for a century and a half (1). The term *carotenoids* was coined by Tswett in 1911 during his early elegant studies on their separation by chromatographic procedures.

CHEMISTRY

Some carotenoids commonly found in foods are shown in [Figure 33.1](#). Although the most prevalent and stable form of each carotenoid is the all-*trans* isomer, many *cis* isomers exist. Indeed, the symmetric reference compound, b-carotene, can theoretically form 272 different isomers, whereas its asymmetric analogue, a-carotene, can form 512. Other than possibly the 9-*cis* isomer, however, few of the *cis* isomers currently are considered important in animal nutrition.

Figure 33.1. Some carotenoids commonly found in foods. (From Olson JA, Krinsky NI. FASEB J 1995;9:1547–50, with permission.)

The carotenoids in large part are hydrophobic molecules and consequently interact with lipophilic parts of the cell; namely, membranes and lipid globules. The hydrocarbon carotenoids tend to be solubilized in the lipid cores of bilayer membranes. Being rigid molecules, they align themselves parallel to the surfaces of the membrane. The oxocarotenoids (xanthophylls) such as lutein and zeaxanthin ([Fig. 33.1](#)) tend to expose their hydroxyl groups at the membrane surface. They may align themselves perpendicular to the surface and even serve as transmembrane entities (2). Thus, dihydroxycarotenoids may affect both the fluidity and the function of membranes.

In nature, hydroxylated carotenoids are often present as esters with long-chain fatty acids (making them more hydrophobic) or as glycosides (making them more polar). Ketocarotenoids, such as canthaxanthin ([Fig. 33.1](#)) and its 3,3'-dihydroxy analogue, astaxanthin, can form discrete complexes with proteins by making Schiff bases with specific lysine residues. This interaction, as in a-crustacyanin of the lobster, shifts the spectrum of the carotenoid 144 nm toward the red to give a blue complex. Most free carotenoids in solution, however, absorb between 440 and 490 nm, depending primarily on the number of conjugated double bonds present and the solvent used.

The C₄₀ carotenoids can be oxidatively cleaved, both chemically and biologically, to yield a family of beta;-apocarotenoids with fewer than 40 carbon atoms. These derivatives usually absorb at wavelengths of 350 to 430 nm, depending primarily on the number of conjugated double bonds present.

Various isotopically labeled analogues, primarily b-carotene, have been synthesized both chemically and biologically from precursors containing ¹⁴C, ¹³C, ³H, and ²H. These labeled compounds have been very useful in studying the metabolism and in vivo kinetics of these compounds.

Carotenoids show two other important chemical characteristics: (a) an ability to quench singlet oxygen and (b) antioxidant/prooxidant properties. Singlet oxygen, which is much more reactive than the triplet oxygen present in the air, can interact with many components of the cell to yield oxidized inactive products. Carotenoids also interact with singlet oxygen to yield triplet oxygen and an excited triplet carotenoid, which in turn releases its energy harmlessly into the ambient solution ([1](#), [2](#)). Carotenoids also form both radical cations and radical anions under suitable conditions ([2](#)). These highly reactive molecules can interact with other free radicals, such as peroxy or hydroxy radicals, to give nonradical products, or they can interact with other molecules to restore the carotenoid to the ground state while producing a new free radical ([2](#)). Removal of free radicals from cells is usually considered beneficial, and generation of free radicals in cells is usually considered harmful. Thus, depending on circumstances, carotenoids can show either antioxidant or prooxidant actions. Under physiologic conditions, however, their antioxidant actions seem to predominate ([2](#), [3](#)).

In addition to the “mediator”-type reactions cited above, carotenoids can also be oxidized, both chemically and biologically, by strong oxidants to give a variety of products ([4](#)). In a physiologic context, these reactions can be beneficial (removal of strong oxidants from cells where they can cause oxidative damage), indifferent (not of sufficient importance to influence cell metabolism), or adverse (provitamin A carotenoids are destroyed).

The most-used methods for separation and quantitation of carotenoids involve high-performance liquid chromatography (HPLC) on reverse-phase or straight-phase columns, combined with spectrophotometric detection and peak integration ([5](#)). A so-called C30 HPLC column gives improved resolution ([6](#)). b-Carotene labeled with deuterium is detected by mass spectrometry combined with a variety of separation

methods (7).

DIGESTION, ABSORPTION, AND TRANSPORT

Digestion and Absorption

Dietary carotenoids in foods exist in two major forms: (a) as true solutions in oil, as in red palm oil, or (b) as parts of matrices within the vegetable or fruit. The matrix is usually complex, consisting of fiber, digestible polysaccharides, and proteins. Because the matrix often is not fully disrupted during food preparation and during its passage through the intestine, the bioavailability of carotenoids can vary from less than 10%, such as in largely intact raw carrots, to more than 50% in oily solutions or in synthetic, gelatin-based, commercial preparations (8, 9 and 10). Hydro-carbon carotenoids such as b-carotene and lycopene are solubilized in the lipid core of micelles in the gut lumen or alternatively form small clathrate complexes with conjugated bile acids, of which deoxycholate and cholate are the most effective (8, 11). Xanthophyll esters must be hydrolyzed before absorption. As in membranes, xanthophylls and carotenes associate differently with micelles (12). The absorption process does not seem to involve special epithelial transporters.

Apart from an incomplete release of carotenoids from the matrices of foods, other factors that lower carotenoid bioavailability include the presence of fiber, particularly pectins, in the diet; a lack of fat in the diet; the presence of nondigested lipids, including fat substitutes; inadequate bile flow; various clinical conditions involving lipid malabsorption; and reduced gastric acidity (10). The absorption efficiency of carotenoids decreases as the amount ingested increases (8, 9 and 10).

Furthermore, carotenoids in substantial amounts interfere with each other's absorption (13, 14). The action is not mutually competitive, however, inasmuch as b-carotene inhibits canthaxanthin and lutein absorption, whereas the latter have little or no effect on b-carotene absorption (10, 13, 14). Vitamin E and carotenoids also interact. Vitamin E supplements tend to lower plasma carotenoid concentrations, although small amounts of vitamin E may prevent carotenoid oxidation in the gastrointestinal (GI) tract (10). b-Carotene supplements have been reported to decrease, increase, or not affect plasma tocopherol concentrations (10).

Bioavailability and Nutritional Equivalency

In a nutritional context, the great range of bioavailabilities of carotenoids makes any definition of their general equivalence as precursors of vitamin A difficult. Indeed, the retinol molar equivalency of small amounts of b-carotene in oil is approximately 0.5 (15), whereas that of carotenoids in rapidly stir-fried vegetables is very poor indeed (<0.05) (16). Carotenoids in fruits seem to be better utilized. Past bioavailability studies, which are often inconclusive and conflicting, have been reviewed (17).

The problem in defining a general factor for converting provitamin A carotenoids to vitamin A is not new. The World Health Organization (WHO) suggested in 1967 that 6

μg of all-*trans* b-carotene or 12 μg of all-*trans* provitamin A carotenoids in foods is equivalent to 1 μg of all-*trans* retinol (18). In the absence of precise information and because of the complexity of the problem, most national and international committees have used the same value.

Isomeric Forms

The 9-*cis* isomer of b-carotene is absorbed from the human intestinal lumen but, unlike the all-*trans* isomer, is not transported in significant amounts in plasma (19, 20). Thus, the 9-*cis* isomer may well be isomerized to the all-*trans* form in the intestinal mucosa before being released into lymph (9) or be cleaved in the intestinal mucosa to all-*trans* and 9-*cis* retinal (21, 22). In contrast, the *cis* isomers of lycopene seem to be absorbed better than the all-*trans* isomer in humans (23). Absorption, transport, and storage in the liver of isomeric forms of carotenoids seem to be species specific. Thus, in monkeys, relative to the all-*trans* form, 13-*cis* isomers of lutein and zeaxanthin seem to be preferentially absorbed and transported, whereas the 9-*cis* isomer seems to be more poorly absorbed (10). Thus, just as some vertebrates (humans, other primates, the preruminant calf, ferrets, and birds) absorb and transport appreciable amounts of carotenoids in the plasma whereas others (most rodents) do not, differential absorption and storage of isomeric forms seem to vary markedly from one species to another.

Relative Rates of Absorption of Different Carotenoids

In general, polar carotenoids seem to be absorbed better by humans than nonpolar ones. Thus, by using the area under the absorption curve (AUC) of plasma as an indicator, lutein seems to be absorbed about twice as well as b-carotene in humans (14). b-Apocarotenals and b-apocarotenols also seem to be absorbed better than less polar carotenoids (24). Relative to their proportions in a carotenoid mixture ingested by humans, lutein and zeaxanthin are enriched in the chylomicra (10). These deductions are based on the assumption that metabolism of carotenoids in the intestinal mucosa is only a minor part of their transfer into plasma and that their relative rates of clearance from plasma are similar. These assumptions may not hold for all-*trans* b-carotene and possibly for other provitamin A carotenoids.

Responders and Nonresponders

When a moderate to large dose of b-carotene is administered orally to humans, some subjects respond with a marked increase in the b-carotene concentration in plasma that peaks at 6 h, decreases, and then rises to higher concentrations with a second peak at approximately 24 h (8, 9 and 10). This is considered a normal response. Other subjects, termed *nonresponders*, show little or no increase in the plasma concentration of b-carotene after dosing (10). Several explanations can be given for this unexpected observation: (a) b-carotene is absorbed, but at a much slower rate; (b) b-carotene may be cleared from the plasma at a much faster rate; and (c) b-carotene may be converted very rapidly to vitamin A in the intestinal mucosa. Although all of these factors may play a role, the rate of cleavage of b-carotene to vitamin A in the intestinal mucosa seems to be a key factor. In human lymph, the ratio of retinyl ester derived from b-carotene to intact b-carotene in several subjects was 2 or more (10). In addition, nonresponders to

b-carotene responded normally to lutein (14) or to canthaxanthin (10), neither of which is appreciably metabolized in the intestinal mucosa. All subjects given carotenoid analogues such as 4,4' dimethoxy b-carotene and ethyl b-apo-8'-carotenoate, responded normally (24). Finally, the rates of clearance of lutein and b-carotene from human plasma after dosing did not differ significantly (14). Thus, “nonresponders” to a dose of b-carotene may rather be “efficient converters” of b-carotene into vitamin A in the intestinal mucosa. Likewise, many animal species that do not transfer intact b-carotene into the plasma are efficient in converting b-carotene to vitamin A.

Plasma Transport

Newly absorbed carotenoids, together with retinyl ester and small amounts of retinol, are transported on chylomicra from the intestinal mucosa via lymph into the general circulation. Lipoprotein lipase hydrolyzes much of the triglyceride in the chylomicron, resulting in a chylomicron remnant (8, 9 and 10). The latter, which retains apolipoproteins B48 and E on its surface, will interact with receptors for them on hepatocytes and be taken up by those cells. Small amounts of chylomicron remnants may also be taken up by other tissues.

The hepatocyte then incorporates much dietary carotenoid into lipoproteins. Hydrocarbon carotenoids predominate in very low density lipoproteins (VLDLs) and low-density lipoproteins (LDLs), whereas the xanthophylls are distributed more or less equally between high-density lipoproteins (HDLs) and LDLs (8, 9 and 10). This distribution accords with the hydrophobicity of the carotenoids and lipoproteins. Specific mechanisms of incorporation, such as the α -tocopherol-transport protein of liver for *RRR*- α -tocopherol, have not been identified for carotenoids. A recently characterized b-carotene-binding protein of liver (25), however, may play some role in this process. HDLs may arise both from de novo synthesis in the liver and from pinching off of excess surface components from chylomicra in the plasma during triglyceride hydrolysis. It seems likely, however, that xanthophylls are primarily incorporated into HDLs in the liver.

In the plasma, VLDLs are rapidly converted by lipoprotein lipase to LDLs, which retain the carotenoids and apolipoprotein B100. Receptors for the latter are present on cells of many peripheral tissues as well as the liver. HDLs pick up cholesterol and possibly xanthophylls from peripheral tissues as well as apolipoprotein E from other plasma lipoproteins before being taken up by the liver. Except as noted above, carotenoids do not seem to be transferred from one lipid class to another, at least during in vitro incubation (10, 26).

Thus, carotenoids are involved in a complex and probably cyclic metabolic pathway involving the intestine, chylomicra, the liver, plasma lipoproteins, and peripheral tissues.

Plasma Carotenoids

In the fasting state, carotenoids are commonly found in human plasma. Of the 30 or more carotenoids present, six comprise 60 to 70% of the total (27, 28): lutein, lycopene, zeaxanthin, b-cryptoxanthin, b-carotene, and a-carotene. Because carotenoids are

noncovalently bound to lipoproteins and apparently are not homeostatically controlled, their concentrations in plasma depend highly on the diet. In a more physiologic context, their steady-state plasma concentrations depend on the amounts in the diet, their intestinal absorption efficiencies, their uptake by tissues, their release from tissues back into plasma, and their catabolic rates. Because the distribution of carotenoids in a population is skewed toward lower values, median concentrations are generally used in data analysis. A preliminary report (29) of median values from NHANES III (1988–1994) for the six major carotenoids and their reference ranges in the United States population is summarized in Table 33.1. The reference ranges are expectedly broad, as they include individuals ingesting various amounts of carotenoids in the diet. Lutein and zeaxanthin, which tend to run closely together on HPLC, are grouped in this analysis. In general, the lutein:zeaxanthin ratio in plasma is 4 or 5:1 (30). Although the distribution and amounts of carotenoids in individuals differ markedly, each person maintains a fairly constant pattern for at least a month (30), probably reflecting a fairly uniform diet during that period, abetted by the presumed buffering effect of tissue carotenoid concentrations. Some key findings that emerge from these surveys (29, 30) are that men show higher lycopene concentrations than women, women show higher b-carotene and a-carotene concentrations than men, and that smoking depresses carotenoid concentrations (except, oddly enough, for lycopene) by approximately 30% in all subjects. Median carotenoid concentrations also vary with age, but not in the same way for all carotenoids (29). Lycopene generally is the most common carotenoid in plasma, followed by lutein/zeaxanthin, b-carotene, b-cryptoxanthin, and a-carotene, in that order (29).

Carotenoid	Men	Women	Reference Ranges ^a 5th–95th Percentile
Lycopene	0.47	0.41	0.13–0.82
Lutein + zeaxanthin	0.35	0.35	0.16–0.72
β-Cryptoxanthin	0.13	0.13	0.05–0.38
β-Carotene	0.22	0.28 ^b	0.09–0.91
α-Carotene	0.065	0.081 ^b	0.02–0.22

Unpublished NHANES III data. CDC, 1996. Summarized by Brielel R, Sowell A, Huff D, et al. FASEB J 1996;10:A813.

^bExtrapolated from values for nonsmoking subjects.

Table 33.1 Median Concentrations (μmol/L) of Serum Carotenoids in 40-Year Old Humans in the United States, 1988–1994

When subjects are fed a diet containing few, if any, carotenoids, plasma carotenoids expectedly decrease (31, 32 and 33). Under these conditions, plasma carotenoid concentrations decrease in approximately a first-order manner for 14 to 30 days and then reach slowly declining plateau values (31). Estimated initial half-lives ($t_{1/2}$) in a 30-day study (32) and those calculated from the first 14 days of a 64-day study (31) are

lycopene (9, 16 days), b-carotene (10, 12 days), lutein/zeaxanthin (12, 19 days), b-cryptoxanthin (16, 11 days) and a-carotene (17, 8 days). Serum concentrations of the above-cited carotenoids in subjects on a low-carotenoid diet for 64 to 72 days were 51% or less of their baseline concentrations ([31](#), [33](#)).

Tissue Carotenoid Content

Carotenoids are found in all tissues of the body ([30](#), [34](#), [35](#), [36](#), [37](#) and [38](#)) ([Table 33.2](#)). On the basis of the relative weights of tissues in the adult human body ([39](#)), they clearly are mainly present in fat, liver, and plasma. Some relatively small tissues (e.g., testes and adrenal) and parts of some tissues (e.g., the corpus luteum [112 nmol/g]) show very high concentrations of carotenoids, whereas some major organs (e.g., muscle and brain) show very low concentrations. The only major human organs not cited in [Table 33.2](#) are the skeleton and the GI tract. The former does not seem to have been studied in this regard and the latter, which deteriorates rapidly after death, also has not been examined in human autopsy specimens.

Organ	Mean Concentration ^a	Approximate Percentage of Body Weight ^b	Mean Total Carotenoid (µg) ^c	Percentage of Total ^d
Fat	3.3 (1.5-6.0) × 10 ³	18.8	42.2	65.3
Liver	0.3 (0.1-0.5) × 10 ³	2.3	7.8	12.0
Muscle	0.3 (0.1-0.5) × 10 ³	42.8	2.0	3.1
Adrenal	2.2 (0.8-4.0) × 10 ³	0.02	0.4	0.6

^aMean concentration, serum concentration mean, and values from ref. 34. For apparent molecular weight of tissue carotenoids in tissues is assumed to be 550. ^bFrom ref. 39. ^cFrom ref. 39. ^dFrom ref. 39. The plasma concentration is assumed to be 1.0 × 10³ nmol/l.

Table 33.2 Estimated Total Carotenoid Content (nmol/g) of Selected Human Tissues

The total amount of carotenoid in the body varies greatly, depending largely on dietary intake. Thus, it is not surprising that the mean concentrations of carotenoids in fat and liver in various studies ([34](#), [35](#), [36](#) and [37](#)) differ markedly.

Inasmuch as 90% or more of the carotenoids in the body are found in tissues and less than 10% in plasma, the carotenoid patterns in various tissues are of interest. In nearly all tissues cited in [Table 33.2](#), lycopene and b-carotene were in highest concentrations, lutein/zeaxanthin were intermediate, and cryptoxanthin and a-carotene were lower ([30](#), [34](#), [35](#), [36](#), [37](#) and [38](#)). Tissue concentrations in most instances reflected the distribution pattern of carotenoids in plasma from the same population group. Some exceptions are the preferential accumulation of b-carotene in the pineal gland ([40](#)) and the corpus luteum ([41](#)) and of lutein/zeaxanthin in the macula of the eye ([42](#)).

In Vivo Kinetics

The in vivo kinetics of an orally administered dose (73 μmol) of octadeuterated b-carotene has been carefully analyzed, albeit only in one male adult (43, 44). A model consisting of 11 compartments and a GI delay parameter has been devised on the basis of measurements of octadeuterated b-carotene and tetradeuterated retinol in the plasma at various times from 0 to 57 days, although measurements were made to 113 days. Compartments are 1 and 2, slow and fast pools of b-carotene in the liver; 3 and 4, slow and fast pools of retinol in the liver; 5, b-carotene in the enterocyte; 6, b-carotene in extrahepatic tissues; 7, b-carotene in plasma chylomicra; 8, retinyl ester in plasma chylomicra; 9, b-carotene in plasma lipoproteins other than chylomicra; 10, retinol bound to retinol-binding protein in plasma; and 11, b-carotene in the GI tract. By using several feasible assumptions, a set of fractional transfer coefficients (FTCs) were defined by use of SAAM 31 software (43, 44). The model predicts that 22% of the b-carotene dose was absorbed; that liver reserves of b-carotene and vitamin A were 7.5 and 324 μmol , respectively; and that 57% of the b-carotene conversion into vitamin A took place in the liver and 43% in the intestinal mucosa (43, 44). With average dietary intakes of b-carotene (7 $\mu\text{mol}/\text{day}$), however, the intestine may well play a larger role in the conversion process.

The mean sojourn time (MST), or residence time, is defined as the mean time that tracer molecules spend in the system from first entry to irreversible exit (10, 43, 44). The MST values of b-carotene and retinol (vitamin A) in the *body* were 51 days and 474 days, respectively, which agree well with estimates based on other data. Empirical MST values for b-carotene and retinol in *plasma* were much shorter; namely, 9 to 13 days and 26 days, respectively (43, 44). These differences between the MST values for plasma and the body may well reflect efficient recycling of retinol (see Chapter 17) and probably of carotenoids as well, in and out of tissue depots.

Plasma MST values for other carotenoids, based on empirical treatments, are similar to that of b-carotene: namely, dimethoxy-b-carotene, 6 days; ethyl b-apo-8'-carotenoate, 9 days; and canthaxanthin, 8 days (10, 24). Experimentally, MST values for carotenoids are not much affected by the dose given (10).

METABOLISM

Biosynthesis

Carotenoids are formed in microorganisms and plants but not in mammals. As polyisoprenoids, the initial rate-limiting step is conversion of b-hydroxy-b-methylglutaryl-CoA into mevalonic acid. Two C5 isoprene intermediates condense to form successively C10, C15, and C20 (geranylgeranyl-pyrophosphate) addition products. Two of the latter compounds condense in a tail-to-tail fashion to yield the first C40 carotenoid, 15,15'-*cis*-phytoene (Fig. 33.1) (45). The latter is successively dehydrogenated to give neurosporene, a C40, acyclic carotenoid with 12 double bonds. Depending on the bacterium or plant, neurosporene can be further dehydrogenated to

lycopene, which either cyclizes to give β -carotene or α -carotene or is methoxylated and oxidized to give the ketocarotenoid, spheroidenone, an important accessory pigment in bacterial photosynthesis (45). Molecular oxygen is then introduced into hydrocarbon carotenoids to give mono- and dihydroxycarotenoids, the xanthophylls α - and β -cryptoxanthin, zeaxanthin, and lutein (Fig. 33.1) and, subsequently, a set of epoxy derivatives, such as antheroxanthin, violaxanthin (Fig. 33.1), and neoxanthin, an interesting allenic species commonly found in plants. Oxocarotenoids, such as canthaxanthin (Fig. 33.1), are formed from β -carotene by action of an oxygenase (45). A variety of other biologic transformations of these structures can also occur.

In addition to their roles as accessory pigments in photosynthesis, the epoxy xanthophylls play an important role in protecting plants from absorbing excessive amounts of energy from light. The intricacies of this so-called xanthophyll cycle in higher plants have been carefully reviewed (46).

Carotenoids are oxidized to a variety of compounds with fewer carbon atoms in plants and microorganisms, including β -apocarotenals, abscissic acid, trisporic acid, bixin, and crocetin (47, 48). Some of these breakdown products have important physiologic functions (47). Thus, nature can modify carotenoids in a variety of ways at almost every carbon atom in the molecule.

Vitamin A Formation

Physiologic Pathways

That β -carotene is converted biologically into vitamin A in mammals was first shown in 1930 (41). For many years, the pathways for its conversion were unclear, largely because the conversion rate is relatively slow, and cell-free preparations of tissues were inactive, β -carotene was rapidly oxidized chemically to various derivatives, and the resolving power and/or sensitivity of available methods was limited.

In 1960, John Glover (49) suggested that two pathways might exist for cleavage of carotenoids into vitamin A: (a) central cleavage to yield two molecules of retinal or (b) asymmetric cleavage to yield a shorter and a longer β -apocarotenal, the latter of which was sequentially shortened by removal of C2 and C3 fragments to yield retinal. The C2 and C3 fragments were subsequently presumed to be oxidized to CO_2 (49). While favoring asymmetric cleavage, Glover found, however, that the amounts of radioactive CO_2 produced by metabolism of ^{14}C - β -carotene and ^{14}C -retinol in the rat were the same, not at all in keeping with asymmetric cleavage as a major pathway. A few years later, ^{14}C - β -carotene was shown to yield labeled retinal as the sole detectable product (50, 51). Indeed, the stoichiometry of the reaction, the ratio of moles of retinal formed to moles of β -carotene consumed, was found to be 1.1 to 1.5. Any value greater than 1.0, of course, favors central cleavage. The enzyme, called carotenoid 15,15'-dioxygenase (EC 1.13.11.21), was found to require molecular oxygen. The issue thus seemed to be resolved; central cleavage was deemed to be the major, if not sole, pathway in mammals.

In 1979, Dmitrovskii reported the existence of an NADPH-dependent carotenoid dioxygenase in the nuclear membrane fraction of chick intestinal mucosa that preferentially cleaved b-carotene at the 11,12 double bond (52). This interesting observation, however, did not become widely known.

An interesting challenge to central cleavage appeared in 1988 (53); Hansen and Maret (53), although unable to repeat earlier studies (50, 51), showed that b-carotene could be converted to b-apocarotenals chemically in the presence of oxygen under normal incubation conditions. They repeated Glover's earlier arguments that asymmetric cleavage was a more logical reaction than central cleavage (53). Their paper refocused attention on the mechanism of cleavage. In a careful reexamination of the cleavage reaction, Lakshman et al. (54) showed that retinal was the primary, if not sole, product of b-carotene cleavage catalyzed by a partially purified enzyme preparation of rabbit and rat intestinal cytosol.

The extent to which asymmetric cleavage occurred in mammals then became a key query. Wang and colleagues subsequently showed that whole intestinal homogenates converted b-carotene to a group of b-apocarotenals in the presence of oxygen (55, 56). Of particular interest in this regard was formation of a pair of b-apocarotenals that are counterparts in a 13':14' oxidative cleavage reaction (56). Inasmuch as retinal was a relatively minor product of the reaction in their studies, they concluded that sequential asymmetric cleavage was a major pathway for conversion of b-carotene to vitamin A. Possible pathways for conversion of all-*trans* b-carotene to retinal, retinol, and retinoic acid are summarized in Fig. 33.2.

Figure 33.2. Possible pathways in conversion of all-*trans* b-carotene to retinal, retinol, and retinoic acid. A, b-carotene; B, retinal; C, retinoic acid; D, b-apo-13'-carotenal; E, b-apo-14'-carotenal; F, b-apo-14'-carotenoyl-coenzyme A; G, b-apo-11'-carotenal; H, b-apo-12'-carotenal; I, b-apo-12'-carotenoyl-coenzyme A; CRBP, cellular retinol-binding protein. All polyenes are in the *trans* configuration. Items in brackets have not been isolated or identified as essential components of the pathway. Cofactors other than NADH may be used in conversion of retinal to retinol and other than FAD in oxidation of retinal to retinoic acid.

The most appropriate way to resolve the relative importance of the two pathways clearly is an examination of the stoichiometry of the reaction. Central cleavage will yield 2 moles of retinal per mole of b-carotene consumed, whereas asymmetric cleavage will yield, via b-apocarotenals, a maximum of 1 mole of retinal. By using whole intestinal homogenates like those used by Wang et al. (55), Devery and Milborrow (57) reported a mean molar ratio of 1.72, and Nagao et al. (58) a molar ratio of 1.88 ± 0.08 (SD). After correcting for the efficiency of solvent extraction, the molar ratio was 2.07 ± 0.09 (SD) (58). b-Apocarotenals were detected, if at all, only in trace amounts in these latter studies (57, 58) as well as in others (59, 60). Furthermore, b-apo-8'-carotenal was converted to retinal very slowly, if at all, under the same incubation conditions in vitro (58). Thus far, no stoichiometric studies that favor asymmetric cleavage as the major pathway have been conducted. Thus, the total available information indicates that central cleavage is the predominant reaction in mammals.

Carotenoid Cleavage Enzymes

Although many of the enzymes involved in biosynthesis of carotenoids from mevalonic acid in plants and microorganisms have been characterized (45), much less attention has been given to mammalian enzymes that act on carotenoids. The only exception is carotenoid 15,15'-dioxygenase, which shows similar properties in various tissues and species (61, 62). It is localized in the cytosol, requires molecular oxygen, shows a K_M value for b-carotene of 1 to 10 $\mu\text{mol/L}$, has a slightly alkaline pH optimum (7.5–8.5), is inhibited by metal ion chelators and sulfhydryl-binding reagents, and is activated by glutathione (62). A possible mechanism for cleavage of all-*trans* b-carotene into molecules of retinal is presented in Figure 33-3. The activity of the intestinal mucosal enzyme is enhanced in vitamin A deficiency (59, 63, 64) and by treatment with polyunsaturated fatty acids (PUFAs) (65), but is depressed by treatment with b-carotene (64). The activity of the liver enzyme, although seemingly less sensitive to vitamin A status (64), is increased by treatment with either b-carotene (64) or PUFAs (65).

Figure 33.3. Postulated mechanism for cleavage of all-*trans* b-carotene into two molecules of all-*trans* retinal. Cleavage at other sites in carotenoids might proceed in a

similar fashion. The highly unstable dioxetane (shown in parenthesis) would spontaneously break down to yield two molecules of retinal.

An enzyme catalyzing excentric cleavage of carotenoids in mammalian tissues has been only partially characterized (52). NADPH-dependent carotene dioxygenase, which is present in the nuclear membrane fraction of chicken intestinal mucosa, acts both on xanthophylls and on b-carotene, preferentially cleaves carotenoids at the 11,12 double bond, requires NADPH or ascorbate, uses molecular oxygen, and is inhibited by iron chelators and sulfhydryl binding agents (52). Inasmuch as the stoichiometry of b-carotene cleavage to retinal and the appearance of b-apo-carotenals were not detectably affected by incubations with whole homogenates or cytosolic fractions of pig and guinea pig intestine (57, 58), however, the excentric cleavage enzyme seems to be much less active in these species than b-carotenoid-15,15'-dioxygenase.

An enzyme catalyzing an excentric cleavage reaction in *Cyanobacterium microcystis* has also been studied (66). b-Carotene 7,8;7'8'-dioxygenase cleaves b-carotene into two molecules of b-cyclocitral and crocetindial, presumably by acting first on one 7,8 double bond and then on the other. It requires molecular oxygen, is membrane bound, and is inhibited by metal ion chelators, sulfhydryl-binding reagents, and antioxidants (66). Iron is probably involved in the reaction, inasmuch as o-phenanthroline inhibits the enzyme. Zeaxanthin is also a substrate for this enzyme. Thus, not surprisingly, many properties of the three dioxygenases are similar, except for their preferential sites of cleavage, localization in the cell, and substrate specificities.

Other Pathways

Other pathways may exist for cleavage of b-carotene into retinoids. Lipoxygenases, which exist in animal cells, convert PUFAs to a *cis, trans*-peroxyacid in the presence of oxygen. b-Carotene can serve as an acceptor of the peroxide group, yielding a group of oxidized products and losing absorption at 450 nm (67). Neither retinal nor retinoic acid have been identified, however, as products of this reaction or of other peroxidative processes (68).

Formation of retinoic acid from b-carotene might proceed by central cleavage followed by conversion of the resultant retinal to retinoic acid by one of several aldehyde dehydrogenases (69). The diisoprenoid aldehyde citral inhibits formation of retinoic acid from retinal. Thus, citral should inhibit formation of retinoic acid from b-carotene if retinal is indeed a free intermediate in the reaction. Following earlier observations that retinoic acid might be produced directly from b-carotene (70), b-carotene, but not retinal, was found to be converted into retinoic acid in the presence of citral in whole intestinal homogenates (56) and was formed in portal blood derived from ferret intestine perfused with these substrates (71).

Several possible explanations might be given for these findings. One is that retinoic acid, probably initially as its coenzyme A derivative, is derived from

b-apo-14'-carotenoyl-CoA by a β -oxidation pathway, presumably in the mitochondria (Fig. 33.2). Another is that retinal derived from β -carotene is immediately bound tightly to cellular retinol-binding protein type II (CRBP-II) (72). Oxidation of the retinal–CRBP-II complex to retinoic acid might possibly be much less affected by citral. A third is that retinal dehydrogenase and carotenoid dioxygenase form a tight complex in vivo, such that the cleavage and dehydrogenation reactions are concerted events on the interface between the two proteins that is not readily accessible to citral. These possibilities should be explored.

Metabolism of β -Apocarotenoids

β -Apocarotenals can be converted, albeit slowly in some cases (58), directly to retinal and to an uncharacterized short-chain aldehyde by the carotenoid 15,15'-dioxygenase (73). The rates of cleavage have been reported both to be higher (73) and to be considerably lower (58, 74) than that of all-*trans* β -carotene. β -Apo-8'-carotenal and presumably other analogues can be reduced to alcohols and then esterified in the human intestine as well as being oxidized to their corresponding acids (24). Several β -apocarotenoic acids can also be converted to retinoic acid in ferret liver mitochondria, presumably by β -oxidation (75). Ethyl β -apo-8'-carotenoate, however, was not detectably metabolized in humans (24), thus metabolically resembling etretinate, the ethyl ester of acitretin, which is stored in the body for long periods (76).

Metabolism of Other Carotenoids

Besides all-*trans* β -carotene, the carotenoid 15,15'-dioxygenase cleaves the all-*trans* isomers of 3,4,3',4'-tetrahydro- β -carotene, 5,6-epoxy- β -carotene, 5,8-epoxy- β -carotene, α -carotene, 5,6-epoxy- α -carotene, 5,8-epoxy- α -carotene, and 3',4'-dehydro- β - γ -caroten-16'-al (62), but usually at rates considerably lower than that of all-*trans* β -carotene. The dioxygenase also cleaves 9-*cis*- β -carotene and possibly 13-*cis*- β -carotene, but again at lower rates than the all-*trans* isomer (21, 22). Carotenoids cleaved either at very low rates (<5% that of all-*trans* β -carotene) or not detectably include 5,6,5',6'- and 5,8,5',8'-diepoxy- β -carotene, 3',4'-didehydro- β -cryptoxanthin, zeaxanthin, lutein, the 5,6 epoxides of several β -apocarotenals, and β -apocarotenoic acids (62). The dioxygenase has recently been reported to cleave β -cryptoxanthin, a fairly common dietary constituent and an active provitamin (77). The lack of activity of the dioxygenase toward β -apocarotenoic acids accords with the demonstrated β -oxidation of the latter to retinoic acid in mitochondria (75).

In humans, 4,4'-dimethoxy- β -carotene is converted to canthaxanthin (4,4'-diketo- β -carotene), to a monoketo-monohydroxylated product, and to a more polar, unidentified metabolite (24). α -Carotene is cleaved to retinal and α -retinal, presumably by carotenoid 15,15'-dioxygenase (77). Lycopene, although absorbed well from oily solutions and taken up by the liver and other organs, is metabolized by poorly understood pathways (78, 79). Radiolabeled lycopene is not converted to detectable products in rats and squirrel monkeys (78), although hydroxylated derivatives of lycopene have been detected in human plasma (79, 80). These derivatives or immediate precursors of them are also found in tomato products. Many isomers of

lycopene are present in human plasma and tissues, of which the major ones are all-*trans* and 5-*cis* lycopene (79). Because a similar pattern of isomers is found in tomato products, however, the extent of isomerization of lycopene in vivo is not known.

Canthaxanthin, like lycopene, is not metabolized to detectable products in rats, squirrel monkeys, or humans (13, 78, 81). In chickens, however, a portion is reduced to the mono- and dihydroxy derivatives, which in turn are acylated (82).

Lutein may be oxidized in vivo in humans to its 3'-keto derivative, isomerized from the 6'*R* to the 6'*S* form, or converted to 3'-epilutein and zeaxanthin (80). Although the enzymatic reactions have not been clarified, such derivatives appear in human plasma after lutein supplementation.

Capsanthin, a major carotenoid in paprika, is a dihydroxymonoketo-carotenoid with one 5-carbon cyclic ring. When orally administered to men, capsanthin is well absorbed, is associated equally with HDL and LDL in plasma, and is cleared rapidly from the circulation (83). No metabolites were identified.

9'-*cis*-Bixin, a monomethylester of an acyclic C₂₅ dicarboxylic acid, and its congeners are found in seeds of the annatto plant. Extracts of these seeds are used as a common food coloring in Spain and Latin America. When ingested by human volunteers, 9'-*cis*-bixin is well absorbed but rapidly cleared from the plasma (84). 9'-*cis*-Bixin is both demethylated to the dicarboxylic acid norbixin and isomerized to all-*trans* bixin in vivo (84).

Little is known about the metabolism in mammals of other carotenoids, such as neoxanthin, violaxanthin, and astaxanthin. Although found in foods, these carotenoids have not been detected in human plasma (85).

CAROTENOIDS IN FOODS

Food composition tables traditionally expressed the carotenoid content of individual foods in IU/unit weight, in which 1 IU = 0.6 µg all-*trans* b-carotene or 1.2 µg of mixed other provitamin A carotenoids, or more recently in µg retinol equivalents, in which 6 µg all-*trans* b-carotene = 1 µg all-*trans* retinol (see Appendix Table I-A-1-b). Because 1 IU of retinol = 0.3 µg, the conventions for IU and for µg retinol equivalents clearly do not agree. The confusion caused by these two systems of units is only slowly being resolved. Factors and formulas used in interconverting units of vitamin A and carotenoids are summarized in Appendix Table I-A-1-b). In the last several years, analysis of individual carotenoids in foods has much improved (85, 86). The carotenoid patterns of some common foods are presented in Table 33.3 (86). In this analysis, the six major dietary carotenoids, with lutein and zeaxanthin pooled, were measured. The richest sources of carotenoids are the palm oils, which primarily contain b-carotene (4.7 mg/100 mL), a-carotene (3.7 mg/100 mL), and smaller amounts of other carotenoids. As already indicated, the bioavailability of carotenoids in vegetables, and to a lesser extent in fruits, is a key consideration in assessing the actual amount of carotenoids absorbed.

Item	β -Carotene	α -Carotene	Lutein/Zeaxanthin	Lycopene	Cryptoxanthin

Table 33.3 Carotenoid Composition of Typical Fruits and Vegetables ($\mu\text{g}/100$ g portion)

BIOLOGIC EFFECTS OF CAROTENOIDS

Carotenoids play many roles in nature. In mammals and in mammalian cells, they clearly serve as precursors of vitamin A. But can they, and do they, serve any other roles in mammals? In the past two decades, carotenoids have been implicated in a large number of biologic processes (87). In considering these effects, it is useful to categorize them as functions, actions, or associations.

Functions

A *function* is an essential role played by the nutrient in growth, development, and maturation. Because carotenoids are not needed by mammals with adequate preformed vitamin A in the diet, they cannot be considered essential. But, in the absence of adequate preformed vitamin A in the diet, they become essential or, more aptly, “conditionally essential,” as in the case of certain amino acids. Because carotenoids are a major dietary source of vitamin A for much of humanity, however, their role as “conditionally essential” nutrients is highly important.

Actions

Actions are demonstrated effects in various biologic systems that may or may not have general physiologic significance.

Cell-to-Cell Communication

A good example of an action is enhancement of cell-to-cell communication in tissue culture (88, 89). Because both provitamin A (b-carotene) and nonprovitamin A (canthaxanthin) molecules show such effects, the action is not linked to formation of vitamin A. Whether 4-oxoretinal and 4-oxoretinoic acid (which also enhances cell-to-cell

communication) play roles in this process as a result of cleavage of canthaxanthin is yet unclear (88, 89). Because retinoic acid is a more effective enhancer of cell-to-cell communication than the carotenoids, the physiologic significance of the carotenoid action in vivo is also unclear.

Cell Differentiation

5,6-Epoxy-b-carotene enhances differentiation of NB4 cells in vitro better than b-carotene does but less well than all-*trans* retinoic acid or 5,6-epoxyretinoic acid (90). Although the preferential action of an epoxy-carotenoid relative to its parent hydrocarbon in mammalian cells is of interest, the physiologic significance is uncertain.

The Immune Response

Carotenoids, like retinoids, can also modulate the immune response in rats (91), mice (92), and lymphocytes in culture (93). In vivo, astaxanthin, canthaxanthin, lutein, and b-carotene stimulate the response (91, 92). In cultures of Th1 clones and primed spleen cells in vitro, astaxanthin, but not other carotenoids, stimulates antibody production and depresses production of interferon-g (93). Under similar conditions with Th2 clones, only astaxanthin stimulates antibody production. In contrast, lycopene suppresses antibody production in Th2 clones incubated together with unprimed spleen cells (92). The key points are that (a) xanthophylls are more active enhancers than b-carotene, (b) various carotenoids differ in their activities in different immune systems, and (c) a primary site of action in humoral immune responses, as in the case of the retinoids, seems to be the T-helper cell. Again, the physiologic significance of these observations is not clear. Indeed, in female subjects fed a b-carotene-free diet for 68 days and then supplemented with b-carotene, mitogen-induced proliferation of blood lymphocytes was unaffected (33). In a similarly treated group of female subjects, however, mixed carotenoids did elicit a response (94). Furthermore, in healthy male nonsmokers, b-carotene supplementation (15 mg/day) significantly increased the percentage of blood monocytes expressing the major histocompatibility complex class II molecule HLA-DR, intercellular adhesion molecule-1, and leukocyte function-associated antigen-3, as well as secretion of tumor necrosis factor- α (95). These actions merit further attention.

Reproduction

Carotenoids might affect reproductive performance in animals and humans in two ways: (a) by being converted into vitamin A, which is essential for a successful outcome of pregnancy, and (b) by modulating per se one or several of the complex events associated with the reproductive process (96).

In dairy cattle, oral b-carotene supplements (100 mg/day) were reported in 1976 to offset various abnormalities found in unsupplemented cows, namely, delayed ovulation, increased incidence of ovarian cysts, lower progesterone production, reduced growth rate of corpora lutea, increased embryonic mortality, and increased diarrhea in calves (97). In subsequent studies conducted elsewhere, however, these positive effects of supplementation could not be confirmed (8, 9 and 10). The Indeed, large b-carotene

supplements (500 mg/day) actually reduced the insemination rate (98).

Female pigs (gilts), when injected with, but not when fed, b-carotene (228 mg/week) during the breeding period, showed lower embryonic mortality, larger litter size, and heavier litter weight than unsupplemented gilts (96). Injection of an equivalent amount of vitamin A, however, showed similar benefits (101). Oral supplements of b-carotene also did not improve reproductive performance of vitamin A-sufficient female rabbits (102). In a more mechanistic sense, b-carotene was reported to induce progesterone formation by luteal cells in vitro better than vitamin A (96) and to enhance vitamin A formation from b-carotene locally in bovine follicular cells (103).

Of women who ingested an essentially carotenoid-free diet (10–66 µg RE/day) for 42 to 120 days, 63% showed delayed ovulation or anovulatory cycles, altered luteal phase length, and prolonged menstrual periods, whereas only 5% who ingested a carotenoid-containing diet showed such abnormalities (104, 105). Supplementation with a small amount of b-carotene (83 µg RE/day), however, did *not* correct these abnormalities (105). Possible dietary factors that may prevent these abnormalities include other carotenoids, phytoestrogens, and yet other components of the foods that were eliminated in the “carotenoid-free” diet. Alternatively, higher supplements of b-carotene might be required. These studies, presented thus far only in abstract form, should soon be published in full.

The upshot of these studies, both in animals and in women, is that carotenoids may modulate some facets of the reproductive process but clearly are not required nutrients. In some of the studies, the initial vitamin A status may have been impaired, in which case the most feasible explanation is that b-carotene is serving as a provitamin. In other cases, positive, albeit elusive, effects have been noted in animals and subjects who clearly were vitamin A sufficient. Thus, the situation is not yet fully resolved.

Other Effects

In various biologic systems, carotenoids inhibit a variety of processes: photoinduced neoplasm, mutagenesis, cell transformation, sister-chromatid exchange, and micronuclei formation induced in buccal epithelia by several stresses (87). These interesting observations also fall in the category of actions that may or may not have physiologic importance in well-nourished individuals.

Associations

The third category is *associations*. Such potential interactions are largely derived from epidemiologic studies of the relationships between specific dietary components and chronic diseases. Carotenoids as a whole, as well as specific compounds of the class, have been implicated in many such relationships. Many other dietary constituents, such as a-tocopherol, ascorbic acid, selenium, flavonoids, phenolic acids, polyphenols, and other phytochemicals have been similarly implicated. The key point is that these associations do not imply causal relationships but rather serve primarily as markers of a dietary pattern, lifestyle, or genetic makeup that is conducive to good health. They may, of course, contribute specifically to protective processes, but the association does not

“prove” that they do.

The design and conduct of rigorous epidemiologic studies are difficult and complex, and their interpretation is subject to a variety of confounding factors (106). When the agreement among various similar studies is poor, the thrust of a given relationship clearly is weakened. Nonetheless, epidemiologic studies provide an analysis of important relationships in health and disease that cannot be obtained by other approaches. Their findings, particularly when agreement is good among various studies, serve as a first step in clarifying causal relationships.

Carotenoids, α -tocopherol, vitamin C, glutathione, and selenium are often termed *antioxidant nutrients*. Clearly, all of these compounds, as well as many others, can serve this chemical function. Antioxidants, by their very nature, prevent oxidation of important cellular structures, usually by being preferentially oxidized, i.e., by providing one or two electrons to some active cellular oxidant. Under different circumstances, such compounds can also accept electrons from a donor and thereby become prooxidants. Whether they serve as antioxidants or prooxidants in a given reaction depends both on their initial redox state and the chemical nature of the other interacting molecule. Thus, an emphasis solely on the ability of these molecules to serve as antioxidants is constraining. Furthermore, carotenoids, as well as these other compounds, may well act in ways that do not involve oxidation/reduction. The actions of carotenoids, for example, in cell-to-cell communication (88, 89) and in the immune response (91, 92 and 93) apparently do not involve redox reactions. Furthermore, the interactions of carotenoids with membranes, which can influence membrane structure and potentially membrane function, do not inherently involve redox reactions (2). Thus, carotenoids, as well as many of these other so-called antioxidants, might better be called “nutritional modulators” (107). This terminology does not imply a mechanism of action, and the actions themselves, which might be either beneficial or adverse, are not presumed from the outset to be favorable.

RELATIONSHIP OF CAROTENOIDS TO CHRONIC DISEASES

Cancer

Lung Cancer

One of the most dramatic and consistent observations in epidemiologic studies is the inverse association between β -carotene intake and the incidence of lung cancer (108, 109). These findings have stimulated intervention trials in two high-risk groups, asbestos workers in Tyler, Texas ($n = 755$), and middle-aged male smokers ($n = 29,133$, 50–69 years old) in Finland. The results of these intervention trials were unexpected. In asbestos workers, no difference in the prevalence of sputum atypia was noted between treated (50 mg β -carotene + 25,000 IU retinol every other day) and control groups over a 5-year period. In the Finnish study (110), the group ($n = 14,564$) treated daily with β -carotene (20 mg) for 5 to 8 years, with or without α -tocopherol, showed a significantly higher incidence of lung cancer (relative risk (RR) = 1.18; 95% confidence interval (CI) = 1.03–1.36) and of total mortality (RR = 1.08; 95% CI = 1.01–1.16) than the placebo group ($n = 7287$ men). Supplemental β -carotene did not affect the incidence of other

major cancers found in this population ([109](#), [110](#)).

The findings of the Finnish study have been confirmed in a similar large study ($n = 18,314$), the Carotene and Retinol Efficacy Trial (CARET), conducted in the northwestern United States ([111](#)). In this case, supplements of b-carotene (30 mg/day) and retinyl ester (25,000 IU/day) were given to smokers and asbestos workers. The trial was terminated after 4 years because lung cancer incidence was increased by 28% (RR = 1.28; 95% CI = 1.04–1.57; $P = .02$), and total mortality was 17% higher (RR = 1.17; CI = 1.03–1.33) in the supplemented group than in the placebo group ($n = 8894$) ([111](#)).

In another large study ($n = 22,071$ male physicians, 40–84 years old), the so-called Physicians' Health Study, b-carotene capsules (50 mg every other day) were ingested by physicians, of whom only 11% were current smokers, for 12 years ([112](#)). No differences in total cancer deaths or in deaths from specific types of cancer between supplemented ($n = 11,036$) and nonsupplemented ($n = 11,035$) groups were noted (RR = 0.98; 95% CI = 0.91–1.06) ([112](#)).

The unexpected enhancement of lung cancer in the Finnish and CARET studies has several possible explanations: (a) Supplemental b-carotene might be interfering with intestinal absorption of other possible chemopreventive nutrients. For example, b-carotene inhibits absorption in humans of lutein and canthaxanthin, which show good antioxidant activity ([13](#), [14](#)). In that same vein, a-carotene, which shows chemopreventive properties, might be similarly affected. The effects of b-carotene supplementation on serum concentrations of other carotenoids, however, were relatively minor, except for an increase in a-carotene, a contaminant in the b-carotene preparation ([113](#), [114](#)). (b) Supplemental b-carotene may be serving as a prooxidant in the well-oxygenated ambient of the lung ([115](#)). (c) Populations of middle-aged male smokers and asbestos workers are not representative of other groups, who might well benefit from a higher intake of carotenoids. (d) Vitamin C, which is low in the plasma of most Finns, may have played some role in the outcome of the Finnish study but not the CARET study. (e) Alcohol intake clearly plays an important role in the outcome. Indeed, in the Finnish study, the lung cancer incidence in abstemious smokers was not enhanced by b-carotene supplementation (RR = 1.03; 95% CI = 0.85–1.24), whereas the incidence in those who drank clearly was (RR = 1.35; 95% CI = 1.01–1.81) ([116](#)).

In a matched case-control study of nonsmoking men and women ($n = 413$ matched pairs, 31–81 years old), increased consumption of green vegetables and fruits was most closely associated with a reduced risk of lung cancer (RR = 0.61; 95% CI = 0.43–0.85; P for trend < .01) ([117](#)). Use of supplements of vitamin E was also associated with reduced risk (RR = 0.55; 95% CI = 0.35–0.85) ([117](#)). Males and females showed similar responses ([117](#)). A thoughtful analysis of the relationship between nutrition and lung cancer has recently appeared ([118](#)). The authors conclude that increased fruit and vegetable intake is strongly associated with a reduced risk of lung cancer in both men and women, but that the totality of epidemiologic evidence is not persuasive for specific effects of any single micronutrient ([118](#)).

Head and Neck Cancers

Development of head and neck cancers, including those of the oral cavity, pharynx, and larynx, is influenced by many factors including smoking, other uses of tobacco, alcohol, and diet (109, 119). Serum carotene concentrations, adjusted for smoking, are inversely related to the incidence of these carcinomas. Supplements of b-carotene can markedly reduce leukoplakia, although the lesion returns upon cessation of treatment (109). Several chemoprevention trials designed to assess the effect of daily supplements of b-carotene (50 mg), with or without vitamin E, on the recurrence of head and neck cancer are currently under way (109).

Esophageal and Stomach Cancers

The effects of various nutrient combinations on esophageal cancer and stomach cancer were evaluated in a large population ($n = 30,000$, 40–69 years old, both genders) living in Linxian, China, where the incidence of esophageal cancer is 100 times that in the United States (109). Of four nutrient treatments administered for 5 years, only one (involving supplements of b-carotene, selenium, and a-tocopherol) showed a positive effect; the reductions in total deaths, cancer deaths, esophageal cancer deaths, and gastric cancer deaths were 9% (RR = 0.91; 95% CI = 0.84–0.99), 13% (RR = 0.87; 95% CI = 0.75–1.00), 4% (RR = 0.96; 95% CI = 0.78–1.18), and 21% (RR = 0.79; 95% CI = 0.64–0.99), respectively (109). Although these results support the concept that diet influences cancer incidence, the general nutritional status of the population was poor. Thus, whether the mixed supplement or one component of it was protective as a result of generally improved health or of a more specific anticancer effect is not clear (109).

Colorectal Cancer

Dietary intake and serum concentrations of carotenoids are often inversely associated with colorectal cancer risk (109, 120). By using adenomas as an indicator in a 4-year clinical trial, however, supplemental b-carotene (25 mg/day) was found ineffective in the treated group ($n = 184$, 61 ± 8 years old, both genders) (RR = 1.01; 95% CI = 0.85–1.20) relative to a similar placebo group in preventing recurrence of this lesion (109, 120).

Breast Cancer

b-Carotene intake has been associated with an improved survival rate in breast cancer patients (109). Whether supplements of carotenoids reduce the incidence of breast cancer in a well-designed clinical trial is not known. An ongoing trial is exploring the effect of hydroxyphenylretinamide on the recurrence of breast cancer (121, 122).

Cervical Cancer

The risk of cervical cancer has been correlated with prediagnostic serum levels of a-, b-, and total carotenoids (RR = 2.7–3.1; 95% CI = 1.1–8.1) (109). On the other hand, invasive cervical cancer among white women in the United States was not related to any specific dietary food group nor to use of supplements of vitamins A, C, and E or folic

acid (123). However, cervical dysplasia, considered to be a precancerous lesion, did respond to b-carotene supplements (30 mg/day) (109).

Prostate Cancer

Lycopene is primarily found in tomato products (Table 33.3) and is also present in watermelon, guava, and to a lesser degree in pink grapefruit (79). Thus, the association of ingestion of tomato-based products with a reduced risk of a given disease raises the possibility that lycopene itself is protective. Just such an epidemiologic relationship exists with prostate cancer (124). While intake of other carotenoids was not associated with reduced risk, dietary lycopene was (RR = 0.79; 95% CI = 0.64–0.99; *P* for trend = 0.04). However, no correlation was found with tomato juice ingestion, possibly because of poor bioavailability (79). Lycopene inhibits cell proliferation in several cancer cell lines in vitro and tumor growth in mice in vivo (79). Furthermore, lycopene scavenges radicals and quenches singlet oxygen somewhat better than b-carotene does (79). Thus, a possible mechanism exists for its protective action. In malignant and nonmalignant prostate tissue, lycopene and b-carotene were the major carotenoids found, with most of the lycopene present as a large number of *cis* isomers (38). Despite these interesting relationships, the risk of prostate cancer, in a broader context, has been primarily associated with genetic makeup, androgenic hormones, and fat intake (125). Indeed, the association of prostate cancer with intake of fruits, vegetables, and their individual components is much less convincing (125). Nonetheless, current studies of this relationship will be followed with interest.

Skin Cancer

Recurrence of skin cancer in a group (*n* = 913, <85 years old, both genders) treated with a b-carotene supplement (50 mg/day) over a 5-year period was not affected (RR = 1.05; 95% CI = 0.91–1.22) (109, 126) relative to a similarly structured placebo group (*n* = 892).

Summation

Thus, a dichotomy exists. Most associations found between diseases and dietary or plasma levels do not agree with the results of intervention trials. The former tend to show strong significant correlations and the latter largely do not. Possible explanations are: (a) b-Carotene, which is only one of approximately 600 known carotenoids, might not be the most active one, or indeed, might inhibit the absorption of other more chemopreventive carotenoids and other nutrients. (b) Carotenoids might be only one of a group of chemopreventive agents in foods that act synergistically in preventing carcinogenesis. The fact that the relative risk (RR) values for colored fruits and vegetables usually are lower (i.e., are more protective) than those for carotenoids or for any other component of the food supports this viewpoint. (c) Carotenoid levels may serve solely as a useful *marker* for a healthful lifestyle or a protective genetic makeup. (d) The preventive action of carotenoids might occur very early in disease progression but be ineffective later. Thus, subjects in identified high-risk groups, who often have had a primary tumor, may be resistant to nutritional supplements. (e) The associations found in observational epidemiology are not causal and can be confounded by a variety of

unanticipated and unmeasured factors (106). In essence, the intervention trials may well be providing more-valid answers (109).

Photosensitivity Disorders

Patients with erythropoietic porphyria and similar diseases benefit by ingesting supplements (180 mg/day) of b-carotene (109, 127). Canthaxanthin, although also protective, is no longer used because of the reversible retinopathy that results (128). Although concentrations of b-carotene and vitamin A are elevated in the livers of these patients, the side effects of b-carotene ingestion over a period of years are minimal (109, 127).

Cardiovascular Disease

Carotenoid intake has often been associated with a reduced risk of both coronary events and stroke (108, 109). In an extensive study in Europe (WHO/MONICA), mortality from ischemic heart disease correlated inversely with serum vitamin E concentrations ($r^2 = 0.63$) but not with b-carotene levels ($r^2 = 0.04$) (129). If the 3 Finnish sites (which were outliers) of the 16 examined were excluded, however, the inverse correlation with b-carotene concentrations markedly improved ($r^2 = 0.50$). A mean serum b-carotene concentration in populations of 0.4 $\mu\text{mol/L}$ or higher was associated with good health in the European studies, whereas a concentration below 0.25 $\mu\text{mol/L}$ in populations was related to an increased risk of coronary disease, stroke, and cancer (129). The risk of myocardial infarction was inversely related to adipose b-carotene content in smokers (RR = 2.62; 95% CI = 1.79–3.83) but not in nonsmokers (RR = 1.07) (109).

In a preliminary report from the Physicians' Health Study, subjects with stable angina or prior coronary revascularizations, who were supplemented with b-carotene for 5 years, showed a 51% reduction in the risk of major coronary events (130). b-Carotene supplements did not show any beneficial effects on the risk of cardiovascular disease (RR = 1.0; 95% CI = 0.80–1.43), however, in the total population enrolled in this study (112). In contrast, the incidence of cardiovascular deaths, including angina pectoris, in the Finnish lung cancer study was increased 11% by b-carotene supplementation (109, 110), 16% in a smaller ($n = 1720$) trial focused on skin cancer (RR = 1.16; 95% CI = 0.82–1.64) (131), and 26% (RR = 1.26; 95% CI 0.99–1.61) in the CARET study (111). These findings cannot be readily explained by any known physiologic mechanism. Inasmuch as the 95% confidence intervals all included 1.0, the observations may well be attributed to chance. On the other hand, in a group of men ($n = 1862$, 50–69 years old) who had a previous myocardial infarction in the Finnish study, the b-carotene group ($n = 461$) had 75% more deaths from coronary heart disease during a 5.3-year period (RR 1.75; 95% CI = 1.16–2.64, $P = .007$) than the placebo group ($n = 438$) (132).

The overall results, therefore, are somewhat mixed. The most likely mechanism of protective action of carotenoids (but by no means the only one) is reduced oxidation of LDLs, which seem to play a key role in atherogenesis (108). Of various antioxidants studied both in vivo and in vitro, however, b-carotene does not seem protective (133). On an opposite tack, b-carotene can serve as a prooxidant under appropriate conditions

(115). Thus, as indicated in a recent review, the relationship among dietary intakes of carotenoids, their plasma and tissue concentrations, and cardiovascular disease remains unclear (134).

Age-Related Macular Degeneration (ARMD)

The macula of the eye predominantly contains two pigments, lutein and zeaxanthin (42, 135). In the eye, these carotenoids are associated with tubulin (136). Because these two pigments account for less than 25% of plasma carotenoids, their uptake from plasma and deposition in the macula show specificity. These pigments might consequently play a role in protecting the macula from damage caused by blue light. In a recent study comparing patients suffering from ARMD with matched controls, subjects in the highest quintile of carotenoid intake had a 43% lower risk (RR = 0.57; 95% CI = 0.35–0.92) of suffering from ARMD than those in the lowest quintile (109, 137). Of various carotenoid-containing foods, intake of spinach and collard greens, rich in lutein and zeaxanthin, was most strongly associated with reduced risk. Several other studies, however, do not support the association between ARMD and intake or serum levels of lutein and zeaxanthin (138).

ARMD, like most chronic diseases in the elderly, is a spectrum of related conditions with similar clinical symptoms. Thus, a variety of nutrients, such as zinc and several antioxidants, as well as other factors, such as smoking and exposure to sunlight, have been associated with the condition (139, 140). Nonetheless, current studies on the possible protective role of supplements of lutein and zeaxanthin will be followed with interest.

Cataracts

Cataract consists of gradual opacification of the lens with aging, which may in part result from oxidative stress. Carotenoid intake, as well as that of vitamins C and E, has been associated with a reduced risk of cataract (109, 139). In the Linxian, China, trial, however, combined supplements of b-carotene, selenium, and a-tocopherol were not associated with a reduced incidence of cataracts, and inconclusive results have been reported by others (109, 139). Thus, whereas the concept that antioxidant and light-absorbing nutrients such as the carotenoids might prevent oxidative damage to a fairly exposed structure such as the lens is highly feasible, the data supporting a protective role of dietary components in the process are mixed.

HIV Infection

In HIV infection, T-helper (CD4) cells are destroyed, thereby impairing the immune response. In humans as well as in experimental animals, both b-carotene (a provitamin A carotenoid) and canthaxanthin (which is not) enhance the immune response (141). Indeed, in HIV-infected patients, large doses of b-carotene increased the CD4:CD8 ratio, which is usually depressed in HIV infection, as well as improving the response to vaccines (141). Ultraviolet light tends both to activate human HIV expression, at least in transgenic mice, and to reduce plasma carotenoid concentrations in humans. In phase II HIV-infected subjects, plasma carotenoid concentrations are reduced by 50%. AIDS

patients treated daily with a combination of b-carotene supplementation (120 mg) and whole-body hyperthermia (42°C, 1 h) showed a better and longer-lasting response than those treated either with b-carotene or with hyperthermia (142). Thus, carotenoids seem to ameliorate the condition of AIDS patients, probably at least in part by enhancing the immune response.

Another quite different effect of a carotenoid has also been reported, namely, that halocynthiaxanthin (5,6-epoxy-3,3'-dihydroxy-7',8'-didehydro-5,6,7,8-tetrahydro-b,b-carotene-8-one) strongly and rather specifically inhibits RNA-dependent polymerase of the HIV virus (141). The use of carotenoids in the treatment of patients with HIV infections clearly merits further attention.

TOXICITY

Orally ingested hydrocarbon carotenoids, such as b-carotene, show no detectable toxicity, even at very large doses (143). The reasons for their lack of toxicity are that (a) carotenoids, because of their rigid polyene structure, are not very well absorbed from the intestine; (b) the absorption efficiency of carotenoids decreases markedly with increasing intake; and (c) the rate of conversion of provitamin A carotenoids to vitamin A, while fully adequate to meet nutritional needs, is relatively slow in an enzymatic sense. Thus, hypervitaminosis A does not result from ingestion of large doses of b-carotene. The only adverse effect is the benign condition hypercarotenosis, in which the plasma contains high carotenoid concentrations, and parts of the skin assume a yellowish hue. This condition is distinguished from jaundice in that the whites of the eyes remain untinted. After the intake of large doses of carotenoids is terminated, hypercarotenosis slowly disappears.

The xanthophylls may be less benign. For example, when given in large doses for long periods as therapy for photosensitivity disorders, the diketocarotenoid canthaxanthin precipitates in a crystalline array in the retina (128). This canthaxanthin retinopathy, however, slowly resolves after the cessation of dosing (128). The effects of very high doses of other xanthophylls have not yet been carefully explored.

SUMMARY

Carotenoids are interesting molecules, both chemically and biologically. Nature uses them in a variety of functional roles in many organisms, from microbes to humans. Nutritionally, in humans and other vertebrates, approximately 50 of them are converted into vitamin A in the intestinal mucosa, liver, and other organs. The major pathway of conversion is central cleavage of the provitamin A carotenoid, although excentric cleavage also contributes to formation of vitamin A and particularly of retinoic acid. Because more than 600 carotenoids exist in nature, the question arises whether the 550 nonprovitamin A carotenoids have any effect on biologic processes in humans. Under various circumstances, not only b-carotene but also several non-provitamin A carotenoids show many biologic actions, including effects on cell-to-cell communication and the immune response. The extent to which these actions have significant impact on

the health of well-nourished persons, however, is still unclear.

On the basis of epidemiologic studies of diet and chronic diseases, carotenoids, as well as many other phytochemicals and some minerals, have been implicated as protective agents. However, intervention trials with supplements of b-carotene have not shown beneficial effects. Indeed, in some instances, b-carotene supplementation yielded adverse outcomes. The current relationship of carotenoids with health and disease has recently been thoughtfully analyzed (144). In an epidemiologic sense, attention has now been focused on other carotenoids, such as a-carotene, lycopene, lutein, and zeaxanthin. Whether these carotenoids will be more effective than b-carotene in supplementation trials is uncertain. Indeed, the protective effect of diets rich in fruits and vegetables seems to exceed that of any single micronutrient (118).

In the evolution of life, nature must certainly have included both redundancy and flexibility as key factors in the competition for survival. Thus, panaceas in the form of single nutrients are not an attractive option. In a similar vein, amulets and magical potions were used in the distant past to ward off evil. The role of genetic makeup in susceptibility to disease is now being actively explored. In specific cases, therefore, we may find that a genetic subgroup of a given disease does respond to dietary intervention with a single nutrient, probably as a result of a specific metabolic defect.

Carotenoids, as found in foods, are nontoxic to humans. Even large oral supplements of b-carotene cause no harm, although canthaxanthin, when given in large oral doses for a long time, causes a reversible retinopathy. In general, however, toxicity is not worrisome with carotenoids.

The biologic roles and actions of carotenoids and their metabolites remain a fascinating field of study. New facets of their activities are constantly being revealed. Probing nature's well-kept secrets is always rewarding and diverting, and there is still much to be learned about this interesting class of compounds.

ACKNOWLEDGMENTS

The author is indebted to Professor John Dietschy for a valuable exposition of the formation of high-density lipoproteins in vivo and to Dr. Anne Sowell for providing unpublished NHANES-III data, CDC, 1996. The writing of this review, as well as some of the studies on which it is based, was supported by USDA-CDFIN 96-34115-2835. This is Journal Paper no. J-17602 of the Iowa Agriculture and Home Economics Experiment Station, Ames, IA; Project no. 3335, and supported by Hatch Act and State of Iowa funds.

Abbreviations: **ARM**D—age-related macular degeneration; **CARET**—Carotene and Retinol Efficacy Trial; **FAD**—flavin adenine dinucleotide; **GI**—gastrointestinal; **HDL**—high-density lipoprotein; **LDL**—low-density lipoprotein; **MST**—mean sojourn time; **NAD**—nicotinamide adenine dinucleotide; **NADPH**—reduced nicotinamide adenine dinucleotide phosphate; **VLDL**—very low density lipoprotein.

HISTORICAL INTRODUCTION

The importance of sulfur amino acids for growth or protein synthesis has been recognized since 1915 when Osborne and Mendel (1) demonstrated that addition of cystine to a low-casein diet restored rapid growth of rats. The amino acid methionine was identified almost two decades after most amino acids in protein had been discovered (2) and was subsequently shown to also be an effective supplement to low-casein diets (3). Womack et al. (4) demonstrated that cyst(e)ine was not essential for rats when dietary methionine was adequate and that the effect of cyst(e)ine was due to its ability to replace part, but not all, of the methionine in the diet. Rose and Wixom (5) demonstrated the same relation of methionine and cyst(e)ine requirements in their studies of amino acid requirements of adult men. Thus, only methionine is considered an essential amino acid, but in practice, the methionine or total sulfur amino acid

requirement is usually met by a combination of methionine and cyst(e)ine.

More recently, the nutritional importance of taurine, a metabolite of cysteine, and the clinical significance of homocysteine, a metabolite of methionine, have been recognized. Homocysteine was discovered by du Vigneaud in 1932 (6) as the product of methionine demethylation. The role of homocyst(e)ine in the conversion of methionine sulfur to cysteine (the transsulfuration pathway) was studied in the following years, and homocyst(e)ine was shown to support growth of animals fed diets deficient in cysteine, methionine, or choline. Homocystinuria, an inborn error of metabolism, was identified in 1962 when mentally retarded individuals were screened for abnormal urinary amino acid patterns (7). During the past decade, it has been recognized that small increases in plasma homocysteine concentrations are associated with increased risk of vascular disease and neural tube defects in the general population (8, 9, 10 and 11).

Taurine is an end product of cysteine catabolism, first isolated from the bile of the ox (*Bos taurus*) in 1827 (12). Interest in taurine surged following the discovery in 1975 that cats fed diets containing little or no taurine suffered retinal degeneration accompanied by low retinal and plasma taurine concentrations (13). This was soon followed by the observation that infants fed purified formulas lacking taurine had lower plasma and urine taurine levels than did infants fed pooled human milk (14, 15). Because of increasing evidence of a possible role of taurine in development, taurine has been added to most human infant formulas since the mid-1980s.

CHEMISTRY, NOMENCLATURE, AND CELLULAR/EXTRACELLULAR FORMS

The structures of cysteine, homocysteine, and taurine and their relations with precursor amino acids (methionine and serine) are shown in [Figure 34.1](#). Like other amino acids with an asymmetric carbon atom, the L-isomers of methionine, homocysteine, and cysteine are the biologically active forms. Both homocysteine and cysteine have a free sulfhydryl group. The carbon skeleton of homocysteine, which is derived from methionine, has one more carbon than the carbon chain of cysteine, which is derived from serine. Taurine, 2-aminoethane sulfonate, is formed from cysteine by removal of the carboxyl group and oxidation of the sulfur to form a sulfonic acid group. The carboxyl ($pK_a \gg 1.7$), sulfonic ($pK_a \gg 1.5$), sulfhydryl ($pK_a \gg 8.3$), and amino ($pK_a \gg 9-11$) groups all undergo ionization; the zwitterionic forms shown in [Figure 34.1](#) are the dominant species at physiologic pH.

Figure 34.1. Structures and metabolic relations of sulfur amino acids.

Technically, the terms cysteine and homocysteine refer to the thiol or reduced form (RSH) of these amino acids. However, cysteine (Cys) and homocysteine (Hcy), like other aminothiols, also exist in free oxidized forms, including the disulfide (RSSR) and mixed disulfides (RSSR'), and in the protein-bound oxidized form (via formation of disulfides with cysteinyl residues of proteins; PSSR) (16, 17). The thiol form of Cys (CySH) dominates intracellularly, whereas disulfide forms of Cys (protein-bound cysteine, PSSCy, and cystine, CySSCy) dominate in the more oxidized extracellular environment. Intracellularly, low concentrations of Hcy are present in free (HcySH) and protein-bound (PSSHcy) forms. Extracellularly, Hcy is present predominantly as mixed disulfides of Hcy with protein (PSSHcy) or Cys (HcySSCy). High levels of the disulfide of Hcy (homocystine, HcySSHcy) are excreted by individuals with the inborn error of metabolism known as homocystinuria.

The distribution of Cys and Hcy in plasma of healthy adults is shown in Figure 34.2. Cys is the major plasma thiol, with total Hcy (tHcy) present at 10% or less of the concentration for total Cys (tCys). Both Cys and Hcy are predominantly present as protein-bound disulfides, with intermediate concentrations of disulfides (predominantly CySSCy and HcySSCy) and with very low concentrations of free thiols. The Cys-containing peptides, cysteinylglycine (CysGly), g-glutamylcysteine (gGluCys), and glutathione (GSH, or gGluCysGly), are also present in plasma and tissues.

Reduced	Oxidized		Total Concentration
	Free	Protein-Bound	
CySH 13.9 $\mu\text{mol/L}$	RSSCy 88.1 $\mu\text{mol/L}$	PSSCy 196.3 $\mu\text{mol/L}$	Cys 296 $\mu\text{mol/L}$

Figure 34.2. Concentrations of various forms of the major aminothiols in human plasma. *Cys*, cysteine; *Hcy*, homocysteine; *CysGly*, cysteinylglycine; *PS*, sulfhydryl group of cysteinyl residue in protein; *RS*, unspecified thiol, usually *Cys* in plasma. The designation *RSH* is used to represent the reduced thiol form, *RSSR* or *RSSR'* to represent the disulfide of the thiol with itself or another thiol, and *PSSR* to represent protein-bound disulfides. Mean fasting values for plasma thiols are based on the data of Mansoor et al. (16) for 34 male and 31 female control subjects. Other plasma thiols include glutathione (total GSH » 7 mmol/L) and g-glutamylcysteine (total g-GluCys » 3 mmol/L) (17).

The protein binding and redox status of different plasma aminothiols are interactive because of presumed ongoing redox cycling and disulfide exchange reactions. For example, *Hcy* will displace protein-bound *Cys* or *CysGly* (18). After ingestion of a methionine load or a protein-containing meal, protein-bound *Cys* tends to decrease, probably because of displacement of protein-bound *Cys* by *Hcy* (16, 19).

Measures of tHcy or tCys are useful in clinical studies because they are not affected in vitro by disulfide exchange reactions and redistribution between forms. Mean fasting plasma tHcy was 11.9 $\mu\text{mol/L}$ (median, 11.6) with a range of 3.5 to 66.8 $\mu\text{mol/L}$ in 1160 subjects aged 67 to 95 years (20); mean plasma tHcy is slightly lower for younger adults than for older ones and for women than for men (21, 22 and 23). Mean fasting plasma tCys concentrations in healthy adults range from about 220 to 320 $\mu\text{mol/L}$ (16, 17, 18 and 19).

A wide range of plasma taurine concentrations has been reported for human subjects. Trautwein and Hayes (24) reviewed values reported in the literature and found the reported mean plasma concentration of taurine in human subjects ranged from 39 to 116 $\mu\text{mol/L}$. Whole blood taurine ranged between 160 and 320 $\mu\text{mol/L}$ with a mean of 225 $\mu\text{mol/L}$ in a small sample of adults (24). Plasma taurine concentrations change more rapidly in response to changes in taurine intake than do whole blood concentrations, and whole blood taurine concentrations are not correlated with plasma taurine concentrations except during periods of depletion or excess intake. Plasma taurine concentrations are somewhat lower in vegans than in omnivores and somewhat

lower in females than in males ([25](#), [26](#)).

Careful handling of blood samples is essential for measurement of plasma concentrations of amino thiols and taurine. Plasma tHcy concentrations may increase with storage of blood because of transsulfuration in blood cells unless the blood is rapidly cooled and processed ([27](#)). Hemolysis or contamination of the plasma fraction with platelets or white cells interferes with analysis of plasma taurine but not with measures of whole blood taurine ([24](#)).

DIETARY CONSIDERATIONS AND TYPICAL INTAKES

Methionine and Cyst(e)ine

The sulfur amino acids, methionine and cyst(e)ine, are normally consumed as components of dietary proteins. Normal Western diets provide 15 to 20 mmol (~2.25–3 g) of sulfur amino acids per day. Mixtures of proteins consumed in the United States contain about 35 mg methionine plus cyst(e)ine per gram of protein ([28](#)). Sulfur amino acids tend to be more abundant in animal and cereal proteins than in legume proteins, and the ratio of methionine to cysteine tends to be higher in animal proteins than in plant proteins ([Table 34.1](#)) ([29](#)).

	Amount		Pattern	
	Met (mg/100 g edible portion)	Cys	Met (mg/g protein)	Cys
Cheese, cheddar	652	125	26	5
Milk, whole	83	30	25	9
Egg, whole, chicken	302	289	32	24
Chicken, flesh only cooked roasted	800	370	28	13
Beef, round, separable lean only	557	224	26	11
Wheat flour, whole meal	186	278	14	21
Corn grits, regular, dry	196	237	22	22
Oats, regular, dry	266	398	17	25
Peanut butter	262	365	10	13
Soybean, green cooked	150	113	12	9
Brown rice, dry	142	152	19	21

Data from or calculated from values in USDA handbook no. 8 (28).

Table 34.1 Methionine and Cysteine Content of Selected Foods

The 1989 RDA committee recommended a sulfur amino acid intake of 13 mg/kg/day, a protein intake of 0.75 g/kg/day, and a desirable amino acid pattern for adults that includes at least 17 mg methionine plus cyst(e)ine per gram of protein ([28](#)). This suggested intake of sulfur amino acids is easily met by mixtures of protein commonly consumed in the United States. However, Young et al. ([30](#)) and Storch et al. ([31](#)) have proposed that the sulfur amino acid allowance set by the FAO/WHO ([32](#)) and the NRC ([28](#)) at 13 mg/kg/day (0.087 mmol/kg/day, or 6 mmol/day for a 70-kg adult) represents the average requirement of healthy adults rather than the upper end of the normal

distribution of requirements (mean + 2 SD). Their studies indicated that an intake of 25 mg/kg/day (0.17 mmol/kg/day or 12 mmol/day for a 70-kg adult) was necessary to ensure an adequate intake for the entire population.

Despite the availability of food proteins that provide ample amounts of sulfur amino acids, some individuals probably have inadequate intakes because of either inadequate intake of total protein or selection of a restricted variety of proteins that provide inadequate sulfur amino acids. Analysis of diets of long-term vegans living in California indicated an average protein intake of 64 g/day and a sulfur amino acid intake of 1.04 g (7.6 mmol) per day (26); this is equivalent to an intake of ~15 mg/kg/day of sulfur amino acids and an amino acid pattern of 16 mg methionine plus cyst(e)ine per gram protein. This level of intake would meet but not exceed the average requirement as estimated by Young et al. (30) and Storch et al. (31) and would be marginal for adults with higher-than-average requirements. Careful selection of plant proteins to ensure an adequate intake of sulfur amino acids may be very important for strict vegan adults and even more so for children fed a strict vegan diet.

Taurine

Although taurine is an end product of sulfur amino acid metabolism, it is usually obtained from the diet as well. Food taurine content has not been widely determined, but data from several reports (33, 34, 35 and 36) are summarized in Table 34.2. Taurine is present in most animal foods and is either absent or present in very low levels in most plant foods. Relatively high concentrations of taurine have been reported for some lower plants such as seaweeds (36, 37). Analysis of the diets of strict vegans living in England yielded no detectable taurine, whereas the diets of omnivores contained 463 ± 156 (SE) $\mu\text{mol/day}$ (25). The analyzed taurine intake of adults fed omnivorous diets in a clinical study center in the U.S. was 1000 to 1200 $\mu\text{mol/day}$ (33).

Animal foods	
Poultry	89–2445 $\mu\text{mol}/100$ g wet wt
Beef and pork	337–489 $\mu\text{mol}/100$ g wet wt
Processed meats	251–981 $\mu\text{mol}/100$ g wet wt
Seafood	84–6614 $\mu\text{mol}/100$ g wet wt
Cow's milk	19–20 $\mu\text{mol}/100$ mL
Yogurt, ice cream	15–62 $\mu\text{mol}/100$ mL
Cheese	Not detected
Plant foods	
Most fruits, vegetables, seeds, cereals, grains, beans, peanuts	Not detected
Soybean, chick peas, black beans, pumpkin seeds, some nuts ^a	≤1–4 $\mu\text{mol}/100$ g wet wt
Seaweeds (marine algae)	1.5–100 $\mu\text{mol}/100$ g wet wt

Data from Ladlow et al. (33), Pasantes-Morales et al. (34), Roe and Weston (35), and Katsika and Ohnishi (36).

^aLow reported values should be regarded as upper limits because contamination of food or methodologic interference by compounds that coelute with taurine could account for these low concentrations of taurine.

Table 34.2 Taurine Content of Selected Foods

The taurine content of milk from lactating women was 41.3 ± 7.1 (SE) $\mu\text{mol}/100$ mL for

early milk (1–7 days) and $33.7 \pm 2.8 \mu\text{mol}/100 \text{ mL}$ for later milk (>7 days) (38). Taurine is added to infant formulas at levels comparable to those in human milk or at somewhat higher levels in formulas for premature infants (33). The mean taurine content of milk of lactating vegan women is lower than that of lactating omnivores, but values overlap considerably between the two groups, and the taurine concentration in milk of vegan mothers is still about 30 times the level in the cow's milk–based infant formulas used prior to the mid-1980s (25).

ABSORPTION, TRANSPORT, AND EXCRETION

Absorption of the products of protein digestion across the intestinal epithelium is highly efficient (~95–99%). Dietary methionine, a precursor of Cys, is transported by neutral amino acid transport systems ($B^{0,+}$, ASC, and L), and as methionine-containing peptides by peptide transport systems. Dietary Cys is absorbed as CySH, CySSCy, and Cys-containing peptides by a variety of L-amino acid and peptide transport systems in the small intestinal mucosa. Cysteine is transported by neutral amino acid transporters including system B in the apical (brush border) membrane and system ASC in both the apical and basolateral plasma membranes of the intestinal mucosa cells; cysteine uptake is largely Na^+ dependent. Cystine is transported by system $b^{0,+}$, a Na^+ -independent system present in the apical membranes of the intestinal mucosa, which serves cationic amino acids as well as zwitterionic amino acids. Efficient absorption of taurine is facilitated by the β -amino acid or taurine transport system, a Na^+ and Cl^- -dependent carrier that serves taurine, β -alanine, and γ -aminobutyric acid, which is present in the apical membrane of intestinal mucosa cells.

Amino acids enter the plasma and circulate as free amino acids until they are removed by tissues. The liver removes a substantial proportion of the sulfur-containing amino acids from the portal circulation and uses them for synthesis of protein and glutathione or for catabolism to taurine and sulfate. GSH is exported into plasma, and this cysteine-containing tripeptide as well as its metabolites, CysGly and γ -GluCys, can be a source of cysteine to tissues. Hcy is not normally present in the diet, and only very low amounts are normally released from tissues into the plasma.

The reabsorptive epithelium of the kidney proximal tubule has transport systems similar to those of the absorptive epithelium of the intestine, and the kidney efficiently reabsorbs amino acids from the filtrate. Renal reabsorption of Cys and methionine is normally very high (94%), and the loss of amino acids in the urine is normally negligible (39). Urinary methionine excretion has been reported to be 22 to 41 $\mu\text{mol}/\text{day}$ (25, 40). Urinary cyst(e)ine excretion by adults has been reported to be 63 to 285 $\mu\text{mol}/\text{day}$ (25, 40).

Cystinuria is an inherited disorder of cystine and dibasic amino acid transport. One cause of cystinuria is a defect in the gene that encodes the rBAT (related to $b^{0,+}$ amino acid transporter) protein, a subunit of the system $b^{0,+}$ transporter that is expressed by the kidney and small intestine (41, 42 and 43). Urinary cystine excretion exceeding 1.2 mmol/day (~2.5 mmol Cys/day) is usually diagnostic of homozygous cystinuria (44). Cystine is very insoluble and can cause cystine stones if it is present above its aqueous

solubility limit (250 mg/L, or 1 mmol/L).

Urinary excretion of extracellular Hcy is limited, even in individuals with defective Hcy metabolism, because the extensive binding of plasma Hcy to proteins limits filtration and because of the normally active renal reabsorption of free Hcy. Of the plasma Hcy filtered by the kidney, only about 1 to 2% is excreted in the urine (45). Normal urinary Hcy excretion ranges from 3.5 to 9.8 $\mu\text{mol/day}$ (45). Higher levels of Hcy in urine indicate very high plasma tHcy concentrations and an inborn error of metabolism. For example, Hcy excretion in urine of patients with $N^{5,10}$ -methylenetetrahydrofolate reductase deficiency ranged from 15 to 667 $\mu\text{mol/day}$ (46).

Unlike most amino acids, taurine is not usually completely reabsorbed, and fractional excretion may vary over a wide range. Normally, the kidney regulates the body pool size of taurine and adapts to changes in dietary taurine intake by regulation of the proximal tubule brush-border membrane transporter for taurine (b system). During periods of inadequate dietary intake of taurine or its sulfur amino acid precursors, more taurine is reabsorbed from the filtrate because of enhanced taurine transporter activity, less taurine is excreted in the urine, and more of the tissue taurine stores are maintained. The renal taurine concentration seems to be the signal for changes in renal taurine transporter activity (47, 48).

Consistent with differences in taurine intake and with adaptive regulation of taurine reabsorption, urinary taurine levels vary widely. Urinary taurine levels of 250 $\mu\text{mol/day}$ have been reported for adult vegans consuming diets with no preformed taurine, whereas excretion of taurine by adult omnivores usually exceeds 600 $\mu\text{mol/day}$, and values above 1000 $\mu\text{mol/day}$ are not uncommon (25, 26, 40).

METHIONINE/HOMOCYSTEINE METABOLISM AND CYSTEINE FORMATION

Metabolic Pathways

Transmethylation

The essential amino acid methionine is activated by ATP to form S-adenosylmethionine in a reaction catalyzed by S-adenosylmethionine synthetase (EC 2.5.1.6). S-Adenosylmethionine serves primarily as a methyl donor via reactions catalyzed by a variety of methyl transferases and involving a variety of acceptors. These S-adenosylmethionine-dependent methylations are essential for the biosynthesis of a variety of cellular components including creatine, epinephrine, carnitine, phospholipids, proteins, DNA, and RNA (Fig. 34.3).

Figure 34.3. Methionine metabolism. Numbered reactions are catalyzed by the following enzymes: (1) methionine adenosyltransferase; (2) various methyltransferases; (3) adenosylhomocysteine hydrolase; (4) N^5 -methyltetrahydrofolate-homocysteine methyltransferase; (5) $N^{5,10}$ -methylene tetrahydrofolate reductase; (6) betaine-homocysteine methyltransferase; (7) cystathionine b-synthase; (8) cystathionine g-lyase; (9) enzymes involved in polyamine synthesis; and (10) enzymes involved in methylthioadenosine salvage pathway.

S-Adenosylhomocysteine, the byproduct of these methyl transfer reactions, is hydrolyzed by S-adenosylhomocysteine hydrolase (EC 3.3.1.1), thus generating adenosine and homocysteine. Although the equilibrium of S-adenosylhomocysteine hydrolase actually favors formation of S-adenosylhomocysteine, the reaction is normally driven forward by rapid removal of the products.

The homocysteine generated by hydrolysis of S-adenosylhomocysteine has two likely metabolic fates, remethylation or transsulfuration. In remethylation, homocysteine acquires a methyl group from N^5 -methyltetrahydrofolate or betaine to form methionine. In transsulfuration, the sulfur is transferred to serine to form cysteine, and the remainder of the homocysteine molecule is catabolized to a-ketobutyrate and ammonium.

Remethylation

The remethylation pathway allows methionine to be regenerated from homocysteine by use of new methyl groups synthesized in the folate coenzyme system or preformed methyl groups, both of which may subsequently be transferred to acceptors via S-adenosylmethionine-dependent methyltransferase reactions. The remethylation of homocysteine by transfer of a methyl group from N^5 -methyltetrahydrofolate is catalyzed by N^5 -methyltetra hydrofolate-homocysteine methyltransferase (EC 2.1.1.13), commonly called methionine synthase. Methionine synthase is widely distributed in mammalian tissues and contains methylcobalamin as an essential cofactor. The methyl group of N^5 -methyltetrahydrofolate is synthesized de novo in the folate coenzyme system. The final step of N^5 -methyltetrahydrofolate synthesis is the irreversible reduction of

$N^{5,10}$ -methylenetetrahydrofolate, which is catalyzed by the flavoenzyme, $N^{5,10}$ -methylenetetrahydrofolate reductase (EC 1.1.1.68), using NADH as the electron donor.

The other homocysteine methyltransferase, betaine-homocysteine methyltransferase (EC 2.1.1.5), is present only in liver and kidney of humans and requires betaine as the methyl donor (49). This reaction uses preformed methyl groups because betaine is derived from choline, which is either obtained from the diet or synthesized through successive *S*-adenosylmethionine-dependent methylations of phosphatidylethanolamine.

Transsulfuration

The transsulfuration of homocysteine to cysteine is catalyzed by two pyridoxal 5'-phosphate (PLP)-dependent enzymes, cystathionine β -synthase (EC 4.2.1.22) and cystathionine γ -lyase (EC 4.4.1.1; cystathionase). Cystathionine β -synthase catalyzes the condensation of homocysteine and serine to form cystathionine. Cystathionine is then hydrolyzed by cystathionine γ -lyase to form cysteine and α -ketobutyrate plus ammonium. Thus, the transsulfuration pathway is responsible for both the catabolism of homocysteine derived from methionine and the transfer of methionine sulfur to serine to synthesize cysteine.

Regardless of the extent of remethylation, in the steady-state metabolic condition, intake of methionine sulfur is balanced by metabolism of an almost equivalent amount of homocysteine sulfur through the transsulfuration pathway (50, 51). Although some methionine (via decarboxylated *S*-adenosylmethionine acting as a donor of aminopropyl groups) is used for polyamine synthesis, the methylthioadenosine that is a byproduct of this pathway is effectively recycled to methionine. The sulfur and methyl carbon of methionine and the carbon chain of ribose are reused in methionine synthesis by the methylthioadenosine salvage pathway (51, 52). Hence, little sulfur is oxidized or lost during methionine metabolism, and essentially all methionine sulfur is transferred to cysteine prior to oxidation/excretion of the sulfur atom.

Regulation of Remethylation versus Transsulfuration

Response to Changes in Methionine Intake

The remethylation and transsulfuration pathways can be considered to be competing for available homocysteine. Studies of whole body methionine kinetics demonstrated that in young adult men fed a diet with adequate methionine (~14 mmol/day), about 17 mmol/day of homocysteine was formed by transmethylation; approximately 38% of this homocysteine was remethylated to methionine, and 62% was catabolized by transsulfuration (31). In another study, transmethylation or homocysteine formation decreased markedly in subjects fed a sulfur amino acid-free diet, from approximately 20 mmol/day in men on an adequate diet to 6 mmol/day in men on a sulfur amino acid-free diet; the percentage of homocysteine remethylated to methionine increased from 36% in men on the adequate diet to 67% in men on the sulfur amino acid-free diet (53). As a

result of decreased transmethylation or homocysteine formation and the greater percentage remethylation of homocysteine, transsulfuration or oxidation of methionine was reduced from 12 mmol/day in men fed the methionine-adequate diet to 2 mmol/day in subjects fed the sulfur amino acid-free diet.

Response to S-Adenosylmethionine as an Effector

Whether homocysteine is metabolized by remethylation or transsulfuration seems to be coordinated in response to cellular S-adenosylmethionine concentrations or the need to generate methionine methyl groups (54). S-Adenosylmethionine is both an allosteric inhibitor of $N^{5,10}$ -methylenetetrahydrofolate reductase and an activator of cystathionine b-synthase. Hence, when the cellular S-adenosylmethionine concentration is low, synthesis of N^5 -methyltetrahydrofolate proceeds uninhibited and cystathionine synthesis is suppressed, which conserves homocysteine for methionine synthesis. Conversely, when the S-adenosylmethionine concentration is high, inhibition of N^5 -methyltetrahydrofolate synthesis is accompanied by diversion of homocysteine through the transsulfuration pathway because of stimulated cystathionine synthesis. This coordinate control results in both regulation of cellular S-adenosylmethionine concentration and maintenance of a homocysteine concentration that is compatible with the need for methyl groups synthesized de novo.

Methionine-Sparing Effect of Cyst(e)ine

Cyst(e)ine is said to have a “methionine-sparing” effect by reducing methionine catabolism via the transsulfuration pathway. The effect of supplemental cyst(e)ine added to a sulfur amino acid-free diet or a low-methionine diet may be at least partially due to promotion of methionine incorporation into protein so that less methionine is catabolized (53, 55). The effect of cyst(e)ine used to replace part of the dietary methionine (keeping total sulfur amino acid level the same) may be explained by a reduction in the hepatic concentrations of methionine and S-adenosylmethionine and, hence, less activation and reduced activity of hepatic cystathionine b-synthase. Less homocysteine catabolism by transsulfuration would result in increased recycling of homocysteine to methionine, using methyl groups generated by the folate coenzyme system.

Response to Supplemental Betaine

Normal adult subjects given a control diet with a betaine supplement had increased rates of methionine transmethylation and transsulfuration (56), suggesting that an increased dietary supply of methyl groups may increase methionine catabolism. A high dietary intake of betaine when coupled with a marginal intake of methionine could interfere with the normal coordinated regulation of remethylation versus transsulfuration by increasing S-adenosylmethionine concentration and stimulating methionine catabolism (56). Presumably, increased remethylation induced by betaine increases S-adenosylmethionine concentrations, resulting in inhibition of N^5 -methyltetrahydrofolate-dependent remethylation and stimulation of homocysteine

catabolism.

HOMOCYSTINURIA AND HYPERHOMOCYSTEINEMIA

Homocystinuria Due to Inborn Errors of Metabolism

Severe forms of hyperhomocysteinemia result in excretion of homocysteine, homocystine, and mixed disulfides of homocysteine in the urine. Homocystinuria (urinary Hcy > 10 $\mu\text{mol}/24\text{ h}$) is rare and results from severe hyperhomocysteinemia caused by several inborn errors of metabolism. The most common inborn error of sulfur amino acid metabolism and the most common cause of homocystinuria is a lack of cystathionine b-synthase activity, which is commonly associated with plasma tHcy concentrations above 200 $\mu\text{mol}/\text{L}$ in untreated patients. Two clinical forms have been described: one not responsive to treatment with the coenzyme precursor pyridoxine and a pyridoxine-responsive form that improves with a high intake of vitamin B₆. The latter is usually associated with residual cystathionine b-synthase activity and milder disease (57). Based on newborn-screening programs, the estimated incidence of cystathionine b-synthase deficiency is 1:170,000 (58). The actual incidence of cystathionine b-synthase deficiency is thought to be closer to 1:340,000, however, because newborn-screening programs fail to detect most infants with the pyridoxine-responsive form of the disease. Cystathionine b-synthase deficiency is inherited as an autosomal recessive disorder and results in dislocation of optic lenses, skeletal abnormalities, mental retardation, neurologic disorders, and widespread thromboembolic phenomena. This disorder has been shown to be due to heterogeneous mutations, and most patients are compound heterozygotes; more than 18 mutations have been identified in patients with cystathionine b-synthase deficiency (59, 60).

A second inborn error of metabolism that causes homocystinuria is a lack of $N^{5,10}$ -methylenetetrahydrofolate reductase activity. This is the major known inborn error affecting folate metabolism and the second leading known cause of homocystinuria. $N^{5,10}$ -Methylenetetrahydrofolate reductase deficiency is inherited as an autosomal recessive disorder with an incidence about 1/10th that of cystathionine b-synthase deficiency. Individuals with severe deficiencies have residual activity that ranges from undetectable to 20% of normal activity. At least nine different mutations have been identified in patients with a severe lack of $N^{5,10}$ -methylenetetrahydrofolate reductase activity (61, 62). Homocystinuria and hyperhomocysteinemia in these patients are usually less severe than in patients with cystathionine b-synthase deficiency, and a wide range of neurologic and vascular disturbances have been observed in these patients (see Chapter 26 and Chapter 95).

A third group of inborn errors giving rise to homocystinuria are those affecting various steps in the synthesis of methylcobalamin, an essential cofactor for methionine synthase (63). Cobalamin metabolism loci C, D, E, F, and G have been shown to result in reduced activity of methionine synthase and homocystinuria (see Chapter 27).

Hyperhomocysteinemia and Its Genetic, Nutritional, and Metabolic Bases

Milder forms of hyperhomocysteinemia have been recognized more recently and are much more prevalent than is homocystinuria. Heterozygosity for one of the inborn errors of metabolism resulting in homocystinuria may be one cause of milder hyperhomocysteinemia. However, the predicted incidence of heterozygosity for these inborn errors is too small to account for a large proportion of the observed hyperhomocysteinemia.

A milder form of $N^{5,10}$ -methylene tetrahydrofolate reductase deficiency that results in approximately 50% residual enzyme activity in homozygotes is caused by a point mutation (677C>T) in the $N^{5,10}$ -methylene tetrahydrofolate reductase gene (62, 64, 65). This genetic deficiency of $N^{5,10}$ -methylene tetrahydrofolate reductase is also described as the “thermolabile variant” because of the marked thermolability of the altered enzyme in vitro (66). Approximately 5% of subjects studied by Kang et al. (66) and 12% of those studied by Rozen et al. (67) were homozygous for this 677C>T mutation in the $N^{5,10}$ -methylene tetrahydrofolate reductase gene. This mutation is hypothesized to be an underlying cause of much of the hyperhomocysteinemia and associated increased risk for vascular disease and neural tube defects (62, 64, 68, 69).

Nutritional disorders that potentially lead to hyperhomocysteinemia, particularly in individuals with underlying genetic predispositions, are deficiencies of folate, vitamin B₁₂, and vitamin B₆ (20, 70, 71 and 72). Selhub et al. (20) estimated that 67% of cases of hyperhomocysteinemia are at least partially due to inadequate B-vitamin status. As noted above, de novo synthesis of methionine methyl groups requires both vitamin B₁₂ and folate coenzymes, whereas transsulfuration requires PLP. Evidence for an inverse correlation between vitamin intake or status and hyperhomocysteinemia is stronger and more consistent for folate than for vitamin B₁₂ or vitamin B₆ (20, 21, 71, 72, 73, 74 and 75). The thermolabile variant of $N^{5,10}$ -methylene tetrahydrofolate reductase is very responsive to folate status; hyperhomocysteinemia is observed most frequently in homozygotes who also have a low folate intake and rarely in homozygotes who have a higher folate intake (65, 75).

Mild-to-moderate hyperhomocysteinemia and increased incidence of atherosclerotic disease are also observed in patients with renal disease. Plasma tHcy levels are significantly increased in patients with moderate renal failure and rise steeply in terminal uremia (76, 77). The rise in plasma tHcy levels in patients with renal failure is attributed to loss of renal parenchymal uptake and metabolism of plasma Hcy rather than to decreased urinary excretion of Hcy.

Clinical Significance of Hyperhomocysteinemia

Apparent associations of mild hyperhomocysteinemia with atherosclerotic disease, venous thromboses, neural tube defects, placental abruption/infarction, and unexplained pregnancy loss have been reported (8, 9, 10, 11, 22, 69, 74, 77, 78, 79, 80, 81 and 82). In populations of individuals with arteriosclerotic disease, mild hyperhomocysteinemia is observed about as frequently as hypercholesterolemia or hypertension. Hyperhomocysteinemia is now considered an independent risk factor for vascular

disease of the coronary, cerebral, and peripheral arteries, with an increase in plasma tHcy of only 5 $\mu\text{mol/L}$ estimated to result in a 50 to 80% increase in risk for cerebrovascular or coronary artery disease (73).

The basis of the association of hyperhomocysteinemia with vascular disease is not clear (9, 83, 84, 85 and 86). Hypotheses related to a direct adverse effect of homocysteine (endothelial cell damage, oxidative damage, promotion of thrombogenesis via alterations in the coagulation and fibrinolytic systems, impaired regulation of vasoconstriction, stimulation of vascular smooth muscle cell proliferation) are currently being investigated. It is also possible that a decreased intracellular ratio of S-adenosylmethionine to S-adenosylhomocysteine or reduced availability of S-adenosylmethionine, either of which may be associated with hyperhomocysteinemia, interferes with essential methylation reactions and leads to the adverse effects associated with hyperhomocysteinemia. Similarly, impaired methylation of proteins has been implicated as a possible cause of neural tube defects (87, 88).

Detection of Homocystinuria and Hyperhomocysteinemia

Inborn errors giving rise to homocystinuria may be detected by newborn-screening programs (see Chapter 61). Most current screening programs detect individuals with cystathionine b-synthase deficiency by primary screening for hypermethioninemia and secondary screening for elevated urine and/or plasma tHcy levels, low plasma tCys concentration, and deficient cystathionine b-synthase activity in fibroblasts, leukocytes, or liver biopsy specimens. These screening programs fail to detect many pyridoxine-responsive forms of cystathionine b-synthase deficiency, which may not give rise to abnormal plasma Hcy or methionine concentrations in infants, especially if the protein intake is low or if testing is done within the first few weeks of life (58). Screening for hypermethioninemia will also not detect homocystinuria due to defects in folate or cobalamin metabolism because plasma methionine concentrations in these patients are either normal or low (46). Patients with defects in folate or cobalamin metabolism tend to have lower urinary Hcy levels than do patients with cystathionine b-synthase deficiency, and analysis of urine or plasma Hcy levels often yields a negative test result in affected newborns. Genotyping will likely be used more widely in the future to identify both homocystinuric individuals and heterozygous carriers.

Milder forms of hyperhomocysteinemia (heterozygotes for cystathionine b-synthase or $N^{5,10}$ -methylenetetrahydrofolate reductase deficiency; B-vitamin deficiency; thermolabile $N^{5,10}$ -methylenetetrahydrofolate reductase; renal failure; etc.) may be indicated by elevated fasting plasma tHcy concentrations (~ 16 – $30 \mu\text{mol/L}$). Normal reference intervals for plasma tHcy vary, depending on methodology and the selection of reference individuals. Because as much as 40% of the population, including individuals with relatively low plasma tHcy values, may respond to folate or B-vitamin supplementation with a reduction in plasma tHcy (20, 71, 74, 80) and because even small elevations in plasma tHcy seem to be associated with increased risk of vascular disease, it has been difficult to establish exact desirable or reference values for the normal population. Use of 90th percentile values as cutoffs has resulted in use of plasma fasting tHcy values above 14 to 16 $\mu\text{mol/L}$ as indicators of hyperhomocysteinemia (21, 89). A lower cutoff for the normal range may be

appropriate, however, because the frequency distribution of plasma tHcy concentrations is positively skewed (74). Use of reference intervals based on presupplementation measurements of plasma tHcy in subjects who can be classified as weak responders to folate supplementation has been suggested. Rasmussen et al. (23) found a mean \pm SD of 7.76 ± 1.54 $\mu\text{mol/L}$ for these weak responders, compared with 12.33 ± 2.04 $\mu\text{mol/L}$ for the high responders; they derived age- and gender-specific 95% confidence intervals including values between 4.5 and 11.9 $\mu\text{mol/L}$ for the weak responders. Ubbink et al. (74) suggested using a mathematical model to predict the plasma tHcy that could be expected for a population with improved vitamin status; their calculated 95% reference range was 4.9 to 11.7 $\mu\text{mol/L}$ for a population with improved folate, vitamin B₁₂, and vitamin B₆ status. Hence, about 12 $\mu\text{mol/L}$ would seem to be the upper end of the normal “desirable” range for adult fasting plasma tHcy.

The use of both fasting and post–methionine load measurements may have benefits in screening for mild forms of hyperhomocysteinemia (54, 90). In one study, fasting plasma tHcy determination alone failed to identify more than 40% of persons classified as hyperhomocysteinemic when both fasting and post–methionine load measurements were used (89). Measurement of plasma tHcy 2 or 4 hours after administration of an oral load dose of methionine (~0.1 g or 670 $\mu\text{mol/kg}$) yielded plasma tHcy concentrations (mean \pm SD) of 29.2 ± 10.4 $\mu\text{mol/L}$, compared with 9.6 ± 4.2 $\mu\text{mol/L}$ for fasting concentrations; the 90th percentile cutoff value used to define hyperhomocysteinemia was 41.4 $\mu\text{mol/L}$ for post–methionine load values, compared with 13.6 $\mu\text{mol/L}$ for fasting tHcy (89).

Dietary Treatment of Homocystinuria and Hyperhomocysteinemia

The goal of dietary treatment of homocystinuria is to decrease the biochemical abnormalities (reduce plasma Hcy, maintain normal concentrations of plasma methionine and Cys) and to minimize development of clinical complications. Treatment of individuals with inborn errors of transsulfuration (cystathionine b-synthase deficiency) usually involves restriction of dietary methionine intake while providing adequate cyst(e)ine intake (see Chapter 61). Small, frequent feedings are also recommended to minimize a methionine load effect. Newborns diagnosed with cystathionine b-synthase deficiency are fed low-protein formula in controlled quantities or formula low in methionine and supplemented with cystine in an effort to maintain normal plasma methionine concentrations (20–40 $\mu\text{mol/L}$) and very low plasma concentrations of tHcy. Inclusion of choline or betaine (25–165 mmol/day; 100–600 mg/kg/day) as a methyl donor is also beneficial (58, 91); these levels of betaine supplementation are very high compared with the normal total choline intake in the adult (5.0–8.3 mmol/day), of which only a portion becomes available as betaine (92). Pyridoxine at levels ranging from 150 to 1200 mg/day has been used successfully in treatment of cystathionine b-synthase-deficient adults; these levels greatly exceed the normal recommended intake of approximately 2 mg/day for adults.

In homocystinuria due to inborn errors in the methionine remethylation pathway, the goal of dietary treatment is to maintain sufficient levels of methionine methyl groups without elevating the plasma Hcy concentration; this usually involves relatively high levels of B-vitamin supplementation (folate, vitamin B₁₂) to stimulate the

N^5 -methyltetrahydrofolate-dependent homocysteine re-methylation pathway, betaine or choline to stimulate the betaine-dependent homocysteine remethylation pathway, and in some cases methionine supplementation to ensure sufficient availability of S-adenosylmethionine (93).

Modest levels of vitamin supplementation (~0.6 mg folic acid, 0.4 mg cyanocobalamin, and 10 mg pyridoxine) reduce plasma tHcy concentrations in a proportion of individuals with mild hyperhomocysteinemia (74, 77, 94, 95 and 96). Some individuals with plasma tHcy levels in the reference range (fasting values <12 $\mu\text{mol/L}$) also respond to folate or B-vitamin supplementation with a reduction in plasma tHcy (74, 94, 95). Although Hcy-lowering therapy reduces the vascular risk of patients with severe hyperhomocysteinemia due to inborn errors of metabolism, the outcome of treatment of mild hyperhomocysteinemia on atherosclerotic and thromboembolic disease is yet to be reported (97). Periconceptual supplementation with folate reduces the incidence of neural tube birth defects in newborns (79). To increase the folate intake of women of childbearing age, the U.S. Food and Drug Administration ruled in 1996 to require fortification of most breads and grain products as of 1998. Fortification of foods with folate may have some beneficial effects on additional pregnancy outcome measures and the incidence of vascular and thromboembolic disease.

METABOLISM OF CYSTEINE

Pathways of Cysteine Metabolism

Cysteine, whether formed from methionine and serine via transsulfuration or supplied preformed in the diet, serves as a precursor for synthesis of proteins and several other essential molecules as shown in Figure 34.4. These metabolites include GSH, coenzyme A, taurine, and inorganic sulfur.

Figure 34.4. Pathways of cysteine metabolism. Numbered reactions are catalyzed by the following enzymes or pathways: (1) protein synthesis; (2) protein degradation; (3) GSH-thioltransferase or nonenzymatic thiol-disulfide exchange of cystine with GSH; (4) g-glutamylcysteine synthetase; (5) glutathione synthetase; (6) glutathione transpeptidase; (7) dipeptidase; (8) pathway of coenzyme A synthesis; (9) cysteine dioxygenase; (10) cysteine sulfinatase decarboxylase; (11) enzymatic or nonenzymatic

oxidation of hypotaurine; (12) aspartate (cysteine sulfinat) aminotransferase; (13) cysteine sulfinat-independent or desulfhydration pathways of cyst(e)ine catabolism; (14) sulfide oxidase; (15) thiosulfate sulfurtransferase or GSH-dependent thiosulfate reductase; and (16) sulfite oxidase.

At intakes near the requirement, a large proportion of available cysteine is used for synthesis of proteins and GSH. In addition to the specific metabolic functions of GSH, GSH serves as a reservoir of Cys and as a means for transporting Cys to extrahepatic tissues (86). A large proportion of the sulfur amino acid intake is converted to GSH by the liver and released into the circulation. γ -Glutamyl transpeptidase, an enzyme located on the outer surface of the plasma membrane of cells in a number of tissues, hydrolyzes GSH (or its disulfide) to yield CysGly (or its disulfide), which can be further degraded by peptidases to release cysteine (or cystine) into the plasma. The normal turnover of GSH in humans is estimated to be 40 mmol/day (99, 100), nearly two to three times the typical sulfur amino acid intake of 15 to 20 mmol/day and six to seven times the estimated sulfur amino acid requirement. This estimate suggests that the magnitude of turnover of the Cys pool as a result of GSH turnover may be slightly greater than that resulting from protein turnover in the body (~30 mmol/day; [31]).

Cysteine is also a precursor for synthesis of coenzyme A and for production of taurine and inorganic sulfate. These three fates of cysteine involve loss of the cysteine moiety as such. Cysteine is substrate for coenzyme A synthesis in that it donates the cysteamine (decarboxylated cysteine) moiety of the coenzyme A molecule and, hence, contributes the reactive sulfhydryl group. Coenzyme A turnover is thought to be slow, such that coenzyme A synthesis does not consume a large amount of dietary cysteine. The functions of coenzyme A are discussed in [Chapter 25](#).

Both taurine and inorganic sulfur are products of cysteine catabolism. As shown in [Figure 34.4](#), there are several pathways for cysteine catabolism. Cysteine catabolism may occur by desulfuration of cysteine to yield pyruvate and reduced sulfur (often in the form of a persulfide such as thiocysteine, mercaptopyruvate, or thiosulfate). Cysteine desulfuration can be catalyzed by the β -cleavage of cyst(e)ine by cystathionine γ -lyase or by transamination of cysteine to β -mercaptopyruvate followed by de- or transsulfuration by mercaptopyruvate sulfurtransferase (51). Individuals with a rare inborn error of metabolism in which β -mercaptopyruvate sulfurtransferase is deficient excrete the mixed disulfide of cysteine and β -mercaptolactate, suggesting that transamination of cysteine to mercaptopyruvate occurs to some extent in humans (101). However, these patients excrete normal levels of urinary sulfate, indicating that overall cysteine catabolism is not impaired. The reduced sulfur may be used in synthesis of molecules requiring a source of reduced sulfur, or it may be oxidized to thiosulfate (inner sulfur), sulfite, and finally sulfate. Although most of the inorganic sulfur is eventually oxidized to sulfate, mammals depend upon the cysteine sulfinat-independent or desulfhydration pathways of cysteine metabolism as a source of reduced forms of inorganic sulfur because they cannot reduce sulfate or sulfite to thiosulfate or sulfide.

In animals fed high-protein or high sulfur amino acid-containing diets, the major pathway of cysteine catabolism involves oxidation of cysteine to cysteine sulfinic acid by cysteine dioxygenase (EC 1.13.11.20), which is an inducible enzyme in rat liver (51, 102). Cysteine sulfinic acid may be decarboxylated to hypotaurine, which is subsequently oxidized to taurine, or cysteine sulfinic acid may be transaminated (with α -ketoglutarate) to the enzyme-bound intermediate, β -sulfinylpyruvate, which gives rise to pyruvate and sulfite. Sulfite is further oxidized to sulfate by sulfite oxidase (EC 1.8.3.1).

In all catabolic pathways except that resulting in taurine formation, the carbon chain of cysteine is released as pyruvate, the sulfur is released as inorganic sulfur, and the amino group is released as ammonium or transferred to a keto acid acceptor. When taurine is the end product, only the carboxyl carbon of the cysteine is released, and the other three carbons as well as the nitrogen and sulfur atoms remain in the end product. Thus, the distribution of Cys among its catabolic pathways potentially affects the use of amino acid carbon chains for energy, the net production of acid or fixed anions (sulfate), and the synthesis of essential metabolites (inorganic sulfur and taurine). Although taurine and sulfate can be regarded as end products of cellular cysteine catabolism, both of these compounds participate in conjugation reactions and have a variety of essential physiologic functions prior to their ultimate excretion.

Adult human subjects remain in sulfur balance, with sulfur excretion essentially equivalent to sulfur intake (15–20 mmol/day). Both sulfate and taurine are excreted in the urine. In studies of total urinary sulfur excretion by children and adults, inorganic sulfate accounted for about 77 to 82%, ester sulfate about 8 to 9%, taurine about 3%, and cyst(e)ine about 0.6 to 0.7%. Other sulfur-containing compounds found in urine in trace amounts (<0.2% of total sulfur) include methionine, Hcy, cystathionine, *N*-acetylcysteine, mercaptolactate, mercaptoacetate, thiosulfate, and thiocyanate (40, 103).

Cysteine Oxidation and Taurine Synthesis in Humans

Relatively little is known about the specific pathways of cysteine metabolism in humans. Taurine synthesis requires both cysteine dioxygenase and cysteine sulfinic acid decarboxylase (EC 4.1.1.29). Significant expression of the cysteine dioxygenase gene was indicated by the presence of mRNA for cysteine dioxygenase in human liver, kidney, and lung (104). *S*-Carboxymethyl-L-cysteine (SCMC) has been used as a marker substrate for cysteine metabolism, presumably by cysteine dioxygenase, in vivo (105). Metabolism of SCMC is polymorphic, and about 20% of healthy individuals are poor *S*-oxidizers, based upon conversion of SCMC to urinary metabolites, SCMC sulfoxide, or methylcysteine sulfoxide. A low capacity to oxidize SCMC has been observed in some individuals with liver diseases or rheumatoid arthritis (105, 106). Individuals who exhibited low capacities for SCMC oxidation also had elevated cysteine:sulfate plasma ratios, excreted a smaller percentage of a dose of acetaminophen as the sulfate (vs. the glucuronide conjugate), and had a lower sulfate concentration in synovial fluid, all of which are consistent with impaired cysteine oxidation.

The human liver has been reported to have low cysteine sulfinatase decarboxylase activity (107). Nevertheless, the adult human seems to have a significant ability to synthesize taurine. In vivo assessment of the ability of adults to synthesize taurine, based upon incorporation of ^{18}O (from inhaled $^{18}\text{O}_2$) into taurine, resulted in conservative estimates of synthesis in the range of 200 to 400 $\mu\text{mol}/\text{day}$ (108). These estimates are equivalent to 1 to 3% of the total sulfur amino acid intake and compare favorably with the mean taurine excretion observed in strict vegans consuming an essentially taurine-free diet (approximately 250 $\mu\text{mol}/\text{day}$ [25, 26]). Thus, the percentage of the sulfur amino acid intake or total urinary sulfur excretion that is represented by urinary taurine in humans fed taurine-free diets is similar to that observed in rats fed taurine-free diets (2–6%) (109), which seems to dispute the often-made statement that the rat has a high capacity for taurine synthesis whereas humans have a low capacity. Possibly, relatively high hepatic cysteine dioxygenase activity in man permits high rates of cysteine catabolism to cysteine sulfinatase, and relatively high concentrations of cysteine sulfinatase allow adequate rates of taurine synthesis despite relatively low cysteine sulfinatase decarboxylase activity.

ESSENTIAL FUNCTIONS OF CYSTEINE AND ITS METABOLITES

Synthesis of Protein and Glutathione

Cysteine, either preformed or synthesized from methionine and serine, is required for protein synthesis and, hence, growth or nitrogen balance. Both the reactive sulfhydryl group of cysteinyl residues in proteins and the ability of these residues to form disulfide linkages play important roles in protein structure and function.

The Cys-containing tripeptide GSH has a number of essential functions in the body in addition to serving as a storage or circulating reservoir of Cys (110, 111). Because GSH has a reactive sulfhydryl group, it can readily form disulfides with itself (oxidized glutathione or GSSG) or with other thiol compounds (GSSR). The ratio of GSH to GSSG in most cells is greater than 500, so GSH serves as a supply of reducing equivalents or electrons. Glutathione is involved in protection of cells from oxidative damage because of its role in reduction of hydrogen peroxide and organic peroxides via glutathione peroxidases and because of its ability to inactivate free radicals by donating hydrogen to the radical; these processes result in oxidation of GSH to GSSG. GSSG and GSH can be interconverted via the glutathione reductase reaction, which uses $\text{NADP}^+/\text{NADPH}$ as the oxidant/reductant; hence, glutathione plays a role in maintenance of the cellular redox state. GSH is an important source of reducing equivalents for the intracellular reduction of cystine to cysteine, which can occur by thiol-disulfide exchange or enzymatically via thioltransferase, with GSH providing the reducing equivalents.

GSH may participate in the transport of amino acids via the membrane-bound enzyme γ -glutamyl transpeptidase, the same enzyme responsible for extracellular hydrolysis of GSH. This enzyme catalyzes the transfer of the γ -glutamyl group of GSH to the α -amino group of an acceptor amino acid such as cystine or glutamine. The γ -glutamyl amino acid is transported into the cell, where the amino acid is released and the glutamyl

moiety cyclizes to 5-oxoproline, which is then hydrolyzed to regenerate glutamate. The CysGly dipeptide that is the byproduct of γ -glutamyl-transpeptidation can be hydrolyzed to Cys and glycine either extracellularly or intracellularly by dipeptidases; hence, no net consumption of amino acids results from this transport cycle. The contribution of this proposed transport system to amino acid transport cannot exceed the rate of GSH turnover, which is ~40 mmol/day in an adult.

GSH also serves as a cosubstrate for several reactions, including certain steps in leukotriene synthesis and melanin polymer synthesis. GSH is the substrate for a group of enzymes, glutathione S-transferases, that form GSH conjugates from a variety of acceptor compounds including various xenobiotics (112). These conjugates are normally degraded by the enzymes of the γ -glutamyl cycle to yield cysteinyl derivatives that may be acetylated using acetyl-CoA to mercapturic acids, which are excreted in the urine. This is usually a detoxification and excretion process.

Functions of Inorganic Sulfur

Reduced sulfur is required for synthesis of iron-sulfur proteins and other compounds. The activated form of sulfate, 3'-phospho-5'-phosphosulfate (PAPS), serves as the substrate for a variety of sulfotransferase reactions. Many structural compounds are sulfated; in particular, the oligosaccharide chains of proteoglycans contain many sulfated sugar residues. In addition, many compounds of both endogenous and exogenous origin are excreted as sulfoesters; sulfoesters of steroid hormones and the drug acetaminophen are examples. Inorganic sulfur is largely obtained from the metabolism of cysteine in the body, but animal studies have suggested that dietary inorganic sulfate may improve growth, feed efficiency, and sulfation of cartilage proteoglycans when sulfur amino acid intake is insufficient (113).

Functions of Taurine

The only physiologic function of taurine that is well understood is its role in bile acid conjugation (37). Taurine conjugates are the major metabolites of taurine formed in vertebrates. Taurocholate is a very efficient bile salt because of the low pK_a of the sulfonic acid group, which facilitates its ionization and hence detergent action, solubility, slower reabsorption, and higher intraluminal concentration. Taurine is also a conjugation substrate for certain other compounds, such as *all-trans*-retinoic acid, increasing polarity, aqueous solubility, and, in most cases, clearance from the body.

Humans can conjugate bile acids with both taurine and glycine. In adults, the taurocholate:glycocholate ratio is about 3:1, but this ratio varies from individual to individual and with changes in the hepatic concentration of taurine. In contrast, the human fetus and neonate are exclusive taurine conjugators. Glycine conjugation is not usually observed until about the 3rd week of life, but it appears sooner in infants deprived of dietary taurine (114). Taurine supplementation resulted in lower cholesterol synthesis and higher bile acid excretion and fatty acid absorption in preterm infants with a gestational age less than 33 weeks but not in older preterm or full-term infants (115).

Taurine is present in high concentrations in many human tissues (~25 $\mu\text{mol/g}$ wet wt in retina and leukocytes), and a number of other physiologic actions of taurine in various tissues have been hypothesized (15, 37). Unfortunately, these actions are not well understood despite several decades of intensive work (15, 37, 48). Taurine is involved in osmoregulation in many marine invertebrates and fish and may also function as an organic osmolyte in mammals. Taurine seems to modulate many Ca^{2+} -dependent processes and to be involved in phospholipid/ Ca^{2+} interactions. Taurine has been said to have “antioxidant or radioprotective” functions, but these are probably largely secondary to its membrane-stabilizing actions. The metabolic precursor of taurine, hypotaurine, can function as an antioxidant; and the cysteine derivative, cysteamine, derived from coenzyme A catabolism, is a good radioprotectant. Additionally, taurine facilitates removal of hypochlorite, a strong oxidant generated from peroxide and Cl^- by myeloperoxidase. Taurine reacts with hypochlorite to form *N*-chlorotaurine, which can then be reduced to taurine and Cl^- . *N*-Chlorotaurine may itself have a regulatory role in the inflammatory process.

Taurine is involved in development, with substantial evidence supporting a crucial role during the pre- and postnatal development of the central nervous and visual systems. The specific manner in which taurine participates in these events is not clear. In primates deprived of taurine, retinal changes, impaired visual acuity, and degenerative ultrastructural changes in photoreceptor outer segments have been observed, with changes being more severe in younger animals (37, 48). Some human infants and children whose only nutrition was taurine-free parenteral infusion or taurine-devoid formulas have exhibited ophthalmoscopically and electrophysiologically detectable retinal abnormalities and immature brainstem auditory-evoked responses (37, 48).

POSSIBLE CAUSES OF DEFICIENCY OF CYSTEINE OR TAURINE

Inability to Synthesize or Conserve

Immaturity

Immaturity may be associated with a conditional requirement for both cysteine and taurine. Preterm infants (<32 weeks gestation) have a low capacity for transsulfuration (low cystathionine γ -lyase activity), low plasma Cys concentrations, elevated plasma cystathionine concentrations, and a low rate of GSH synthesis from methionine in erythrocytes (116, 117). These observations all suggest that transsulfuration may be insufficient to meet the cysteine requirements of the very premature infant. Full-term formula-fed infants have also been observed to have increased cystathionine and decreased taurine levels in urine, suggesting a limited capacity for transsulfuration even in term infants (118).

In addition to a limited capacity to convert methionine to cysteine and hence to taurine (low synthetic rate), several other characteristics of premature infants contribute to their conditional requirement for taurine and/or cysteine (15, 48). First, the premature infant may have a greater requirement for cysteine because of more rapid growth and for

taurine because of a likely role of taurine in development of the nervous and visual systems. The brain and retina of developing animals have high taurine concentrations, and morphologic and functional impairments have been observed in animals deprived of taurine during development. Second, premature infants are born with lower stores of taurine than are mature infants. Third, the b-amino acid transport system in the immature kidney does not adapt to poor taurine status by increasing reabsorption of taurine. The urinary taurine content of premature neonates is markedly elevated, with a fractional excretion ranging from 38 to 60%, compared with fractional excretion below 10% in term infants. Premature infants who received parenteral nutrition solutions devoid of taurine had high urinary taurine excretion rates despite very low plasma taurine values ([47](#), [119](#), [120](#)). By contrast, term neonates given a taurine-deficient parenteral nutrition solution can maintain plasma taurine concentrations by increased renal reabsorption of taurine with as little as 1% of the filtered taurine load being excreted. (See also [Chapter 51](#) concerning taurine administration parenterally.)

Hepatic Dysfunction

Because liver is the major site for transsulfuration and taurine synthesis, hepatic dysfunction can adversely affect sulfur amino acid status. Patients with advanced forms of liver dysfunction or cirrhosis had low plasma taurine, Cys, and glutathione concentrations, an elevated plasma cystathionine concentration, decreased urinary taurine excretion, a decreased ratio of urinary sulfate to total sulfur, and increased urinary excretion of Cys and cystathionine ([121](#), [122](#)). These patients appeared to have a decreased ability to metabolize methionine (to cysteine, with cystathionine accumulation) and cysteine (to taurine and inorganic sulfate, with thiosulfate, Cys, and *N*-acetylcysteine accumulation).

Inadequate Supply Relative to Need

Total Parenteral Nutrition

Patients on long-term total parenteral nutrition (TPN) have experienced adverse effects on their sulfur amino acid status, both because of the route of administration and the composition of the TPN solutions. The amino acid mixtures used for TPN solutions usually contain little if any cysteine, because cysteine is rapidly converted to its disulfide, cystine, which is very insoluble in aqueous solution. Taurine is not routinely added to adult TPN solutions. Hence, patients on TPN must synthesize both cysteine and taurine from the methionine provided by TPN (see [Chapter 101](#)). However, synthesis of cysteine and taurine from methionine is restricted when first-pass metabolism by the liver is bypassed with parenteral alimentation. In adult subjects given parenteral alimentation solutions free of Cys via different routes, plasma Cys concentration dropped markedly when the feeding was via the parenteral route whereas it rose when feeding was switched to the oral route ([123](#)). The liver apparently removes much of the methionine on the first pass when solutions are administered by the oral route, thus facilitating cysteine and taurine synthesis from methionine.

Vegan Diets

Because strict vegan diets tend to be lower in total sulfur amino acid content and virtually free of taurine, adult vegans and particularly children consuming vegan diets are at somewhat greater risk of inadequate sulfur amino acid status. Adult humans who consume a strict vegetarian diet have been reported to have lower plasma taurine concentrations and greatly reduced urinary taurine excretion compared with omnivores. However, vegans consuming little or no preformed taurine are healthy, and the children born to and nursed by vegan mothers have normal growth and development (25). (See [Chapter 106](#).)

Drug Metabolism

Various drugs and toxins are partially metabolized and excreted by conjugation with sulfate, glutathione (mercapturic acid synthesis), or even taurine. Rats fed up to 1 g (6.6 mmol) of acetaminophen per 100 g diet experienced dose-dependent inhibition of growth that was independent of hepatotoxicity and that could be overcome by addition of methionine or cyst(e)ine to the diet (99, 124). Lauterburg and Mitchell (99) found that therapeutic doses of acetaminophen (600 and 1200 mg, or 4 and 8 mmol) administered to healthy adult subjects markedly stimulated the rate of turnover of the pool of Cys available for synthesis of GSH. Patients and volunteers with prolonged ingestion of acetaminophen in doses of 2 to 4 g (13–26 mmol) per day had a decreased urinary output of inorganic sulfate but no decrease in plasma sulfate concentrations (125). Subjects produced a maximum of 0.6 mmol/h of acetaminophen sulfate, whereas total sulfur excretion was 7.5 to 26.7 mmol/24 h (0.3–1.1 mmol/h). A marginal sulfur amino acid intake accompanied by prolonged ingestion of high doses of drugs or toxins that are metabolized by sulfate and/or glutathione conjugation could have adverse effects on both sulfur amino acid status and drug metabolism.

MEASURES OF TAURINE STATUS AND OF CYSTEINE AND/OR SULFUR AMINO ACID STATUS

Sulfur amino acid adequacy has generally been assessed by measures of nitrogen balance or growth. Although growth and nitrogen balance have been used to define the nutritional requirements for amino acids, they are not necessarily good indicators of whether or not sulfur amino acid intake is sufficient for optimal rates of production of glutathione, inorganic sulfur, or taurine.

Plasma and blood taurine concentrations, plasma tCys concentration, and the plasma glutathione concentration have been used as indicators of sulfur amino acid status. Normal values for these measures are discussed above in this chapter.

Because most of the sulfur from sulfur amino acids is excreted in the urine, primarily as inorganic sulfate, measures of total urinary sulfur or of urinary sulfate are useful indicators of sulfur amino acid intake and/or metabolism. The urinary taurine level can also be used as an indicator of adequate supply of sulfur amino acids or taurine

because taurine excretion increases as plasma taurine concentration and/or taurine intake increases.

RECOMMENDED INTAKES FOR HUMANS

The estimated upper-end requirement for sulfur amino acids (methionine plus cyst(e)ine) is 58 mg/kg/day for infants, 27 mg/kg/day for children (~age 2 years), 22 mg/kg/day for older children (~10–12 years), and 13 mg/kg/day for adults (28). A conservative estimate of methionine replacement by cyst(e)ine, up to 30% of the methionine requirement, is suggested (28). In cases of limited ability to convert methionine to cysteine (whether due to hepatic dysfunction, inborn errors of methionine metabolism to cysteine, or prematurity), the total amount of sulfur amino acids in the diet, the balance of cysteine and methionine, and the adequacy of taurine should all be considered.

By consensus, taurine is considered conditionally essential during infant development and probably for adults in some special circumstances. Because brain and retina of human infants are not fully developed at birth and may be vulnerable to the effects of taurine deprivation, it has been judged prudent to supplement human infant formulas and pediatric feeding solutions with taurine (15, 37). During the 1980s, manufacturers of infant formulas began adding taurine to their products, and taurine is presently added to virtually all human infant formulas and pediatric parenteral solutions throughout the world. The taurine content of human milk has been used as a guideline for supplementation levels.

TOXICITY

Large doses of cysteine or cystine are neuroexcitotoxic in several species. The effect of cysteine seems to involve the *N*-methyl-D-aspartate subtype of the glutamate receptor for which cysteine sulfinate and cysteic acid are agonists (125, 126, 127, 128 and 129). Single injections of cysteine (0.6–1.5 g/kg) into 4-day-old rat pups resulted in massive damage to cortical neurons (130), permanent retinal dystrophy (131), atrophy of the brain (132), and hyperactivity (126). Cats fed a 5% cystine diet had no obvious immediate ill effects but exhibited acute neurotoxic symptoms after several months (133). The onset of symptoms in the cats was sudden, with rapid progression to a moribund state or death, usually within 48 hours. The morphologic changes observed in the retinas of cats fed the cystine-rich diets were comparable to those described in the retinas of young rodents treated with glutamate or certain other acidic or excitotoxic amino acids. It is not clear whether cysteine or a metabolite (cysteine sulfinate) is responsible for the cytotoxicity. These observations have given rise to concerns about administration of excess cyst(e)ine to humans, especially to infants.

Studies in rodents also demonstrated influences of dietary sulfur amino acids on lipid metabolism, with 2 to 5% (by wt) L-cystine resulting in elevated plasma cholesterol concentration, increased hepatic cholesterol biosynthesis, and depressed plasma ceruloplasmin activity (134, 135). Excess L-cysteine (0.8 or 2% of diet by wt) did not result in an elevation in plasma cholesterol whereas addition of 0.8% L-methionine did

(135, 136).

Sturman and Messing (137) found no evidence of adverse effects of prolonged feeding of high taurine diets (up to 1 g [8 mmol]/100 g diet) on adult female cats or their offspring. In fact, taurine may protect against toxic effects of some other compounds. Taurine addition to cat diets provided some protection against the adverse effects of a high level of cystine, supporting a neuroprotective role of taurine against the excitotoxic damages in the mammalian nervous system (133). Studies in rodents have suggested that dietary taurine also has hypolipidemic and antiatherosclerotic effects (138, 139).

Abbreviations: **Cys**—cysteine (any form), with thiol and disulfide forms indicated as CySH, CySSCy, and CySSR; **tCys**—sum of all forms of Cys including that present as thiol, half-disulfide, mixed disulfide, and protein-bound disulfide; **Cyst(e)ine**—cysteine and/or cystine; **Hcy**—homocysteine (any form) with thiol and disulfide forms indicated as HcySH, HcySSHcy, and HcySSR; **tHcy**—sum of all forms of Hcy; **Homocyst(e)ine**—homocysteine and/or homocystine; **Glu**—glutamate; **Gly**—glycine; GSH, glutathione; **SCMC**—S-carboxymethylcysteine; THF, tetrahydrofolate.

[Chapter References](#)

The amino acids glutamine (GLN) and arginine (ARG) are of special interest because they have been recently classified as conditionally essential amino acids, indicating that they may be required in increased amounts by patients suffering from a catabolic insult such as injury, cancer, or severe infection (see [Chapter 1](#)). However, the utility of including glutamine or arginine in the nutritional support of patients recovering from surgery or suffering from trauma, infection, or cancer has yet to be conclusively demonstrated in clinical settings. Most studies examining the metabolism of these two amino acids have used cultured cells and animal models of trauma or infection. A wealth of experimental data proves the ability of glutamine-supplemented parenteral nutrition to support gut function, improve nitrogen balance, and alleviate catabolic demands upon muscle mass. In addition, limited clinical trials have found that glutamine feeding improves patient outcome in a number of settings ([Table 35.1](#)). Similarly, experimental data have shown that arginine can promote intestinal function and repair, promote wound healing, stimulate endocrine hormone production, and improve immune system function. Limited clinical trials have confirmed that inclusion of arginine in enteral and parenteral nutrition can improve nitrogen balance and immune defenses of patients (see [\[1\]](#) for a recent review). This chapter reviews a selection of these experimental and clinical studies and examines the limitations of these two nutrients as therapeutic

adjuvants.

Reference number	Type of study	Interventions/Measurements	Effect of GLN supplementation	Limitations/Remarks
Preoperative (contaminated wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Reduced nitrogen balance, improved nitrogen balance, improved muscle protein synthesis	Glutamine plus essential amino acids and glucose improved nitrogen balance and muscle protein synthesis
Preoperative (clean wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance
Preoperative (contaminated wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance
Preoperative (clean wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance
Preoperative (contaminated wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance
Preoperative (clean wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance
Preoperative (contaminated wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance
Preoperative (clean wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance
Preoperative (contaminated wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance
Preoperative (clean wound)	Randomized controlled clinical trial	Glutamine (10g/kg) + essential amino acids + glucose	Improved nitrogen balance, improved nitrogen balance	Glutamine plus essential amino acids and glucose improved nitrogen balance

Table 35.1 Clinical Studies Demonstrating Benefits of Supplementing TPN with Glutamine (GLN)

GLUTAMINE METABOLISM

Glutamine as a Nitrogen Carrier

The presence of two nitrogen atoms, an α -amino group and an amide group, as well as the abundance of glutamine in plasma combine to make this amino acid the most important “nitrogen shuttle” in the body. In fact, approximately one-third of all amino acid–derived nitrogen transported by the blood is in the form of glutamine. This amino acid serves as a vehicle for transportation of ammonia in a nontoxic form from peripheral tissues to visceral organs where it can be excreted as ammonium by the kidneys or converted to urea by the liver. The vast majority of nitrogen supplied by muscle in the postprandial period is exported as glutamine (2). Ammonia derived from glutamine in the mitochondria (by hydrolysis of glutamine to glutamate by the enzyme glutaminase or by hydrolysis of glutamate to α -ketoglutarate by the enzyme glutamate dehydrogenase) can combine with CO_2 to form carbamoyl phosphate that then enters the urea cycle (3). The amino group of glutamate can be used in the synthesis of aspartate from oxaloacetate. Through aspartate, the amino nitrogen of glutamine can also enter the urea cycle. In fact, glutamine is the major source of both nitrogen used in hepatic ureagenesis (4) and nitrogen excreted in urine (5). In addition, perfusion of isolated rat livers with glutamine greatly stimulated urea output (6, 7).

The liver has evolved an elegant mechanism for concerted ammonia detoxification and glutamine supply (8). In the periportal region, high incoming concentrations of ammonia from the splanchnic bed are utilized for urea synthesis while at the same time ammonia and glutamate are being generated from incoming glutamine by the hepatic isozyme of the enzyme glutaminase. In the perivenous portion of the liver, high levels of glutamine

synthetase convert glutamate and excess ammonia into glutamine, effectively reducing the ammonia concentrations in hepatic venous blood to non-toxic levels. With this intraorgan glutamine cycle, the liver is able to effectively detoxify incoming blood of ammonia and control output of glutamine. In contrast, the kidney counteracts acidosis by utilizing a the “kidney-type” isozyme of glutaminase to generate ammonia from glutamine (9). The kidney disposes of excess nitrogen by consuming glutamine and excreting the ammonia produced (10).

Glutamine as a Metabolic Intermediate

Glutamine also plays a key role in cellular energetics and metabolism by functioning as an important source of cellular fuel as well as a source of carbon and nitrogen for metabolic intermediates and macromolecular synthesis (Fig. 35.1). Glutamine acts as a fuel through its partial oxidation to form lactate or its complete oxidation to form CO₂. In fact, glutamine can serve as the primary respiratory substrate in enterocytes, lymphocytes, and cells in culture (discussed below). Glutamine plays a key role in regulating protein synthesis in tissues and cultured cells (11, 12 and 13). Glutamine itself is used in peptide synthesis and is a precursor to many other amino acids. In addition, glutamine is converted to numerous metabolic intermediates and donates an amine group in many metabolic pathways including those leading to purine and pyrimidine nucleotide synthesis and the formation of glucosamine. Acetyl groups derived from glutamine are used in the synthesis of fatty acids and therefore incorporated into membrane phospholipids. In the kidney and liver, the carbon skeleton of glutamine is used for gluconeogenesis during times of starvation (14, 15). Thus, glutamine has many important metabolic and synthetic roles essential for cellular viability.

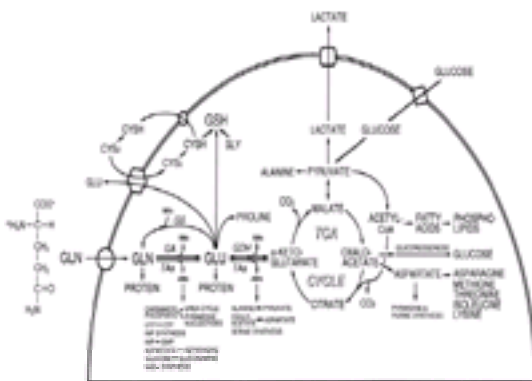

Figure 35.1. Metabolic functions of glutamine (*GLN*). Glutamine enters the cell by an active carrier-mediated process. Most utilized glutamine is converted to glutamate (*GLU*) through hydrolysis catalyzed by the enzyme glutaminase (*GA*) and by a number of transaminase enzymes (*TAs*). Glutamate is used in protein synthesis, used for glutathione (*GSH*) synthesis, and potentially converted back into glutamine by the enzyme glutamine synthetase (*GS*). *GLU* is also exported from the cell in exchange for import of cystine (*CYS2*). Imported cystine is converted to cysteine, which together with glutamate and glycine (*GLY*) form glutathione. *GLU* is converted to proline or converted

to α -ketoglutarate by glutamate dehydrogenase (*GDH*) or transaminases. As α -ketoglutarate, the carbon backbone of glutamine enters the TCA cycle. Once in the TCA cycle the glutamine-derived carbons can be oxidized to CO_2 or serve as a backbone for formation of numerous metabolites and amino acids. In addition to glutamate and lactate, appreciable amounts of glutamine carbons are exported from the cell as aspartate, citrate, malate, pyruvate, alanine, and proline (16).

The first step in the use of glutamine as a respiratory fuel, metabolic precursor, and nitrogen donor is its conversion to glutamate (GLU). Glutamate is the most abundant intracellular amino acid in most tissues, with the notable exception of muscle, in which intracellular glutamine levels exceed those of glutamate (16, 17). Glutamate and ammonia are formed by hydrolysis of glutamine's amide group by the enzyme glutaminase. Glutamate is also formed by transfer of glutamine's amide group, catalyzed by a number of transaminase enzymes. Enzymatic transfer of glutamine's amide nitrogen occurs in various synthetic reactions. For example, glutamine is the nitrogen donor in formation of cytosolic carbamoyl phosphate, which is then used with aspartic acid in the committed step in pyrimidine synthesis (formation of *N*-carbamoylaspartate). Transamination from glutamine occurs in synthesis of the pyrimidine nucleotide CTP from UTP. In the purine biosynthetic pathway, glutamine contributes two amine groups in reactions leading to the synthesis of IMP and donates a third amine group in the conversion of IMP to GMP. Glutamine also provides an amide group for synthesis of asparagine, glucosamine, and nicotinamide adenine dinucleotide (NAD^+). Glutamate formed from glutamine can in turn be further deaminated, converted to proline or back into glutamine, used for glutathione synthesis, or exported. As glutamate, the α -amino group of glutamine is used in several transamination reactions including synthesis of alanine from pyruvate, synthesis of aspartate from oxaloacetate, and formation of phosphoserine, which is subsequently hydrolyzed to serine.

The five-carbon backbone of glutamine enters the tricarboxylic acid (TCA) cycle through conversion of glutamine-derived glutamate to α -ketoglutarate (2-oxoglutarate) by glutamate dehydrogenase or one of several transaminases. Via the TCA cycle, glutamine serves as a respiratory fuel source and the precursor of many synthetic intermediates. For example, through oxaloacetate, a TCA cycle intermediate, glutamine is used for gluconeogenesis or converted to aspartate or alanine. Aspartate can in turn be converted to asparagine, methionine, threonine, isoleucine, and lysine, be a precursor in pyrimidine synthesis, and again be an amine donor in purine synthesis (discussed above). Through malate and then pyruvate (the precursor of alanine), the carbon backbone of glutamine can be converted to lactate or acetyl-CoA. The acetyl group of acetyl-CoA can reenter the TCA cycle, eventually leading to the complete respiratory oxidation of glutamine carbons to CO_2 . Acetyl-CoA also provides glutamine-derived carbon in the synthesis of fatty acids that can be used in production of phospholipids for cellular membranes.

Glutamine as a Supporter of Glutathione Metabolism

Considerable evidence suggests that glutamine may play a key role in the support of glutathione synthesis ([Fig. 35.1](#)) (see also [Chapter 34](#)). Glutathione, a tripeptide composed of glutamate, cysteine, and glycine, is the major store of cellular reducing equivalents and serves to protect cells from oxidative stress ([18](#)). As a source of intracellular glutamate, glutamine provides one of the constituents of glutathione. Glutamine carbons are incorporated into glutathione by rat kidney glomeruli ([19](#)), and the decline of hepatic glutathione levels during acetaminophen-induced liver injury was inhibited by treating rats with glutamine-supplemented parenteral nutrition ([20](#)). In fact, radioactive glutamine carbons are incorporated into glutathione in several animal tissues ([20](#)). Glutamine may also be essential for maintenance of cellular cysteine levels. Bannai and Ishii demonstrated a functional link between the use of glutamine and cystine (CYS2) by human diploid fibroblasts when they found that both the quantity of glutamine used and the quantity of glutamate released by these cells depended upon the concentration of cystine in the culture media ([21](#)). They concluded that approximately one-third of the glutamine used by these fibroblasts was used to produce extracellular glutamate. Tracer studies demonstrated that exported glutamate is a major end product of glutamine used by kidney cells ([22](#)) as well as several tumor cell lines ([16](#)). In our laboratory, we have found that approximately 40% of glutamine consumed by human breast cell lines and breast cancer cells is released as glutamate, and the rate of glutamate release by these cells also depends upon the extracellular concentration of cystine ([16a](#)). A working model predicts that glutamine, by serving as a source of glutamate, provides two of the three precursors for glutathione synthesis: glutamate itself, which is directly utilized in glutathione synthesis, and cysteine, which is derived from cystine imported via the export of glutamate. This role in glutathione synthesis suggests that glutamine availability may have profound effects upon cellular redox control and that glutamine utilization may be increased under conditions of oxidative stress.

Glutamine as an Energy Source

A substantial portion of glutamine can be used for cellular respiration. For example, HeLa and CHO cells each convert approximately 30% of catabolized glutamine carbons to CO₂ and 15% to lactate, while approximately 20% of its carbons are incorporated into macromolecules ([23](#), [24](#)). The total amount of cellular energy derived from glutamine depends upon the extent of oxidation and the rate of glutamine utilization. These factors in turn depend largely on the absolute amounts and relative proportions of glutamine and glucose available as well as the type and proliferative state of the cell. For example, glutamine is a primary fuel source for the intestine and for enterocytes in culture ([25](#), [26](#)). Likewise, thymocytes derive a large portion of their energy from glutamine oxidation, especially after mitogenic stimulation ([27](#)). Under physiologic conditions, glutamine oxidation can account for as much as one-third of the cellular ATP production in cultured cells of many types ([28](#), [29](#) and [30](#)), and relative glutamine oxidation increases at lower glucose levels ([24](#), [31](#)). Cells survive and even grow in glucose-free media containing sufficient glutamine and nucleic acid precursors ([32](#), [33](#)). Thus, glutamine is an important source of cellular energy. However, little is known about what determines the rate of glutamine use or oxidation for a cell or tissue type.

GLUTAMINE IN CATABOLIC STATES

Interorgan Glutamine Transfer

During catabolic states, a combination of increased glutamine use and decreased nutrient uptake creates a glutamine demand that is met primarily by increased glutamine efflux from lung and muscle tissue (see also [Chapter 98](#)). Although plasma glutamine levels are usually maintained in septic rats and injured patients ([34](#), [35](#) and [36](#)), lung and muscle glutamine stores can be rapidly depleted after injury or infection ([34](#), [37](#), [38](#), [39](#) and [40](#)). Muscle is a major producer of glutamine during normal and catabolic states. In the normal postabsorptive 200-g rat, glutamine is released from the hindquarter at a rate of approximately 0.4 mmol/min ([35](#)). Given that skeletal muscle glutamine concentrations are approximately 6 to 8 mmol/L intracellular water ([41](#)), even a normal rate of release cannot be sustained for long without de novo glutamine synthesis. During catabolic states the efflux of glutamine from rat and dog muscle increases markedly ([34](#), [37](#), [42](#), [43](#)), and increased net production rate must eventually compensate for this heightened release. The muscle can maintain a rapid efflux of glutamine in part by increasing the rate of proteolysis while decreasing the rate of protein synthesis ([44](#)). This increases the intracellular pool of amino acids for export and for production of glutamine, which can be derived from a large number of amino acids through their conversion to glutamate, either directly or through α -ketoglutarate ([Fig. 35.1](#)). Thus, any amino acid that can feed into the TCA cycle can support glutamine production. Glutamate can then be converted to glutamine by the action of glutamine synthetase (GS).

Muscle glutamine levels may be an indication of severe catabolic stress. Investigators have shown a significant correlation between survival in septic patients and skeletal muscle glutamine stores ([45](#)). In addition, an association between reduction of plasma and muscle glutamine levels and disease severity has been reported for pancreatitis patients ([46](#)). Presumably, muscle glutamine stores and glutamine supplied by muscle proteolysis do not suffice to meet demand for glutamine in some cases, because of either the magnitude of glutamine use or depletion of muscle mass.

Hormonal Influences on Glutamine Synthesis

Adrenocorticoids may play a pivotal role in regulation of glutamine metabolism in response to stress. Glucocorticoid hormones increase glutamine production and glutamine efflux from skeletal muscle, as well as GS mRNA levels in this tissue ([47](#), [48](#) and [49](#)). In addition, the glucocorticoid receptor antagonist RU38486 reduces muscle glutamine content as well as the rate of glutamine release from muscle ([50](#), [51](#)). One established effect of glucocorticoids is augmentation of the GS transcription rate in muscle cells via the glucocorticoid receptor ([52](#), [53](#)). Results from our laboratory have demonstrated that GS expression is induced in a tissue-specific fashion in rats following dexamethasone injection and major burn injury, with augmentation of GS mRNA levels in lung and muscle ([54](#)). In addition, we have found that the level of GS mRNA in rat skeletal muscle following burn injury and endotoxemia depends largely on the presence of the adrenal gland ([55](#), [56](#)). Although the adrenal glands produce other hormones

(aldosterone and the sex steroids as well as epinephrine and norepinephrine), to our knowledge only glucocorticoids have been demonstrated to stimulate GS expression in skeletal muscle. However, glucocorticoids may not be the sole regulator of GS expression in catabolic states. We have found that GS expression in muscle does increase in response to injury and infection in adrenalectomized rats, although not to the levels observed in sham-operated animals with functional adrenal glands (55, 56).

The level of GS protein and activity is also influenced by posttranscriptional mechanisms. Depletion of glutamine in the media of cultured muscle cells causes a pronounced increase in GS activity and protein levels (57, 58). This effect is not due to an increase in GS mRNA levels, but instead, intracellular glutamine depletion causes the stability of GS protein to increase and thus the steady-state level to rise (59). Consistent with this mechanism, we have observed that the increase in GS protein levels observed in lung and muscle in response to glucocorticoids or sepsis is much lower than the increase in GS mRNA levels (54, 56).

Muscle-Sparing Effect of Glutamine

A major benefit of nutritional support including glutamine or glutamine precursors is to spare muscle mass. In the absence of nutritional support, the precursors for enhanced glutamine production by muscles of traumatized rats are derived from proteolysis of muscle protein (60, 61). Protein synthesis correlates with glutamine concentration in perfused rat muscles (41), and postoperative nutritional support including glutamine spares the muscle glutamine pool and stimulates muscle protein synthesis in both humans and animals (38, 62, 63). Provision of α -ketoglutarate (which can be converted to glutamate) can also help spare muscle glutamine pools in postoperative patients (64), demonstrating that synthesis of glutamine can keep pace with release if ample precursors are provided.

Glutamine Effect on Intestinal Repair and Function

Another clear benefit of glutamine supplementation during catabolic states is the promotion of gut structure and function. Several studies have found that enteral and parenteral glutamine reduces intestinal permeability and improves gut mucosal integrity in rat models of sepsis (65, 66). Intestinal sodium absorption in diarrheagenic *Escherichia coli*-infected rabbits can be enhanced by enteral administration of glutamine (67). Infusion of glutamine into the lumen of transplanted rat small intestine increases small bowel protein content and augments glucose absorption (68). Addition of glutamine to total parenteral nutrition (TPN) attenuated the endotoxin-induced damage to the jejunum and ileum in septic rats (69). In addition, enteral diets containing glutamine decreased bacterial translocation across the intestines of mice with major burn injuries (70). Inclusion of glutamine in parenteral nutrition formulations reduced the villous atrophy associated with long-term TPN administration to rats (71, 72 and 73) and increased jejunal mucosal weight and DNA content (74). The intestine's dependence upon glutamine was also illustrated by the finding that depletion of plasma glutamine levels by intravenous injection of bacterial glutaminase caused diarrhea, mild villous atrophy, mucosal ulcerations, and intestinal necrosis in experimental animals (75). Work by Burke and colleagues suggested that addition of glutamine to TPN decreased

bacterial translocation because of glutamine's ability to enhance the rat's gut immune function (76). Thus, glutamine may support gut function by a dual mechanism including stimulation of mucosal growth and intestinal immune surveillance.

Glutamine and Cancer

Numerous rodent studies have suggested that tumor burden creates an exaggerated glutamine demand that is met by increased glutamine production by host tissues (for examples see [77] and [78]). In light of the role of glutamine as a fuel for tumor cells, a pressing issue is whether glutamine-supplemented nutritional support will improve the outcome of cancer patients or accelerate tumor growth. Animal studies in which bacterial glutaminase was used to reduce plasma glutamine concentrations as well as those using glutamine antagonists have demonstrated the dependency of experimental tumors on glutamine for growth (for examples see [79] and [80]). Conversely, rodent studies also suggested that glutamine feeding benefits the tumor-bearing animals without enhancing tumor growth (81, 82 and 83). It is conceivable that provision of glutamine can help alleviate glutamine depletion in muscle and thus reduce protein catabolism associated with cancer cachexia (83, 84). Recent studies found that glutamine enhanced the effectiveness of methotrexate in treatment of experimental tumors (85, 86). Glutamine also boosted the immune response to tumors implanted in rats by increasing killer cell activity (87).

Glutamine may be particularly useful for increasing tolerance to radiation and chemotherapy, thus allowing use of more effective dosages. For example, glutamine-supplemented nutritional support may accelerate healing of the intestinal injury that results from chemotherapy or radiation therapy. Addition of glutamine to an elemental enteral diet significantly reduced the severity of enterocolitis and mortality of rats given large doses of methotrexate (88). Addition of glutamine to this diet also reduced endotoxin transmigration from the gut lumen, caused by methotrexate. A glutamine-enriched intravenous diet accelerated healing of the gut mucosa in rats receiving 5-fluorouracil (5-FU) (89). Likewise, provision of oral glutamine following abdominal irradiation also supported gut glutamine metabolism and decreased the morbidity and mortality of rats subjected to abdominal radiation (90). Administration of a glutamine-enriched oral diet prior to abdominal radiation was equally beneficial to rats (91).

On balance, considerable evidence from rodent systems suggests that glutamine supplementation of the diets of cancer patients could provide benefits without increasing tumor proliferation. Theoretically, the impact of glutamine feeding on tumor growth would be determined by the actual impact upon plasma glutamine concentration, the effectiveness of glutamine delivery to the growing tumor, and whether or not growth of that particular tumor is indeed limited by glutamine availability. An examination of 65 human tumor xenografts found that only 20% exhibited appreciable net glutamine uptake, demonstrating that many tumors do not obtain sustenance from this nutrient (92). It is likely that many tumors ultimately become relatively glutamine-independent as they adapt to growth in the nutrient-deprived tumor microenvironment. These adapted tumors may not exhibit accelerated growth even if plasma glutamine supply is increased. It is conceivable that the benefits of glutamine-enriched nutrition upon

muscle mass preservation, immune system function, and intestinal healing and function will consistently outweigh the risk that this nutrient might facilitate tumor growth.

ARGININE METABOLISM

Arginine and Nitrogen Balance

Although arginine contains four nitrogen atoms, it is not considered a major interorgan nitrogen shuttle. However, arginine does play an integral role in nitrogen metabolism as an intermediate in the urea cycle and is therefore essential for ammonia detoxification (Fig. 35.2). In the cytoplasm, arginine is hydrolyzed by arginase to form urea and ornithine. Ornithine is transported into the mitochondria where it is combined with carbamoyl phosphate to form citrulline. In contrast to cytosolic formation of carbamoyl phosphate, in which an amine group is derived by transamination from glutamine, mitochondrial carbamoyl phosphate is formed from carbon dioxide and ammonia derived largely from hydrolysis of glutamine. Citrulline then combines with aspartic acid in the cytosol to form arginosuccinate, which is then cleaved to form arginine and succinate. As arginine completes the cycle, two nitrogen molecules are shuttled into urea for excretion. One of these nitrogens is derived from mitochondrial ammonia and the other from cytosolic aspartate with the formation of fumarate. Fumarate enters the TCA cycle through malate and regenerates aspartate when oxaloacetate is transaminated via the conversion of α -amino acids to α -keto acids.

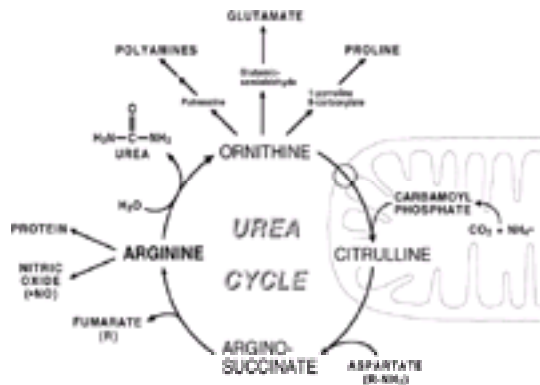

Figure 35.2. Metabolic functions of arginine. Arginine is used for protein synthesis, as an intermediate in the urea cycle, as a substrate for nitric oxide production and phosphocreatine synthesis as well as a precursor to glutamate, proline, and putrescine via ornithine. In the urea cycle, two nitrogen molecules are shuttled into urea for excretion. One of these nitrogens is derived from mitochondrial ammonia and the other from cytosolic aspartate with the formation of fumarate. In the cytoplasm, arginine is hydrolyzed by arginase to form urea and ornithine. Ornithine is transported into the mitochondria where it is combined with carbamoyl phosphate to form citrulline. Mitochondrial carbamoyl phosphate is formed from carbon dioxide and ammonia (as well as 2 ATPs and water). Citrulline then combines with aspartic acid in the cytosol to form arginosuccinate, which is then cleaved to form arginine and fumarate. Nitric oxide synthetase enzymes convert arginine to nitric oxide (\bullet NO) and citrulline. Ornithine

formed from arginine can be converted to glutamate via glutamic semialdehyde, to 1-pyrroline 5-carboxylate (a precursor for proline synthesis), or to the polyamine putrescine.

Arginine is not considered an essential amino acid because adult mammals can synthesize this amino acid de novo. However, plasma arginine levels are largely dictated by dietary intake, because arginine synthetic rates do not increase to compensate for inadequate supply (93, 94). In young rats and dogs, dietary arginine is essential and can be limiting for optimal growth (95, 96), and in mature animals, an arginine-free diet can cause ammonia toxicity (97). Arginine deficiency causes an increase in plasma ammonia levels by affecting function of the urea cycle. A large increase in orotic acid excretion in the urine is observed (98, 99), which may reflect use of carbamoyl phosphate for formation of carbamoyl aspartate (and subsequently orotate) rather than for synthesis of citrulline from ornithine. Arginine deficiency causes an increased flux of ornithine (but not of citrulline) across the portal-drained rat viscera (99). Arginine or ornithine supplementation alleviates ammonia toxicity while increasing liver citrulline and urea content as well as plasma urea levels in rats (100). This was interpreted as indicating that arginine increases ornithine decarboxyltransferase activity by increasing ornithine availability. Paradoxically, arginine deficiency in rats was alleviated by citrulline but not ornithine supplementation (101). Citrulline supplementation elevated plasma levels of arginine in the absence of increased splanchnic output of this amino acid, suggesting that arginine was produced from citrulline in nonsplanchnic organs such as the kidney. In fact, in the rat, citrulline, either infused or produced by the liver, is converted to arginine by the kidneys (102).

Arginine as a Metabolic Intermediate

Aside from its role in protein synthesis and as an intermediate in the urea cycle, arginine is a substrate for nitric oxide production (discussed below) and phosphocreatine synthesis as well as a precursor to glutamate, proline, and putrescine via ornithine (Fig. 35.2). Arginine is rapidly converted to ornithine in vivo so that administration of arginine causes a large increase in plasma ornithine levels (103). Many (but not all) of the therapeutic effects of arginine can be attributed to elevated plasma ornithine levels. Ornithine can be converted to glutamate via glutamic semialdehyde (104); however, there is little evidence of an appreciable flux of arginine to glutamate or glutamine in vivo, with the possible exception of the lactating mammary gland (105). By the action of ornithine aminotransferase, ornithine can also be converted to 1-pyrroline 5-carboxylate, a precursor for proline synthesis (104). In fact, much of the proline in extracellular wound fluid may be derived from arginine via ornithine (106). Ornithine is also used in the polyamine synthesis pathway, in which the initial step is the conversion of ornithine to putrescine by ornithine decarboxylase (107, 108). Polyamines play a key role in cellular proliferation for both normal and tumor cells (109). In fact, blockade of polyamine synthesis by inhibition of ornithine decarboxylase combined with limiting dietary intake of polyamines provides effective inhibition of experimental tumor growth

(110).

Arginine as a Source of Nitric Oxide

An important role of arginine is as a substrate for nitric oxide ($\bullet\text{NO}$). Nitric oxide has received considerable attention since its identification as endothelium-derived relaxation factor in 1987 (111, 112). Soon thereafter, arginine was shown to be the biologic precursor of nitric oxide (113, 114). This molecule and citrulline are formed from arginine by nitric oxide synthetase (Fig. 35.3). Three isoforms of this enzyme have been identified; two are constitutively expressed and one is inducible (115). An immense body of literature has been produced concerning the biologic roles and properties of nitric oxide (for recent reviews see [116] and [117]). This molecule plays a role in hypertension (118), myocardial dysfunction (119), inflammation (120), cell death (121), and protection against oxidative damage (122). Nitric oxide may mediate many of the effects of septic shock including vascular (123), myocardial (124), and hemodynamic instability (125). In fact, inhibition of nitric oxide synthesis (or specifically, inhibition of inducible nitric oxide synthetase, which is upregulated in many tissues during sepsis) has been explored as a therapy for septic shock. Inducible nitric oxide synthetase inhibitors increase blood pressure and vascular resistance and cause a decrease in cardiac output (126, 127). However, the utility of such treatments is still in question (125).

Figure 35.3. Biosynthesis of nitric oxide ($\bullet\text{NO}$) from arginine. One of three isoforms of nitric oxide synthase (NOS) combines nitrogen from arginine, oxygen from molecular oxygen (O_2) and electrons from NADPH to form $\bullet\text{NO}$ along with citrulline and NADP^+ .

Nitric oxide synthesis provides protection to tissues after ischemia and reperfusion. During reperfusion, basal tissue nitric oxide synthesis is diminished, causing increased neutrophil adherence and infiltration (128, 129 and 130). Numerous studies have demonstrated that inhibition of nitric oxide synthesis increases ischemia-reperfusion injury, whereas perfusion with nitric oxide or nitric oxide donors decreases injury and neutrophil accumulation (for recent reviews see [131] and [132]). In the lung, inhalation

of nitric oxide gas can lower pulmonary vascular resistance after lung injury, surgery, and heart or lung transplant ([133](#), [134](#)). In other organs, arginine has been successfully used to increase basal nitric oxide synthesis and thus reduce ischemia-reperfusion injury ([128](#), [135](#), [136](#), [137](#) and [138](#)). This effect of arginine could also be due to increased vascular dilation. Extended oral supplementation of arginine to hypercholesterolemic young men with endothelial dysfunction increased endothelium-dependent dilation of the brachial artery during increased cardiac output ([138a](#)).

ARGININE IN CATABOLIC STATES

Arginine Deficiency in Catabolic States

During catabolic states, arginine may become a conditionally essential amino acid. This may be due to a number of contributing factors including an increased rate of arginine degradation ([139](#)), reduced dietary intake ([140](#)), and reduced gut absorption ([141](#), [142](#)), as well as reduced synthesis of citrulline by the gut ([143](#)).

Effect of Arginine upon Intestinal Function and Repair

Arginine has beneficial effects on gut function and repair following trauma or bowel resection. Bacterial translocation in septic rodents is reduced by arginine-supplemented diets ([144](#), [145](#)). This effect was largely abrogated by inhibition of nitric oxide synthesis, suggesting that arginine's beneficial effects may be due to support of the bactericidal function of immune cells. In rats, arginine promoted mucosal repair after intestinal ischemia ([135](#)) and relieved mucosal damage during endothelin-induced ulceration ([146](#)). Both of these effects were abrogated by inhibition of •NO synthesis. Arginine may also promote mucosal growth and repair by supporting polyamine synthesis ([147](#)). Brzozowski et al. found that intragastric injection of arginine accelerated healing of gastric ulcers in rats and that this effect could be attributed to stimulation of blood flow through increased nitric oxide synthesis, stimulation of mucosal growth through polyamine synthesis, and stimulation of plasma gastrin levels ([148](#)).

Effect of Arginine on Wound Healing

Arginine-supplemented diets and TPN can also promote wound healing. This supplementation increased both wound strength and collagen deposition in rats ([106](#), [149](#), [150](#)). Likewise, arginine-deficient diets reduced wound strength and collagen deposition in rats ([151](#)). Arginine promotes collagen synthesis by serving as a substrate for proline synthesis ([106](#)). Healing may also be stimulated by increased growth hormone secretion. This hypothesis is supported by the observation that the beneficial effect of arginine supplementation on wound healing was diminished in hypophysectomized rats ([152](#)).

Effect of Arginine on Endocrine Systems

Arginine administration has pronounced effects upon the adrenal and pituitary systems

of humans. Arginine stimulates release of catecholamines ([153](#)), insulin ([154](#), [155](#)), glucagon ([155](#), [156](#)), growth hormone ([157](#), [158](#)), and prolactin ([159](#)). In addition, arginine increases insulin-like growth factor (IGF-1) levels in elderly patients ([160](#), [161](#)). However, little is known of how arginine exerts these effects upon endocrine systems. Regardless of the mechanisms involved, an increase in hormone levels may be key to some of arginine's positive metabolic effects following trauma and infection. As discussed above, stimulation of growth hormone secretion may play a key role in the support of wound healing by arginine. Stimulation of anabolic steroid levels may contribute to arginine's ability to increase the growth of rats following surgery or trauma ([151](#), [162](#)). Heightened growth hormone levels also counteract muscle glutamine depletion and preserve muscle protein synthesis rates in postoperative patients ([163](#), [164](#)). In addition, growth hormone replacement therapy positively affects natural killer cell activity levels in women ([165](#)).

Arginine and the Immune System

Arginine can alleviate posttraumatic immune depression as characterized by reduced lymphocyte function. Several studies by Barbul and colleagues have demonstrated that intravenous hyperalimentation including arginine abrogates the immune suppression observed in rats after bilateral femoral fractures (see [166](#) and references therein). A study of 30 cancer patients demonstrated that enteral supplementation with arginine can prevent immune depression following major gastrointestinal operations ([167](#)). In addition, enteral feeding with arginine, in combination with RNA and w-3 fatty acids, attenuated immune depression and improved recovery of cancer patients undergoing major gastrointestinal surgery ([168](#), [169](#)). Similar TPN formulas containing arginine, RNA, and w-3 fatty acids improved the immune function and outcomes of ICU patients suffering from persistent sepsis syndrome ([170](#)). Elderly patients and those suffering from chronic infections may also benefit from immune stimulation by arginine supplementation ([160](#), [171](#)).

The mechanism by which arginine stimulates the immune system has not been defined ([172](#)). However, arginine increases thymic weight and cellularity in rats as well as lymphocyte responsiveness to mitogenic stimulation in both rats and humans ([166](#), [167](#), [173](#), [174](#)). Arginine also seems to improve neutrophil function ([171](#)), and arginine promotes the bactericidal capability of rat and murine macrophages by supporting nitric oxide synthesis ([145](#), [175](#), [176](#)). However, this may not be the case for human macrophages, which have not consistently produced nitric oxide in culture ([177](#)).

Arginine in Cancer

In several studies using rodent experimental tumor models, arginine-supplemented diets suppressed tumor incidence, growth, and metastasis ([178](#), [179](#) and [180](#)). In contrast, some experimental tumors are stimulated by arginine-containing diets or inhibited by arginine-free diets ([181](#), [182](#)). Arginine's ability to inhibit tumor growth has been attributed to its effect on immune function. In fact, the inhibitory effect of arginine-supplemented diets may depend upon stimulation of the host's immune system and the immunogenicity of the experimental tumor ([183](#), [184](#)). Arginine-supplemented diets improve nitrogen balance and increase protein synthesis in muscle of

tumor-bearing rats (185). In breast cancer patients, arginine has been reported to increase protein synthesis rate in the tumor (186); however, arginine stimulates lymphocyte and killer cells activity in breast cancer patients as well (186, 187).

[Chapter References](#)

[Selected Readings](#)

Gene expression is a term that has different interpretations. These are dictated by the context in which the term is used. For example, exhibited phenotypes are manifestations of gene expression. Similarly, the mechanics of gene transcription and mRNA translation that influence which proteins are produced also constitute gene expression. From the standpoint of nutritional influences on gene expression, processes are envisioned in which dietary conditions, through either direct interaction of specific nutrients with transcription factors or, more commonly, through indirect means (e.g., hormones or signaling systems) produce changes in transcription of specific genes to yield proteins, including mediators and enzymes, that define phenotypic expression. Alternatively, nutrients can influence gene expression via control of mRNA translation. Again, this can be mediated by direct or indirect means.

HISTORICAL PERSPECTIVE

It is not possible to identify exactly when the fact that specific nutrients influence gene expression was first appreciated. It was clear by the 1950s that essential amino acids, when not available in sufficient amounts, limited the production of proteins. The classic experiments of the Nobelists François Jacob and Jacques Monod in 1961, although conducted in bacteria (*Escherichia coli*), demonstrated that regulatory genes under nutrient control influence genes needed for the synthesis of enzymes involved in the metabolism of that nutrient. In the case studied, lactose (the nutrient inducer) increased the expression of three structural genes (lac operon) coding for lactose metabolizing

enzymes (1).

Experiments with eukaryotic systems followed after the operon model was proposed. Classic experiments of particular note were those demonstrating that polyribosome formation depended upon the presence of essential amino acids in the diet (2). In addition, inhibitors of mRNA synthesis (actinomycin D and cordycepin) and translation (cycloheximide) were used in animal experiments to study, for example, the iron-induced synthesis of ferritin (3), regulation of phosphoenolpyruvic-carboxykinase by high carbohydrate intake and fasting (4), and biochemical and physiologic changes induced by vitamin D (5).

The area of nutrient regulation of gene expression is a well-recognized research emphasis in contemporary nutritional science. In this area of research, it is essential to be able to separate direct effects from those caused by nutrient-induced changes in secondary systems remote from the nutrient's initial effects. Unfortunately, it is difficult to separate direct effects of nutrients on gene expression from those produced indirectly through mediators (Fig. 36.1). Consequently, experiments at the level of individual cells are essential to identify clearly direct effects of nutrients. However, interpretation of cell-level findings must be kept within an integrative context of the whole multicellular organism to fully appreciate how dietary components influence the expression of genes in various tissues. How the external environment, including nutrients, hormones, cytokines, and growth factors, can influence the general process of protein synthesis as well as the differential expression of specific genes provides an excellent opportunity for investigators in the science of nutrition (6). Furthermore, the technical approaches described in this review are relatively low cost and do not require expensive or complex equipment or elaborate instrumentation.

Figure 36.1. Direct and indirect effects of nutrition on regulation of gene expression.

GENOMIC ORGANIZATION AND REGULATION

Our understanding of the complexity of genomic organization has advanced

considerably since the early experiments on nutrient influences on gene expression. The basics of gene expression include activation of the gene to a transcribable structure followed by transcription, transcript processing and splicing, translocation to the cytoplasm, mRNA translation and, for some proteins, posttranslational modification. The general scheme, as shown in [Figure 36.2](#), has been described in exquisite detail ([7](#), [8](#)). The response to changes in nutrient intake likely influences expression of many genes. Since only about 30% of the genes in the total human genome have been identified, it would appear that dietary patterns influence unidentified genes of yet unknown function.

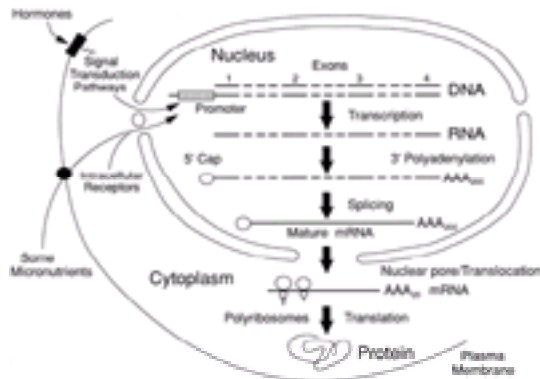

Figure 36.2. Basic aspects of gene expression and protein synthesis. Nutritional regulation of genes can occur directly or through hormones or other mediators that activate signaling systems.

Transcription rates for individual genes can be altered by various mechanisms and represent the major point of gene regulation. Factors influencing the binding of RNA polymerase to DNA, specifically the promoter region of the gene (the 5'-flanking region) and other sequences in close proximity, control transcription. These factors (transcription factors) are proteins with domains that recognize a specific nucleotide sequence (response element) located in the promoter. Response elements are usually short sequences found within the first few hundred nucleotides upstream from the start site of the structural gene. There are exceptions, however. As more promoter sequence information is obtained for upstream (>1000 bases) sequences, it is clear that distant response elements may, through various mechanisms or interactions, influence basal-level transcription rates. Specific transcription factors form dimers or other complex combinations through protein-protein interactions among regulatory proteins or molecules to influence transcription. These aspects of transcription have been reviewed in detail ([7](#)).

The direct interaction of response elements and transcription factors with nutrients has been documented. Examples include the sterol response element for sterol-regulated genes ([9](#)), the calcitriol receptor-response elements for vitamin D-regulated genes ([10](#)), the retinoic acid receptor-response element combinations for vitamin A-regulated genes

(11), fatty acids and some of their metabolites (11A, 11B) and the metal response elements for zinc-regulated genes (12) and associated transcription factors. The human genome contains approximately 100,000 genes, of which 10% may be transcriptionally active at any one time (13). Consequently, many unidentified response elements may be under nutrient control. In addition, cytokines and hormones act by altering gene expression, usually transcription (8), and response elements for these factors may exist at other locations within a gene's promoter that are also influenced by a specific nutrient or dietary pattern. Furthermore, the abundance of some transcription factors in cells can be regulated by physiologic processes that may be influenced by diet.

It is unlikely that a specific gene is regulated by a single response element or even multiple copies of a response element in a promoter. An example of the likely complexity is the phosphoenolpyruvate carboxykinase promoter which, within the first 1 kb of upstream sequence (5' from the transcription start site), has five response-element sequences (cAMP, glucocorticoid, insulin, peroxisome proliferator-activated receptor, and thyroid hormone) and may interact with at least 10 transcription factors (14).

IDENTIFICATION OF GENES REGULATED BY INDIVIDUAL NUTRIENTS OR DIETARY PATTERNS

The following section describes some techniques and approaches of particular interest to investigators studying the effect of nutrition on gene expression. Examples of these techniques from the contemporary literature concentrate on the results of experiments with animals or human subjects fed diets that produce metabolic changes.

Polyacrylamide Electrophoresis of Proteins and Immunoblotting

Extremely valuable information can be obtained by measuring specific gene products (proteins) related to altered phenotypic expression. For such purposes, proteins are most frequently separated by sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE) using any of the innumerable variations of the PAGE format (15). To identify the proteins of interest, proteins are electroblotted to nitrocellulose (or another membrane) from the polyacrylamide gel for specific times to ensure that the proteins are retained on the nitrocellulose. The protein(s) of interest is usually detected immunologically by a process referred to as western blotting.

Immunodetection methods allow investigators to examine a specific protein among the thousands of tissue proteins transferred to the membrane. The spectrum of antibodies available for these applications (western blot) from commercial sources is substantial. Alternatively, many investigators working on newly identified or rare proteins use antibodies produced to chemically synthesized peptides corresponding to a specific region of the intact protein that is likely to be highly antigenic. These peptides usually correspond to 20 to 30 amino acids of the protein. Frequently, the amino acid sequence is deduced from the cDNAs of genes for which the gene product has not yet been isolated and sequenced (16). This approach allows examination of the nutritional regulation of proteins encoded by newly identified genes. Furthermore, the sensitivity of some immunodetection methods allows examination of proteins present in low

abundance.

Small proteins or peptides used to elicit antibodies are conjugated to keyhole limpet hemocyanin or another protein to enhance antigenicity. Larger proteins are most frequently used without conjugation. Antibodies are most frequently raised in rabbits, but goats and sheep are often used (15). Immunization of chickens and recovery of antibodies from egg yolk is gaining in popularity (17). Mammalian polyclonal antibodies are usually purified by protein A or G chromatography to obtain the IgG fraction. Frequently, these are further selected by chromatography using a support to which the protein or peptide antigen has been coupled to yield a monospecific IgG population.

Monoclonal antibodies are also widely used in nutrition-related studies on gene expression. The availability of hybridoma facilities has greatly furthered production of monoclonal antibodies derived from proteins and peptides generated by the procedures described above.

Protocols for incubating the blotted proteins on nitrocellulose with the primary antibody (immunoblot) vary widely (15). Options for detection via a secondary antibody include colorimetric detection, binding of ^{125}I -labeled protein A, or the very sensitive method in which the secondary antibody provides a luminescent signal detected by x-ray film (or a luminescence detector). The latter approach has become very widely used. In Figure 36.3, GLUT4 (see Chapter 3) protein levels in transgenic mice are determined by ^{125}I -labeled protein A which binds to anti-GLUT4 antibody (18). The response to high-fat or high-carbohydrate diets shows that overexpression of the GLUT4 transgene results in considerably more transporter protein being produced.

Figure 36.3. SDS polyacrylamide gel electrophoresis of proteins from muscle (gastrocnemius) or adipose (white adipose tissue) homogenates from transgenic mice that overexpress the *GLUT4* gene. Western blotting: proteins were transferred to membranes, incubated with antiserum against GLUT4 protein, and detected with ^{125}I -protein A. The transgenic mice were fed control (-), high fat or high carbohydrate (+) diets for 14 weeks. (From Ikemoto S, Thompson KS, Takahashi M, et al. Proc Natl Acad Sci USA 1995;92:3096–9, with permission.)

Immunohistochemistry and Immunocytochemistry

Advances in microscopy have dramatically increased the use of fluorescent antibodies for intracellular localization of specific proteins. Epifluorescence, confocal, and 3D deconvolution microscopic techniques can all take advantage of fluorescently tagged antibodies. Flow cytometry can also be used effectively in nutrition-related research, particularly that focused on immunology (19). In the future, these approaches will see further application in experiments focused on nutrition, especially in human studies in which sample sizes are small.

Northern Analysis

The universal availability of cloned gene sequences through computer-searchable databases provides the opportunity to use this information to identify nutritionally regulated genes (13). Northern analysis (northern blotting) gives researchers interested in examining genes that are nutritionally regulated a powerful experimental technique. Using DNA sequence information, it is possible to produce oligonucleotides (oligomers, oligos) that can be used directly for northern analysis or, as described below, as primers for production of complementary DNA (cDNA) probes by polymerase chain reaction (PCR) methods. Alternatively, there are commercially available probes for specific genes, and most investigators are willing to share cDNAs for use as probes for northern analysis studies.

The task of identifying which genes are regulated by nutrient intake level and specific diet formulations or consumption patterns is formidable indeed. Northern analysis has clearly been a workhorse for these studies to date. Hundreds of examples could be cited. The original method has been modified innumerable times (15). Similarly, tissue RNA extraction procedures have evolved, and currently, guanidinium isothiocyanate-based methods, some with proprietary formulations, are almost universally used.

The purpose of northern analysis is to detect a specific mRNA and determine its relative static abundance. The method involves agarose gel electrophoresis (AGE) of the RNA extract, transfer to a filter (nylon or nitrocellulose), binding the RNA to the filter by UV-induced cross-linking, and hybridization to a ^{32}P -labeled DNA probe (15). The hybridization is detected by autoradiography or phosphorimaging instrumentation, but nonradioactive alternatives are evolving. Intensity of the RNA-DNA hybridization is usually quantified by video densitometry. Another constitutively produced mRNA should be concurrently examined as a control for equal loading of the RNA extracts being compared. b-Actin and glyceraldehyde-3-phosphate dehydrogenase cDNAs are frequently used for comparative purposes. Ethidium bromide staining of RNA separated by AGE prior to transfer can also be used. Results of typical northern blot analyses are shown in Figure 36.4. In panel A, leptin mRNA levels (see Chapter 87) are lower in fasted rats than in those refed and/or given insulin (20). In panel B, metallothionein mRNA levels (see Chapter 11) are virtually undetectable in zinc-deficient rats compared with levels in rats fed adequate amounts of zinc (21). Here, northern blot data are used

to assess nutritional status.

Figure 36.4. A. Northern analysis of total RNA from adipose tissue of rats showing the effects of food intake and insulin on leptin mRNA (*ob gene*) expression. b-Actin mRNA is the control for gel-loading efficiency. *Left panel* shows the relative abundance of the leptin mRNA as determined by densitometry as well as the plasma glucose concentration. *Right panel* shows the actual northern blot of leptin and b-actin mRNA. (From Saladin R, De Vos P, Guerre-Millo M, et al. *Nature* 1995;377:527–9, with permission.) **B.** Northern analyses of total RNA from rats showing the effect of zinc deficiency (-Zinc) on kidney metallothionein mRNA, compared with rats fed adequate amounts of zinc ad libitum (Control) or pair fed. b-Actin is the control mRNA. (From Blanchard RK, Cousins RJ. *Proc Natl Acad Sci USA* 1996;93:6863–8, with permission.)

As described in the section on antisense techniques, solution hybridization and RNase protection assays provide an alternative to northern analysis for estimating the mRNA abundance of a gene suspected of being influenced by nutrition. Dot blots are occasionally used in screening experiments; however, since no size separation of the RNA is involved, the method requires that the probe used produces a signal specific for the mRNA of interest (15). Recent advances in the technique of in situ hybridization using fluorescent probes allow estimation of the intracellular abundance of a specific mRNA (22).

Polymerase Chain Reaction

The PCR technique has been used in experiments focused on nutrition and gene expression. PCR can provide multiple copies of a DNA or RNA sequence. Two oligonucleotide primers (a 5' primer and a 3' primer) that span the targeted sequence of interest must be synthesized (15, 23). Repeated sequential polymerase reactions of the target sequence in both directions under controlled temperatures with a thermocycler allow the targeted sequence to be amplified as a double-stranded cDNA copy in sufficient quantity for further use. Frequently, the amplified DNA is cloned by standard

methods and purified by AGE as needed (15, 24).

Reverse transcriptase–PCR (RT-PCR) is used to produce cDNA copies of mRNA. The mRNA is first converted to cDNA with reverse transcriptase, using a specific 3' primer for the target mRNA (25). PCR is then performed with another specific primer to provide sufficient quantities of the DNA sequence of interest for purification and/or analysis by AGE. RT-PCR is usually semiquantitative at best, since the amplification process is exponential and differences in mRNA levels usually encountered with nutritionally regulated genes are not large enough for the technique to be widely applicable. Nevertheless, RT-PCR is valuable for production of cDNAs for use in northern analysis experiments (26). Availability of cDNA sequence information allows development of primers for production of a specific cDNA by PCR and subsequent cloning to retain the cDNA for labeling and use in hybridizations as needed.

In contrast, competitive RT-PCR (C-RT-PCR) provides a measure of amplification efficiency and an internal control of known concentration so that the C-RT-PCR technique is quantitative (25, 27, 28). Consequently, this approach is very attractive for nutrition experimentation, particularly in human studies or others in which the number of available cells is very small (29). The steps in C-RT-PCR are shown in Figure 36.5 (30). C-RT-PCR requires construction of a third primer to generate a cDNA to act as the internal control competitor. In practice, prior to PCR, the mRNA is reverse transcribed soon after RNA isolation, since cDNA is more stable during storage. The method has been applied to zinc status assessment in humans (30).

Figure 36.5. Competitive reverse transcriptase-polymerase chain reaction (C-RT-PCR). Extracted RNA is reverse transcribed to cDNA and, together with a competitor cDNA of known concentration, is amplified by PCR. Comparison of amplification to the competitor concentration allows determination of the relative abundance of the original mRNA. (Modified from Sullivan VK, Cousins RJ. J Nutr 1997;127:694–8, with permission.)

PCR can be used to identify allelic differences in genotypes that may respond differently

to nutrients. A notable example is the polymorphism in the human vitamin D receptor (VDR) gene and its corresponding link to bone mineral density (BMD) (31, 32). Expression of the osteocalcin gene is regulated by the VDR, a *trans*-acting transcription factor that requires 1,25(OH)₂ vitamin D₃ (calcitriol) as a ligand for binding to the vitamin D response element of the osteocalcin promoter. For these experiments, PCR was used to amplify genomic DNA from each subject. Subsequent AGE separation of the DNA, after restriction enzyme digestion, produced bands of different lengths for the two alleles of the VDR gene. The genotypes were differentiated in this way. This approach was also used to examine the positive effects of dietary fat modulation of plasma low-density-lipoprotein (LDL) cholesterol in individuals with the *apoE4* allele (33). The approach has wide application for genes that produce differences in the use or actions of nutrients and thus serve as biomarkers for differences in nutritional effects.

Promoter Analysis

A number of experiments within the past decade have shown direct interactions between specific nutrients and transcription factors regulating the expression of specific genes. Metabolites of fat-soluble vitamins, trace metals, sterols including cholesterol, and fatty acids are examples. In each case, an initial interaction between the nutrient and a receptor or transcription factor(s) is followed by a direct interaction of the transcription factor with specific nucleotide sequences within the nucleus. Typically, this occurs in the promoter/regulatory region located upstream from the start site of the coding sequence.

The approach taken to examine transcriptional regulation generally follows one of two techniques. The first is the nuclear run-on experiment. This requires generating purified nuclei from cells or tissues from animals fed a specific diet or provided a nutrient of interest. The nuclei are incubated in the presence of α-³²P-UTP to produce a radioactive RNA transcript. The transcript is then detected by hybridization to a specific probe (15). Since this ³²P-nucleotide is only incorporated into mRNA during transcription, the change in the rate of transcription produced in response to the nutrient is believed to reflect regulation at the level of transcription. A number of genes for hepatic proteins involved in carbohydrate and lipid metabolism have been shown by nuclear run-on assays to have altered transcription rates in response to a high carbohydrate diet (34, 35). However, these experiments provide little information about mechanisms involved in transcriptional regulation.

Another approach to promoter analysis enables determination of specific sequences involved in gene expression but requires sequence information about the genes of interest. In this technique, the promoter region, usually a few thousand bases (kb) of the 5' flanking region, is excised with appropriate restriction enzymes and ligated to a reporter gene. Usually the chloramphenicol acyltransferase (CAT) or β-galactosidase (β-Gal) genes are used as reporters. The heterologous promoter-reporter construct must be transfected into a cell type of interest. The cell type is critical since transcription factors are specific to certain cells. Reporter genes generate products that may be analyzed by liquid scintillation counting or thin layer chromatography (for CAT) or colorimetrically (for β-Gal). The approach has been used for a number of nutritionally relevant genes (11A, 11B, 34, 36, 37 and 38). Promoter/reporter gene systems can be

used as an in vitro model for examining the responses of a promoter to specific nutrients, hormones, or drugs. The leptin gene promoter/reporter construct is an example of this potential (39).

Using deletion analysis with restriction enzymes, the location of the nucleotide sequence(s) of a promoter that is essential for the nutrient regulation can be identified. Mutational analysis of the promoter can define the exact nucleotides needed for specific regulation. Frequently, the latter analysis shows that the response element (sequence) is not always completely uniform. Consequently, response elements are usually reported as consensus sequences.

Differential Hybridization

The technique of differential hybridization, or plus-minus screening, allows comparison of a gene's expression with two dietary treatments or different periods of development (40, 41). A plasmid cDNA library is produced by reverse transcription of mRNA from one of the treatment groups. The cDNA is made double-stranded, ligated into a vector, and used to transform competent *E. coli*. In addition, a single-stranded cDNA probe is separately generated from mRNA of the other treatment groups. After *E. coli*-containing recombinant plasmids are grown with antibiotic selection, the plasmid DNA is cross-linked to nylon filters. The DNA-containing filters are hybridized separately with the single-stranded cDNA probes (after ³²P labeling). The signals generated in autoradiographs will be similar except in a few cases. The latter potentially represent differentially expressed genes. The colony hybridization procedure is usually repeated for confirmation that a signal is different with the two different probes. Finally, a northern analysis is carried out using cDNAs from the bacterial colonies in which differential signals originated. These cDNAs must then be sequenced and searches of genome databases (e.g., the BLAST search program for GenBank) carried out to identify what genes the recovered sequence represents. This procedure has been used for intestinal genes responsive to dietary zinc intake (41).

Differential mRNA Display

An elegant approach to examine differential gene expression was developed in 1992. Differential mRNA display is based on reverse transcription combined with PCR. It enables identification of mRNAs that increase or decrease in quantity in response to various conditions (42). Differential display was designed initially to identify genes differentially expressed in transformed and nontransformed cells. Recently, the technique has been used to identify genes regulated or influenced by micronutrients: zinc (21, 43, 44), selenium (45), and copper (46, 47).

Isolation of RNA from tissues is the first step in this technique. Reverse transcription of the RNA uses an oligo d(T) primer that has two non-T bases at the 3' end. This is the "anchored primer" because it anchors cDNA synthesis at the end of the poly(A) tail and 3' untranslated region. Four anchored primers, each with a different nucleotide, are used independently for cDNA synthesis to obtain the full array of sequences that can be displayed (Fig. 36.6). The anchored primer used for the RT reaction and one of 24 decanucleotide primers (arbitrary primers) are used for cDNA amplification by PCR.

These constitute the 3' and 5' primers, respectively. A ^{32}P - or ^{33}S -labeled nucleotide is included in this PCR reaction. The resulting labeled cDNA then represents one of 24 possible subsets of mRNAs from the original RNA used for analysis. The four anchored primers, when used with the 24 arbitrary primers, require 96 separate PCR reactions to provide a thorough differential display from a given tissue or cell type. A few mRNAs may not be recognized because of a lack of sufficient poly(A) tail sequence or poor priming with the random primers used. As shown in [Figure 36.6](#), differential mRNA display can be viewed as a library with four floors (one for each anchored primer) and 24 shelves with many books (one for each arbitrary primer). When all shelves on all floors have been read, all of the information has been viewed.

Figure 36.6. Differential mRNA display. Cell RNA is converted to cDNA, which is amplified by PCR using one anchored primer (3') and one arbitrary primer (5'). These are analogous to a floor and stack in a library, respectively. The cDNA products are then separated by polyacrylamide gel electrophoresis and compared as shown in [Figure 36.7](#).

Figure 36.7. Differential display of intestinal mRNA from zinc-deficient rats. The mRNA is converted to cDNA by reverse transcription. cDNA is amplified by PCR with one of four anchored primers (3') and one of 24 arbitrary primers (5'), followed by PAGE of the cDNAs run in duplicate (as outlined in [Fig. 36.6](#)). RNA was from rats fed a zinc-deficient

($-Zn$) diet or zinc-adequate diet provided ad libitum ($+Zn$) or pair fed (*P.F.*). The display series to the *left* shows a cDNA (**A**) derived from an mRNA increased in $-Zn$ while the display series to the *right* shows a cDNA (**B**) derived from an mRNA decreased in $-Zn$. (From Blanchard RK, Cousins RJ. Proc Natl Acad Sci USA 1996;93:6863–8, with permission.)

Denaturing polyacrylamide gel electrophoresis (PAGE) and autoradiography allow separation and isolation of individual cDNA bands ([Fig. 36.7](#)). Bands are usually up to 400 bp, but newer variations of the original method may significantly increase that size, thus increasing the probability of sequence identification. The cDNA bands resulting from mRNAs of animals fed under differing dietary conditions are resolved by PAGE and those that differ in intensity are considered manifestations of altered levels of a specific mRNA (i.e., one that is differentially expressed). In the example, there are cDNAs that increase and decrease in relative abundance during zinc deficiency ([21](#)).

Subsequently, the cDNA band from a differentially expressed mRNA is cloned into a plasmid to maintain a renewable source of the cDNA. Verification of differential expression requires northern analysis using the cDNA in question (after ^{32}P labeling) and RNA from other experimental animals subjected to the same dietary conditions. If northern analysis confirms differential expression, this cDNA is sequenced, and its identity is determined through genome database searches as described above. Some searches do not reveal any previously reported sequences. Other searches identify a specific gene sequence, a gene of close homology, or an expressed sequence tag (EST). The latter represents a partial cDNA sequence of an unidentified gene. As more of the genomes of humans and experimental animals are sequenced, the EST data will become more useful.

Positional Cloning

An excellent example of positional cloning is that of the *ob* gene ([48](#)). This led to identification of a new peptide hormone, leptin, which, when secreted by adipocytes, regulates food intake and energy expenditure and influences non-insulin-dependent diabetes in obese individuals ([49](#)). This research was based on observations of mutations in mouse strains made over four decades earlier. (See [Chapter 87](#) for more information.)

The first step in this approach is obtaining genetic maps to identify the locus of the mutation of interest. In many cases the chromosomal location of a mutation is known in the murine and human genomes. For genes that influence nutrition, phenotypic expression (i.e., the development of obesity) is used to segregate the mutant gene through specific genetic crosses. Linkage studies position the gene relative to molecular markers or known/identifiable areas of the genome. Establishing linkages to known genes helps greatly, particularly if they are “tightly linked” to the gene of interest. In the case of the *ob* gene, the region of chromosome 6 where the *ob* gene was located had been identified by two flanking markers. Using this location information, the appropriate

region of the DNA is cloned. The use of yeast artificial chromosomes (YACs), specific restriction enzyme digests, and specific crosses refine the location. Subsequent screening of restriction digests will yield smaller sections of DNA, some of which will hybridize to RNA from a tissue in which the gene is expressed. Using this DNA as a probe, the mRNA of interest is identified, the cDNA sequence of the gene can then be established, and eventually, as in the case of leptin, the primary sequence of protein product deduced (48).

Experiments of this type are extremely time consuming and expertise in molecular genetics is essential. Nevertheless, the results have great benefit for understanding important aspects of nutrition. The fruits of such efforts are usually extensive, rapid, and enlightening. A database search for leptin reveals recent studies on the use of leptin protein and analytical assays (50), production of corollary animal models (51), therapeutic opportunities (49, 52), and additional components, such as neuropeptide Y (53), of the system of body composition regulation.

MANIPULATING GENES REGULATED BY INDIVIDUAL NUTRIENTS OR DIETARY PATTERNS

Transgenic Animals

The opportunity to overexpress a gene and thus increase production of a gene product has significant potential for nutrition research. Genes responsive to specific nutrients can be beneficial or deleterious when overexpressed.

The transgenic overexpression technique involves production of a construct consisting of a promoter and structural gene. The promoter can be the gene's normal promoter (homologous) or a different promoter (heterologous). A purified sample of the construct is injected into fertilized eggs (usually murine or porcine) and, if the construct DNA becomes integrated into the genome of some eggs, transgenic animals will be produced from them after full gestation in foster mothers. Southern (DNA) blotting or PCR is required for detection of the unique DNA construct to initially distinguish transgenic animals from their nontransgenic littermates. Selective breeding can produce homozygous lines of animals carrying transgenes.

A salient example of the transgenic approach used the metallothionein gene promoter to direct expression of the growth hormone (GH) gene in mice and pigs (54, 55). In pigs, additional GH was produced and secreted that greatly increased lean body mass. Since the metallothionein gene is induced by dietary zinc (56), adding extra zinc to the food or drinking water was used to increase expression of the transgene. This approach was used to produce transgenic animals with a construct composed of the metallothionein promoter and LDL receptor structural gene (57). Injection of the inducer metal activates the promoter and yields a lowered circulating cholesterol level within hours, coincident with increased production of the LDL receptor protein.

Other examples of the use of transgenic animals to address questions of nutritional interest are available. The glucose transporter (GLUT4) was overexpressed in mice

using the aP2 fatty acid-binding protein promoter and a genomic DNA fragment containing the entire human GLUT4 gene as the construct (58). Overexpression was detected by increased GLUT4 protein in membranes from both white and brown fat (Fig. 36.8). These transgenic mice also had higher glucose transport rates, lower glucose tolerance curves, and more body fat than littermates. In contrast, overexpression of metallothionein, a zinc/copper-binding protein, did not produce very dramatic gross effects on body composition or growth (59) but influenced zinc homeostasis (60). The genes for phosphoenolpyruvate carboxykinase, copper/zinc superoxide dismutase, hepatic lipase, lipoprotein lipase, and several apolipoproteins (see Chapter 74 and Chapter 75) have been overexpressed in transgenic mice (61, 62, 63, 64, 65, 66 and 67). Table 36.1 lists some genes of nutritional interest that have been overexpressed in transgenic mice.

Figure 36.8. Overexpression of the human *GLUT4* gene in transgenic mice. *Top panel*, the transgene construct consisting of the mouse aP2 fatty acid-binding promoter ligated to 6.3 kb of human genomic DNA that includes all 11 exons of the *glut4* transporter gene. Bottom panels, Growth and body composition comparisons for control (*crosshatched bars*) and *GLUT4* transgenic mice (*solid bars*) fed a normal diet. (From Shepherd PR, Gnudi L, Tozzo E, et al. *J Biol Chem* 1993;268:22243–6, with permission.)

Gene Overexpressed	Ref.	Metabolic Consequences
Low-density lipoprotein receptor	57	Increased disappearance of LDL from circulation
GLUT4 glucose transporter	18, 58	Increased body fat; glycomic control maintained with a high-fat diet
Metallothionein 1 and 2	59, 60	Protection against zinc deficiency and reduced zinc absorption
Phosphoenolpyruvate carboxylase	61	Development of non-insulin-dependent diabetes mellitus
Copper/zinc superoxide dismutase	62	Enhanced tolerance of pancreatic β cells to oxidative stress
Hepatic lipase	63	Decreased total plasma cholesterol
Lipoprotein lipase	64	Reduced plasma VLDL
Apolipoprotein A-I	38, 65	Increased HDL cholesterol levels; increased HDL cholesterol and apoA1 levels after fenofibrate treatment
Apolipoprotein C-III	66	Increased VLDL cholesterol and hypertriglyceridemia
Apolipoprotein B	67	Increased LDL cholesterol levels
Cellular glutathione peroxidase	61a	Increased GPX1 in BBRLA; normal lipid peroxidation

Table 36.1 Transgenic Mice Overexpressing Genes of Interest in Nutrition Research—Examples

An encouraging aspect of the application of transgenic animals for nutrition research is that as these strains become more available through the Jackson Laboratory and other specialized distributors or from individual investigators, major new insights into nutrient metabolism and function will emerge.

Gene Knockout (Null Mutation) Animals

Gene knockout technology provides the opportunity to delete expression of a specific gene (null mutation). As a result, the normal gene product is not produced. Consequently, this technology is the engineered counterpart to spontaneous mutations that occur in laboratory animals and are propagated by selective breeding. The *ob* gene mutation of mice is an example of a spontaneous mutation.

Knockout technology in animals has, thus far, been applied exclusively to murine genes. In some cases, the animals die prior to birth if a critical gene product is not produced. Numerous examples of this phenomenon have been reported. Deletion of the C/EBPa gene, which is required for energy (glucose) utilization, is an example relevant to nutrition (68). In some instances of deletion of a gene that may appear critical for nutrient metabolism (e.g., metallothionein for zinc metabolism), mice bearing the null mutation still reproduce and develop normally, albeit metabolic abnormalities can be demonstrated (60, 69). Similarly, a null mutation in the cellular retinoic acid-binding protein I gene (CRABPI), which is believed to be required for the function of vitamin A (retinol) via the metabolite retinoic acid, produces animals that appear to have a normal phenotype (71). These latter results indicate that, in some instances, another gene product provides the same phenotypic effect through redundancy of functional roles of specific genes or a gene family. Redundancy of function can obscure the true function of the deleted gene. Deletions of the genes for b₂-microglobulin, metallothionein, a-lactalbumin, Cu/Zn superoxide dismutase, cellular glutathione peroxidase, and apolipoprotein E have been reported to have metabolic consequences (72, 73, 74, 75, 77, 78 and 78a). Table 36.2 shows examples of nutrient-related consequences detected in mice with null mutations.

Gene Deletion	Ref	Metabolic Consequence
C/EBP α Metabolism 1 and 2	68, 69, 70, 77, 78	Hypoglycemia (both); increased zinc absorption
Cellular retinoic acid-binding protein 1	71	No effect
β_2 -Microglobulin	72	Iron overload (increased absorption)
α -Lactalbumin	77	Increased milk viscosity; increased milk cholesterol; pups cannot remove milk from mammary gland
Copper/zinc superoxide dismutase	74	O ₂ sensitivity
Apolipoprotein E	75, 76, 79–82	Severe hypercholesterolemia when fed low-fat, low-cholesterol diet; reduction of atherosclerotic lesion development by estrogen; atherosclerotic lesions in females; severe atherosclerosis resulting from impaired uptake of LDL cholesterol from macrophages; increased plasma LDL cholesterol levels
Low-density lipoprotein receptor	66	Increased plasma LDL cholesterol levels
Cellular glutathione peroxidase	70a	Decreased tissue glutathione peroxidase activity and total liver antioxidant content

Table 36.2 Knockout (Null Mutation) Mice with Deleted Genes of Interest in Nutrition Research—Examples

In an interesting extension of the knockout technique, transgenic mice overexpressing apolipoprotein A-I were bred to apolipoprotein E null mice. The offspring had higher HDL levels and increased atherosclerotic lesions (79). Similarly, a mouse model with features of familial combined hyperlipidemia can be produced by crossing transgenic mice carrying the human apolipoprotein C-III to mice null for the LDL receptor (66).

The technique of creating a knockout animal model or null mutation is more correctly called “gene targeting by homologous recombination.” Animal cells are diploid, i.e., they contain two copies (alleles) of a gene. The targeted gene is disrupted in one allele (producing heterozygotes with the null mutation), and homozygous genotypes are then produced by selective breeding of the heterozygous strain.

There are two approaches to developing knockout mice. The original approach is to isolate the murine gene under investigation, identify the exons by mapping, delete part of an exon, and replace it with the gene encoding neomycin resistance (thus producing a marker for selection). An entire exon can also be deleted. This construct is the gene targeting vector. The targeting vector is linearized and transfected into embryonic stem (ES) cells by microinjection or electroporation. The transfected cells are then injected into the blastocysts of mice at 3.5 days of pregnancy and introduced into pseudopregnant mice. Chimeric pups are often identified by the agouti coat color provided by genes from the ES cells. Selective breeding to obtain a null mutant (– / –) follows (15, 83).

The second and more recent approach allows cell type–specific targeting of a gene deletion (84, 85). The gene is engineered to have specific sequences (lox P sites) on either side and, by ES cell technology, a transgenic line is created carrying the target gene and flanking lox P sites. Another transgenic strain is produced with a construct comprising the Cre recombinase gene and a promoter (e.g., Mx1) that can be activated by an inducer (e.g., Interferon- α [IFN α]) in a tissue-specific manner. These mouse strains are crossed and, when IFN α is injected into offspring, the Cre gene product

(CRE recombinase; a bacteriophage enzyme) acts at one of the lox P sites, deleting the target gene in a specific tissue/cell type where the CRE gene product is produced (84, 85).

These techniques, while specialized, are yielding murine strains that will be generally available for nutritional and metabolic studies. As with transgenic overexpressing mice, commercial suppliers may act as a resource for such animals.

Inhibition of Specific Gene Expression by Antisense Oligonucleotides and Transgenes

Antisense RNA has recently been used as a research tool for questions of nutritional interest. There are three ways in which antisense sequences can be used. Computer searches of the literature usually do not differentiate between these uses.

The first is the use of antisense RNA as probes in solution hybridization/RNase protection assays. When sequence information is known, specific oligonucleotides can be generated and used to obtain information about the relative abundance of a specific mRNA. Tissue RNA is hybridized with the ³²P-labeled antisense RNA probe, treated with RNase to hydrolyze single-stranded RNA, and then the protected ³²P-labeled RNA (hybridized RNA) is precipitated and separated by electrophoresis followed by autoradiography. Abundance is measured by densitometry. Once the assay has been established, the precipitated ³²P-labeled hybrid is measured by liquid scintillation counting for comparison of mRNA abundance. This approach has been used to examine GLUT4 transporter expression and glucagon receptor expression (86, 87).

The second application of antisense oligonucleotides is selective permanent inhibition of a targeted RNA (88). Usually, oligonucleotides are at least 12 to 25 nucleotides long to provide the specificity needed for identification of a unique mRNA. Sites where targeting is most effective are the double-stranded regions of secondary mRNA structure. This approach has been used in experiments with cells. To address directly questions of nutritional interest, antisense sequences can be used to generate transgenic mice. The antisense sequences are introduced by the construct used for microinjection. Mice carrying the transgene continually produce antisense sequences that neutralize the effect of the targeted mRNA, thus preventing formation of the gene product. Consequently, these transgenics have altered phenotypes. This approach has received limited use in experiments focused on nutrition and gene expression (89, 90).

The third use of antisense sequence information is for transient inhibition of translation of specific mRNAs by hybridization. This approach has received attention because of the potential therapeutic use of antisense oligonucleotides. The exact mechanisms of their action are also actively investigated (reviewed in [88, 91]). These oligonucleotides appear to be taken up by cells in the brain and some tissues. The approach has been recently applied to inhibition of mRNAs for peptides involved in regulation of feeding behavior and body weight (92, 93, 94 and 95). In these cases, antisense DNA sequences are introduced into specific areas of the brain. Examples of use of this

technique are shown in [Table 36.3](#).

Gene	Ref.	Metabolic Consequence
Neuropeptide Y (NPY)Y1 receptor	92	Increased food intake
Neuropeptide Y	93	Increased food intake and body weight
Corticotropin-releasing factor	94	Increased food intake
Oxytocin	95	Decreased salt intake

Table 36.3 Antisense Oligonucleotide-Inhibited Gene Expression—Examples

SUMMARY

The area of nutrition and gene expression is gaining interest rapidly and is now a recognized research discipline in nutritional sciences. As our knowledge of animal and human genomes expands, the technologies described here and new approaches still to be developed will have a profound impact on nutrition as a field and on our understanding of how the diet influences genetic expression.

ACKNOWLEDGMENTS

The author expresses his appreciation to Drs. Barbara A. Davis of Virginia Polytechnic Institute and State University and Cathy W. Levenson of Florida State University for their review of this chapter and valuable comments, and to Mr. Walter M. Jones for drawing some of the figures.

Abbreviations: **PCR**—polymerase chain reaction; **PAGE**—polyacrylamide gel electrophoresis; **RT**—reverse transcriptase; **AGE**—agarose gel electrophoresis.

[Transmembrane Signaling Defects Leading to Disease](#)

[Chapter References](#)

[Selected Readings](#)

The evolution of life forms from unicellular to multicellular organisms necessitated a mechanism for cells to communicate with each other. One of the primary modes of cellular communication is the release of soluble factors from one cell or organ to influence the metabolism and biology of another. These soluble factors—which include hormones, neurotransmitters, growth factors, and cytokines—are generally hydrophilic molecules that cannot cross the hydrophobic plasma membrane of cells. A system is therefore required to recognize these extracellular signals and transmit the information across the plasma membrane to direct appropriate changes in the intracellular environment. This tutorial focuses on the basic principles underlying this signaling system, with an emphasis on those mechanisms pertinent to physiology and nutrition. Then, we see how aberrations in this signaling system can result in diabetes, cancer, and a host of other metabolic disturbances.

Any transmembrane signaling system requires several features. First, there must be specificity in responding to a given extracellular signal. Recognition of this signal will then generate a specific response. This response should also be specific to the cell type or organ involved. Next, the response to a specific signal must be rapid. An efficient mechanism is required to shut off that signal when it is no longer needed. Finally, there must be a means of regulating a host of processes that will ultimately produce the biologic response desired (1).

Extracellular signals are recognized through their specific binding to cell surface *receptors*. These receptors, generally transmembrane proteins, interact with an intracellular effector system that often results in production of small soluble molecules (*second messengers*) that diffuse through the cell to mediate the actions of the given extracellular stimulus (Fig. 37.1). The concept of a second messenger was first proposed by Sutherland in 1959 when he identified cyclic AMP as a second messenger capable of mimicking the effects of the hormone epinephrine. Sutherland proposed that the hormone is the first messenger released into the bloodstream to interact with a specific membrane receptor on the target tissue. The specific binding of the hormone to its cell-surface receptor leads to generation of a second, intracellular messenger that then mediates the intracellular actions of the given hormone. This model of hormone action has been borne out for many different extracellular signals. Although there are

few second messenger systems, they are used by a myriad of different extracellular stimuli. Along with cyclic AMP, the other main second messengers mediating hormone action include cyclic GMP, calcium, and diacylglycerol. In most cases, GTP-binding proteins (*G-proteins*) act as molecular switches to couple receptor binding to the enzymes that generate the specific second messenger. All these signaling pathways share a final common mechanism in activating *protein kinases* that alter subsequent enzyme activities through covalent addition of a phosphate group to serine, threonine, or tyrosine residues of various proteins. Although many hormones act through the generation of second messengers that then stimulate specific protein kinases, some directly lead to protein kinase activation by binding to receptors that have intrinsic tyrosine kinase activity. Regardless of the route leading to protein kinase activation, subsequent changes in protein phosphorylation alters the activity of proteins involved in nutrient flux, transcription of specific genes, protein synthesis, and cellular trafficking of proteins.

Figure 37.1. General schematic overview of ligand-receptor pathway of biologic effects.

The steroid hormones are more hydrophobic and capable of crossing the plasma membrane. They bind specifically to a soluble receptor in the cytoplasm. The hormone-receptor complex then enters the nucleus to function as a DNA-binding protein that directly affects transcription of specific genes. We will not cover this nuclear hormone signaling mechanism here but, instead, will focus on transmembrane signaling at the plasma membrane. The prototypical signaling pathways through which the vast majority of other hormones act and, finally, how aberrations in these signaling mechanisms may underlie diseases from cancer to diabetes are described in detail below.

The rapid advances in understanding transmembrane signal transduction have been aided by the use of several powerful techniques. Recombinant DNA technology (see [Chapter 36](#)) has permitted the rapid cloning of members of signaling families, i.e., structurally and functionally related groups of proteins. The hundreds of different receptors can be grouped into only a few large families of receptor types. The

introduction of several mutants and inhibitors of signaling pathways into cultured cells has allowed further dissection and understanding of the transmembrane signaling pathway. Finally, the development of transgenic animals in which a particular gene and protein can either be overexpressed or “knocked-out” allows integration of cellular signaling pathways with physiologic studies.

RECEPTORS

The initial step in transmembrane signaling involves the binding of the extracellular signal or hormone to a cell-surface receptor. Receptors provide the first level of specificity by their presence on only certain tissues and cell types. These receptors have several characteristics that poise them for recognition of extracellular signals (2). First, they have *high affinity* for the *ligand* (hormone or other extracellular signal that binds to the receptor). This is necessary because most hormones circulate in the bloodstream at concentrations below 10^{-8} M. This high affinity enables cells to respond to small changes in hormone concentration. Receptors are also *specific* for their ligand or hormone. This means that insulin binds only to the insulin receptor, whereas glucagon binds only to the glucagon receptor. Various structural analogues of a given hormone bind to their receptor with differing affinities that correspond to their biologic activity. For example, insulin binds to the insulin receptor with 50 times higher affinity than proinsulin and is 50-fold more potent than proinsulin in stimulating glucose uptake. Receptor binding can be plotted as shown in [Figure 37.2](#). Agents can be found that have higher affinity for a receptor (potent *agonists*), whereas others may bind to receptors with high affinity but not trigger the usual transmembrane signaling and biologic responses (*antagonists*). These principles have led to the development of a large number of widely used pharmacologic therapies.

Figure 37.2. Concentration dependence of the effects of an agonist and an antagonist relative to native hormone on a typical biologic response.

Hormone-receptor interactions can be studied by a variety of techniques. The receptor number and affinity on a particular target cell is classically measured using a *Scatchard*

analysis (Fig. 37.3). By allowing labeled hormone to compete with unlabeled (cold) hormone for receptor binding, the amount of hormone bound to receptor is determined at a number of hormone concentrations. This amount of bound hormone is plotted against the ratio of bound to free hormone, typically yielding a straight line. The slope of this line is the negative value of the association constant ($-K_a$), which indicates the receptor affinity for the hormone or ligand. The intercept on the abscissa represents the total receptor concentration (R_T).

Figure 37.3. Diagram of Scatchard analysis, showing the relationship of slope to $-K_a$ and of the intercept to the total number of receptors.

A given hormone can bind to several different receptors, each of which communicates with a unique intracellular effector system. For example, epinephrine can bind to both α - and β -adrenergic receptors. β -Adrenergic receptors are coupled to a cyclic AMP-generating second-messenger system, whereas α -adrenergic receptors use calcium as their second messenger or act by decreasing the level of cyclic AMP (3). Further specificity of action is obtained by the presence of various receptor subtypes located in different tissues. For example, β_1 -adrenergic receptors are present primarily in the heart, where they function to stimulate heart rate and increase the force of cardiac contraction. β_2 -Receptors, on the other hand, are primarily located in the lungs, where they cause bronchial dilation. This specificity in receptor subtype tissue distribution has been used to develop specific pharmacologic agents with high affinity for particular receptor subtypes (e.g., β_1 -adrenergic receptor-blocking agents that selectively decrease heart rate without causing bronchoconstriction or β_2 -agonists that cause bronchial dilation with minimal effects on cardiac function).

The ligands that bind to receptors can take many forms. Initially, the study of receptors focused on protein hormones as the ligands of interest. Since that time, a variety of ligands including neurotransmitters, cytokines (proliferating and differentiating agents of the hematopoietic and immune systems), and various growth factors also have been shown to act through receptor binding to specific cell-surface receptors. Metabolites

also can act as ligands through binding to specific receptors. For example, fatty acids released by fat metabolism can bind to a specific transcription factor receptor (peroxisome proliferator-activating receptor, PPAR α) to stimulate specifically adipose cell differentiation. Another “ligandlike” agent is light, which, through photoisomerization of 11-*cis*-retinal, stimulates a specific receptor in the eye to begin the transmembrane signaling cascade responsible for vision (see [Chapter 17](#)).

Receptor Types

Receptors can be divided into four major types: (a) G-protein-linked receptors; (b) enzyme-linked receptors; (c) ion-channel-linked receptors; and (d) steroid hormone receptors. *G-protein-linked receptors* use a GTP-binding protein to couple the receptor to the particular effector system that, typically, generates a second messenger (i.e., cyclic AMP, cyclic GMP, inositol trisphosphate, or diacylglycerol). *Enzyme-linked receptors* either have intrinsic enzyme activity or are tightly coupled to proteins with enzyme activity. As discussed above (see [Chapter 17](#) and [Chapter 18](#)), steroid/retinoid hormone receptors are located in the cytoplasm and/or nucleus where they recognize steroid hormones that have diffused across the plasma membrane. These receptors still possess the same basic properties of receptors described above (i.e., high affinity and specificity), but they have several unique features as described in other chapters. Ion channel receptors, also termed *ligand-gated channels*, act to increase ion flux (usually calcium, potassium, or sodium) across the plasma membrane, either as direct conduits for ion flow or through coupling to ion channels (see [Chapter 38](#)). The following sections focus on the G-protein-linked and enzyme-linked receptors.

G-Proteins

Over the last 25 years, many receptors linked to effector systems by trimeric GTP-binding proteins (G-proteins) have been described. These proteins regulate the activity of a specific plasma membrane enzyme or ion channel in response to receptor binding. This transmembrane signaling pathway, first described by Gilman, uses a trimeric GTP-binding protein as a molecular switch to activate the appropriate effector system rapidly. Hormone binding leads to G-protein activation through the binding of GTP. The G-protein, which is active in the GTP-bound state, can then move through the plasma membrane to modulate the appropriate effector system. G-Proteins have an intrinsic GTPase activity that hydrolyzes the bound GTP to GDP, inactivating the G-protein. This permits both the rapid turning on (binding of GTP) and turning off (hydrolysis by GTPase) of the signal that is needed to respond to rapid fluctuations in hormone levels.

Several different types of G-proteins couple to specific plasma-membrane enzyme-effector systems leading to generation of soluble second messengers (5). Cyclic AMP was the first second messenger discovered. Subsequent research showed that a specific G-protein (G_s) couples receptor binding to the activation of the enzyme that generates cyclic AMP (*adenylate cyclase*). As a second messenger, the cyclic AMP that is generated mediates all the intracellular actions of the hormone. The rapid generation of cyclic AMP can be turned off by hydrolysis with phosphodiesterase, providing a transient response to a given signal ([Fig. 37.4](#)). In addition, the G protein

has an intrinsic GTPase activity that hydrolyzes the GTP bound to G_s , restoring G_s to the inactive form. Finally, a different G-protein (G_i), when activated by other receptors, leads to direct inhibition of adenylate cyclase activity and, thus, cyclic AMP generation. A host of hormones act through this G_s –adenylate cyclase–cyclic AMP mechanism (Fig. 37.4).

Figure 37.4. Schematic overview of the pathway from receptor through a G-protein signaling cascade involving formation of cyclic AMP.

Several naturally occurring bacterial toxins have been instrumental in unraveling the role of G-proteins in cyclic AMP signaling and disease processes. Cholera toxin was discovered to attach the ADP-ribose moiety from NAD to the G_s protein, thereby blocking its GTPase activity (also see Chapter 23). The resulting inability of the G_s protein to turn off its signal leads to prolonged elevation of cyclic AMP levels in the intestinal epithelium. In turn, this causes the large efflux of sodium ions and water into the gut that is responsible for the severe diarrhea of cholera. Similarly, pertussis toxin (from the bacteria causing whooping cough) transfers ADP-ribose from NAD to the G_i protein, thereby preventing interaction of G_i with its receptor, rendering G_i unable to lower cyclic AMP levels. In this situation, the prolonged elevation in cyclic AMP in the bronchial epithelium appears to contribute to cellular necrosis.

Different receptors are coupled to different G-proteins, and the same hormone sometimes can either decrease or increase cyclic AMP levels, depending on which receptor it binds to. For example, epinephrine can bind to both the α - and β -adrenergic receptors. The β receptor for epinephrine is coupled to G_s , and therefore, the binding of epinephrine increases cyclic AMP levels; whereas the α_2 -adrenergic receptor is coupled to G_i , so that epinephrine binding leads to a decrease in cyclic AMP levels. The specificity of these responses is governed by the receptor and its specific localization in a particular tissue (Table 37.1).

Target Tissue	Hormone	Major Response
Heart	Epinephrine	Increase in heart rate; increase force of contraction
Liver	Glucagon	Glycogen breakdown; gluconeogenesis
Kidney	Vasopressin	Water reabsorption
Fat	Epinephrine	Triglyceride breakdown
Muscle	Epinephrine	Glycogen breakdown
Thyroid gland	TSH	Thyroid hormone synthesis and secretion
Adrenal gland	ACTH	Cortisol secretion
Ovary	LH	Progesterone secretion

Table 37.1 Some Hormones That Act Through Cyclic AMP

Actions of Cyclic AMP. Cyclic AMP actions are mediated by the stimulation of *cyclic AMP-dependent protein kinase*. This protein kinase family phosphorylates a series of different proteins leading to activity changes that account for the hormone's biologic actions. Activation of protein kinases upon receptor binding is a fundamental aspect of hormone action. The first delineation of these protein phosphorylations responsible for hormone action was in the pathways for skeletal muscle glycogen metabolism.

The release of epinephrine in response to a threat to an animal (the fight-or-flight response) leads to rapid mobilization of muscle glycogen for fuel requirements. As illustrated in [Figure 37.5](#), the binding of epinephrine to the β -adrenergic receptors on skeletal muscle leads to activation of G_s and adenylate cyclase. The cyclic AMP that is formed and released activates cyclic AMP-dependent protein kinase, which then phosphorylates phosphorylase kinase. This enzyme, upon the covalent addition of a phosphate group, becomes an active kinase that phosphorylates the enzyme phosphorylase. Phosphorylase is converted to the active form by this phosphorylation so that it may catalyze the hydrolysis of glycogen to glucose-1-phosphate, which can now enter the glycolytic pathway and the tricarboxylic acid cycle to provide metabolic energy for muscle activity. Knowledge of this phosphorylation cascade in muscle energy metabolism has served as the paradigm for hormone regulation of metabolic processes in other systems.

Figure 37.5. The glycogen cascade, illustrating the sequence of phosphorylation events that lead to glycogenolysis.

The different G-protein-coupled receptor signaling mechanisms (cyclic AMP, calcium, diacylglycerol) all share certain basic properties. In general, they involve the generation of mediators that initiate a cascade of intracellular reactions (well characterized in the example of epinephrine regulation of glycogen metabolism in [Figure 37.5](#)). One inherent advantage of this cascading signaling mechanism is *amplification* of the signal as it is relayed along the chain. For example, a single signaling molecule or hormone binds to one receptor that can then activate several G-proteins, each of which may activate its coupled enzyme (i.e., adenylate cyclase). Each adenylate cyclase may catalyze formation of multiple cyclic AMP molecules, each of which may activate one cyclic AMP-dependent protein kinase. This kinase can then phosphorylate multiple molecules of other kinases; thus, the cascade continues to amplify as it travels “downward” toward the ultimate target. The advantage of such an amplification system is that a very small amount of hormone (often in the nanomolar range) can lead to a thousandfold increase in the level of a second messenger, leading to a robust biologic response. The circulating concentration of hormone must be quite low to enable the organism to respond to small changes and to ensure that the given hormone does not bind to other, somewhat similar, but lower-affinity, receptors that may exist within a given receptor family. In addition, systems with multiple steps have the potential for additional regulation from other factors at each step in the pathway. The additional regulation allows fine-tuning of the signal as well as the ability to override a given stimulus under appropriate circumstances.

Counterbalancing Mechanisms. For this exquisitely sensitive amplification system to be useful, there must be powerful counterbalancing mechanisms to shut off the signal and restore the resting state. This is accomplished at several levels of the signal transduction system. First, after hormones bind to receptors they are often internalized for destruction of the ligand. Next, as described above, G proteins are inactivated by their intrinsic GTPase activity. In addition, second messengers such as cyclic AMP are rapidly hydrolyzed by phosphodiesterase. In the case of intracellular calcium as a second messenger, intracellular pumps exist to remove cytosolic calcium, thereby

returning the cell to the resting state.

Organisms have also developed mechanisms to desensitize themselves to a continuous stimulus. Prolonged stimulation by a growth factor, for example, could have devastating effects on homeostasis. Desensitization mechanisms provide another level at which a signal can be shut off (4). The most common form of desensitization is through decreasing hormone receptor number (i.e., regulation of receptor number at the cell surface). Therefore, despite continued presence of the hormone in question, transmembrane signaling is blunted because there are fewer receptors to bind the hormone. Recently, a new mechanism of signal desensitization has been described for the b-adrenergic receptor. Prolonged receptor stimulation leads to activation of a b-adrenergic receptor kinase that phosphorylates the receptor, causing it to uncouple from the G_s protein.

The cyclic AMP signaling system can also control transcription of specific genes. Cyclic AMP-dependent protein kinase phosphorylation of the cyclic AMP response element-binding protein (CREB) enhances CREB's binding to a specific site on the promoter of a gene termed the *cyclic AMP response element* (CRE). This protein-DNA (CREB-CRE) interaction results in changes in transcription of the particular gene containing the CRE, altering gene expression (see [Chapter 36](#)).

Analogous to the cyclic AMP system, another enzyme, guanylate cyclase, produces cyclic GMP that specifically activates a cyclic GMP-dependent protein kinase. This system is particularly important in the response of the photoreceptors of the eye to light. As shown below, a related system is implicated in the actions of atrial natriuretic factor—a regulator of renal fluid handling and vascular tone.

Calcium As a Second Messenger

The next major second-messenger system involves increases in *intracellular calcium*. Cells maintain an intracellular calcium concentration of about 10^{-7} M in the face of an extracellular calcium concentration of 10^{-3} M. This 10,000-fold concentration gradient is maintained by a number of plasma membrane-associated calcium-ATPase pumps that remove calcium from cells. These pumps can be either voltage-gated as in excitable cells (i.e., they release calcium in response to changes in cellular depolarization) or, in most cells, not regulated. The pool of intracellular calcium that is regulated in these cells resides in the endoplasmic reticulum and in a newly described calcium-storage site called the *calciosome*. The first evidence that calcium can serve a messenger role within the cell came from experiments in which injection of calcium into skeletal muscle cells resulted in muscle cell contraction. Since that time, an elegant transmembrane signaling system has been unraveled in which the turnover of phosphatidylinositides leads to a rise in intracellular calcium.

Hokin and Hokin (6) first suggested a role for phosphoinositide turnover in cellular signaling in 1953 when they observed that various extracellular signaling molecules stimulated incorporation of ^{32}P from ATP into plasma membrane phosphoinositides. This was later explained by the rapid breakdown and resynthesis of

phosphatidylinositols in response to these stimuli (6). In particular, the breakdown of phosphatidylinositol bisphosphate generates two second messengers: *inositol 3,4,5-trisphosphate (IP₃)* and *diacylglycerol*. Analogous to the generation of cyclic AMP, a specific G-protein (G_q) couples receptor binding to activation of a phosphoinositide-specific phospholipase C that hydrolyzes phosphatidylinositol to generate these two intracellular messengers (7).

IP₃ is released into the cytoplasm where it binds to a receptor on the sarcoplasmic reticulum, leading to release of calcium into the cytoplasm. IP₃ is then dephosphorylated to shut off this calcium release signal. In addition, IP₃ can be phosphorylated to inositol 1,3,4,5-tetrakisphosphate, a molecule that has been implicated in the sustained release of calcium from the endoplasmic reticulum that is observed in response to stimulation by some hormones. *Calcium-binding proteins* within cells mediate the effects of increased intracellular calcium. For skeletal muscle contraction, troponin binds calcium to initiate actin-myosin-mediated contraction. A more ubiquitous mediator of intracellular calcium is the calcium-binding protein calmodulin. A family of serine/threonine protein kinase (*calmodulin-dependent protein kinases*) is stimulated by this calcium-binding protein. Analogous to the situation with cyclic AMP, some extracellular stimuli result in G-protein-mediated generation of an intracellular signal (calcium) that then activates a protein kinase (calmodulin-dependent protein kinase), leading to a host of biologic responses (8).

One of the first-described calmodulin-dependent protein kinases was phosphorylase kinase, the enzyme that activates phosphorylase in skeletal muscle glycogen breakdown. As described above (Fig. 37.5), this enzyme is part of the phosphorylation cascade, in which it acts as a substrate for cyclic AMP-dependent protein kinase, thereby mediating cyclic AMP effects on glycogenolysis. However, in addition, a rise in intracellular calcium from signal-initiated phosphatidylinositol breakdown and IP₃-mediated calcium release directly activates phosphorylase kinase by binding to the calmodulin subunit of this enzyme. In this way, the same calcium signal that initiates muscle contraction also ensures that there is adequate glucose to power the contraction. Smooth muscle also contracts in response to extracellular signal-mediated calcium release through activation of myosin-light chain kinase, another calmodulin-dependent protein kinase. Several other calmodulin-dependent protein kinases have been described, with varying tissue localization and substrate specificities.

Diacylglycerol and Protein Kinase C

G-protein-coupled phosphatidyl inositol hydrolysis leads to generation of another messenger besides IP₃, namely diacylglycerol. Diacylglycerol, in conjunction with calcium, stimulates another kinase, protein kinase C. This enzyme has several isoforms, some of which are translocated from the cytosol to the plasma membrane in response to hormone stimulation. Generation of diacylglycerol in the plasma membrane is crucial for activation of certain isoforms of protein kinase C. Protein kinase C phosphorylates various substrates, leading to a wide variety of biologic effects. Like most signaling molecules, diacylglycerol is short-lived, either being reincorporated into phosphoinositides as part of the phosphatidylinositol turnover process or hydrolyzed to

arachidonic acid, the precursor of the prostaglandins (see [Chapter 4](#)). Prolonged stimulation of protein kinase C appears to mediate some of the proliferative and differentiation responses that are observed for some cells. It appears, however, that sustained levels of diacylglycerol are supplied by a second pathway involving stimulation of phosphatidylcholine hydrolysis.

The list of hormones and extracellular signals that act through the IP₃/diacylglycerol signaling system is extensive ([Table 37.2](#)). Just as the effects of hormones that use cyclic AMP as their second messenger can be reproduced by exogenous addition of this small molecule, diacylglycerol effects are mimicked by the protein kinase C activator, phorbol ester, while the calcium ionophore A23187 mimics the effects of IP₃ release. Using A23187 and phorbol esters, many of the effects of the hormones in [Table 37.2](#) can be mimicked in cell culture.

Target Tissue	Signaling Molecule	Major Response
Pancreas	Acetylcholine	Amylase secretion
Smooth muscle	Acetylcholine	Contraction
Liver	Vasopressin	Glycogen breakdown
Blood platelets	Thrombin	Aggregation
Mast cells	Antigen	Histamine release

Table 37.2 Hormones That Act, with Calcium, through Phosphatidylinositol Phosphate Breakdown

Crosstalk among Signals

An increased level of complexity exists whereby one signaling mechanism or messenger system can interact with another—this is termed *crosstalk* ([Figure 37.6](#)). As examples, several interactions between the cyclic AMP and calcium messenger systems have been discovered, and some forms of the enzyme that hydrolyzes cyclic AMP (phosphodiesterase) are regulated by calcium/calmodulin interactions. Cyclic AMP-dependent protein kinase can also phosphorylate the IP₃ receptor, altering its sensitivity to IP₃-induced calcium release. More than one signal may influence the same downstream kinase. We have mentioned above how the enzyme of glycogen metabolism, phosphorylase kinase, is activated by both cyclic AMP-dependent protein kinase phosphorylation and through the binding of calcium to its calmodulin subunit. It appears that the cyclic AMP-dependent phosphorylation of phosphorylase kinase makes the enzyme more sensitive to calcium, allowing skeletal muscle glucose

metabolism to respond more robustly to the initiation of muscle contraction in response to a fight-or-flight stimulus. Recently, interactions within the same signaling cascade have been uncovered. As we will see below, it now appears that insulin stimulation of the signaling protein ras (see below) also can lead to some effects on phosphatidylinositol-3-kinase that were initially believed to represent a separate pathway activated in response to insulin receptor binding.

Figure 37.6. Schematic overview of potential crosstalk between two hormone-responsive receptor-mediated pathways.

G-Proteins Linked to Ion Channels Directly

As discussed in more detail in the next chapter (see [Chapter 38](#)), many receptors directly activate ion channels; however, in some cases G-proteins can link receptor binding to the opening of ion channels. For example, acetylcholine, through the muscarinic receptor, activates G_i , which along with lowering cyclic AMP levels, directly opens potassium ion channels. Other cyclic nucleotide-regulated channels (through adenylate cyclase or calmodulin-dependent protein kinase) similarly are coupled to ion channels; some of these play a crucial role in the chemical senses, vision and smell.

RECEPTORS AS ENZYMES

Not all extracellular signals mediate their responses through the classic mechanism of G-protein-coupled generation of intracellular messengers. Some receptors bypass the G-proteins and second messengers and directly initiate the final common pathway that transduces the signals for the vast majority of extracellular stimuli; this common pathway involves protein phosphorylation. The best studied receptors in this group are the *tyrosine kinase receptors*. A large family of different growth factors uses this transmembrane signaling system ([Table 37.3](#)). Several mutations in the signaling molecules described below lead to unrestrained cellular growth and cancer. The tyrosine kinase receptors have an extracellular surface (domain) that contains a

hormone-binding site and an intracellular domain with tyrosine kinase activity. In each case, receptor binding by its cognate ligand causes dimerization of the plasma membrane receptor, which activates the intrinsic tyrosine kinase activity, leading the receptor to phosphorylate itself (*autophosphorylation*). These tyrosine phosphorylated sites then act as high-affinity binding sites for various intracellular signaling molecules that contain specific protein sequences called an SH2 domain (*src* homology 2, based on their initial identification in the *src* cancer gene) (1). Different receptors bind different combinations of these signaling molecules, providing one level of signal specificity. Autophosphorylation functions as a switch for the transient assembly of intracellular signaling molecules. Insulin and insulin-like growth factor-1 (IGF-1) (8) differ somewhat from other hormones in that activation of their receptor tyrosine kinases leads to phosphorylation of other proteins (primarily insulin receptor substrates, IRS-1 and IRS-2) which then, similar to one another, function as assembly anchors for a variety of other signaling molecules. The identification of some extremely insulin resistant patients whose disease results from mutations in the insulin receptor that block tyrosine kinase activity has helped confirm the central role of tyrosine phosphorylation in insulin action.

Insulin
IGF-1 (insulin-like growth factor-1; somatomedin-C)
Epidermal growth factor (EGF)
Platelet-derived growth factor (PDGF)
Colony-stimulating factor-1 (CSF-1)
Fibroblast growth factor (FGF)

Table 37.3 Protein Ligands That Signal through Tyrosine Kinases

The phosphotyrosine anchor, in the form of the autophosphorylated receptor or IRS-1, binds a variety of signaling molecules through its SH2 domains. The ras/MAP kinase system is one of the best studied pathways integral to cell growth that is activated by the phosphotyrosine anchor binding described above. *Ras* is a small, monomeric, GTP-binding protein that, like the trimeric G-proteins discussed above, is active in the GTP-bound state and inactive when GDP is bound. *Ras* plays a central role in the regulation of cell differentiation and growth. In fact, the *ras* proteins were first discovered based on mutations that promote cancer by disrupting the normal controls on cell proliferation and differentiation (9, 10). About 30% of human cancers have mutations in the *ras* gene. Two intermediate proteins function to couple receptor binding and tyrosine phosphorylation to the activation of *ras*. *Sos* (son-of-sevenless, named on the basis of its original identification in *Drosophila* development) is a guanine nucleotide-releasing protein, which results in the release of GDP from *ras*. Since *ras* is present on the cytoplasmic side of the plasma membrane and the cytosol contains 10 times more GTP

than GDP, once ras has lost its GDP, it is activated by binding GTP. A second protein, Grb-2, binds to both the phosphotyrosine group on either the tyrosine kinase receptor or IRS-1 and the Sos-Ras complex to bring them together. In this way, tyrosine kinase receptor binding leads to activation of ras ([Fig. 37.7A](#)).

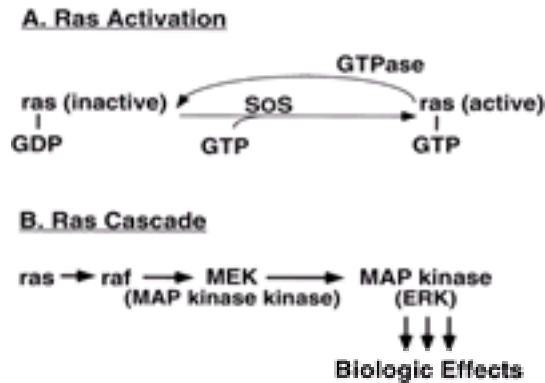

Figure 37.7. *A.* The *ras* activation pathway. *Sos*, son-of-sevenless, an intermediate protein that functions to couple receptor binding and tyrosine phosphorylation to the activation of *ras*. *B.* The *ras* cascade leading through intermediate protein kinases to biologic effects. *raf*, a protein kinase also known as MAP kinase kinase kinase; *MAP*, mitogen-activated protein; MAP kinase and *ERK*, alternative nomenclatures.

As discussed above, the final mechanism through which transmembrane signaling leads to intracellular events involves activation of various protein kinases, and this is true for the tyrosine kinase receptors as well. Ras activation initiates another specific protein kinase cascade leading to activation of *MAP kinase* (*mitogen-activated protein kinase*, also sometimes called extracellular-regulated kinase [ERK]). Ras activates the protein kinase known as *raf* (or MAP kinase kinase kinase) which phosphorylates and activates MEK (MAP kinase kinase) which activates MAP kinase through phosphorylation. MAP kinase relays signals downstream by phosphorylating various proteins within the cell, including other protein kinases and nuclear DNA-binding proteins involved in gene regulation ([Fig. 37.7B](#)).

Several studies have indicated that the *ras*/MAP kinase pathway plays a central role in mediating the growth-promoting effects of the tyrosine kinase receptor family of hormones. As mentioned above, activated mutants of *ras* result in unrestrained cell growth and cancer. In general, it seems that activating mutations in any component of this signaling pathway results in uncontrolled growth. In fact, many of the signaling molecules just described were first identified as mutant forms in cancer cells or cancer-promoting tumor viruses. These mutant genes were called *oncogenes* (cancer genes) before their origins from normal genes were understood; therefore, the normal genes are now sometimes called *proto-oncogenes*.

Insulin, although capable of acting as a growth factor in cell culture, has a host of metabolic effects not shared by the growth factors in the tyrosine kinase receptor family. The signaling molecules mediating these effects are still incompletely understood. One signaling molecule that appears to play a central role is *phosphatidylinositol 3-kinase (PI 3-kinase)*. PI 3-kinase catalyzes phosphorylation of the inositol ring of phosphatidylinositol at the 3 position. PI 3-kinase contains an SH2 domain that binds to a specific phosphorylated tyrosine group on IRS-1, leading to its activation. Growth factors other than insulin and IGF-1 whose autophosphorylation provides direct anchoring for SH2-containing molecules can bind PI 3-kinase directly. The mechanisms through which PI 3-kinase activation leads to biologic responses are still unclear. Recently, several possible downstream targets have been identified, including specific subtypes of protein kinase C and a newly identified protein kinase called Akt or protein kinase B (based on its intermediate homology to protein kinases A and C).

Much of the evidence implicating an important role for PI 3-kinase in insulin factor signaling has come from the use of specific inhibitors of the enzyme. It appears, for example, that PI 3-kinase activation is critical for both the growth-promoting effects of insulin and for many of the metabolic effects of insulin such as glycogen synthesis, glucose transport, and gluconeogenesis. In contrast, the ras/MAP kinase pathway appears to be involved primarily in the growth-promoting actions of insulin and is not necessary for many of the classic metabolic actions of this hormone.

In addition to the receptor tyrosine kinases described above, some receptors, although not containing an intrinsic kinase activity, rapidly associate with a tyrosine kinase upon receptor binding. Many of the cytokines (soluble factors involved in proliferation and differentiation of the hematopoietic and immune systems), the antigen-specific receptors of B and T lymphocytes, and certain protein hormones (growth hormone, prolactin, and possibly the adipostat, leptin [see [Chapter 87](#)]) act through such a pathway. The binding of cytokines, antigens, or hormones to these specific receptors leads to receptor aggregation and activation of specific tyrosine kinases that can then initiate the biologic responses directed by the given stimulus.

One important example of such a system is the *JAK-STAT* regulatory pathway. For certain cytokines, as well as the adipose tissue–signaling molecule leptin, receptor binding leads to the binding of JAK, a tyrosine kinase. JAK thus activated phosphorylates various proteins, perhaps the most important of which is the transcription factor family, STAT (signal transducer and activator of transcription). STAT proteins then migrate to the cell nucleus where they influence the transcription of responsive genes.

Another group of enzyme-linked receptors are those receptors that are protein tyrosine phosphatases. When activated, these receptor enzymes remove phosphate groups from phosphotyrosine proteins. One example of this family of tyrosine phosphatase receptors is CD45, a transmembrane receptor protein that has an integral function in the immunologic activation of B and T lymphocytes by foreign antigens.

Enzyme-linked receptors can also be linked to guanylate cyclase. The prototype for this

is the receptor for atrial natriuretic factor (ANF). This hormone, released from the heart, stimulates the kidneys to excrete sodium ions and water, and thereby stimulates smooth muscle cell relaxation. The extracellular domain of the ANF receptor binds ANF, leading to activation of the intracellular portion of the receptor that is a guanylate cyclase. The cyclic GMP that is formed then stimulates a cyclic GMP–dependent protein kinase, analogous to the actions of cyclic AMP on cyclic AMP–dependent protein kinase that were described above.

TRANSMEMBRANE SIGNALING DEFECTS LEADING TO DISEASE

Given the myriad physiologic responses that depend on transmembrane signaling, it is not surprising that disturbances in these signaling pathways lead to disease. In fact, one might expect that many mutations in signaling molecules would be lethal. There are, however, several well-described defects underlying specific diseases. What is even more intriguing is the evidence that aberrations in signaling may underlie many common diseases. Modern molecular biologic tools have only recently made it possible to investigate the role of discrete signaling defects in human disease. As discussed above, many of the signaling molecules involved in growth factor and insulin action were discovered on the basis of mutations that lead to cancer. We shall first discuss examples of defects in particular sites of transmembrane signaling and then focus on the possible involvement of signaling disturbances in some common diseases ([Table 37.4](#)).

Receptor defects
Color blindness
Retinitis pigmentosa
X-Linked diabetes insipidus
G-protein defects
Cholera
Pertussis
Pseudohyperparathyroidism
Tyrosine kinase pathway defects
Many human cancers
Postreceptor defects likely
Non-insulin-dependent diabetes mellitus (NIDDM)
Possibly congestive heart failure, obesity

Table 37.4 Abnormal Transmembrane Signaling in Human Disease

Receptor Defects

Mutations may occur in receptors that affect the initial step in transmembrane signaling. These mutations often lead to decreased responsiveness or resistance of the cell to the stimulus in question. The first disorder discovered to be secondary to a defect in a G-protein-coupled receptor was color blindness, in 1989. Red and green cone opsins are essentially retinal light receptors. These light receptors, when stimulated by various

light frequencies, are coupled to a specialized G-protein (transducin) that mediates stimulation of a specific cyclic AMP phosphodiesterase. A mutation has been found in the light receptor (opsin, see [Chapter 17](#)) that causes color blindness. Similarly, a mutation in the light receptor of the rod cells (rhodopsin) causes retinitis pigmentosa.

Several other receptor mutations have been uncovered as the cause for disease. Mutations in the growth hormone receptor are responsible for Laron-type dwarfism. The characteristic phenotype of this disease is altered growth hormone transmembrane signaling in various tissues, including the musculoskeletal system, leading to short stature. In X-linked nephrogenic diabetes insipidus, a mutation in the vasopressin receptor makes the kidneys insensitive to the urine-concentrating effects of vasopressin. As mentioned above, several specific insulin receptor mutations have been found in a small subset of patients with severe insulin resistance and non-insulin-dependent diabetes mellitus (NIDDM). A characteristic of all the receptor defects described above is marked elevation in hormone levels in an attempt to compensate for the hormone resistance.

G-Protein Defects

As discussed above, the bacteria that cause cholera release a toxin that causes ADP-ribosylation of the G_s subunit and results in constitutive activation of adenylate cyclase. This constitutively elevated cyclic AMP signal leads to excessive transport of sodium and water across the intestinal lumen, culminating in severe diarrhea. G-protein abnormalities underlie other diseases as well. Pseudohypoparathyroidism (Albright's hereditary osteodystrophy) is a disorder in which the bones are resistant to the calcium-mobilizing effects of parathyroid hormone. Parathyroid hormone is coupled to G_s and adenylate cyclase activation. A genetic defect in G_s blocks parathyroid hormone action.

Diabetes

The most common form of diabetes mellitus, NIDDM, (type 2, or adult-onset diabetes), has long been known to result from a combination of resistance to the actions of insulin and a relative deficiency of insulin secretion. Early characterization of the insulin receptor indicated that a change in insulin receptor number or hormone-binding affinity could not explain this insulin resistance. This led to the concept that NIDDM results from a postreceptor defect in insulin action. Several sites in the newly discovered insulin signaling pathway have been examined as potential sites of this lesion. Adipose cells from diabetic patients have decreased tyrosine kinase activity; but, when tested in vitro, this does not seem to account for the insulin resistance observed clinically. Several families have been identified with mutations in the insulin receptor leading to blunted transmembrane signaling and profound insulin resistance. At present, many genes encoding signaling molecules are being screened in the hopes of discovering the central lesions in NIDDM.

Recently, an intriguing hypothesis has been proposed to explain the long-known clinical phenomenon whereby hyperglycemia itself exacerbates peripheral insulin resistance.

Hyperglycemia, through a yet unexplained mechanism, appears to stimulate protein kinase C activity. In an example of crosstalk between signaling cascades, this protein kinase C can phosphorylate specific serines on either the insulin receptor or IRS-1, rendering it a poorer substrate for the tyrosine phosphorylation reaction involved in insulin signaling and, consequently, desensitizing the cell to insulin's action. To what extent this type of crosstalk can explain the pathogenesis of diabetes mellitus remains to be determined.

Obesity

Obesity is probably the most common disease in the Western world. A powerful link between obesity and insulin resistance has long been described. Obesity leads to hyperinsulinemia that—likely through receptor desensitization—causes a decrease in insulin receptor number. However, the mechanism through which obesity leads to insulin resistance (presumably a transmembrane signaling defect) remains to be established.

One possible receptor defect that may contribute to a genetic predisposition to obesity is alterations in the β_3 -adrenergic receptor. This receptor appears to mediate the thermogenic effect of brown adipose tissue. Several new pharmacologic tools are currently under development to stimulate this receptor in the hopes of increasing fuel metabolism and weight loss. Recently, a mutation has been identified in this receptor that appears to be present in several population groups at high risk for development of obesity and insulin resistance. Whether altered β_3 -adrenergic signaling significantly contributes to obesity awaits the results of further investigation.

An exciting new insight into the pathogenesis of obesity came with discovery of a new hormone, leptin, released from adipose tissues. Leptin appears to act as an adipostat by signaling the brain regarding the amount of adipose tissue stores. Administration of exogenous leptin to deficient rodents leads to decreased food intake, increased metabolic activity, and weight loss. However, in humans with obesity, leptin levels appear quite high, suggesting that obesity may represent a state of leptin resistance. With the recent cloning of a leptin receptor, studies are under way to determine what defects in leptin-receptor signaling may explain development of obesity.

Finally, as signaling pathways involving many hormones, neurotransmitters, cytokines, and growth factors are uncovered, searches for defects in human disease are moving rapidly. Congestive heart failure may result from a signaling defect. Several studies have suggested reduced β -adrenergic receptor function in these patients. Some data have suggested that an increase in the β -adrenergic receptor kinase, a serine kinase that phosphorylates the β -receptor leading to receptor desensitization, may be activated in congestive heart disease. The net result of this β -receptor desensitization would be a reduced response to the cardiostimulatory effects of epinephrine. Asthma has been linked with defects in β_2 receptors. Defects in brain transmembrane signaling systems have been implicated in several neuropsychiatric conditions including alcoholism, schizophrenia, and Alzheimer's disease. Clearly in the coming years, as our understanding of transmembrane signaling expands, new insights into several disease

states will be on the horizon.

All nutrients have to cross one or more cell membranes before reaching their final destination in the organism. For more than 100 years, scientists have used a variety of approaches to inquire into the nature of these movements. The outcome has been nothing short of prodigious: detailed molecular mechanisms of membrane permeation are now well on their way to full elucidation.

This inquiry started with the realization that cells have an internal composition that differs markedly from their surrounding environment. Since both the intracellular and the extracellular environments are aqueous solutions, an envelope, the cell membrane, is necessary to prevent complete mixing of the two solutions. Moreover, cells are not static, impermeable structures; many substances continuously enter and leave the cytoplasm. Hence the membrane must be understood in terms of both the substances allowed to pass through and those that are held back.

Our understanding of selective movement of substances through biologic membranes stems from formulating biologic problems in terms of physical processes. A major step in such a formulation is establishing the relationship between the forces acting on a substance and its movement across the membrane. Such an approach reveals a great deal about the organization of the membrane and has provided the basis for definition of the several fundamentally different molecular mechanisms of membrane permeation.

This chapter attempts to provide the nonspecialized reader with an overview of the different types of mechanisms for membrane permeation and their regulation. Instead of a simple summary of current findings and theories, it describes how the major concepts in the field were developed. The purpose of this approach is not merely historical but to illustrate how new concepts originate from careful analysis of experimental observations.

STRUCTURE OF THE MEMBRANE

The first major insight into the chemical nature of the cell membrane dates from 1895, when the English physiologist Ernest Overton, working in Switzerland, compared the rates at which a large number of diverse compounds penetrated the cell membrane. He found that the ability of substances to penetrate the cell membrane correlates with their solubility properties (1).

The capacity of a substance to dissolve into a given solvent is a function of both the structure of the solvent and the solute. At one end of the spectrum is water and all the solutes that dissolve readily in it. Compounds that readily mix with water are called *hydrophilic*. This property arises because hydrophilic solutes have a molecular structure that strongly interacts with water molecules. At the other end of the spectrum we have *hydrophobic* compounds, so called because their molecules do not interact with water, and therefore they separate from it. Hydrophobic solutes dissolve well in hydrophobic solvents; extreme examples of hydrophobic solvents are oils, such as olive oil.

Overton discovered that the higher the solubility of a compound in oil, the faster it penetrates cell membranes, i.e., the higher is its membrane permeability. He reasoned that oil-soluble substances passed through the membrane faster because they can dissolve in the membrane; hence, the membrane must be made of lipids.

A second important insight emerged when other investigators, following Overton's original strategy, i.e., deducing membrane properties from measurements of the pattern of permeability of a great variety of compounds, discovered that a number of molecules that are very hydrophilic, i.e., lipid insoluble, also pass rapidly through biologic membranes (2). This observation appeared to contradict Overton's proposal, since it was difficult to explain how substances that do not dissolve in lipids could pass rapidly through the membrane. An acceptable explanation came when it was realized that the hydrophilic substances that pass the membrane are of low molecular volume. Urea and many ions, for instance, enter cells rapidly although they are practically lipid insoluble.

If substances of very different solubility properties can pass through the membrane, then the membrane is not a homogeneous structure. Separate pathways must exist for the movement of hydrophilic and hydrophobic substances. The concept of the membrane as a noncontinuous lipid barrier with pores that permit the passage of hydrophilic particles of small volume was proposed to reconcile all the observations. This concept of a heterogeneous membrane composed of lipids that include multiple pathways for the movements of hydrophilic substances remains the basis of our current understanding of the structure and function of the membrane. Of course, the original model has been considerably refined and our understanding advanced since the model was proposed.

The first advance concerns the organization of the lipids. In agreement with Overton's original idea, it is now well established that most of the surface area of the membrane is composed of lipids. Chemical, biophysical, and structural analyses show that the membrane lipids form a continuous bilayer enveloping the cell. In biologic membranes,

the lipids are mostly phospholipids and are packed in a regular pattern. Hydrophilic heads are aligned adjacent to each other along the cytoplasmic and external faces of the cell membrane while the hydrocarbon tails face each other inside the membrane ([Fig. 38.1](#)). Lipid-soluble solutes pass through this phospholipid bilayer ([1](#)).

Figure 38.1. Schematic representation of the structure of the membrane. The lipid bilayer is depicted showing the polar heads of the phospholipids as *circles* and the fatty acid (hydrocarbon) tails as *wavy lines*. The proteins are shown as *solid bodies with stippled surfaces*. (Modified from Singer SJ, Nicholson GL. *Science* 1972;175:720–31, with permission.)

The other important advance concerns the nature of the pathways for hydrophilic solutes. It turns out that membranes are not made solely of lipid; they contain large amounts of protein. An important number of these proteins, called *integral membrane proteins* span the whole thickness of the membrane extending from the extracellular to the intracellular surface. Many integral membrane proteins exist in each cell, and quite a few of them form the pathways through which hydrophilic solutes permeate the membrane ([3](#)). The remainder of this chapter concerns the manners in which these proteins are involved in individual permeation processes.

To understand the permeation processes associated with different types of membrane proteins, we must first consider the forces driving the movement of substances across the membrane.

FORCES AND FLOWS: ACTIVE AND PASSIVE TRANSPORT

Gradients across Biologic Membranes

No movement can be understood unless the forces driving it are known. Hence, to understand how substances pass through a membrane, we must analyze the forces causing such flows. This approach has been extremely fruitful because it led to the

realization that substances pass membranes by two fundamentally different mechanisms: passive and active transport.

The flow of a substance across a membrane occurs by passive transport when movement is caused by gradients of force that exist across the membrane. What forces can drive such flows across the membrane? The most common process for passive solute flow is diffusion.

Diffusion is a common, everyday phenomenon; molecules in a liquid or gas tend to distribute themselves uniformly throughout the vessel in which they are contained. A familiar example is the fate of a lump of sugar deposited in a cup of tea. If enough time is allowed to pass, the sugar will be distributed evenly throughout the tea solution.

The concentration difference generates the driving force for the movement of sugar molecules from a region of higher concentration to one of lower concentration; this movement ceases when the concentration is uniform throughout the cup. In other words, a concentration difference causes the net movement of molecules.

In addition to concentration gradients, voltage is a source of force driving solutes passively across the membrane. Of course, voltage only acts on charged particles, but an important number of solutes in an organism bear an electrical charge; the most abundant osmotically active solutes in extracellular fluid are Na^+ and Cl^- and in intracellular fluid, K^+ . When a charged particle is placed in a region in which a voltage gradient exists, the positive particles will be pushed toward the negative pole and the negative particles toward the positive pole. There are important voltage gradients across almost every biologic membrane. Hence, ions in the organism are under the influence of two sources of force: the voltage gradient and the concentration gradient.

In which direction will a particle move when influenced by two forces? To intuitively understand this problem, consider a rather familiar situation in which two major forces are at work. A flying airplane's height is determined by two major forces: the gravitational pull of the earth and the upward driving force generated by the engines. When does a plane climb? When the upward force generated by the engines exceeds the gravitational field of the earth. When does it come down? When the opposite is true. Under what conditions does the aircraft maintain a constant height? When the two forces are opposite and equal.

Similarly, the movement of substances across membranes should be determined by the concentration gradient and, in the case of charged particles, the voltage gradient.

These considerations of how more than one force can affect the movement of a particle are important when considering the cell composition. When the forces driving solute movements across cell membranes are considered, one remarkable fact emerges: an important number of substances move, and are distributed in the organism, in a manner that obeys predictions based on *neither* the voltage nor the concentration gradient. For example, $[\text{Na}^+]$ inside most cells is 10 mM and its concentration in extracellular fluid is about 140 mM, while the voltage inside the cell is negative relative to the outside,

increasing further the inward force driving Na^+ into the cells. Regardless of these enormous inward-driving forces, Na^+ is kept low within the cell, being expelled almost as soon as it enters the cytoplasm. Therefore, some additional force must cause the difference in composition.

Active Transport and Ion Pumps

If the distribution and movement of certain solutes do not obey predictions based on concentration and voltage gradients across the membrane, what is causing them?

Early clues to solving this enigma came from work with erythrocytes, cells that are made almost exclusively of cell (plasma) membranes. By the time they reach maturity, all their intracellular organelles have degenerated, and they consist of a cell membrane surrounding a solution rich in hemoglobin and containing relatively few enzymes. The ionic composition of this solution is similar to most other intracellular fluids: high in K^+ and very low in Na^+ , compared with extracellular fluid. This concentration difference is maintained indefinitely if erythrocytes are incubated under appropriate conditions, e.g., body temperature and an adequate supply of substrates. One remarkable property becomes apparent when they are incubated at 4°C . The ions in the interior of the erythrocyte equilibrate with the extracellular fluid; Na^+ and K^+ reach equal concentrations in the intracellular and extracellular solutions. More remarkably, when these erythrocytes are rewarmed to body temperature they regain their original ionic gradients, K^+ moves into the cell, and Na^+ moves out. Since these movements occur against concentration gradients, there must be a component in the erythrocyte membranes that moves ions against their concentration gradients (4).

Another interesting feature of this ion movement against the gradients is that it requires metabolic activity. In erythrocytes, use of glucose by the glycolytic pathway is the only way to generate energy. If glycolysis is interrupted by either incubating erythrocytes in a solution free of glucose or by specifically inhibiting glycolysis with poisons such as iodoacetate, the reaccumulation of K^+ in the cell and the extrusion of Na^+ are blocked. This means that these movements against gradients are coupled to the energetic metabolism of the cell. Glycolysis makes energy available to the cells because an end result of this process is the synthesis of adenosine triphosphate (ATP). This compound acts as a source of energy because it has a high-energy chemical bond that, when hydrolyzed, releases large amounts of energy. The release of energy by the breakdown of high-energy chemical bonds is a familiar phenomenon: gasoline is a substance with high-energy chemical bonds that, when broken down, can release energy explosively. That is why gasoline is useful in propelling car engines or manufacturing Molotov cocktails.

Once we stop glycolysis in the erythrocyte and interrupt, in turn, synthesis of ATP and movement of Na^+ and K^+ against their gradients, we can restore these ion movements by supplying ATP. The restored ion transport occurs as ATP is hydrolyzed. This means that the component in the membrane that moves Na^+ and K^+ against their gradients uses the hydrolysis of ATP as a source of energy. Such membrane components that use ATP as a source of energy and move ions against their concentration gradients are

called *ion pumps* by analogy with the device that brings water up from the bottom of a well against a pressure gradient by using energy from an external source.

Once it was known that membranes contained a structure that could pump ions against their concentration gradients, it was natural to try to purify this component to characterize it. An enormous advance in this process occurred when it was discovered that a class of substances, the cardiac glycosides, acting at low concentrations block the activity of the Na^+ , K^+ pump, i.e., they selectively stop active transport of ions and ATP hydrolysis in the erythrocyte without blocking such other processes as glycolysis or passive ion movements (4).

To purify a component of the membrane, it is necessary to break down the membrane and then separate the desired component from the many other molecules that make up the membrane. If broken membranes yield many kinds of molecules, how is it possible to identify which one is the Na^+ pump? The answer was to use cardiac glycosides together with the physiologic properties of transport as markers. Since transport involves hydrolysis of ATP, membrane components that hydrolyze ATP, i.e., ATPases, were first targeted. Indeed, several ATPases could be purified from the membrane, but only one was inhibited by cardiac glycosides. Moreover, the activity of this enzyme required Na^+ and K^+ in the solution. This parallelism between the activity of the purified enzyme in a test tube and the pump in the whole cell provided the first credible evidence that the purified membrane protein was the ion pump of the whole cell (4). The Na^+ pump is not the only structure that pumps ions against concentration and voltage gradients using ATP as a source of energy. Two other ions, Ca^{2+} and H^+ , are transported actively in many instances by the action of specific ATPases. A number of H^+ ATPases and Ca^{2+} ATPases have been isolated, identified, and sequenced.

Passive Movements: Ion Channels

The Early Revolution in Electrophysiology

A great deal of the progress in our understanding of how ions passively cross membranes was the result of analyzing the responses of excitable tissues. Excitable cells (e.g., nerve, cardiac, and muscle cells) respond by briefly changing the voltage across their membranes. These electrical signals are due to the movement of ions down their concentration and voltage gradients. The ions move through specialized membrane structures that are now called *ion channels*.

The first proposal that hinted at the existence of channels as we know them today was made by Bernstein in 1906 (2). He was trying to explain the origin of the continuous voltage difference that exists across the resting membrane of most cells, making their interior negative relative to the outside. He based his explanation on two points. One is a fact: the concentration of K^+ is much higher inside the cell than outside. This concentration gradient drives K^+ continuously out of the cell. The second was a brilliant conjecture that turned out to be correct: voltage is generated because the pathway by which K^+ leaves the cell is selective for K^+ , that is, only K^+ passes through this pathway, other ions cannot go through. This conjecture has a solid physical basis: to generate a

voltage, charges have to be separated. If other ionic species were moving together with K^+ , they would neutralize the charge separation and there would be no voltage generated (2, 5).

Bernstein had a second important insight: if cells can change their voltage under different physiologic conditions, then the membrane can change the amount and nature of charges being separated at any time (i.e., charge separation is regulated). He went further and suggested that this regulation occurred because the membrane changed permeability under different physiologic conditions.

Bernstein's proposals were based on relatively scant evidence because the methodology of his time was extremely limited. Full experimental proof had to wait until after World War II, when Hodgkin, Huxley, and Katz (5) brought new and sophisticated technology to the analysis of these problems and provided extraordinary quantitative proof for the notion that membranes had a variety of individual pathways with selectivity for specific ions and that the passage of ions through them was regulated. Their studies on nerve and the nerve-muscle junction demonstrated an additional general property of the system: very different parameters in the cell environment can regulate the permeability of each specific pathway. The permeability of the pathways in nerve membrane is controlled mostly by the voltage across the membrane, while the permeability of the muscle membrane right at the junction with its nerve terminal is controlled not by the voltage across the membrane but by the action of a substance released by the nerve ending, acetylcholine. Thus, there are two major agents that control ion permeability. One is the voltage across the membrane, the other is the interaction of the membrane with a chemical agent that appears normally in its environment.

Hodgkin, Huxley, and Katz (2, 5) made their analysis on the basis of measurements of ion movements through large areas of the membrane. But they clearly understood that the behavior they observed corresponded to the responses of discrete areas of the membrane. For example, the property of selectivity raised an important problem already mentioned above: if charged hydrophilic particles such as ions pass through simple pores that only select on the basis of size, how can they permit the movement of K^+ while blocking other ions of similar size? Evidently, the pathway for hydrophilic substances cannot be such a simple structure as a pore. This view is further strengthened when one considers that ion permeability is precisely controlled by either chemicals or voltage acting on the membrane.

Channels and Poisons. Proof of the chemical nature of the pathways through which ions passively cross the membrane emerged from the use of specific poisons (2). The strategy involved was, in broad outline, similar to that discussed above for the purification of the sodium pump. It hinged on the discovery that some toxins are poisonous because they selectively block specific passive ion pathways; for example, tetrodotoxin, responsible for the poisoning caused by Japanese puffer fish, blocks the Na^+ channel with exquisite selectivity. Bungarotoxin, one of the most toxic components of the venom of the Siamese cobra snake (*Naja naja siamensis*) blocks the acetylcholine-regulated channel of the neuromuscular junction (2).

Once the specificity of these toxins was established, they were used to purify the components responsible for ion permeability from solubilized membranes. Because of their high affinity, they bind the proteins involved in the permeation process, which then are extracted and used to determine amino acid sequences.

Tetrodotoxin had another important use: it provided one of the first pieces of quantitative support for the existence of channels in the membrane. After it became evident that ions do not traverse the membrane through simple pores, two possible mechanisms for permeation were considered. One was that carriers with binding sites for specific ions ferried back and forth across the membrane. The other was that permeation was due to channels, i.e., continuous openings with walls of complex structure that could select among different ions and close and open in response to regulatory influences. The availability of radioactive tetrodotoxin permitted counting the number of Na^+ permeation sites in the membrane. Since the maximum number of Na^+ ions crossing the membrane was known from measurements of membrane ionic currents, it was a simple matter to calculate the speed at which Na^+ moved through a single site. It turned out that a carrier mechanism, shuttling back and forth across the membrane, was too slow to accommodate the large currents through each site, while a small number of open channels could easily pass the measured ion flows (2).

The Second Revolution: Patch Clamp and Molecular Biology

Two developments, the use of the patch clamp and the application of the methods of molecular biology, have permitted the observation and manipulation of molecules involved in the passive movement of ions across the membrane. The patch clamp permits recording and analysis of the activity of single channels in the membrane. The methods of molecular biology allow the analysis of the relationship between structure and function of the channels.

Patch Clamp and Gating in Single Channels. The patch clamp is a technique for making electrical recordings of very small patches of cell membrane, usually a few square microns in diameter. By recording from such small patches of membrane it is possible to record the behavior of single channels. The technique hinges on pushing a glass pipette with a polished tip diameter of about $1\ \mu$ against the cell membrane surface until the edge of the pipette makes a very high resistance seal with the membrane. In this manner only the electrical activity of the area within the pipette tip is recorded. Since this area is so small, it frequently contains only a single channel (6).

The passage of ions through the channel is detected by measuring the electrical current that passes through the membrane in the patch. [Figure 38.2](#) shows recordings of the current measured when a single channel is within the pipette. In the absence of any additional experimental perturbation, the current shifts between two values: zero and some other fixed value. The transition between the two states is extremely rapid, because chemical transition states are very short lived. This behavior indicates that the channel structure spontaneously fluctuates through two major configurations, one in which it is closed and does not permit any ion flows and the other in which it is open and permits the passage of an ionic current. This spontaneous transition between open and

closed states is termed *channel gating*. Channel function is mostly regulated by controlling the time that the channel spends in the open position (i.e., the probability that the channel is open at any moment). Agents that increase membrane permeability increase the open time of the channel, while the converse is true for agents that decrease it.

Figure 38.2. Patch-clamp recordings of a single channel. The records show the channel fluctuating spontaneously between open (*upper level of the tracing*) and closed (*lower level of the tracing*) positions and the effects of membrane voltage. Two effects of voltage are shown. First, as the voltage across the patch is changed from 50 to -20 mV (see voltage values at the right end of each tracing) the time that the channel spends in the open state is greatly reduced. Second, as the voltage is shifted from 50 mV to -20 mV the current passing through the open channel is reduced because the driving force for ion movements is reduced by the change in voltage. The lower tracing (*e*) shows the final portion of tracing a (from the *point marked* to the *arrow* to the end of the tracing) with an expanded time scale. The 500-msec bar is the time calibration for all tracings except tracing e, in which it is equivalent to 30 msec. (Modified from J Gen Physiol 1988;92:187, with permission.)

The size of the current passing through the open channel (i.e., the height of the current deflection between open and closed states) depends on two parameters. One is the driving forces for the ion moving through the channel, namely, voltage difference and concentration gradient. The other is the channel conductance, measured by comparing the ionic current forced through the channel by a driving force of fixed magnitude. Channel conductance is approximately proportional to channel diameter: more ions are forced by the same driving force through a channel of larger diameter than through a smaller one.

Voltage-Gated Channels. One of the most remarkable contributions of the Hodgkin-Huxley studies was the demonstration that the electrical responses of excitable cells are due to the existence of separate voltage-controlled pathways for Na^+ and K^+ in the nerve membrane. As indicated above, this means that the voltage across the

membrane changes the time that a channel spends open (i.e., there are certain values of membrane voltage for which the channel will be mostly open and values at which it will be mostly closed).

With the aid of tetrodotoxin and the techniques of molecular biology, the Na⁺ channel composition has been determined. Its main component is a glycosylated protein of 1820 amino acids (7). This protein contains four homologous domains, each containing about 300 amino acids. What is the shape of this protein within the membrane?

Depending on their amino acid composition, polypeptide chains arrange themselves in space to present a surface of different degrees of hydrophobicity. This is important because the hydrophobic surface of a polypeptide will separate itself from any aqueous or polar environment and become embedded in the lipid core of the membrane (8). It turns out that each of the four homologous domains of the sodium channel contains six hydrophobic regions that stay within the lipid phase of the membrane. These four domains arrange themselves to surround a pore, as shown in Figure 38.3.

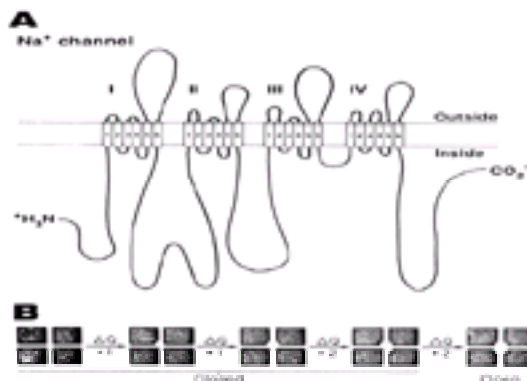

Figure 38.3. Schematic representation of the Na⁺ channel protein. Panel A shows the complete channel polypeptide with four homologous domains (*I* to *IV*). Each domain has six hydrophobic regions (*cylinders labeled 1 to 6*) that are located within the lipid bilayer. Panel B shows the topologic arrangement of the channel viewed in a cross-section parallel to the surface of the membrane. Each of the four homologous domains is shown forming a quarter of the channel. Depolarization produces a sequential series of voltage-induced changes in channel conformation that result in an opening at the core of the channel. (From Catterall W. *Science* 1988;242:50–61, with permission.)

The fact that membrane voltage changes channel gating implies that a portion of the channel molecule can sense the voltage across the membrane. One of the intramembrane domains of the channel proteins has a high number of positively charged amino acid residues that would be displaced when the voltage within the membrane is changed. Displacement of this portion is responsible for voltage-dependent gating. Quite a few voltage-gated channels that operate following

similar principles have been identified: at least three Na⁺ channels, four Ca²⁺ channels, and many types of K⁺ channels (7, 9).

Ligand-Gated Channels. As mentioned above, gating in certain channels is not altered by modifying the membrane voltage, but the presence of specific substances in the extracellular space will markedly change gating. These substances, which act at very low concentrations, are called *ligands*; they bind to specific proteins of the cell membrane called *receptors*. The consequence of the interaction between ligand and receptor is a change in cell function (2).

Some types of channels are also receptors, that is, ligands bind directly to the channel. The interaction between ligand and receptor produces a conformational change that opens the channel and permits movement of ions across the cell membrane.

The best studied ligand-activated channel is the acetylcholine receptor of the vertebrate neuromuscular junction. Other transmitters directly activate postsynaptic channels in a variety of neurons. In many cases, these involve inhibitory responses in which the transmitters are amino acids such as glycine and GABA (g-aminobutyric acid), which act by opening anion-selective channels. There is a ubiquitous transmitter in the central nervous system, glutamic acid, that affects many synapses by directly opening channels that have selective permeability for monovalent cations.

G-Proteins and Channel Control

Many channel types change gating in response to ligands in the extracellular environment, although the channels themselves are not receptors. These responses are initiated through receptors that are separate proteins in the membrane. When receptor-ligand interactions occur, a sequence of steps is initiated that finally modifies channel behavior (2, 9).

Two major steps follow the receptor-ligand interaction. The first is the coupling of the receptor-ligand complex with another type of intramembrane protein that binds guanine nucleotides, called for this reason a *G-protein*. The second step involves the coupling of G-proteins with other membrane proteins, the effectors, whose activity is in turn modified.

By now more than 10 different varieties of G-proteins have been identified. These G-proteins activate effector proteins when their guanine binding site is occupied by GTP. In the resting state, the site is occupied by GDP, when the receptor-ligand complex couples with the G-protein, the bound GDP is released and GTP takes its place. The activity of the GTP protein ceases when GTP is hydrolyzed to GDP (9).

Two major types of effector proteins are activated by G-proteins. In one type, G-proteins interact directly with the channel. The most typical example is the K⁺ channel activated by acetylcholine in the heart. It is important to note that the receptor that mediates this response to acetylcholine is fundamentally different from the acetylcholine receptor described in the previous section that mediates the responses of skeletal muscle. In the

second group of G-protein-mediated responses, the effector that is activated by a phosphorylated G-protein is an enzyme that generates a second messenger. This second messenger in turn activates a sequence of reactions whose products modify gating of a channel (9) (Fig. 38.4).

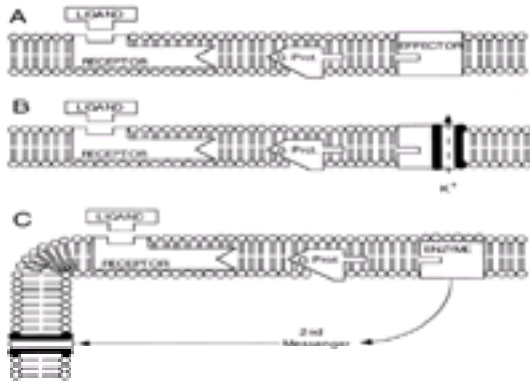

Figure 38.4. Schematic representation of the effectors for G-protein regulation of cell membrane function. *A.* General organization of the G-protein pathway. *B.* A channel as effector for G-protein action. *C.* An enzyme as effector for G-protein action. Synthesis of a second messenger initiates activity in a pathway whose products eventually will modify channel behavior.

There are four common ways in which G-proteins control the rate of second messenger production: (a) stimulation of adenylyl cyclase; (b) inhibition of adenylyl cyclase; (c) activation of phospholipase A; and (d) activation of phospholipase C. These four methods of control probably affect the greatest number of channels.

The multiplicity of ion channels and regulatory mechanisms allows for an enormous number of possible permutations. Indeed, channels and their regulatory mechanisms are being discovered in every cell type. A testimony to this variety is the latest edition (1996) of the “Receptor and Ion Channel Nomenclature Supplement” published by the journal *Trends in Pharmacological Sciences*; it has 80 pages filled with tables summarizing channel and receptor properties (10).

Facilitated Diffusion

In addition to the movement of lipid-soluble substances that pass through the lipid bilayer of the membrane driven by their concentration gradient and the movement of ions that move through specific channels driven by electrical and concentration gradients, there is a third modality of movement, also driven by the concentration gradient across the membrane (11). This modality is called *facilitated diffusion*. The concept of facilitated diffusion evolved when it was recognized that there is a group of organic solutes that pass cell membranes down their concentration gradient but are not

lipid soluble. The most widely studied of these substances is glucose.

It was recognized very early that glucose diffuses through the membrane of most cells by interacting with a specific transporter in the cell membrane. Now, molecular techniques have shown the existence of a family of proteins, the GLUT transporters, which are responsible for glucose transport down its concentration gradient. Although ubiquitous, these transporters are notably absent from the microvilli of the small intestine and kidney where massive glucose transport takes place. At these locations glucose passes through a special active process called *cotransport* (see below). However, the GLUT transporters are essential to permit passage of glucose across almost all other cell membranes. In the case of the small intestine, they play a central role in allowing the exit of glucose from the intestinal cell into the interstitial spaces, after glucose has been absorbed into the cytoplasm by a specialized process in the apical microvilli.

Secondary Active Transport and the Absorption of Nutrients

Analysis of the mechanisms of absorption of carbohydrate and protein nutrients in the small intestine led to the recognition that these functions involve a unique process. This process is neither diffusion nor a form of active transport in which metabolic energy stored in a biochemical intermediary such as ATP is used directly to drive the movement of solutes.

For more than a century we have known that both carbohydrate and protein nutrients are completely absorbed from the intestinal lumen, where their concentrations fall to negligible levels. The precise mechanisms of such powerful absorption processes were unknown until quite recently. However, even before the detailed mechanisms were elucidated, it was clear that some form of active transport must be involved, because substrates moved from low- to high-concentration regions. The key discovery was that the specialized event in this active transfer occurs at the cell membranes that line the lumen of the small intestine (12).

The first indication that such a specialized event occurs in the luminal membrane of the epithelial cell of the small intestine came from studies in isolated sacs of intestine. In these studies the composition of the solution bathing the lumen of the intestine was compared with the composition of the cytoplasm of intestinal epithelial cells and of the solution in contact with the interstitial spaces of the intestine. As expected, both amino acids and monosaccharides were passed from luminal to serosal solution, raising substrate levels in the interstitial fluid. The unexpected and fascinating finding was that by far the highest concentrations of substrate were found in the cytoplasm of the intestinal cells. This means that the membrane of the intestinal cell facing the lumen contains a system or systems that can actively accumulate nutrients in the cytoplasm of the intestinal cell, and from there they can pass into the interstitial spaces, driven by their concentration gradients.

Other important findings followed. Foremost was the observation that nutrient absorption only occurred when sodium was present in the luminal solution. Active absorption of nutrients was abolished when the lumen was incubated with Na⁺-free

solutions; no other cation can substitute for Na⁺.

The other major observation was that abolishing the gradient of [Na⁺] across the cell membrane, normally maintained by the Na⁺, K⁺ ATPase, also abolishes accumulation of nutrients within the intestinal cell. Crane (13) synthesized these apparently unrelated facts into an elegant explanation. He reasoned that nutrient uptake depends on Na⁺ because the transporter allows the movement of glucose only when it occurs simultaneously with Na⁺, i.e., the movements of Na⁺ and glucose are strictly coupled by a single transporter molecule. In addition, he proposed that the force for nutrient accumulation is provided by the Na⁺ gradient, and for this reason, dissipation of the Na⁺ gradient interferes with nutrient accumulation.

Since Crane's original proposal, a great mass of data has accumulated supporting his fundamental concept that two different substrates move together through a single transporter, with the concentration gradient for one of them providing the energy to drive the active transport of the second. All forms of active transport that do not directly use energy derived from metabolism but rather use energy from a concentration gradient are now known as *secondary active transport*. The forms of active transport that derive their energy directly from metabolism through such compounds as ATP are called *primary active transports*.

Subsequently, it has been recognized that secondary transport occurs in two forms. In the first, described above and called *cotransport*, or *symport* the transported solutes ride together in the same direction across the membrane. The second form of secondary transport, called *countertransport*, or *antiport* involves exchange of a solute of one species on one side of the membrane for a solute of a different species on the other side of the membrane. A concentration gradient for at least one of the species involved is necessary to produce a net flow of solute. Again, in this case, the energy for moving one species against its gradient comes from the other species moving down its concentration gradient.

After these two forms of secondary active transport were identified, two major advances occurred in the field. One was recognition of the ubiquitous nature of secondary transport systems. The other was development of molecular techniques that revealed correlations between the structure of transporters and their function.

The number of substances transported through cotransport mechanisms is enormous; they range from nutrients in the small intestine and kidney to neurotransmitters in the nerve terminals of the brain. The most significant, from the nutritional point of view, are located in the small intestine where they are important in the absorption of free amino acids, di- and tripeptides, monosaccharides, and water-soluble vitamins. Operation of most of these cotransporters appeared to be coupled to the Na⁺ gradient across the mucosal membrane. However, recent observations have revealed an important difference. Uptake of di- and tripeptides in the intestine and kidney is driven by the H⁺ gradient that exists across the apical membrane of the epithelial cells and not by the Na⁺ gradient; this is an exception to the more general situation in which the energy for

cotransport comes from the transmembrane gradient for Na^+ (14).

The exception is important because, in the small intestine, absorption of di- and tripeptides is quantitatively more important than absorption of free amino acids. Moreover, a common cotransporter is responsible for transport of di- and tripeptides in the kidney and the intestine, and in both cases, the transport of peptides is not affected by the Na^+ gradient but is markedly affected by the H^+ gradient that exists across the brush border membrane (14).

As with all other types of transporters, the techniques of molecular biology are now being used to identify the relationship between molecular architecture and function of counter- and cotransporters (12). Although detailed strategies vary, the pattern established early for the sodium/glucose cotransporter of the intestinal brush border, SGLT1, has been repeated; after cloning and establishing a full amino acid sequence of the transporter, its arrangement across the membrane and the orientation of different moieties have been deduced. Then the clone and a variety of analogues have been functionally expressed in *Xenopus* oocytes, permitting determination of the role of specific amino acids in controlling the behavior of the molecule.

SUMMARY AND CONCLUSIONS

After more than a century of research, the study of membrane function has culminated in identification of a variety of specific modalities of permeation across the cell membrane. This chapter briefly describes the different modalities by which substances pass across cell membranes. Table 38.1 lists these modalities, with some selected examples of each that are of significance to nutrition. Since the major criteria that distinguish the different modalities are the relationship between fluxes and the forces that produce them, they are also listed in the table. It is now also clear that except for the movement of lipid-soluble compounds, each modality of permeation is due to the action of a specific intramembrane protein.

Mechanism	Driving force	Significant Examples
Passive		
Diffusion through lipid membranes	Concentration gradient	Absorption of lipid-soluble compounds like oils and fats, fat-soluble vitamins, and drugs
Facilitated diffusion	Concentration gradient	Glucose movement across renal cell membranes
Channel permeation	Electrochemical gradient	All passive movements, essential to function of compressor
Primary transporters		
Na^+ -ATPase	ATP or other high-energy intermediates	Extrusion of Na^+ and uptake of K^+ against electrochemical gradients; the formation of an gradient serves as a sum to drive cotransport and countertransport
Secondary transporters		
Cotransport (symport)	Na^+ or H^+ gradient	Na^+ or H^+ dependent absorption of most hydrophilic solutes in brush border of apical membrane of small intestine
Countertransport (antiport)	Na^+ or H^+ gradient	Na^+ - H^+ exchange that maintains H^+ gradient across intestinal cells

Table 38.1 Distinct Modalities for Transmembrane Movements of Solutes with Selected Examples of Nutritional Relevance

An outline of the strategies that initially permitted purification of the intramembrane proteins involved in the different forms of permeation is also included in the chapter to give the reader a glimpse of how individual components of the membrane were identified as subserving individual functions. The last two decades have seen great acceleration in this task with the introduction of the patch clamp and molecular biology techniques. We now know so many channels and transporters in molecular detail that specific study of each family of transporters has become a subspecialty in itself.

The alimentary tract is a tubular structure that extends from the posterior oropharynx to the anus. Its primary function is to digest and absorb ingested nutrients. This chapter reviews the structural and functional components of the alimentary tract and describes the interactions of these components in response to a meal. Gastrointestinal (GI) tract flora and the immune system are also reviewed briefly because of their importance in overall GI function.

GASTROINTESTINAL TRACT STRUCTURE

Substructures and Cells

The GI tract consists of four contiguous segments: the esophagus, stomach, small

intestine, and colon ([Fig. 39.1](#)). The wall of each segment contains four distinctive layers: the mucosa, submucosa, muscularis propria, and serosa or adventitia ([Fig. 39.2](#)). The mucosa is composed of three distinct layers: the epithelium, lamina propria, and muscularis mucosae. The epithelial layer forms a barrier between the lumen and the underlying tissues. Many of the different region-specific secretory, absorptive, and barrier functions of the alimentary tract are accounted for by differences in the type and distribution of various differentiated epithelial cell populations along the length of the gut; thus, the epithelium shows the greatest variability among different regions of the GI tract. The lamina propria is a connective tissue space between the epithelium and the thin layer of muscle fibers, the muscularis mucosae, which forms the lower boundary of the mucosa. The lamina propria contains many cells involved in immunologic functions, including immunoglobulin-secreting plasma cells, macrophages, and lymphocytes. In addition, abundant lymphoid nodules that often extend through the muscularis mucosae into the underlying submucosa are present. Subepithelial fibroblasts produce collagen and many other extracellular matrix components that underlie the basal lamina of the epithelium. These fibroblasts and the extracellular matrix that they secrete have an important role in regulating cell proliferation and differentiation events within the overlying epithelium.

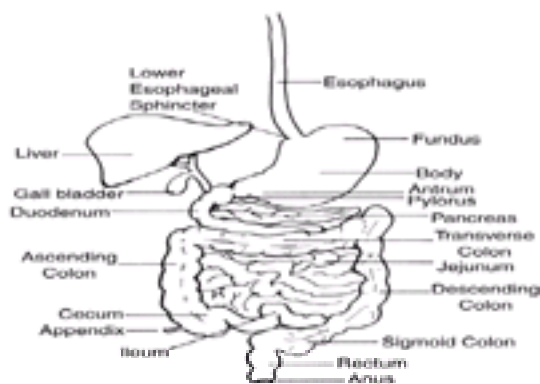

Figure 39.1. Diagram of the major parts of the gastrointestinal tract. Anatomy of the stomach, small intestine, and large intestine. The *duodenum* is located in the retroperitoneal space and bends around the head of the *pancreas*. The *jejunum* lies within the peritoneal cavity and begins at the ligament of Treitz. Jejunal bowel loops are predominately located in the left and middle upper abdomen. The proximal *ileum* lies in the middle abdominal region. The distal ileum lies in the right lower quadrant and joins the *colon* at the ileal cecal valve. The cutout reveals the duodenum and the ligament of Treitz, which lie behind the transverse colon. (From Greene HL, Moran JR. The gastrointestinal tract: regulatory nutrient absorption. In: Shils ME, Olson JA, Shike M, eds. Modern nutrition in health and disease. 8th ed. Philadelphia: Lea & Febiger, 1994; 551.)

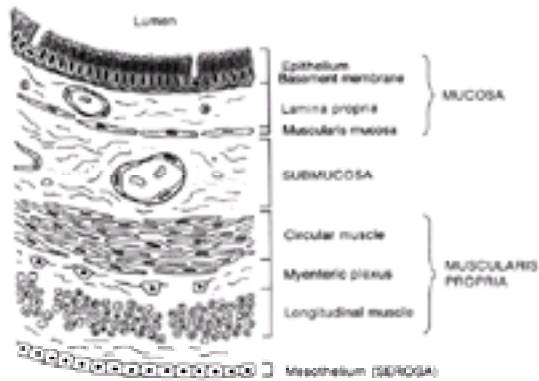

Figure 39.2. Schematic organization of the wall of the gastrointestinal tract. (From Yamada T, Alpers DH, Owyang C, et al., eds. Textbook of gastroenterology. 2nd ed. Philadelphia: JB Lippincott, 1991;142, with permission.)

The mucosal epithelium contains numerous enteroendocrine cells in addition to cells with secretory, absorptive, and barrier functions. The enteroendocrine cells, found in gastric, intestinal, and colonic epithelium, are characterized by their polygonal shape, broad base, and the numerous membrane-bound secretory granules in their basilar portion. Enteroendocrine cells are joined to other adjacent cells in the epithelium via junctional complexes located near the apical pole. The regulatory peptides or bioamine products stored in the basally located secretory granules are secreted through the basolateral membrane and act through paracrine or endocrine mechanisms as mediators of gastrointestinal secretion, absorptive function, and motility in response to lumenally and/or basolaterally derived signals.

The submucosa extends from the mucosa to the muscularis externa and contains numerous small- to moderate-sized veins, arteries, and lymphatic channels surrounded by connective tissue. Ganglion cells and autonomic nerve fibers of Meissner's plexus are also found in the submucosa. Fibers of this submucosal plexus together with the myenteric plexus form the enteric nervous system, which regulates and coordinates a number of intestinal functions including motility. Additionally, scattered lymphoid aggregates or nodules may be found in this layer of the gut wall.

The muscularis propria is organized into two layers of muscle: an inner circular layer, in which muscle cells circle the intestine, and an outer longitudinal layer, in which muscle cells run parallel to the long axis of the intestine. In the upper esophagus, skeletal muscle fibers interdigitate with smooth muscle fibers, whereas the muscularis of the remaining alimentary tract is composed entirely of smooth muscle.

Esophagus

The adult esophagus is approximately 25 cm long and extends from the posterior oropharynx at the level of the cricoid cartilage to just below the diaphragmatic hiatus,

where it enters the stomach at the esophagogastric junction. The esophageal mucosa is lined by a thick, incompletely keratinized, stratified squamous epithelium that provides protection against abrasion during passage of a swallowed food bolus and against refluxed stomach acid. The lamina propria contains occasional lymphoid aggregates and mucosal glands that secrete neutral mucus. Submucosal glands that secrete acidic mucus extend through the lamina propria and muscularis mucosae and are most abundant in the upper half of the esophagus.

In the upper esophagus, skeletal muscle fibers blend with the smooth muscle fibers found throughout the rest of the esophagus. The upper esophageal sphincter is formed by a thickened band of oblique muscle. These skeletal muscle fibers are under voluntary control and are involved in regulating initial passage of a swallowed bolus into the upper esophagus. The remaining smooth muscle of the muscularis is innervated by parasympathetic fibers originating from the vagus nerve. A thickened band of circular smooth muscle adjacent to the esophagogastric junction form the lower esophageal sphincter. Contraction of this specialized region of smooth muscle coupled with the abrupt angulation of the esophagus as it passes through the diaphragmatic hiatus where it joins the gastric cardia provides a mechanism for preventing reflux of the acid contents of the stomach into the esophagus.

Stomach

The stomach is an asymmetric organ that extends from the gastroesophageal junction in the cardia to the duodenum ([Fig. 39.3](#)). The upper portion of the stomach, which lies under the left hemidiaphragm, is called the fundus. The gastric body comprises the largest portion of the stomach and extends to the angularis, where the stomach abruptly bends. The pyloric sphincter is a round band of muscle that forms the opening of the stomach into the duodenum. The flat glandular mucosa of the stomach changes to the villus epithelium seen in the duodenum at the pylorus. The gastric antrum lies between the angularis and the pylorus.

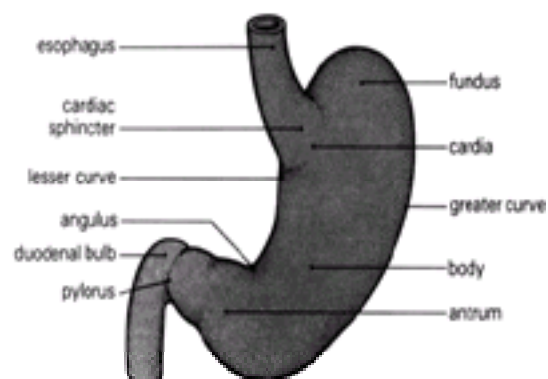

Figure 39.3. Regional organization of the stomach and proximal duodenum. (From Yamada T, Alpers DH, Owyang C, et al., eds. Textbook of gastroenterology. 2nd ed. Philadelphia: JB Lippincott, 1991;1304, with permission.)

The entire stomach is lined by a simple columnar epithelium. The mucosa contains numerous invaginating gastric pits, or foveolae, which form glands at their base. Each glandular unit is composed of three regions: the upper pit region lined by surface mucus-secreting cells; a narrow isthmus or neck containing many immature undifferentiated cells and mucous neck cells; and a basilar gland that contains three cell types—parietal cells, chief cells, and enteroendocrine cells. Most of the gastric body and fundus is lined by oxyntic mucosa consisting of fundic-type glands responsible for secretion of acid pepsinogens and intrinsic factor. These glands contain abundant parietal cells in their upper half. Chief cells predominate near the base of glands in fundic-type mucosa. The cardiac glands found in the first 3 to 4 cm adjacent to the esophagogastric junction are primarily mucus-secreting glands, with few parietal or chief cells. Pyloric glands in the prepyloric antrum are coiled and remarkable for their fairly long foveolae and increased population of enteroendocrine cells.

Surface mucous cells form a uniform population of columnar epithelial cells lining the surface mucosa and gastric pits. These cells secrete a glycoprotein-rich neutral mucus layer that protects the epithelium from the acid environment of the stomach. Surface mucous cells are constantly shed into the gastric lumen and are replaced by replication of undifferentiated cells within the neck or isthmus region of each gastric gland, which differentiate during migration up the foveola and onto the gastric mucosal surface.

Parietal cells secrete hydrochloric acid and are located in the middle and basilar portions of the gastric glands. These cells are large, with clear or acidophilic cytoplasm and abundant mitochondria. They have well-developed intracellular canaliculi containing a microvillus border that greatly expands the apical surface available for acid secretion. Receptors for histamine, gastrin, and acetylcholine located at the basolateral surface regulate parietal cell secretory function. Intrinsic factor, a binding protein for vitamin B₁₂, is secreted by parietal cells.

Chief cells, or zymogenic cells, are found near the base of the gastric glands. These cells are characterized by an extensive basilar rough endoplasmic reticulum and supranuclear zymogen granules, reflecting their role in the production of pepsinogens and other proteases. Pepsinogens are synthesized and secreted by these cells into the gastric lumen. Hydrochloric acid in the lumen converts the pepsinogen proenzyme to the active pepsins, which begin digestion of proteins to lower-molecular-weight polypeptides.

Enteroendocrine cells are most abundant in the prepyloric antrum and secrete many different neuropeptides and regulatory molecules discussed below. Gastrin-secreting G cells predominate in the antrum; enterochromaffin cells (ECs) are found throughout the gastric mucosa and secrete serotonin and either substance P or motilin; glucagon-secreting A cells are found in the proximal third of the stomach; and somatostatin-secreting D cells can be found in both the upper third of the stomach and the antrum but not in the midstomach. This complex web of enteroendocrine signals is

important in integrating responses to both luminal conditions and basolateral signals.

Small Intestine

The small intestine extends from the gastric pylorus to the ileocecal valve and is divided into three regions—the duodenum, the jejunum, and the ileum.

Duodenum

The duodenum is approximately 30 cm long and is fixed in place, molded around the head of the pancreas. Histologically, the duodenum is characterized by the presence of abundant submucosal Brunner's glands that secrete alkaline mucus. The first portion of the duodenum, known as the bulb, is attached to a mesentery. The second (descending), third (transverse), and fourth (ascending) portions of the duodenum are retroperitoneal. Bile and pancreatic secretions enter the second portion of the duodenum from the common bile duct at the ampulla (papilla) of Vater. The junction of the duodenum and jejunum is defined by the position of the ligament of Treitz, where the duodenum reenters the peritoneal cavity. The histologic appearance of the small intestine does not change at this transition.

Jejunum and Ileum

The jejunum and ileum are mobile because of their attachment to an extensive mesentery. The proximal two-fifths of the small intestine beyond the ligament of Treitz is defined as jejunum, while the distal three-fifths are ileum. The jejunum is characterized by a larger diameter, more-prominent folds, and longer villi than the ileum. The ileum is characterized by the presence of abundant lymphoid follicles (Peyer's patches) in the submucosa.

The length of the jejunum and ileum in adults ranges from 320 to 846 cm. Several structural features of the small intestine amplify the mucosal surface area available for nutrient absorption to more than 200 m², which is larger than a doubles tennis court ([Fig. 39.4](#)). The surface area is magnified by a series of folds and invaginations. First, the cylinder of the intestine is heaped up into circular folds (plicae circulares) involving both submucosa and mucosa. These folds are particularly prominent in the jejunum. Second, the mucosal surface is further expanded by numerous villi, long fingerlike projections of mucosa containing an arteriole, vein, and central draining lacteal. Third, the apical surface of each small intestinal epithelial cell along the villi is covered by microvilli, providing thousands of hills and valleys for surface expansion. The folds, villi, and microvilli increase the surface area 600 times that of the surface area present in a simple cylinder.

Figure 39.4. The intestinal surface area is expanded by intestinal folds (plicae conniventes) and villi. Microvilli further expand the surface area of epithelial cells in contact with luminal contents. These structural features taken together expand the surface area of the small intestine approximately 600-fold. (From Yamada T, Alpers DH, Owyang C, et al., eds. Textbook of gastroenterology. 2nd ed. Philadelphia: JB Lippincott, 1991;327, with permission.)

Epithelium

The simple columnar epithelium that lines the small intestine is composed of four principal differentiated cell types: absorptive enterocytes, goblet cells, Paneth cells, and enteroendocrine cells. Cells are joined to adjacent cells by junctional complexes that regulate the paracellular movement of fluid and macromolecules (see [“Fluid and Electrolytes”](#)). Absorptive enterocytes are responsible for digestion of di- and tripeptides and disaccharides and for nutrient absorption. The microvilli of absorptive enterocytes are supported by a central core of actin filaments that join with a dense terminal web of actin and myosin filaments oriented parallel to the apical surface of the enterocyte. The apical surface is covered by a glycoprotein-rich glycocalyx. Many enterocyte-encoded proteins important for digestive function are present at the apical surface, including dipeptidases, disaccharidases, enterokinase, and intestinal alkaline phosphatase. Goblet cells are flask-shaped cells with large apical vesicles that store and secrete mucus. This mucus forms a viscous gel that functions both as a lubricant and to protect the surface epithelium against adherence of invading pathogens. Paneth cells reside at the base of the intestinal crypts and produce proteins involved in antibacterial defenses, including lysozyme and a variety of defensins.

Enteroendocrine cells contain a large number of neuroendocrine mediators (see [“Gastrointestinal Hormones”](#)). The distribution of individual enteroendocrine cell subpopulations within the epithelium differs along the length of the small intestine. Although enteroendocrine cells arise from the same stem cell as the other differentiated cell types found in the small intestine, they have a much longer half-life than enterocytes or goblet cells. Thus, their migration onto and along the intestinal villi is uncoupled from

the migration of the other epithelial cell types in the intestine.

Renewal

Under normal physiologic circumstances, cells within the intestinal epithelium are continuously and rapidly replaced by migration of cells onto the villus from several adjacent crypts of Lieberkuhn or intestinal glands (Fig. 39.5). The four principal differentiated cell types of the small intestinal epithelium are all derived from multipotent stem cell(s) located near the base of each intestinal crypt. Under normal circumstances, these crypt stem cells divide rarely to produce a daughter stem cell (self-renewal) as well as a more rapidly replicating transit cell. Transit cells, in turn, undergo four to six rapid cell divisions in the proliferative zone located in the lower half of each crypt, and their progeny subsequently differentiate during a bipolar migration away from this zone. Goblet cells and enterocytes undergo terminal differentiation as they are rapidly translocated upward from the zone of proliferation to the apical extrusion zone (a process lasting 48 to 72 hours) located adjacent to the villus tip where they undergo apoptosis and are sloughed into the lumen. Paneth cells arise during downward migration to the crypt base, and enteroendocrine cells differentiate during migration from the zone of proliferation in either direction. Cell renewal, migration, and differentiation are interrelated processes regulated at multiple levels.

Figure 39.5. Schematic organization of the epithelium in the adult mouse small intestine. The small intestinal crypt contains approximately 250 cells. The lower five cell positions contain 40–50 cells that have an average cycle time (T_c) \approx 26 hours. This region includes Paneth cells and is postulated to include undifferentiated, anchored stem cells at the fifth cell position above the base. The undifferentiated cells divide asymmetrically to give rise to proliferating transit cells ($T_c \approx$ 13 hours) that migrate upward toward the villus and subsequently differentiate into enterocytes, goblet cells, and enteroendocrine cells. Paneth's cells differentiate during downward translocation to the crypt base. Senescent cells are extruded near the villus tips. (From Yamada T, Alpers DH, Owyang C, et al., eds. Textbook of gastroenterology. 2nd ed. Philadelphia: JB Lippincott, 1991;1561, with permission.)

Colon

Structure

The colon is approximately 100 to 150 cm long, extending from the ileocecal valve to the proximal rectum ([Fig. 39.1](#)). The colon consists of the cecum, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, and sigmoid colon. The terminal ileum enters the cecum on its posteromedial border at the ileocecal valve. The cecum is a large blind pouch approximately 7.5 to 8.5 cm in diameter that projects from the antimesenteric side of the ascending colon. The appendix extends from a narrow opening in the base of the cecum. The diameter of the colon diminishes progressively; the sigmoid colon is approximately 2.5 cm in diameter and is the narrowest portion of the colon. The omentum is attached to the transverse colon on its anterior superior edge. The ascending colon, descending colon, rectum, and posterior surface of the hepatic and splenic flexures are fixed retroperitoneal structures. The cecum, transverse, and sigmoid colon are intraperitoneal and thus lack a complete serosal layer.

Epithelium. Three principal differentiated epithelial cell types are found in the adult colonic epithelium: absorptive colonocytes, goblet cells, and the enteroendocrine cells. All of these cell lineages appear to be derived from a common epithelial cell stem cell precursor. Undifferentiated cells, replicating cells, and enteroendocrine cells predominate near the base of each colonic gland (crypt). Cells belonging to each of the principal cell lineages differentiate as they migrate away from the zone of proliferation toward the surface epithelium. The average life span of goblet cells and absorptive cells, from their birth deep in the crypt until they are sloughed into the lumen, is approximately 6 days. As in the small intestine, some enteroendocrine cell subtypes appear to have a much longer life span than goblet cells or absorptive colonocytes.

As absorptive colonocytes differentiate during their migration up the crypt, they develop short microvilli and clear apically oriented vesicles containing a fibrillar, glycoprotein-rich secretory product that may contribute to a glycocalyx. These apical vesicles are lost, and microvilli elongate and increase in number as the maturing absorptive cells emerge onto the surface epithelium. At this point, alkaline phosphatase activity appears on the brush border, and the basolateral membranes have acquired a considerable amount of $\text{Na}^+\text{-K}^+$ ATPase activity, reflecting their function in water and electrolyte transport.

Many different enteroendocrine cell types are found within the colonic epithelium, including L cells, which contain both enteroglucagon and peptide YY (PYY); cells that secrete only PYY; EC_1 cells that secrete serotonin, substance P, and leu-enkephalin; pancreatic polypeptide-secreting cells; and rare somatostatin-secreting cells. Enteroendocrine cells are more numerous in the appendix and the rectum than in the rest of the colon.

Other Layers. The inner circular muscle fibers form a continuous layer around the colon. The outer longitudinal smooth muscle fibers are condensed into three bands

(taeniae coli) equidistant around the circumference of the colon. Haustra are the bulging sacculations that form between adjacent taeniae coli. The serosa is a mesothelial derived cell layer that covers the peritoneal aspects of the colonic wall. Therefore, regions of the ascending colon, the descending colon, and rectum that do not lie within in the peritoneal cavity have no outer serosal layer.

Appendix

The appendix is similar in histologic organization to the rest of the colon. The mucosa of the appendix consists of deep folds lined by a columnar epithelium forming simple tubular or forked glands. This epithelium contains abundant goblet cells and enteroendocrine cells. Numerous lymphoid nodules are found in the lamina propria. The normal histologic architecture of the adult appendix is often replaced by fibrous scar tissue as a result of subclinical bouts of appendicitis.

Rectum

The rectum is approximately 12 to 15 cm long and extends from the sigmoid colon to the anal canal following the curve of the sacrum ([Fig. 39.1](#)). The rectal wall consists of mucosal, submucosal, inner circular, and outer longitudinal muscular layers. There is no serosal layer in the rectum. The anal canal is approximately 3 cm long. The anal verge is the junction between anal and perianal skin. Anal epithelium (anoderm) lacks hair follicles, sebaceous glands, or sweat glands. The dentate line is the true mucocutaneous junction located just above the anal verge. A 6- to 12-mm transitional zone exists above the dentate line where the squamous epithelium of the anoderm becomes cuboidal and then columnar epithelium.

VASCULATURE

Blood and lymphatic vessels provide the transportation system for delivering absorbed nutrients to other body tissues. In addition, the arterial blood supply provides nutrients to the alimentary tract itself. In the small intestine, each villus contains a single arteriole that breaks into a capillary network at the villous tip before anastomosing with a draining venule. Each villus contains a lymphatic vessel (lacteal) that drains into a submucosal plexus connected to larger lymphatics. In the colon, arterioles pass between crypts to the epithelial cell surface and form a network of capillaries around the crypts. Lymphatic vessels in the colon do not extend higher than the base of the crypts.

Blood from the small intestine and colon drains into the portal vein, which delivers absorbed water-soluble nutrients directly to the liver, where they can be metabolized or released directly into the hepatic veins and ultimately the systemic circulation. Bile salts absorbed in the terminal ileum travel through the portal vein to the liver where they can be secreted back into the small intestine, providing an enterohepatic circulation for bile salt recycling, which is critical for normal bile salt homeostasis and fat absorption. Intestinal lymphatic vessels, which are closely associated with arteries supplying the alimentary tract, carry absorbed fat-soluble nutrients to the thoracic duct, which drains

into the left subclavian vein and the systemic circulation.

Adequate intestinal blood flow is critical because it provides oxygen necessary for intestinal cell survival. Therefore, GI tract blood flow is carefully regulated by metabolic, vascular, and hormonal factors to ensure adequate tissue oxygenation. Food ingestion increases intestinal blood flow and oxygen requirements.

ENTERIC NERVOUS SYSTEM AND MOTILITY

Many GI tract motor patterns have been described and involve complicated interactions between a series of stimulatory and inhibitory impulses from the enteric nervous system (ENS) to GI smooth muscle. Intestinal smooth muscle consists of circular and longitudinal muscle layers, so the interaction of muscular contraction between layers determines the pattern of motility. The two most important motility patterns are the migrating myoelectric complex (MMC) and peristalsis, which are programmed by the ENS.

The MMC, the major complex motility pattern in mammals, is cyclical and passes from the stomach to the terminal ileum. During digestion this complex consists of irregular contractions that promote mixing and propulsion over moderate distances, modulated by distention and by chemical and mechanical stimulation of the mucosa. Sleeve contractions facilitate mixing of core and peripheral intestinal fluid contents and enhance nutrient contact with intestinal mucosa. During interdigestive periods, the MMC consists of coordinated activity that empties the stomach and sweeps down the intestine. The frequency of interdigestive ring contraction waves varies with location. Contractions occur at a rate of 3/min in the stomach and 11 to 12/min in the duodenum and decrease progressively down the small intestine to 7/min in the ileum. These interdigestive movements clear the gut for the next meal. The MMC also includes sleeve contractions that are also rhythmic, and their periodicity declines along the small intestine.

The regulation of peristalsis, the smallest unit of the propulsive reflex, is one of the simplest programmed motor activities of the ENS but is still quite complex ([Fig. 39.6](#)). The reflex has two components: oral contraction and caudad relaxation, whose combination moves intestinal contents in a caudad direction. The propulsive movement is the end result of contractions and relaxations of the longitudinal and circular external muscles and of the muscularis mucosae. The circular muscle has the major role in mixing and propulsion by ring contractions that decrease the diameter of the intestine, whereas the longitudinal muscle shortens the segment by sleeve contractions, with little alteration in luminal diameter. Excitatory and inhibitory motor neurons supply the muscle, and inhibitory reflexes modulate these activities by monitoring luminal contents. Multiple chemical mediators are involved in this reflex ([Fig. 39.7](#))([Table 39.1](#)).

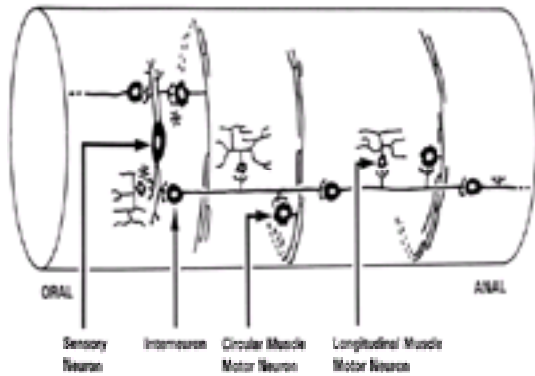

Figure 39.6. Pathways for propulsive reflexes in the intestine. A short segment of intestine is represented, on which the descending inhibitory reflex pathway and the first connections of the ascending pathway are depicted. They provide outputs to ascending and descending interneurons and monosynaptic connections to motor neurons (*). The interneurons form descending and ascending chains and provide outputs to motor neurons. In the descending pathway, some neurons excite the longitudinal muscle, and some neurons inhibit the circular muscle. Ascending reflex pathways supply inputs to excitatory longitudinal muscle motor neurons and excitatory circular muscle motor neurons (From Yamada T, Alpers DH, Owyang C, et al., eds. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1991;15, with permission.)

Figure 39.7. Regulation of peristaltic reflex by neurons of the myenteric plexus. The reflex has two components: ascending or oral contraction and descending or caudad relaxation. The stimulus (i.e., distension or mucosal stimulation) is relayed by sensory neurons to cholinergic interneurons coupled to vasoactive intestinal peptide (*VIP*) and nitric oxide (*NO*) synthase neurons caudad and acetylcholine (*Ach*) and tachykinin (*SP*, *SK*) neurons oral. Somatostatin, opioid, and g-aminobutyric acid (*GABA*) neurons exert a modulatory influence on *VIP* and *NO* synthase neurons. (From Yamada T, Alpers DH, Owyang C, et al., eds. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1991;105, with permission.)

Hormone	Source	Site of Release	Target
Gastrin	Stomach (G cells)	Stomach	Stimulates gastric acid secretion
Secretin	Small intestine (S cells)	Small intestine	Stimulates pancreatic bicarbonate secretion, inhibits gastric acid secretion
Cholecystokinin (CCK)	Small intestine (I cells)	Small intestine	Stimulates gallbladder contraction, pancreatic enzyme secretion, inhibits gastric emptying
Glucagon	Pancreas (A cells)	Pancreas	Stimulates glycogenolysis, gluconeogenesis, lipolysis
Insulin	Pancreas (B cells)	Pancreas	Stimulates glucose uptake, inhibits gluconeogenesis
Glucagon-like peptide-1 (GLP-1)	Small intestine (L cells)	Small intestine	Inhibits gastric emptying, stimulates insulin secretion
Peptide YY (PYY)	Small intestine (K cells)	Small intestine	Inhibits gastric emptying, slows small intestinal transit
Enteroglucagon	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide (ELP)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-2 (ELP-2)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-3 (ELP-3)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-4 (ELP-4)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-5 (ELP-5)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-6 (ELP-6)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-7 (ELP-7)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-8 (ELP-8)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-9 (ELP-9)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying
Enterostatin-like peptide-10 (ELP-10)	Small intestine (E cells)	Small intestine	Inhibits gastric emptying

Table 39.1 Gastrointestinal Hormones*

The presence of luminal nutrients can increase absorption by feedback regulation of intestinal motility. Fat or carbohydrate in the ileum and colon stimulates the release of PYY from ileal and colonic endocrine cells. PYY then enters the systemic circulation and inhibits gastric emptying and slows down small intestinal transit. Thus, this ileal and colonic brake mechanism enhances absorption by increasing the contact time between luminal nutrients and intestinal mucosa.

The ENS is able to regulate such complex and diffuse motility functions by its vast network throughout the GI tract. The ENS consists of approximately 100 million nerve cell bodies (neurons) and their processes, which are embedded in the wall of the GI tract. These neurons lie in clusters (ganglia) and are segregated largely into two layers: (a) the myenteric ganglia, which form a continuous plexus between the circular and longitudinal muscle layers of the muscularis propria and extend from the upper esophagus to the internal anal sphincter, and (b) the submucous plexus, which is located in the submucosa and is especially prominent in the small and large intestines. The processes from these ganglia form dense networks and innervate the muscularis propria, muscularis mucosae, epithelium, and other structures. Nonganglionated plexuses supply all the layers of the tubular GI tract, accompanying the arteries that supply the gut wall.

The ENS is connected to the central nervous system (CNS) by transmission along axons in both directions, from GI tract to brain and from brain to ENS. The connections are largely due to the vagus nerve and to pathways leaving the spinal cord. Most vagal fibers (>90%) are afferents that interact with neurons in the nucleus tractus solitarius in the midbrain. Because there are relatively few efferent vagal fibers compared with the large number of ENS neurons, the vagus functions more to initiate activity of the integrated circuits in the ENS rather than to coordinate gut function by direct signaling. Efferent centers in the spinal cord can receive efferent signals from the CNS, which are relayed to the ENS. In addition, the spinal centers can process afferent signals from the

gut.

The vagal and spinal components comprise the extrinsic branches of the autonomic nervous system, including the parasympathetic and sympathetic systems (Fig. 39.8). The striated muscles in the upper esophagus and external anal sphincter are directly innervated by cholinergic fibers, whereas the remaining gut is innervated by a variety of neural mediators, including acetylcholine, gut peptides, and nitric oxide (NO). These preganglionic fibers form synapses with the enteric plexuses, which in turn are connected with smooth muscle, secretory, and endocrine cells. The sympathetic nervous system contains preganglionic connections between prevertebral ganglia and the spinal cord, but the gut itself is innervated by postganglionic connections, mediated largely by epinephrine and norepinephrine. These postganglionic fibers innervate the plexuses of the ENS as do the parasympathetic fibers, but the sympathetic fibers also directly innervate blood vessels, smooth muscle layers, and mucosal cells.

Figure 39.8. Extrinsic branches of the autonomic nervous system. *A. Parasympathetic. Dashed lines* indicate cholinergic innervation of the striated muscle in the esophagus and external anal sphincter. *Solid lines* indicate afferent and preganglionic innervation of the remaining gastrointestinal tract. *B. Sympathetic. Solid lines* denote the afferent and preganglionic efferent pathways between the spinal cord and the prevertebral ganglia (C, celiac; SM, superior mesenteric; IM, inferior mesenteric). *Dotted lines* indicate the afferent and postganglionic efferent innervation. (From Johnson LR, Alpers DH, Jacobson ED, et al., eds. *Physiology of the gastrointestinal tract*, vol 1. 3rd ed. New York: Raven Press, 1994;451, with permission.)

The sympathetic nervous system affects intestinal secretion, blood flow, and motility. The sensory fibers that accompany the sympathetic nerves (intestinofugal neurons) are primary sensory neurons that are not part of the autonomic nervous system and are not really “sympathetic” sensory nerves. Sympathetic efferent neurons inhibit motility by decreasing contractile activity and by constricting sphincters. These various effects can be relayed along the gut to other regions before returning to the region of the initial stimulus by means of prevertebral ganglia connections. Examples of these inhibitory

reflexes include slowing of gastric emptying by acidity or hypertonicity in the upper small intestine.

Intestinal smooth muscle is of unitary type and is characterized by spontaneous activity, including active tension to stretching, and activity that is not initiated by nerves but modulated by them. The circular muscle is innervated by both excitatory and inhibitory motor neurons and forms a thick syncytium surrounding the submucosa. Contraction shortens the radius but increases the length of each fiber and in turn the syncytium. In contrast, the longitudinal muscle layer surrounding the circular muscle is thin, is shortened by contraction (with enlarged radius), and is only innervated by excitatory neurons. Electrical slow waves derive from the muscle itself and trigger action potentials that lead to contractile activity. Action potentials in intestinal smooth muscle are propagated through gap junctions from cell to cell, creating an electrical syncytium.

GASTROINTESTINAL HORMONES

The mucosa of the GI tract contains an abundance of regulatory substances that are critical for precise coordination of activities necessary to handle a meal. These substances are mostly peptides that communicate by endocrine, neurocrine, and paracrine pathways (Fig. 39.9, Table 39.1), not all of them mutually exclusive. Endocrine peptides are hormones released from sensory cells in the intestine in response to a mechanical or chemical stimulus, which enter the bloodstream to act on a distant target organ. Gut neurocrine peptides are produced within the ENS and are located in nerves within the gut itself. Most of these peptides are also produced by the brain and represent a gut-brain axis. Paracrine peptides (and histamine) are produced by intestinal cells and act on adjacent or nearby cells, either by direct cellular extension to other cells or by release of the peptide (or histamine) into the mucosa (e.g., somatostatin, histamine) or the intestinal lumen (e.g., monitor peptide, CCK-releasing peptide, trefoil peptides).

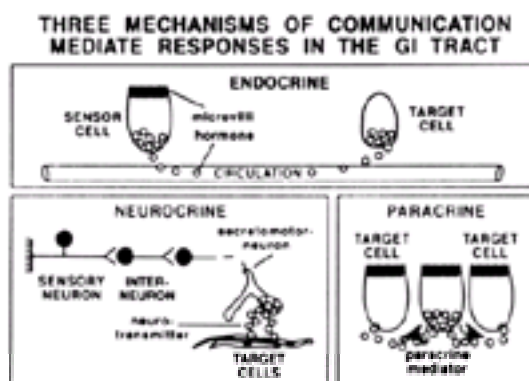

Figure 39.9. Three mechanisms of communication that mediate responses in the GI tract: endocrine, neurocrine, and paracrine. For the endocrine mechanism, sensory cells respond to stimuli by releasing transmitters that travel via the blood to their target cells or tissues. There are many examples of endocrine sensory cells in the GI tract that respond to either mechanical or chemical stimuli to release their hormones. Some types

of endocrine cells respond to changes in pH or osmolality; others respond to changes in specific nutrients. For the neurocrine mechanisms, sensing and transmissions to the target tissue are completely mediated by nerves and neurotransmitters. Nerves sense stimuli such as nutrients, pH, and osmolality in the luminal contents, as well as movement of the contents and distention of the gut lumen. (From Raybould H, Pandolfi SJ. Integrated response to a meal, undergraduate teaching project, unit 29. Bethesda, MD: American Gastroenterological Association, 1995.)

Some of the hormones listed in [Table 39.1](#) are especially important in the response to a meal (e.g., gastrin, CCK, secretin, motilin, glucose-dependent insulinotropic peptide [GIP], somatostatin) and all three major fuels (protein, carbohydrate, fat) are responsible for release of these substances. Other hormones are also released in response to a meal, but they do not act at the level of intestinal mucosal cells (e.g., insulin, glucagon) and are not considered further here. Because the coordination of function in the upper intestinal tract is so crucial, involving the stomach, duodenum, pancreas, and gallbladder, it is not surprising that these sites are most important in the release of GI hormones.

The specificity and coordination of action of GI hormones depend on three major factors: the multiple functions of each hormone, the paracrine actions between neuroendocrine and mucosal cells, and the regulatory functions of the ENS. Most GI hormones have multiple actions and mediate both stimulatory and inhibitory functions (e.g., gastrin, CCK, secretin, GIP, vasoactive intestinal polypeptide [VIP], enkephalins) ([Table 39.1](#)). Other GI hormones or amines are solely stimulatory (e.g., histamine, motilin, gastrin-releasing peptide [GRP], monitor peptide, CCK-releasing peptide) or inhibitory (e.g., somatostatin, pancreatic polypeptide). Thus, release of these hormones has the potential to create multiple effects on GI organs, coordinated in time. The presence of multiple cells in the mucosa, each possessing receptors to many of the GI hormones, also helps to create specificity of response. For example, in isolated cell systems, CCK stimulates acid production. However, CCK injected into the intact animal does not stimulate acid production because of a greater effect of CCK on the D cell producing somatostatin, an inhibitor of acid secretion, than on the parietal cell that produces acid. Gastrin, on the other hand, has the reverse effects on those two mucosal cells. In this way, the multiplicity of mucosal specific cells adds a layer of complexity and control to the multiple hormones present in the mucosa. Finally, the ENS with its many neuronal connections to mucosal cells, integrates the stimuli controlling GI hormone release. Both preganglionic parasympathetic cholinergic nerves and postganglionic fibers, mediated by neurocrine peptides, are important regulators of the gastrointestinal response to feeding. In addition, chemosensory neurons detect intraluminal events and regulate mucosal function by intrinsic mucosal reflexes.

INTEGRATED RESPONSE TO A MEAL

The integrated response of the GI tract to a meal represents a coordinated series of events, including regulation of food intake, stimulus-evoked responses in anticipation of

the meal, ingestion and transfer of the meal to the stomach, digestion and absorption of the meal, and elimination of waste products of the meal, bringing into play all the individual regulatory controls reviewed above.

Regulation of Food Intake

The GI tract is involved in the earliest part of feeding beginning with the control of nutrient ingestion. Peptide hormones and other neurotransmitters in the gut have been implicated in the short-term regulation of energy intake (see [Chapter 40](#)). Olfactory and visual signals, along with mood and degree of physical activity can regulate intake via hypothalamic and brainstem centers (see [Chapter 41](#)). Taste buds in the tongue can affect energy intake during a meal. Gut hormones suggested to be regulators of food intake include insulin, glucagon, CCK, and GRP. Neurotransmitters possibly involved include serotonin, dopamine, epinephrine, opiates, and g-butyric acid. Considerable evidence supports the role of CCK and GRP as satiety factors, both of them neurally released. Insulin probably stimulates the hunger drive. Recently, evidence has implicated two nonhormonal gut peptides as physiologically relevant satiety factors, enterostatin (the amino-terminal peptide of colipase) and apolipoprotein A-IV. The abundance of potential satiety agents makes it appear likely that the gut signals important in the short-term control of energy intake are multiple and perhaps additive.

Stimulus-Evoked Responses

The anticipatory responses to a meal are mediated by the CNS. Visual, olfactory, and auditory senses as well as the presence of food in the mouth can activate secretory responses from the salivary glands, stomach, and pancreas and can initiate relaxation in the stomach, contraction of the gallbladder, and relaxation of the sphincter of Oddi. These actions prepare the GI tract to initiate digestion when the meal arrives. This preparation is important, because digestive products of foodstuffs (e.g., amino acids, free fatty acids) are important stimuli in creating the maximum responses necessary to digest and absorb a meal. Thus, these nutrient products must be produced early in the meal. This cephalic phase of the meal is mediated through various brain centers, but the efferent signals all reach the gut through the vagus nerve. Once the meal enters the GI tract, the ENS becomes activated and works in concert with the CNS. For example, distention of the esophagus and/or stomach causes a contractile response mediated entirely by the ENS.

The best studied anticipatory CNS-mediated response is the cephalic phase of gastric secretion. Sensory input from the eye, nose, ear, and mouth sends afferent signals to the dorsal vagal complex in the midbrain where they are integrated and transmitted to GI organs by vagal efferent nerves. The stomach responds by producing acid and pepsin. Acetylcholine release from the vagus stimulates pepsinogen release into the lumen of the stomach. In the distal stomach, the vagal efferents activate the ENS to produce GRP to release gastrin, stimulating acid and pepsinogen production. Thus, when food enters the stomach, some of the protein is rapidly converted to oligopeptides by the action of pepsin, produced from pepsinogen and activated by the low pH. These oligopeptides stimulate release of more gastrin to perpetuate the digestive process. In this process, as well as in other anticipatory responses, appetizing meals elicit more

response than bland or unappetizing meals. Thus, the higher centers of the CNS are important in regulating the initial response of the GI tract.

Although these anticipatory responses clearly occur at each meal, it is not certain to what degree they are essential for the assimilation of nutrients. For example, the stomach can be removed and digestion and absorption can proceed fairly completely. Anticipatory responses to a meal may be more important in determining the amount of food eaten at a meal than in the absorption of nutrients. The loss of anticipatory relaxation of the proximal stomach allows only small volumes to be consumed at one time, so that consuming enough food to maintain weight becomes difficult. Although this deficit can be overcome by cognitive training, the response to a meal is impaired. Impairment in the senses of sight, taste, and/or smell affects the cognitive drive that creates the desire to eat.

Mouth

Chewing and salivary secretion form the food into a round and smooth portion that can be swallowed. The mouth is the receptacle for two functions: secretion and motility. Secretion into the oral cavity originates from the salivary glands and consists of fluid, electrolytes, and proteins. The structure and function of salivary glands, which are composed of acini that secrete their products through ducts, are analogous to those of the pancreas. Chloride enters the lumen of the salivary gland through chloride channels, and sodium enters paracellularly to maintain electroneutrality. In the ducts, the fluid is modified as sodium and chloride leave the lumen; some sodium is exchanged for potassium and some chloride is exchanged for bicarbonate, producing a final salivary secretion rich in bicarbonate. Stimulation of the parasympathetic nerves is the major factor in regulating salivary secretion by direct acinar and duct cell innervation and by altering the blood supply. However, vasoactive peptides are also released to regulate blood flow. Sympathetic nerve input also stimulates secretion, but to a much lesser extent.

Proteins present in salivary secretions are important during the initial stages of nutrient assimilation. The influence of salivary amylase on starch digestion in the mouth and esophagus is small because of the short residence time of food in the mouth. However, in the stomach, attachment of amylase to its substrate protects the enzyme from inactivation at the slightly acid environment (pH 5–6) of the stomach when it is buffered by food. Thus, the enzyme achieves significant initial hydrolysis of dietary starch while still in the stomach. In addition, a non-bile-salt-dependent triglyceride lipase is produced by Ebner's glands at the base of the tongue. Although the oral production is relatively small, the gastric mucosa produces more of this lipase. As is the case with salivary amylase, the digestion of triglycerides due to this lingual/gastric lipase occurs primarily in the gastric lumen. The best dietary substrates for this enzyme are triglycerides that contain medium-chain fatty acids. The salivary glands also secrete haptocorrin (also known as R protein), a carrier protein that protects vitamin B₁₂ from acid-peptic digestion in the stomach. Most of the other salivary proteins largely enhance lubrication, provide antibacterial action, and enhance mucosal integrity.

The motility functions of the oral cavity are coordinated with the upper esophageal

sphincter to propel the food bolus into the esophagus. This action requires the coordination of extrinsic muscles to modify the shape of the pharyngeal cavity and to close the airways and of intrinsic muscles to propel the bolus caudally. These two groups work in succession, so that food does not reflux into the nose or larynx. These muscular units work in reverse order during the act of vomiting, again with the purpose of preventing luminal contents from entering the airways.

Esophagus

The esophagus carries the food bolus from the mouth to the proximal stomach. The upper esophageal sphincter relaxes immediately after swallowing, along with increased pharyngeal pressure. These pressure changes move the bolus into the esophagus. The esophagus is the first gut organ in which the phenomenon of peristalsis is encountered. Peristalsis along the length of the esophagus (primary peristalsis) is enhanced by esophageal distention produced by the food bolus (secondary peristalsis). The coordinated caudal movement of contraction and relaxation waves moves the food bolus along the length of the esophagus. The act of swallowing initiates both pharyngeal and esophageal peristalsis and relaxation of the lower esophageal sphincter (LES), allowing the swallowed bolus to enter the proximal stomach. Immediately after a swallow, the LES pressure falls to that of the stomach and remains low until the swallow is completed. At the end of the swallow, the LES contracts, stripping the end of the esophagus of any remaining food contents. The most important neurotransmitters for the motility pattern in the esophagus are acetylcholine (contraction) and VIP/NO (relaxation). Although the esophagus is often depicted as an open tube, the walls of the esophagus are actually approximated to each other during fasting conditions and in areas not distended by a food bolus during feeding. Thus, the bolus cannot travel down the esophagus in the absence of peristalsis. Surprisingly, gravity is not a significant factor in the function of the esophagus.

Stomach

Although the oral cavity initiates some changes in the food bolus, not until residence in the stomach are the physical and chemical characteristics of the meal altered. The food bolus enters the stomach as large particles, following chewing action in the mouth. In the stomach, the food is mixed and ground with secreted fluid and enzymes and converted to a suspension of particles small enough to pass the pylorus into the duodenum. In addition, fats are converted into an emulsion by mixing action, and small amounts of fatty acids and monoglycerides are formed. Protein and starch digestion also proceeds to create monomeric and oligomeric nutrients that can act further in the duodenum to potentiate the intestinal response to a meal. The two major components responsible for these overall actions of the stomach are motility and acid/peptic secretion.

The anticipatory cephalic phase and distention of the stomach by a meal both lead to receptive relaxation of the proximal stomach, thus accommodating the meal without increasing gastric pressure. Vagal afferent fibers in the gastric wall respond to changes in tension in the muscular coat of the stomach. These responses are processed in the dorsal vagal nucleus in the medulla and create vagal efferent responses that not only

relax the proximal stomach but also increase gastrin, acid, and pepsinogen secretion, initiate antral and gallbladder contraction, relax the sphincter of Oddi, and stimulate pancreatic secretion. These vagovagal reflexes are important in the coordinated function of the organs of the upper GI tract (stomach, duodenum, gallbladder, and pancreas) and are part of the reason why these organs are considered a cluster unit. The likely neural mediators of these reflexes are VIP and NO. Although the functions of the four upper GI organs are being considered separately, they do not proceed in isolation but as part of a carefully programmed response involving the entire cluster unit.

Antral (distal stomach) contractions are initiated by distention of the stomach. Propulsion, grinding, and retropulsion in the distal stomach grinds the meal into small pieces and mixes it with gastric secretions rich in acid and pepsin. The food bolus is ground until the particle size is less than 2 mm and it can pass through the pylorus during the propulsive component. Peristalsis in the stomach is slow, at a frequency of approximately three cycles per minute, mediated in large part by vagal and intrinsic gastric wall cholinergic neurons.

Gastric emptying is closely regulated and is modulated by factors other than particle size. The fastest gastric emptying occurs with isotonic solutions. Most solid meals produce hypertonic solutions, and most liquids are either hypo- or hypertonic. Thus, most meals are not emptied at the fastest possible rate. The rate of gastric emptying following a meal is normally about 2 mL/min. At this rate, the digestive and absorptive functions of the upper small intestine are not overwhelmed. Other inhibitory mechanisms affecting the rate of gastric emptying involve H⁺ ion concentration and caloric load delivered to the duodenum.

Another major function of the stomach is to produce secretions rich in hydrogen and pepsinogen. The parietal and chief cells are most responsible for the products entering the gastric lumen after a meal ([Table 39.2](#)). Postprandially, the volume of gastric secretion increases and the ion concentration changes, almost entirely because of parietal cell secretion. Non-parietal-cell secretion from mucous and chief cells contributes bicarbonate-rich fluid in the fasting state. After a meal, hydrogen is exchanged for Na⁺, and Cl⁻ replaces HCO₃⁻ secretion. Most of these secretory changes occur during the gastric phase of acid secretion, which occurs maximally about 60 to 90 min after ingestion of food.

Cell Type	Product	Function
Surface cells	Mucus	Lubrication
Neck cells	HCO ₃ ⁻ Trefol peptides	Protection
Parietal cells	H ⁺ Intrinsic factor	Protein digestion Binding of cobalamin (vitamin B ₁₂)
Chief cells	Pepsinogen Gastric lipase	Protein digestion Triglyceride digestion
Endocrine cells	Gastrin Histamine Somatostatin	Regulation of acid secretion

Table 39.2 Gastric Cell Secretory Products and Function

The mechanism of enhanced parietal cell secretion involves four different cell types: parietal cells, enterochromaffin-like (ECL) cells, D (somatostatin) cells, and G (gastrin) cells. These cells are distributed in two different anatomic portions of the stomach; the parietal, ECL, and fundic D cells are in the fundus, and the antral D cell and G cells in the antrum. It is mainly the interaction of gastrin, somatostatin, and other transmitters that affects the production of histamine from the ECL cell, which in turn determines the rate of gastric acid secretion. Gastrin is released from the G cell in response to a meal by multiple mechanisms; acetylcholine and GRP acting through vagal and intrinsic nerves release gastrin during the cephalic and gastric phases of secretion, and luminal amino acids released by pepsin also stimulate gastrin release during the gastric phase. Gastrin acts in an endocrine fashion by binding to CCK-B receptors on the ECL cell, causing histamine release by exocytosis. Somewhat later, synthesis of histidine decarboxylase is activated causing additional histamine production. Finally, gastrin stimulates ECL cell growth. As a result of these three effects, ECL cell histamine production increases and drives parietal cell activation and secretion. Gastrin accounts for about 70% of the stimulated histamine release, the remainder being driven by acetylcholine via muscarinic receptors, by epinephrine via adrenergic receptors, and by gastrin directly via CCK-B receptors. Thus, multiple neural transmitters and peptides are involved in regulation of acid secretion, working as endocrine and paracrine hormones.

Gastric acid secretion is further regulated by feedback inhibition, mediated largely by somatostatin released from specialized endocrine (D) cells in the antrum and fundus. The fundic D cells are probably more important than antral D cells in regulating histamine production from ECL cells. Different conditions mediate release of somatostatin from D cells in these two locations. Calcitonin gene-related peptide (CGRP), secretin, and VIP all seem to stimulate release of somatostatin from fundic D cells. The second arm of the feedback loop occurs in antral D cells. When the pH in the antral lumen falls below 3.0, somatostatin is released from antral D cells, inhibiting gastrin release from G cells by paracrine mechanisms. Moreover, luminal acid directly decreases gastrin release from G cells. This example of regulation of gastric acid secretion after a meal is provided as one of the best known examples of the intricate and complex coordination of gastrointestinal function, using elements of the CNS, ENS, and GI hormones.

Gastric parietal cells also produce intrinsic factor, a carrier protein necessary for ileal absorption of vitamin B₁₂. Vitamin B₁₂ fits into a hydrophobic pit of the intrinsic factor protein, which enhances binding of the intrinsic factor–vitamin B₁₂ complex to receptors in the terminal ileum.

Duodenum

The duodenum is at the center of another elaborately coordinated regulatory process, integrating the functions of gastric emptying, bile formation, gallbladder and duodenal motility, and pancreatic and biliary secretion. For this reason the concept of the “duodenal cluster unit” was developed. The duodenal cluster unit concept is also embryologically cogent. Each of the organs of the duodenal cluster unit (stomach, duodenum, liver, common bile duct, gallbladder, and pancreas) are derived from closely related structures at an early stage of fetal development. The liver, gallbladder, common bile duct, and ventral pancreas bud off together from the antimesenteric side of the duodenum, while the dorsal pancreatic bud develops from the mesenteric surface. The ventral pancreas then rotates to join the dorsal pancreas. It is not surprising, therefore, that sensors in the duodenum can regulate function in the other organs of the cluster unit.

The duodenum acts as both a simple mixing chamber and a regulatory center by containing cells and nerve endings that sense nutrient content, pH, and osmolarity. The major hormones involved in regulating the duodenal cluster unit are CCK and secretin, although their effects are not exclusive. Moreover, the GI hormones that act in the duodenal cluster unit may act via an endocrine mechanism (through the bloodstream) or via paracrine mechanisms (locally within the intestinal mucosa). An acid pH leads to release of secretin and activation of extrinsic and intrinsic nerves to increase pancreatic and biliary secretion of water and bicarbonate. The presence of digestive products of nutrients (amino acids, fatty acids, monosaccharides) leads to release of CCK and activation of extrinsic and intrinsic nerves that inhibit gastric emptying and acid secretion, stimulate gallbladder contraction, stimulate pancreatic enzyme secretion, and initiate the small bowel motility pattern of the fed state.

Gastric acid secretion can be inhibited by the duodenum ([Table 39.3](#)). This process is distinguished from inhibition by antral somatostatin in that the regulation of gastric acid secretion by duodenal acid, hyperosmolarity, and fatty acids also leads to inhibition of gastric emptying. In this way the duodenal mucosa is doubly protected from an excessive influx of acid. GIP (formerly called “gastric inhibitory polypeptide”) released by the duodenum inhibits gastric acid secretion.

Region	Stimulus	Mediation	Inhibits Gastrin Release	Directly Inhibits Acid Secretion
Oxyntic gland area	Acid (pH < 3.0)	Somatostatin	Yes	Yes
Antrum	Acid	Secretin Nervous reflex	Yes No	Yes Yes
Duodenum	Hyperosmotic solutions	Unidentified Enterogasterone	No	Yes
Duodenum and jejunum	Fatty acids	GIP Unidentified Enterogasterone	Yes No	Yes Yes

Table 39.3 Regulation of Gastric Acid Secretion

Release of CCK from duodenal CCK cells after a meal is critically important for meal digestion. CCK acts as a hormone to stimulate pancreatic secretion and to increase antral, pyloric, and duodenal contractions. Moreover, CCK acting as a neurocrine peptide stimulates vagal afferent fibers that form part of the vagal efferent outflow after a meal, with subsequent effects on proximal gastric relaxation, increased acid output, gut motility, and pancreatic secretion. In fact, most of the effects of CCK after a meal are thought to be mediated through its role as a neurocrine peptide. CCK is important in regulation of the biliary system and its components. The peptide stimulates gallbladder contraction and relaxes the sphincter of Oddi, allowing concentrated bile to enter the duodenum. This action is mediated by both the hormonal and neurocrine functions of CCK. Fatty acids in the duodenal lumen release CCK, which in turn acts humorally on CCK-A receptors in the gallbladder. Moreover, in response to sensory afferents activated by CCK, vagal efferents mediated by acetylcholine contract the gallbladder and vagal afferents releasing VIP/NO relax the sphincter of Oddi.

A complex system regulates release of CCK from endocrine I (CCK-secreting) cells in the duodenum. Luminal nutrients, especially protein, amino acids, and free fatty acids, initiate the signal. Protein in particular is involved in stimulating release of two peptides that in turn release CCK: monitor peptide produced in pancreatic acinar cells and CCK-releasing peptide (CCK-RP) produced in duodenal mucosal cells. Release of both of these peptides can be affected by parasympathetic (vagal) efferent nerves. Between meals, these peptides are degraded by luminal trypsin, which is highly concentrated. Thus, little CCK is secreted during fasting. However, as large quantities of protein enter the gut after a meal, the amount overwhelms luminal trypsin activity, and thus most of the monitor peptide and CCK-RP escapes degradation. In this way, ingestion of protein regulates the release of CCK, which in turn stimulates release of proteolytic enzymes from the pancreas in conjunction with vagal efferent stimulation.

Another important function of the duodenal cluster unit is to neutralize the gastric acid delivered to the proximal duodenum and maintain a constant intraluminal pH. Multiple organs are involved in this regulation, including the duodenal mucosa, biliary system, and pancreas. The meal itself provides buffers, mostly in the form of peptides and fatty acids. Most of the neutralization comes from bicarbonate secreted from the pancreas, biliary ducts, and duodenal mucosa. Secretin mediates the biliary and pancreatic response, while the ENS mediates the mucosal response. The major mucosal sensor is the endocrine S, or secretin, cell, which is activated to release secretin when the luminal pH falls below 4.5.

A final important function for the duodenum is to produce and maintain isotonicity of luminal contents, thereby avoiding large shifts of fluid across the semipermeable membrane of the gut. This function is performed by the duodenal mucosa alone, without other organs in the cluster unit. Most meals are either hyper- or hypotonic. Thus, the

duodenum must either add or absorb fluid and electrolytes. Remarkably, this adjustment is made within the first 50 cm (20 in) of the duodenal bulb. Under normal circumstances, however, the maximum rate of gastric emptying is about 2 mL/min so the proximal duodenum is not presented with larger volumes than it can accommodate for isotonic adjustment.

Thus, passage through the duodenum changes the physical properties of the meal because of the contributions of the organs in the duodenal cluster unit. Large amounts of pancreatic hydrolases and bile salts are added, digesting nearly all ingested macromolecules (except dietary fiber) to oligomers or monomers solubilized in a form compatible with absorption. Intestinal fluid leaving the duodenum is more isoosmotic, and the pH is more neutral.

Biliary System

Bile salts are crucial for solubilization and absorption of lipid-soluble nutrients. Bile salts are synthesized and secreted by the liver, conjugated to either taurine or glycine to improve solubility, stored and concentrated in the gallbladder, and delivered to the duodenal lumen in response to a meal. Between meals, the gallbladder stores and concentrates the bile salts extracted by the liver from the blood. Two major factors regulate the supply of bile salts following a meal. First, contraction of the gallbladder and relaxation of the sphincter of Oddi releases the gallbladder contents into the upper duodenum. This provides the first and immediate load of bile salts to enhance pancreatic lipase digestion and fatty acid/monoglyceride and cholesterol solubilization. Second, bile salts subsequently move down the small intestine to the ileum, where they are absorbed by a receptor-mediated mechanism and returned to the liver via the bloodstream. The enterohepatic circulation (reabsorption in the ileum, uptake by the liver, and secretion back into the intestine) preserves bile salts and diminishes the need for new synthesis in the 1 to 2 hours after a meal. The entire body pool of bile salts (approximately 3–4 g) is recirculated two to four times after each meal, providing 6 to 16 g of bile salts to the upper duodenum during the first hours after a meal. With a total luminal volume from diet and secretions of 2 to 3 L after each meal, this provides a large margin of safety for maintaining a luminal concentration above the critical micellar concentration of 2 to 4 mM needed for lipid solubilization and activation of pancreatic lipase.

Pancreas

Three phases of pancreatic secretion follow a meal: cephalic, gastric, and intestinal ([Table 39.4](#)). These phases have been described in an attempt to classify the multitude of events that occur postprandially. As seen in the other organs described above, pancreatic secretion is mediated by neural (vagal) efferent responses and by gut hormones. The cephalic phase of secretion is largely, if not exclusively in humans, mediated by the vagus nerve. In this and the gastric phase, the pancreas secretes mostly water and bicarbonate. Pancreatic polypeptide (PP), located in specific PP cells in the pancreatic islets, acts as a negative feedback mechanism for the vagally stimulated portion of pancreatic secretion. PP is released in response to vagal efferent

stimulation and inhibits the vagal efferent effect on the pancreas.

Phases	Pancreatic Response (%)	Stimulants	Mediators
Cephalic	25	Sight, smell, taste, eating	Vagal innervation
Gastric	10	Distention	Vagal-cholinergic pathways
Intestinal	50-75	Amino acids	Cholecystokinin, secretin
		Fatty acids	Enteropancreatic reflexes
		Ca ²⁺ , H ⁺	Other hormones (?)
		Distention	

Adapted from Yamada T, Alpers DH, Quyang C, et al., eds. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1991:2-110-158-278.

Table 39.4 Phases of Pancreatic Secretion after a Meal

In the intestinal phase, pancreatic enzymes are added to the large volume of fluid secreted. As noted above, products of proteolysis and lipolysis stimulate the CCK (endocrine I) cell to release CCK, which acts humorally on the pancreatic acinar cells to produce enzymes. At the same time, H⁺ ions stimulate the S cell to release secretin, which acts humorally on the pancreatic duct cells to secrete a bicarbonate-rich fluid, necessary to neutralize gastric acid and allow pancreatic enzymes to be effective. In addition, enteropancreatic reflexes within the ENS, sensitive to distention, osmolarity, and various nutrients, stimulate pancreatic enzyme secretion mediated by acetylcholine, GRP, and VIP. Most of the hydrolases secreted by the pancreas are proteases, secreted in an inactive precursor form to prevent digestion within the pancreas ([Table 39.5](#)). Trypsinogen accounts for 40% of the pancreatic protein secreted. In the intestinal lumen, trypsinogen is activated to trypsin by the enzyme enterokinase, produced by duodenal enterocytes. Trypsin in turn converts trypsinogen and all other proenzymes to their active forms, and the intraluminal phase of intestinal digestion is initiated.

Hydrolase	Approximate Activity (units/g protein)
Glucosylase	250
Sucrase	100
α-Dextrinase	100
Lactase	45

Table 39.5 Intestinal Brush Border Membrane Hydrolase Activity in Normal Human Biopsy Specimens

Pancreatic insulin secretion in response to a meal is enhanced by the release of GIP from the GIP cell, a mucosal endocrine cell. Although GIP was first recognized for its ability to inhibit gastric acid secretion, it was later found that the major function of this peptide is to mediate meal-stimulated insulin release from the pancreas. This observation led to changing the name of GIP from “gastric inhibitory polypeptide” to “glucose insulinotropic polypeptide.” Intraluminal glucose stimulates GIP release, which acts humorally to augment the glucose-mediated release of insulin from b cells in pancreatic islets. This action of GIP helps maintain blood glucose levels within a reasonable range after a meal and provides another example of the redundancy characteristic of the regulation of gastrointestinal function following a meal.

NUTRIENT ABSORPTION

Fluid and Electrolytes

The GI tract absorbs large volumes of fluid each day. Approximately 9 L of water is delivered to the upper small intestine daily from dietary intake (2000 mL), saliva (1500 mL), gastric secretions (2500 mL), bile (500 mL), pancreatic secretions (1500 mL), and small intestinal secretions (1000 mL). Some 98% of the daily fluid load is absorbed, while only 100 to 200 mL/day is excreted in stool; approximately 85% (7.5 L) of water is absorbed in the jejunum and ileum, and 13% (1.4 L) in the colon.

Water is absorbed passively throughout the intestine and is regulated primarily by active electrolyte absorption. Specific features of epithelial cells throughout the intestine are important in regulating fluid and electrolyte absorption. First, the apical (luminal) membrane contains specific electrolyte transporters and channels. Second, the basolateral (serosal) membrane contains a sodium pump that provides the drive for electrolyte absorption. Third, intestinal epithelial cells are linked to each other by tight junctions located close to the apical surface. The “permeability” of intestinal epithelium depends on the number of tight junctions. The permeability of these intercellular junctions to solute, ion, and water movement decreases distally through the intestine. Therefore, the jejunum is more permeable or “leaky” than the ileum, which is more “leaky” than the cecum, which is more “leaky” than the rest of the colon.

Fluid and electrolytes are absorbed from the intestinal lumen directly through (transcellular pathway) or between (paracellular pathway) epithelial cells. Passive transport does not require energy and can occur transcellularly or paracellularly. The lipid content of the epithelial cell membrane prevents passive diffusion of charged electrolytes. Specialized proteins present in the apical membrane form channels or pores that permit electrolyte transport (see [Chapter 38](#)). Passive transport through

membrane channels is regulated by concentration and electrochemical gradients across the membrane. Ion channels are usually specific for certain ions and can be opened or closed by cellular “messages.” In the open state, more than a million ions can pass through per second, but no ions pass when the channel is closed. Passive transport can also occur via carriers, which are proteins, located in the cell membrane. Carriers are specific for certain solutes or ions and facilitate their passive movement along a concentration or electrochemical gradient across the cell membrane. Carrier-mediated transport is much slower than movement through channels.

Active transport requires energy and permits movement of a solute or ion against a concentration or electrochemical gradient. Active transport only occurs transcellularly and is mediated by a “pump” that moves ions in and out of the cell. The most important epithelial cell pump is the Na^+ pump (also known as Na^+ - K^+ ATPase), which moves three Na^+ ions across the basolateral membrane in exchange for two K^+ ions (Fig. 39.10). Thus, the Na^+ pump lowers intracellular sodium concentration and makes the intracellular potential difference negative compared with the extracellular environment.

Figure 39.10. Electrolyte and solute absorption. Sodium can travel from the intestinal lumen into the epithelial cell by an ion channel (*apical side top*), the Na^+ -glucose cotransporter (*apical side middle*), or a Na^+ - H^+ exchanger (*apical side bottom*). Release of H^+ creates a favorable gradient for HCO_3^- exit, which facilitates Cl^- entry via the Cl^- - HCO_3^- exchanger. The Na^+ - K^+ - Cl^- cotransporter in the basolateral membrane also increases Cl^- uptake. Electrogenic Cl^- secretion occurs via a Cl^- channel on the apical membrane. Intracellular glucose accumulation favors glucose transport across the basolateral membrane via a specific carrier protein. The Na^+ pump (Na^+ - K^+ -ATPase) provides the energy for these processes by generating low intracellular sodium concentrations and a transmembrane electrochemical gradient. (From Sleisenger MH, Fordtran JS, Scharschmidt BF, Feldman M, eds. *Gastrointestinal disease*. 5th ed. Philadelphia: WB Saunders, 1993;954–76.

Secondary active transport is transport that combines both passive and active

processes. For example, the negative intracellular voltage of epithelial cells enhances cation entry and anion exit from the cell. Thus, ions may move passively against their concentration gradients because of the electrical potential difference across the cell generated by the active sodium pump. The use of oral rehydration therapy in patients with severe diarrhea, such as those with cholera or short bowel syndrome, takes advantage of secondary active transport and the Na-glucose cotransporter in small intestinal epithelium (Fig. 39.10). This transporter, present in the apical membrane, binds both sodium and glucose. Glucose is transported across the cell membrane into the cell against its concentration gradient because of the low sodium concentration and the negative potential difference present in the cell. As glucose accumulates in the cell, it moves along its concentration gradient across the basolateral membrane via a specific transport carrier. Similar sodium-cotransport mechanisms also facilitate absorption of amino acids, vitamins, and bile salts. The Na⁺ pump also drives passive absorptive or secretory transport of hydrogen, chloride, potassium, and bicarbonate (Fig. 39.10). Transport regulation can occur at the channel, carrier, or pump levels.

Water is absorbed passively throughout the GI tract and follows the absorption of electrolytes and other osmotically active nutrients. As noted above, water moves both transcellularly and paracellularly in response to increased osmolarity of the intracellular and subepithelial spaces. Sodium absorption is the most important factor in regulating water absorption. The Na-nutrient cotransporter and electroneutral NaCl exchange transporter are responsible for most water absorption. Furthermore, water absorbed between epithelial cells can increase absorption of solutes present in water, a process known as "solvent drag" (Fig. 39.11). Both sodium and water movement in response to an osmotic gradient is much greater in the jejunum than in the ileum because the junctions between epithelial cells are leakier in the jejunum than in the ileum. In the jejunum, sodium is primarily absorbed by uptake via the sodium-nutrient cotransporter and solvent drag. Therefore, ingestion of fluids or a meal with a low sodium content increases the osmolality in the upper small intestine and causes net secretion of water and sodium into the lumen. Patients with a jejunostomy and less than 100 cm of jejunum have difficulty maintaining fluid and electrolyte balance; thus, longer lengths of small intestine are often required for optimal fluid and electrolyte absorption. Balance studies performed after liquid ingestion by patients with a very short bowel ending in a jejunostomy demonstrate that drinking solutions with sodium concentrations below 90 mmol/L leads to net sodium and water losses, while drinking a solution with 90 mmol/L or more causes net sodium and fluid absorption. Although most water is absorbed in the small intestine, approximately 1 to 1.5 L enters the colon each day. Some 95% of the fluid that enters the colon is absorbed. Moreover, the colon can absorb up to approximately 5 L/day of fluid.

Figure 39.11. Electrolyte and water absorption in the jejunum. The Na-glucose cotransporter in the small intestinal binds both sodium and glucose and transports them across the epithelial cell membrane. As glucose accumulates in the cell, it moves along its concentration gradient across the basolateral membrane via a specific transport carrier. Water is absorbed passively by both transcellular and paracellular routes in response to increased osmolarity in the intracellular and subepithelial spaces. The Na-nutrient cotransporter shown in this figure and the electroneutral NaCl exchange transporter are responsible for most water absorption. Water absorbed between epithelial cells can increase the absorption of solutes present in water by “solvent drag.”

Lipid

Approximately 100 g of fat, equivalent to about 40% of total energy intake, is consumed daily in an adult Western diet. Most (95%) fat intake consists of long-chain triglycerides (LCTs); the remainder includes cell membrane phospholipids, cholesterol, other sterols, and fat-soluble vitamins. In addition, a large quantity of endogenous lipids (~60 g) is delivered into the intestinal lumen daily from bile (containing ~30 g bile salts, 10–15 g phospholipids, and 1–2 g cholesterol), desquamated intestinal cells (containing ~5 g membrane lipids), and dead bacteria (containing ~10 g membrane lipids). The upper limit of normal fecal fat output while consuming a 100-g fat diet is about 7 g/day. Therefore, at least 95% of fat delivered to the intestine is usually absorbed. Most dietary fat is absorbed before the fat contained in a meal reaches the ileum. However, even when no dietary fat is ingested, a small amount of fat can still be detected in stool because of the contribution from endogenous sources.

Assimilation of dietary fat provides a good general index of intestinal absorptive function because it involves most of the components involved in digestive and absorptive processes. Triglycerides are particularly difficult to digest and absorb because they are insoluble in water. Therefore, absorption requires (a) breakdown of ingested fat into an emulsion, which enhances contact between lipolytic enzymes and triglycerides; (b) enzymatic hydrolysis of triglycerides; (c) water-soluble micelle formation, which permits transport across the unstirred water layer to intestinal epithelial cells; (d) uptake of fatty acids by epithelial cells; (e) repackaging of fatty acids into water-soluble chylomicrons

within the epithelial cell; and (f) secretion of chylomicrons into the systemic circulation by lymphatic vessels.

The stomach is important in initiating fat digestion. Approximately 20% of ingested triglycerides are hydrolyzed in the stomach by gastric lipase, which is produced by chief cells, functions in an acid environment, and is resistant to denaturation by pepsin. In addition, gastric muscle contractions, gastric acidity, and pepsin mash food particles and release dietary lipids from their protein interactions, generating an emulsion of small particles that is delivered into the duodenum.

In the duodenum, the emulsion particles are further stabilized by addition of bile salts and phospholipids secreted by the gallbladder. The presence of gastric acid in the duodenum stimulates secretin release from duodenal mucosa. Secretin enters the portal circulation and stimulates the pancreas to secrete bicarbonate, which raises the intraluminal pH above 6. The presence of fatty acids and amino acids in the duodenum stimulates CCK release from duodenal mucosa, which then enters the portal circulation and stimulates the pancreas to secrete lipase, colipase, and other digestive enzymes, and stimulates gallbladder contraction and bile flow into the duodenum. Lipase and colipase are secreted by the pancreas in a 1:1 molar ratio and act at the surface of the emulsion particles to hydrolyze triglycerides to monoglycerides and fatty acids. The near neutral pH of the duodenum maximizes lipase and colipase activity; pancreatic lipase is not functional in an acidic environment. Colipase is a critical cofactor for lipolysis, acting as a link between pancreatic lipase and triglycerides. In fact, pancreatic lipase cannot gain access to triglycerides within the emulsion without colipase because of interference from bile salts and phospholipids coating the emulsion particles. Although pancreatic lipase is responsible for most intestinal triglyceride lipolysis, the pancreas also secretes bile salt-activated lipase that hydrolyzes ester linkages in cholesterol, phospholipids, and fat-soluble vitamins. Fat digestion by gastric and pancreatic lipases is very effective, and most ingested triglycerides are hydrolyzed within the first 100 cm of jejunum.

Fatty acids, monoglycerides, and other lipids interact with bile salts to form water-soluble mixed micelles. Bile salts contain both water-soluble and lipid-soluble portions, allowing them to surround the digested lipid products—their hydrophobic side pointing toward the interior and the hydrophilic side toward the exterior. Thus, bile salts make fatty acids, monoglycerides, cholesterol, and other intraluminal lipids soluble in water by “hiding” them inside mixed micelles ([Fig. 39.12](#)). Although bile salts secreted in bile are diluted by luminal fluid, the intraduodenal concentration (10–20 mmol/L) is still well above the critical micellar concentration (2–3 mmol/L). The products of triglyceride digestion by pancreatic lipase can also coalesce to form vesicles. Lipid within vesicles is usually transferred to micelles but these vesicles can also transport lipid directly to the mucosa. Vesicle formation is believed to permit absorption of more than half of ingested triglycerides when bile salts are absent (e.g., in patients with severe cholestasis). However, vitamins D, E, and K are particularly insoluble and require micelle formation for adequate absorption.

Figure 39.12. Structure of a mixed lipid–bile salt micelle. The products of lipolysis are solubilized in the interior of the particle. The bile salt molecules orient with their hydroxyl groups (*black circles*) facing the aqueous phase or, when they are in the interior of the micelle, facing each other. Fatty acids and monoglycerides orient in the micelle with their polar head groups in contact with the aqueous phase and their hydrocarbon tails in the interior of the micelle. (From Chang EB, Sitrin MD, Black DD, eds. *Gastrointestinal, hepatobiliary, and nutritional physiology*. Philadelphia: Lippincott-Raven, 1996;147, with permission.)

Mixed micelles must pass through a 40- μm deep unstirred water layer at the surface of intestinal epithelium to deliver their contents to the apical portion of the enterocytes. Quantitative diffusion of fatty acids through the unstirred water layer is enhanced more than 100-fold when fatty acids are carried within micelles rather than as monomeric fatty acids. Fatty acid and lipid uptake across the epithelial brush border membrane occurs by both passive diffusion, facilitated diffusion, and active transport. A membrane fatty acid–binding protein has been identified that may transport fatty acids, monoglycerides, and cholesterol across the enterocyte apical membrane.

After fatty acids and lipolytic products enter the intestinal epithelial cell, they are bound to cytosolic fatty acid–binding proteins. These binding proteins are found predominantly in villous cells in the jejunum; their expression declines progressively down the GI tract. Fatty acid–binding proteins are important for intracellular trafficking by directing fatty acids from the cell membrane to the smooth endoplasmic reticulum for triglyceride synthesis. Furthermore, this intracellular fatty acid–transport system enhances fatty acid uptake by maintaining a fatty acid concentration gradient and prevents potentially toxic interactions between fatty acids and intracellular organelles.

Fatty acids and monoglycerides present in smooth endoplasmic reticulum are used to produce triglycerides and phospholipids. Triglyceride, phospholipid, cholesterol, and fat-soluble vitamins are joined by apolipoproteins made in the rough endoplasmic reticulum to form chylomicrons, which consist of a core of triglyceride, cholesterol esters, fat-soluble vitamins and other lipids and a surface of phospholipids, free cholesterol, and apolipoproteins (apolipoproteins B-48, A-IV, and A-I) ([Fig. 39.13](#)).

These nascent chylomicrons are transferred to the Golgi apparatus and incorporated into secretory vesicles that fuse with the basolateral membrane of the epithelial cell and are released by exocytosis into the extracellular space. These chylomicrons move through the lamina propria into the villous core, which contains a network of capillaries and a single lymph lacteal. Chylomicrons cannot enter the bloodstream directly because they are too large to pass through the fenestrations between capillary endothelial cells. Fat absorption stimulates lacteal distention, which produces gaps between endothelial cells and facilitates chylomicron uptake by the lymphatic system and ultimate delivery into the systemic circulation. Newly formed circulating chylomicrons interact with other circulating lipoproteins and exchange components, thereby acquiring additional apolipoproteins including apolipoproteins C-II and E, which have important functions in chylomicron metabolism.

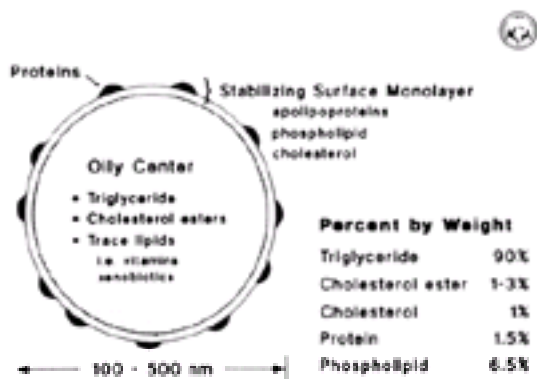

Figure 39.13. Chylomicrons are fat droplets that are coated with a monolayer of phospholipid and cholesterol. Dispersed in the monolayer are apoproteins (Apo)A-1, apoA-IV, and ApoB, and probably also some ApoC-11 and ApoC-111. These proteins help direct the tissue uptake and catabolism of the chylomicrons. In the circulation, chylomicrons acquire additional apoproteins. Although triglycerides are the major lipid carried in chylomicrons, they also carry cholesterol, fat-soluble vitamins, and small amounts of many other trace lipophilic molecules. (From Patton JS, Hoffman AF. Lipid digestion, undergraduate teaching project, unit 19. Bethesda, MD: American Gastroenterological Association, 1986, with permission.)

Medium-chain triglycerides (MCTs) contain fatty acids with a chain length of 6 to 12 carbon atoms. A normal diet usually does not contain appreciable amounts of MCTs, but specialized diets for patients who have fat malabsorption or who require a low-LCT diet may include supplementation with MCT oil or MCT-enriched liquid formulas. Absorption of MCTs differs markedly from that of LCTs. MCTs are hydrolyzed more rapidly by lipases than are LCTs, do not require bile salts for absorption because they are water soluble, and can be absorbed as intact triglycerides. Once inside the intestinal epithelial cell, MCTs and medium-chain monoglycerides are rapidly hydrolyzed to medium-chain fatty acids (MCFAs) by specific cellular lipases. MCFAs do not bind to fatty acid-binding proteins, are not reesterified to triglycerides, and are not packaged in

chylomicrons. After leaving the enterocyte, MCFAs enter the portal system where they are bound to albumin and transported to the liver.

Carbohydrate

A typical Western diet contains 200 to 300 g/day of carbohydrate (45% of total energy intake), which includes starch derived from cereals and plants (amylose, amylopectin), sugars derived from fruits and vegetables (glucose, fructose, sucrose), milk (lactose), and refined processed foods (sucrose, fructose, oligosaccharides, polysaccharides), and fiber derived from plant wall polysaccharides and lignin. Starch consists of long chains of glucose molecules joined together by α -1,4 linear linkages (amylose) or by both α -1,4 linear and α -1,6 branched linkages (amylopectin) (Fig. 39.14). Ingested sugars consist of monosaccharides (glucose, fructose) and disaccharides (sucrose, containing glucose linked with fructose; lactose, containing glucose linked with galactose). Approximately 10 to 20 g of dietary fiber is ingested daily in an average Western diet, consisting mostly of celluloses and hemicelluloses but also including pectin, gums, and lignin. Cellulose consists of glucose molecules joined together by β -1,4 linear linkages, whereas hemicellulose consists of pentose and hexose monomers joined together by both β -1,4 linear and branched linkages. Most dietary carbohydrates are completely digested and absorbed in the jejunum. However, dietary fiber cannot be digested in the small intestine because the β -1,4 bond is resistant to amylase.

Figure 39.14. Starch (amylose and amylopectin) digestion by pancreatic amylase produces maltose, maltotriose, and a limit dextrins. (From Chang EB, Sitrin MD, Black DD, eds. Gastrointestinal, hepatobiliary, and nutritional physiology. Philadelphia: Lippincott-Raven, 1996;122, with permission.)

Amylases secreted by the salivary glands and pancreas cleave the α -1,4 bond but not the α -1,6 bonds of starch, generating linear oligosaccharides, branched α limit dextrins, maltotrioses, and maltoses (Fig. 39.14). Pancreatic amylase is responsible for most starch digestion. The contribution from salivary amylase is not clear and depends on the duration and amount of contact between salivary amylase and ingested starches.

Presumably, slow and careful chewing increases starch digestion by salivary amylase. Furthermore, the physical interaction between salivary amylase and its substrate provides some protection from acid denaturation after ingested carbohydrates and amylase enter the stomach.

Brush border membrane hydrolases, glucoamylase (maltase), sucrase- α -dextrinase (sucrase-isomaltase), and lactose-phlorizin hydrolase (lactase), are required for complete hydrolysis of dietary disaccharides and the products of amylase starch digestion before they can be completely absorbed. Glucoamylase cleaves α -1,4 bonds, releasing one glucose molecule at a time from oligosaccharides containing up to nine residues. Sucrase- α -dextrinase represents two enzyme subunits with distinct properties. Sucrase hydrolyzes sucrose disaccharides to glucose and fructose and short-chain α -1,4 linked oligosaccharides to glucose. α -Dextrinase also hydrolyzes short-chain α -1,4 linked oligosaccharides to glucose and can also hydrolyze α -1,6 linked limit dextrins. Lactase hydrolyzes lactose to glucose and galactose. Digestion of di-, tri-, and oligosaccharides at the surface brush border membrane usually exceeds the capacity of monosaccharide enterocyte transport. However, hydrolysis of lactose is the rate-limiting step for absorption because lactase activity is lower than that of all other brush border hydrolases, even in persons who have complete lactase activity ([Table 39.5](#)).

The brush border membrane hydrolases are glycoproteins produced by enterocytes. These hydrolases are secreted from the cell and inserted into the brush border membrane; the hydrophobic end attaches to the membrane while the oligosaccharidase component projects into the lumen. Brush border hydrolases are only expressed in villous enterocytes, predominantly in the duodenum and jejunum, with decreased expression distally. Enzyme expression and activity are regulated by transcriptional, translational, and posttranslational processes that are modified by dietary intake, pancreatic enzyme activity, trophic factors, and GI diseases.

Transport proteins known as “glucose transporters,” present in the apical and basolateral cell membranes, facilitate monosaccharide absorption ([Fig. 39.15](#)). These transporters are expressed only in villous cells. Glucose and galactose absorption occurs principally by a Na-monosaccharide cotransporter, SGLT1, which delivers two Na molecules for every monosaccharide across the cell membrane. GLUT-5 facilitates Na-independent fructose absorption, but fructose is not as well absorbed as glucose. Glucose and fructose exit the enterocyte through the basolateral membrane into the portal circulation via the Na-independent GLUT-2 transporter.

Figure 39.15. Monosaccharide absorption by the enterocyte occurs by active and passive processes. Glucose and galactose are absorbed by a Na-dependent glucose/galactose transporter (SGLT₁), driven by a Na⁺ gradient generated by Na⁺/K⁺ ATPase at the basolateral membrane of the enterocyte. Fructose is absorbed by facilitated diffusion using a transporter called GLUT 5. All monosaccharides exit the enterocyte by facilitated diffusion via a carrier protein called GLUT 2. (From Chang EB, Sitrin MD, Black DD, eds. *Gastrointestinal, hepatobiliary, and nutritional physiology*. Philadelphia: Lippincott-Raven, 1996;125, with permission.)

Starches and dietary fiber not absorbed in the small intestine enter the colon, where colonic bacteria can metabolize these carbohydrates to short-chain fatty acids (SCFAs) (acetate, propionate, and butyrate), carbon dioxide, and hydrogen. Absorption of SCFAs allows the colon to salvage a considerable amount of energy that would otherwise be lost in stool; butyrate is a preferred large intestine fuel that provides about 70% of daily colonic fuel requirements, propionate may have important effects on hepatic metabolism, and acetate provides an important systemic fuel. Furthermore, SCFA absorption enhances colonic sodium and water absorption.

Protein

Approximately 70 to 100 g of protein, representing about 15% of total energy intake, is ingested daily as part of a typical Western diet. Additional proteins are presented to the GI tract from salivary, gastric, biliary, pancreatic, and intestinal secretions (~35 g/day), desquamated intestinal cells (~30 g/day), and plasma protein (~2 g/day). Normally, more than 95% of the total protein load delivered to the gut is absorbed.

Protein digestion begins in the stomach, where a family of proteolytic enzymes (pepsins) hydrolyzes peptide bonds. Pepsins are generated from pepsinogens, which are inactive proenzymes produced mostly by chief cells. When exposed to the acidic environment of the stomach, pepsinogen undergoes a conformational change with loss of a terminal peptide to its active pepsin form. Pepsin is active at low pH and is inactivated in an alkaline environment. The stomach is not essential for protein digestion, and patients with atrophic gastritis and even a total gastrectomy can absorb

protein normally. However, release of amino acids in the stomach triggers part of the initial GI response to a meal: gastric acid secretion, CCK secretion, gastrin secretion, and gastric emptying.

A significant amount of protein digestion occurs in the duodenum; 60% of protein is digested by the time it reaches the proximal jejunum. Several proteases ([Table 39.6](#)), in the form of inactive proenzymes, are secreted into the duodenal lumen by the pancreas. Enterokinase, a brush border enzyme that is released into the lumen by bile acids, cleaves the N-terminal peptide from trypsinogen to form trypsin. Trypsin activates additional trypsinogen molecules as well as the other pancreatic proenzymes. Pancreatic proteases act as either endopeptidases (trypsin, chymotrypsin, and elastase) or exopeptidases (carboxypeptidase A and B). Endopeptidases and exopeptidases work efficiently in concert to degrade protein into smaller subunits. However, proline-containing peptides are resistant to cleavage by pancreatic proteases. After pancreatic hydrolysis of proteins is complete, approximately 70% of amino nitrogen is present as oligopeptides containing 2 to 6 amino acids, and 30% is present as free amino acids.

Protease	Function
Endopeptidases	
Trypsin	Cleaves internal bonds at lysine or arginine residues and cleaves other pancreatic proenzymes
Chymotrypsin	Cleaves bonds at aromatic or neutral amino acid residues
Elastase	Cleaves bonds at aliphatic amino acid residues
Exopeptidases	
Carboxypeptidase A	Cleaves aromatic amino acids from carboxy-terminal end of protein and peptides
Carboxypeptidase B	Cleaves arginine or lysine from carboxy-terminal end of proteins and peptides

Table 39.6 Pancreatic Proteases

The mucosal brush border membrane contains approximately 20 peptidases that cleave specific amino acids present in di-, tri-, and oligopeptides, thereby generating free amino acids, dipeptides, and tripeptides. These peptidases are produced by enterocytes, released at the cell surface, and anchored to the cell membrane with the active site projecting into the lumen. Most brush border peptidases are aminopeptidases that sequentially cleave the N-terminal amino acid from oligopeptides. Several specific peptidases can hydrolyze proline-containing peptides, thus compensating for the inability of pancreatic proteases to cleave the proline–amino acid bond.

Amino acids, dipeptides, and tripeptides generated by intraluminal and brush border protein hydrolysis are transported across the enterocyte apical cell membrane by specific transport mechanisms. Amino acid transport is facilitated by several transport

systems (Table 39.7). Some amino acids can use many different carriers because of overlapping specificity between systems. Amino acid transport in most systems is coupled to sodium uptake (sodium dependent). However, amino acid uptake can also occur by sodium-independent processes by facilitated or passive diffusion. Di- and tripeptides are absorbed intact by intestinal epithelia by a sodium-independent process that involves hydrogen-peptide cotransport along a hydrogen gradient. Peptide transport is an important mechanism for amino acid absorption; in the jejunum, most amino acids are absorbed faster as peptides than as free amino acids.

Transport System	Amino Acids	Na-Dependent
Neutral amino acids		
NBB	Neutral amino acids	Yes
PHE	Phenylalanine, methionine	Yes
IMINO	Proline, hydroxyproline	Yes
β	β -Alanine	Yes
Acidic amino acids		
X_{Ca}^-	Glutamate, aspartate	Yes
Basic		
Y^+	Basic amino acids	Yes
y^-	Basic amino acids	No

Table 39.7 Brush Border Membrane Amino Acid Transport Systems

Enterocyte absorption of digested dietary and intestinal proteins generates intracellular amino acids, dipeptides, and tripeptides. Peptides present in the enterocyte are hydrolyzed to individual amino acids by several cytosolic peptidases. In fact, dipeptidases and tripeptidases are much more abundant inside the cell than in the brush border membrane. Intracellular amino acids are transported out of the enterocyte through the basolateral membrane by active transport, facilitated diffusion, and simple diffusion. During meals, most amino acid transport out of the cell occurs by facilitated or simple diffusion because of the large amino acid concentration gradient across the cell membrane. Several amino acid transport systems have been identified. Passive diffusion and the L facilitated carrier system are principally involved in amino acid exit from the enterocyte, whereas the active Na^+ -dependent A and ASC systems and the Na^+ -independent asc and y^+ systems are principally involved in amino acid uptake.

Absorbed amino acids can have several fates: some provide fuel for the small intestine itself (particularly glutamate and glutamine), some are used for protein synthesis, and most are transported into the portal circulation for metabolism in the liver or for subsequent delivery to peripheral tissues via the bloodstream. Despite the presence of intracellular peptidases, approximately 10% of portal blood amino nitrogen is in the form of peptides that have escaped intracellular hydrolysis. After a meal, villous cells receive their amino acid requirements from absorption of luminal proteins. In contrast, crypt cells receive most of their amino acids from the bloodstream, as do villous cells during

postabsorptive conditions.

Minerals

Mineral absorption involves three types of events: (a) intraluminal events that transform ingested minerals into absorbable forms, (b) mucosal events that govern mineral uptake by intestinal epithelium, and (c) postmucosal events that regulate mineral transport into the mesenteric and portal circulation for subsequent delivery to the liver and peripheral tissues. Although some general comments regarding intestinal mineral absorption are made in this section, specific absorptive processes for each mineral are reviewed in specific chapters in this book.

Minerals ingested in the diet are frequently bound to proteins within a matrix of organic molecules. Therefore, mechanical separation by mastication and dispersion and digestion by pancreatic enzymes are needed to convert ingested minerals into forms necessary for effective absorption. Unlike other nutrients, intestinal absorption of some minerals is regulated by body stores to prevent excessive uptake and toxicity. Furthermore, absorption of one mineral can decrease absorption of another. For example, there are absorptive interactions between calcium and magnesium and between iron, zinc, and copper. These interactions can be used therapeutically; oral zinc supplementation inhibits copper absorption in patients with Wilson's disease, who have excessive tissue copper loads.

Mineral absorption can be complicated because some minerals are released into the lumen as charged ions while others are part of an organic complex. For example, iron is ingested as a component of heme (animal sources) and nonheme (animal and plant sources) iron compounds (see [Chapter 10](#)). Dietary nonheme iron is usually present in the ferric (Fe^{3+}) form, which is soluble in the acid pH of the stomach but insoluble at a pH above 3. Other dietary compounds and intestinal secretions can either enhance iron absorption by making iron more soluble (by forming unstable chelates or reducing iron to the more soluble ferrous [Fe^{2+}] form) or decrease iron absorption by making iron less soluble (by precipitating iron or forming stable chelates). Heme iron is soluble at the alkaline pH of the small intestine and is more efficiently absorbed than nonheme iron. Iron is predominantly absorbed in the duodenum, while other minerals are predominantly absorbed throughout the small intestine. Absorption of macrominerals is discussed in [Chapter 6](#), [Chapter 7](#), [Chapter 8](#) and [Chapter 9](#) and that of trace minerals in [Chapter 10](#), [Chapter 11](#), [Chapter 12](#), [Chapter 13](#), [Chapter 14](#), [Chapter 15](#) and [Chapter 16](#).

Vitamins

Water-soluble vitamins (thiamin, riboflavin, niacin, pyridoxine, biotin, pantothenate, folate, cobalamin, and ascorbic acid) are usually present in foods as part of a coenzyme system and are often associated with proteins. This complex arrangement must be digested to a simpler form before the vitamins can be transported across the apical epithelial cell membrane. Vitamins are usually present in the diet in low concentrations and require active carrier systems for adequate absorption. However, water-soluble vitamins are also absorbed by passive diffusion. Therefore, oral vitamin

supplementation with large doses can often overcome defects in normal vitamin transport by achieving high intraluminal concentrations. All water-soluble vitamins are absorbed primarily in the upper small intestine with the exception of vitamin B₁₂, which is absorbed principally in the terminal ileum. The specific mechanisms involved in absorption of each water-soluble vitamin are reviewed in [Chapter 21](#), [Chapter 22](#), [Chapter 23](#), [Chapter 24](#), [Chapter 25](#), [Chapter 26](#), [Chapter 27](#), [Chapter 28](#) and [Chapter 29](#).

Absorption of fat-soluble vitamins (vitamins A, D, E, and K) requires bile salts for solubilization within micelles, which enhances their delivery through the unstirred water layer to the enterocyte apical membrane. Thus, the absence of bile salts can seriously impair fat-soluble vitamin absorption, particularly that of the highly insoluble vitamins D and K. Vitamin K is unique in that body stores reflect absorption of both vitamin K₁ (phyloquinone) ingested in the diet and vitamin K₂ (menaquinone) produced by intestinal bacteria. Vitamin K of bacterial origin comes predominantly from vitamin K synthesized by small-intestinal bacteria or colonic bacteria, which refluxed into the small intestine because absorption by the colon is limited. Once inside the enterocyte, fat-soluble vitamins are incorporated within the core of chylomicrons for transport into intestinal lymphatics. Most ingested fat-soluble vitamins are absorbed in the proximal small intestine, although often less than 50% of total dietary intake is absorbed. The specific mechanisms involved in the absorption of each fat-soluble vitamin are reviewed in [Chapter 17](#), [Chapter 18](#), [Chapter 19](#), [Chapter 20](#).

INTESTINAL MICROFLORA

The human gastrointestinal tract contains approximately 10¹⁴ bacteria representing more than 500 different species. The number of bacteria increases progressively down the gastrointestinal tract; the colon has more than 100 times more species and 100,000 times more organisms than any other intestinal area ([Table 39.8](#)). These organisms serve important metabolic and defense functions.

	Aerobes/Facultative Anaerobes	Anaerobes	Total Bacteria
Stomach	0-10 ³	0	0-10 ³
Jejunum	0-10 ⁶	0	0-10 ⁶
Ileum	10 ² -10 ⁵	10 ³ -10 ⁷	10 ⁵ -10 ⁸
Colon	10 ² -10 ⁹	10 ⁹ -10 ¹²	10 ¹⁰ -10 ¹²

^aValues are per milliliter or gram of contents.

Table 39.8 Intestinal Microflora^a

The mouth contains mostly anaerobic bacteria. However, the distribution of the oral flora is not uniform, and bacterial composition and density vary with location. The most densely populated areas are the gingival crevices. Poor oral hygiene and immunologic variations permit overgrowth of subgingival organisms, leading to gingivitis. Most bacteria that enter the stomach are killed by the acid environment. However, some species, such as *Lactobacillus*, *Streptococcus viridans*, *Staphylococcus*, *Peptostreptococcus*, and *Neisseria*, and the yeast *Candida* are found in the stomach because they are more acid-resistant than other organisms. *Helicobacter pylori*, an important cause of gastritis and ulcer disease, may be the only organism to truly colonize the stomach. The duodenum and proximal small bowel (jejunum) also contain few microorganisms, mostly aerobes and facultative anaerobes. In the ileum, bacterial numbers increase markedly and there is a shift from aerobic to anaerobic organisms. In the colon, the number of microorganisms increases a millionfold and the flora consists almost entirely of strict anaerobes such as *Bacteroides* spp., anaerobic lactobacilli, and clostridia. The ileocecal valve is a physical barrier between the small and large intestine. Resection of the ileocecal valve permits translocation of bacteria from the colon to the remaining ileum, where the bacterial population becomes similar to that of the colon.

The interaction between enteric microflora and the host is complex. The presence of enteric organisms enhances the defense against pathogenic bacteria by stimulating antibody production, increasing cell-mediated immunity, and preventing the overgrowth of more pathogenic organisms. Normal flora effectively compete for intraluminal fuels and adhere better to the intestinal wall, preventing pathogenic bacteria from establishing residence. The importance of this defense mechanism is illustrated by germ-free animals who cannot survive exposure to hostile microbes.

Intestinal bacteria also have important metabolic and nutritional functions, including hydrolysis of cholesterol esters, androgen, estrogen, and bile salts; utilization of carbohydrate, lipid, and protein; and consumption (vitamin B₁₂ and folate) and production (biotin and vitamin K) of vitamins. All compounds that enter the alimentary tract by ingestion or intestinal secretion are potential substrates for bacterial metabolism (Table 39.9).

Reaction	Representative Substrate
Hydrolysis	
Glucuronides	Estradiol-3-glucuronide
Cyclodextrin	Cyclasin
Sulfonamides	Cyanamide, amygdalin
Amides	Acetophenone
Esters	Acetylcholine
Nitrates	Pentaerythritol tetranoate
Dehydroxylation	
C-hydroxy groups	Bile acids
N-hydroxyl groups	N-hydroxyfluorenylacetamide
Dealkoxylation	Amino acids
o-Dealkylation	Biochanin A
Demethylation	Amino acids
Dehydrogenase	Cholesterol, bile acids
Dehalogenation	DDT
Reduction	
Nitro groups	p-Nitrobenzoic acid
Double bonds	Unsaturated fatty acids
Azo groups	Food dyes
Aldehydes	Benzaldehydes
Alcohols	Benzyl alcohols
N-oxides	4-Nitroquinoline-1-oxide
Nitroamine formation	Dimethylnitrosamine
Aromatization	Quinic acid
Acylation	Histamine
Esterification	Gallic acid

Table 39.9 Biochemical Reactions by Intestinal Bacteria

IMMUNE SYSTEM

The alimentary tract houses a major portion of the body's immune system and is directed toward defending the host against bacterial, viral, parasitic, and food antigens that are constantly present in the intestinal lumen. The intestinal immune system consists of (a) T lymphocytes, (b) B lymphocytes, (c) natural killer cells, (d) myelomonocytic cells (monocytes, neutrophils, eosinophils, and basophils), (e) cytokines, (f) antibodies (IgG, IgM, and secretory IgA), and (g) gut-associated lymphoid tissue (GALT). (See also [Chapter 45](#).)

Secretion of the dimeric immunoglobulin, IgA, is an important GI tract protective mechanism. Secretory IgA, the predominant intestinal immunoglobulin, is produced by B lymphocytes in the lamina propria. Secretory IgA binds dietary antigens, thereby preventing their absorption, and can bind to pathogenic microorganisms thereby preventing epithelial cell adherence and intestinal colonization.

GALT contains anatomically organized and nonorganized compartments within the submucosa, lamina propria, and epithelium to provide specialized host defense functions ([Fig. 39.16](#)). An important component of GALT is organized follicle-associated epithelium, which contains M cells that overlie Peyer's patches. M cells provide a selective site for sampling intraluminal antigens by permitting transport of large molecules and microorganisms. These antigens come into contact with lymphocytes and macrophages located within an indented space below the M cell before entering Peyer's patches. A Peyer's patch consists of a collection of lymphoid follicles that release lymphocytes after antigen processing (see [Chapter 45](#)). These lymphocytes migrate to mesenteric lymph nodes, the systemic circulation, and back to specific mucosal sites, where they provide protective immunity from the offending antigen. In addition, GALT contains a nonorganized distribution of intraepithelial T lymphocytes, lamina propria immune cells (T and B lymphocytes, plasma cells, and macrophages), and mucosal and submucosal mast cells.

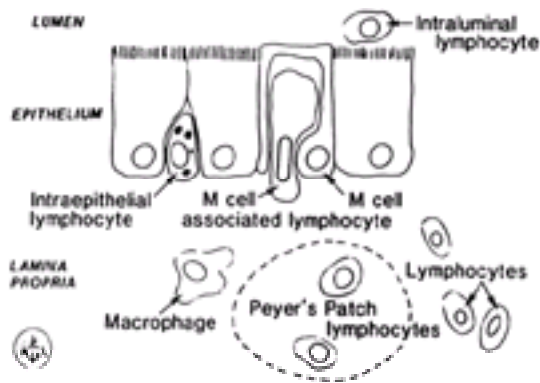

Figure 39.16. Gut-associated lymphoid tissue (GALT) including intraepithelial lymphocytes, M cells, and M cell–associated lymphocytes overlying the lymphoid follicles of a Peyer's patch. In addition, lymphocytes and macrophages are present within the lamina propria. (From Ernst PB, Befus AD, Bienenstock J *Immunol Today* 1985;6:50, with permission.)

[Selected Readings](#)

Our understanding of the controls of food intake has been transformed during the past decade. The traditional view that intake was tightly controlled by hypothesized deficits of nutrient metabolism has been replaced by a neuroendocrine system that uses peptides, steroids, and amines to encode ingested food stimuli and metabolic state. This system depends on the brain to integrate the neural effects of these mediators to control intake and to coordinate it with the mechanisms of energy expenditure and storage to achieve energy balance. This transformation was driven by shifts in experimental strategies and new techniques.

There have been five shifts in experimental strategy. The first was to analyze neural control in terms of the integrated activity of forebrain (brain anterior to the brainstem, i.e., the cerebral cortex, basal ganglia, limbic system structures, and hypothalamus) and brainstem (brain between the hypothalamus and the spinal cord) networks rather than as reciprocal interactions of lateral and medial hypothalamic regions. This expanded neural system is capable of distributed processing (i.e., using neurons in different parts of the brain to transform and integrate incoming sensory information into appropriate motor commands), and thus can deal with the multiple stimuli that stimulate or inhibit a central pattern generator for control of the rhythmic movements of eating.

The second shift was to see the meal as the functional unit of eating and to concentrate

on how the size of an individual meal is controlled. This revealed that meal size was determined by quantitative interaction between the positive- and negative-feedback effects of ingested food during a meal and led to identification of some of the underlying mechanisms.

The third shift in strategy was to search for controls of intake that transcend an individual meal and explicitly serve metabolic requirements. Investigating the endocrine controls of intake that operate after a prolonged period of food deprivation or during severe food restriction demonstrated that peripheral endocrine responses to deprivation-induced metabolic changes affect eating by changing the synthesis and release of brain peptides with reciprocal actions on food intake.

The fourth shift was to apply molecular genetics to the syndromes of genetic obesity in rodents. Besides yielding precise descriptions of genomic mutations and altered gene products, this strategy uncovered a peptide secreted from adipose tissue that decreases intake while activating neuroendocrine mechanisms for energy expenditure.

The fifth shift was to investigate the impact of learning on the controls of intake. This shift demonstrated that learned controls are potent and pervasive and account for the preferences and aversions observed in a variety of circumstances.

The shifts in experimental strategy exploited new techniques, including behavioral techniques such as computer-assisted lickometers, and videotape and electromyographic analysis (used to record the electrical activity associated with movements of muscles involved in eating and swallowing) that measure the rate and pattern of ingestive behaviors used during a meal; neurochemical, pharmacologic, and molecular techniques for measuring synthesis, storage, and release of steroids, peptides, and amines in the brain and periphery; molecular genetic techniques; and techniques for investigating learning and memory at the level of behavioral and synaptic plasticity (i.e., changes in behavior and the functional connections between neurons that result from prior experience).

This chapter considers these five areas of investigation in separate sections.

NEURAL CONTROL OF EATING

Eating refers to rhythmic oral movements elicited by food stimuli. The oral movements depend on the nature of the food stimuli: Solid food elicits mastication and liquid food elicits licking and lapping. Ingestion of either type of food is accomplished by lingual and palatal movements that move food to the oropharynx where the food stimulates the swallowing reflex. Thus, the control of food intake is fundamentally a problem in the sensory control of rhythmic movements. This is heuristic because it directs us to the extensive literature on the neural control of other rhythmic movements, such as locomotion.

The general plan of a neural system to control rhythmic movements consists of two categories of neurons. The first is a network (i.e., a group of neurons that interact to

accomplish a function) that generates rhythmic motor output; such a network is termed a *central pattern generator*. The second category includes all of the afferent neural inputs that turn the central pattern generator on and off. In the case of locomotion, central pattern generators exist in the brainstem and the spinal cord. They are turned on and off by local afferent projections from segmental stimuli, as well as by long afferent projections from forebrain and brainstem sites that integrate information from visual, auditory, proprioceptive, tactile, and olfactory stimuli (1).

Recent work shows a similar arrangement of the components of the neural system that controls licking and mastication (2, 3). The central pattern generators are in the hindbrain, the part of the brainstem lying underneath the cerebellum. They are controlled by local afferent stimuli from the mouth, stomach, small intestine, and liver, and by forebrain stimuli carrying information about the current environment, metabolic state, and the effects of prior ingestive experience. Thus, the caudal brainstem's relation to the controls of eating is similar, if not functionally identical, to the spinal cord's relationship to limb movement and locomotion.

If the caudal brainstem is the spinal cord of eating, then disconnecting the caudal brainstem from the forebrain should reveal the potency of orosensory and postingestive afferent stimuli that project to the caudal brainstem below the level of the disconnection to control the central pattern generator in the absence of forebrain afferent stimuli. Grill and Kaplan (4) used this approach to investigate the control of liquid intake in the chronic decerebrate rat.

The chronic decerebrate rat is produced by cutting through the brainstem at the level of the superior colliculus just behind the hypothalamus. This lesion disconnects the forebrain from the brainstem because it completely severs the ascending and descending fiber connections between them (Fig. 40.1).

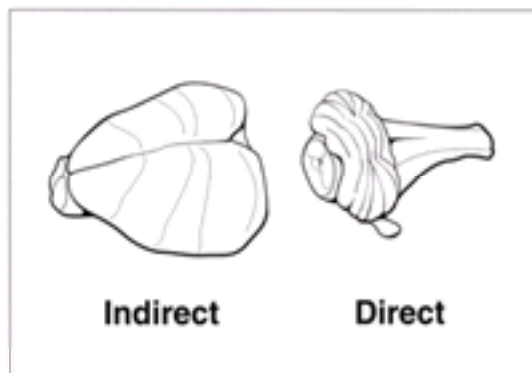

Figure 40.1. The space between the forebrain (*left*) and the hindbrain (*right*) emphasizes the disconnection produced by the chronic decerebrate lesion at the upper brainstem. Functional analysis of the controls of eating in such rats (4, 5) revealed that the direct controls of eating that are mediated by stimulation of orosensory and viscerosensory neurons by food are effective because these afferent neurons project to the hindbrain. The indirect controls that depend on distributed processing of diverse

types of relevant information (see text) are not, however, because the efficacy of indirect controls depends upon connections between the forebrain and the hindbrain. When the connections are intact in the normal rat, eating is the integrated action of indirect and direct controls of the central pattern generator in the hindbrain that organizes the oral movements of eating.

With appropriate care, such rats remain healthy for long periods of time. Most importantly for our purposes, this rat never initiates eating despite the presence of food in its environment. Thus, nutritional balance must be produced through periodic tube feedings. In contrast to this total lack of spontaneous eating, the decerebrate rat initiates eating and swallowing when milk or other liquid food stimuli are infused into its mouth through an implanted oral catheter. Ingestion continues until the decerebrate rat is satiated and allows the infused liquid to drip out of its mouth. Thus, the chronic decerebrate rat, like the neurologically intact rat, eats meals. Furthermore, the size of these meals varies with the food stimulus infused. For example, the shape of the intake-response function to a series of concentrations of sucrose solutions is identical to that of intact rats. Furthermore, gastric preloads of nutrients given prior to an oral infusion of a liquid food reduces intake and decreases meal size. But even when liquid food is infused into the mouth, the chronic decerebrate rat does not change its meal size in response to the metabolic consequences of food deprivation (5), acute metabolic deficits produced by 2-deoxy-D-glucose or insulin hypoglycemia, or experimental toxic effects associated with prior ingestive experience (conditioned taste aversion).

These results demonstrate that the disconnected brainstem contains the central pattern generator for eating and that it has sufficient neural complexity to integrate orosensory and postingestive food stimuli into premotor commands that can turn the pattern generator on and off and produce a discrete bout of eating, i.e., a meal. Meal size is dynamic under these conditions. The size of the meal varies according to the type of food stimulus infused into the mouth and the amount of food loaded into the stomach.

The fact that metabolic state and the aversive consequences of prior ingestive experience have no effect on meal size suggests that normal control of meal size depends on the connections between the forebrain and brainstem that have been severed in these rats. Furthermore, because the central pattern generator is a “final common path” to the rhythmic movements of eating, controls that require the forebrain and controls for which the brainstem suffices must both affect this common path. This is the classic Sherringtonian analysis of movement and posture applied to eating.

A MEAL IS THE FUNCTIONAL UNIT OF EATING

A meal is the functional unit of eating because food intake over time is completely determined by the number and size of meals (6). A meal is a discrete bout of eating. Thus, it has three phases—initiation, maintenance, and termination. The functional analysis of a meal is concerned with the adequate stimuli and sufficient mechanisms for

each of the three phases.

Initiation of Eating

Eating can be initiated by numerous external and internal stimuli. The external stimuli include visual, auditory, and olfactory stimuli related to food, diurnal cycle, temperature, temporal schedules of access to food, the relative density of predators and food in an environmental niche, social stimuli, and, in humans, culinary preferences, ethnic and religious rituals, and psychologic distress. Many of these external stimuli are conditioned by prior experience, and the ease of such conditioning has been clearly demonstrated in the rat (see "[Learning and Eating](#)," below) and experienced by us.

All internal stimuli for initiation of eating are related to metabolism. Food deprivation and acute decreases in the utilization of glucose and oxidation of fatty acids produced by specific metabolic inhibitors initiate eating. The effects of metabolic inhibitors have been viewed as emergency responses ([7](#)), and their relationship to the effects of food deprivation and nondeprived eating remains to be demonstrated.

Le Magnen, Campfield, and their colleagues discovered a new stimulus for initiation of eating in the rat ([8](#), [9](#)), namely, the pattern of plasma glucose changes that begin to occur about 10 minutes before a spontaneous meal. This pattern is characterized by a decline in plasma glucose concentration of approximately 12%, which is not sufficient to produce hypoglycemia. Eating is initiated when the glucose level is returning toward baseline after its nadir. The metabolic mechanism(s) responsible for this pattern is unknown and its presence in humans is controversial ([10](#), [11](#)).

Maintenance and Termination of Eating

Once initiated, the size of a meal is determined by the mechanisms that maintain and terminate eating. That these mechanisms are separate was demonstrated by using the sham-feeding rat ([Fig. 40.2](#)). In sham feeding, the ingested liquid food is withdrawn or drained continuously out of the stomach after eating is initiated ([12](#), [13](#) and [14](#)). Sham feeding increases intake markedly. The increase is larger after longer deprivation or after repeated tests during which a conditioned inhibitory control extinguishes (see below). After overnight deprivation, sham feeding is almost continuous for hours, so that a meal never ends under these conditions ([12](#)). Thus, orosensory food stimuli in the absence of postingestive stimuli suffice to maintain eating for much longer than the duration of the usual meal of the same diet under the same conditions.

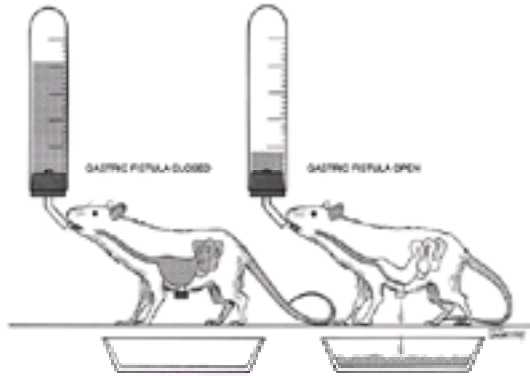

Figure 40.2. Chronic gastric fistula rat preparation for sham feeding. When the cannula is opened during a test (*right*), ingested food drains out of the stomach so that the postingestive, negative-feedback effects of food are minimized or eliminated. Outside the test situation, the cannula is closed with a screw cap (*left*), ingested food is digested and absorbed normally, and the rat maintains normal nutrition and body weight. (From Smith GP, Gibbs J, Young RC. *Fed Proc* 1974;33:1146–9, with permission.)

This suggested that postingestive food stimuli are involved in terminating a meal rather than maintaining it, which was confirmed by a large number of experiments. Food stimuli in the stomach or small intestine terminate eating. Volume is the primary stimulus in the stomach (15), and chemical load is the primary stimulus in the small intestine (16). Although experiments showed that gastric or small intestinal stimuli acting alone suffice to terminate eating, they are synergistic when they are stimulated simultaneously by food stimuli during the normal meal (17).

Note that the small intestinal stimuli act prior to absorption into the portal blood, and most, if not all, probably act at the mucosal surface. Thus, a meal is terminated before significant amounts of nutrients are available for metabolism and storage. Thus termination of a meal is not primarily determined by *immediate* metabolic consequences, with the possible exception of rapid changes in the liver. In the rat (18), the metabolic consequences of one meal can affect the initiation of the next meal but not its size. This effect of metabolism on the timing of meals has not been observed in humans (19).

The demonstration that orosensory stimuli control the mechanisms that maintain eating, and postingestive, preabsorptive stimuli control the mechanisms that terminate eating facilitates investigation of these mechanisms. This has been exploited in the rat and to a less extent in the human.

Positive and Negative Feedbacks

Because orosensory and postingestive stimuli are the consequences of eating, they stimulate feedback mechanisms for the control of eating. The feedback effect of

orosensory stimuli is positive; the feedback effect of gastric and small intestinal stimuli is negative (20). The duration and size of a meal is determined by the interaction of the positive and negative feedbacks activated by ingested food stimuli. Because the path of ingestion leads from the mouth through the stomach to the small intestine, positive feedback always occurs before negative feedback. Eating is maintained as long as the potency of positive feedback exceeds the potency of negative feedback as judged by a comparator function located somewhere in the brain (i.e., the function of a postulated neural network somewhere in the brain that compares the potency of positive- and negative-feedbacks). Eating ends when the potency of negative feedback equals or exceeds that of positive feedback (Fig. 40.3).

Figure 40.3. Temporal interaction of positive and negative feedback effects produced by ingested carbohydrate solutions during a scheduled meal. Eating stops and the meal ends when the potencies of the positive- and negative-feedbacks are judged to be equal by a comparator function(s) of the central networks for the control of eating. Note that the negative-feedback effect during the early part of the meal is a conditioned orosensory effect, and the unconditioned effect in the later part of the meal is an unconditioned postingestive effect (see text). The relative contributions of conditioned and unconditioned positive-feedback has not been analyzed yet. (From Smith GP, Davis JD, Greenberg D. The direct control of meal size in the Zucker rat. In: Bray GA, Ryan DH, eds. Molecular and genetic aspects of obesity. Pennington Biochemical Medical Center nutrition series, vol 5. Baton Rouge: Louisiana State University Press, 1996;161–74, with permission.)

Microstructure of a Meal and Feedback Effects

Although the identification of orosensory positive feedback and postingestive negative feedback derived from sham feeding and other experimental preparations, the same feedback effects have been shown to operate when rats eat scheduled meals of carbohydrate solutions or oil emulsions (21, 22). Given access to a sucrose solution (0.8 M) after 4 hours of food deprivation, a rat begins to lick almost immediately (Fig. 40.3). The rate of licking is a monotonic function of sucrose concentration, and it is sustained

for at least 1 minute. The number of licks during this interval is a measure of the orosensory stimulation by positive feedback of sucrose on the central network that controls licking.

The number of licks per minute then decreases at an approximately exponential rate over the next 15 minutes until licking stops. Because this exponential rate of decay of licking does not occur in a rat that has sham-feeding experience, it depends on postingestive negative feedback from gastric and small intestinal stimuli. Note that the exponential rate of decay is not a measure of the negative-feedback effect alone. Instead, it reflects the interaction of positive- and negative- feedback effects on the control of licking. As the meal proceeds, the potency of the negative feedback increases, and so licking slows and finally stops. The potency of negative feedback on licking increases because the amount of ingested sucrose in the stomach and small intestine is increased.

The early part of the curve of the potency of negative feedback in [Figure 40.3](#) is labeled *conditioned* and the latter part is labeled *unconditioned*. Evidence for this distinction comes from experiments with the sham-feeding rat ([21](#)). The first time the postingestive effects of sucrose are prevented by having a rat sham feed 0.8 M sucrose, the number of licks increases significantly during the latter part of the meal, but the decay in the number of licks during the first 5 minutes does not change. In subsequent sham-feeding tests, the number of licks in the first 5 minutes gradually increases until there is little or no decrease in the rate of licking from the beginning to the end of the test. Thus, the decay of licking that occurs during the first 5 minutes of real feeding is due to a conditioned inhibitory control, because it does not change during the first sham-feeding test and it extinguishes gradually during subsequent sham-feeding tests. This conditioned negative feedback results from a learned association between the oral stimulus and its postingestive effects ([23](#)). This association can be formed within one or two meals, and two meals suffice to maintain it ([21](#)). In contrast, the decay of licking during the latter part of the meal appears to be unconditioned because the number of licks increases in the first sham-feeding test and does not increase further during subsequent sham-feeding tests ([21](#)).

The changes in the pattern of licking in meals of 0.8 M sucrose are assumed to be paradigmatic. Although similar changes were observed in a recent analysis of scheduled meals of corn oil ([22](#)), a different pattern has been observed in spontaneous meals or during meals in which rats must press a lever to obtain food ([24](#), [25](#)). No matter what pattern of licking occurs during a meal, however, that pattern and the size of the meal result from the interaction of the positive- and negative-feedback effects of the food that was eaten. We now consider the mechanisms of these feedback effects.

Mechanisms of Positive Feedback

Food in the mouth stimulates gustatory, thermal, tactile, and olfactory receptors (by the retronasal route). The receptors transduce these stimuli into afferent neural activity in cranial nerves 1, 5, 7, 9, and 10. With the exception of the olfactory projections to the anteroventral forebrain, all afferent neurons project directly to the caudal brainstem that contains the network for the control of licking. Second- and third-order neurons also

carry this afferent information to the forebrain where it is processed and eventually influences forebrain neurons (especially in the amygdala, ventral striatum, and hypothalamus) that project back to the caudal brainstem ([Fig. 40.4](#)).

Figure 40.4. Schematic drawing of sagittal and coronal sections of the rat brain. The *black vertical line* marks the plane of the complete disconnection of the forebrain from the hindbrain that occurs in the chronic decerebrate rat. The *lines from the four coronal sections to the sagittal sections* indicate the site of each coronal section. AC, anterior commissure; ACB, nucleus accumbens; AP, area postrema; ARC, arcuate nucleus; CB, cerebellum; CC, corpus callosum; CU, cuneate nucleus; DM, dorsomedial hypothalamic nucleus; F, fornix; H, hippocampus; IC, inferior colliculus; NTS, nucleus of the solitary tract; OT, optic tract; OX, optic chiasm; PVN, paraventricular hypothalamic nucleus; PY, pyramidal tract; SC, superior colliculus; SP5, spinal tract of the trigeminal nerve; STR, striatum; TS, solitary tract; VMH, ventromedial hypothalamic nucleus; LV, lateral ventricle; 3V, third ventricle; 4V, fourth ventricle; 10, dorsal motor nucleus of the vagus nerves; and 12, hypoglossal nucleus. (Adapted from Paxinos G, Watson C. The rat brain in stereotaxic coordinates. New York: Academic Press, 1982.)

Substantial evidence indicates that dopaminergic and opioid neurons in the forebrain are important for normal processing of the orosensory feedback stimuli that maintain eating. For example, specific antagonists of dopamine and opioids decrease licking during sham feeding in a dose-related manner ([26](#), [27](#)). Furthermore, dopamine is released in the hypothalamus and nucleus accumbens during eating ([26](#)).

Microstructural analysis of the effect of a dopamine antagonist on sham feeding revealed that it decreases intake primarily by prolonging the intervals between bursts of licking. This suggests that central dopamine maintains eating by reinitiating licking during a meal ([26](#)). This hypothesis was confirmed by the observation that dopaminergic antagonists did not decrease intake when the need to reinitiate eating during a meal was abolished by continuously infusing sucrose into the mouth through a sublingual oral catheter ([26](#)). Because intact and decerebrate rats adjust their intake during sham feeding to the concentration of sucrose infused orally, neural mechanisms other than

dopamine and opioids are clearly involved in the positive-feedback effect of orosensory stimuli that maintain eating. These mechanisms remain to be identified.

Mechanisms of Negative Feedback

Food stimuli in the stomach and small intestine activate mechanical and chemical receptors distributed along the mucosal membrane of these organs. Mechanical stimuli are most potent in the stomach, and chemical stimuli are most potent in the small intestine. Gastric mechanoreceptors are well characterized and their activation of vagal afferent activity has been studied intensively (28, 29). However, the relationship of this mechanoreceptor-induced vagal afferent activity to the inhibitory effect of food stimuli in the stomach is not clear.

Splanchnic visceral afferent fibers are sensory fibers from the gut that have their cell bodies in the dorsal root ganglia, and project to neurons in the spinal cord that convey this sensory information to the caudal brainstem. These fibers are also activated by gastric mechanoreceptors (28), and they may carry important negative-feedback information from the stomach for the control of meal size. This function, however, has not been investigated.

Results with administration of the exogenous peptide gastrin-releasing peptide have repeatedly suggested a role for it and possibly the structurally related peptide neuromedin B in the genesis of nutrient-related, negative-feedback, afferent activity from the stomach (30). Attempts to demonstrate that the endogenous peptides produce this effect, however, have not been successful so far.

In contrast to the uncertain role of vagal afferent fibers in mediating the negative-feedback effect of gastric stimuli, extensive evidence supports the importance of vagal activity in the negative-feedback effect of digestive products of fats and carbohydrates in the small intestine. Vagal afferents are stimulated by nutrient stimuli directly (31, 32) and by cholecystokinin (29), pancreatic glucagon (33), and insulin (34) released by preabsorptive nutrient digestive products. Other peptides released by small intestinal nutrients, such as neurotensin (35), may also stimulate vagal afferents, but this remains to be demonstrated.

The negative-feedback effects of ingested food and cholecystokinin are mediated by the central serotonergic system, because pretreatment with serotonergic antagonists, particularly of the 5-HT_{2c} receptor subtype, decreases their inhibitory effects on intake (36). This may be the basis of the hyperphagia observed in mice with a genetic knockout lesion of the gene that encodes this receptor (37).

Direct and Indirect Controls

If meal size depended totally on the positive- and negative-feedback effects of the stimuli of ingested food, then the meal size for a specific food (e.g., 0.8 M sucrose) would be the same under all conditions. But meal size is dynamic; it varies over a relatively large range in response to changes in external conditions and metabolic

states. The external conditions include the phase of the diurnal rhythm, environmental temperature, ecologic niche, and psychosocial stimuli that increase in complexity from animals to humans. The metabolic states include those produced by deprivation, overfeeding, obesity, growth, lactation, pregnancy, and ovarian steroid rhythms and the chronic effects of diets that differ in macronutrient composition.

Furthermore, animals and people readily associate metabolic states, environmental stimuli, and ingested food stimuli. Thus, external stimuli become conditioned stimuli (i.e., stimuli that control intake because of a prior association with eating or its consequences) for the effects of preabsorptive food stimuli and the pattern of stimuli produced by metabolic states. In this way, conditioned preferences and aversions are formed that influence the size of the meal (see "[Learning and Eating](#)").

Repeated attempts have been made to classify these various controls of meal size. Classification criteria have been derived from three perspectives: (a) presumed site of control (internal and external or central and peripheral); (b) presumed category of stimuli (physiologic and psychologic); and (c) the time over which a control was presumed to act (short term and long term). Although each of these perspectives provides a framework for discussion and investigation of some of the controls of meal size, none of them is comprehensive, and all of them are based on assumptions that are plausible but not proven.

Furthermore, none of these classifications provides a rationale for research on how to determine the relative potencies of the different controls in a specific situation. This is a crucial limitation, because the most urgent scientific need in this field is to understand how eating and metabolism are coordinated to determine body weight the gap between the meal and the scale ([6](#)).

To attempt to close this gap, Smith ([20](#)) recently proposed a new classification, derived from an unambiguous criterion, which is comprehensive, provides a metric to measure the potency of different controls, and is heuristic for mechanistic research. The criterion of this new classification is direct contact of peripheral preabsorptive receptors by food stimuli. Controls that result from such contact are direct controls of meal size. Direct controls are stimulated by the chemical, colligative, and mechanical stimuli of ingested food as it passes from the mouth to the small intestine during a meal. The core of the direct controls consists of afferent neural activity from the gut to the brain and the central processing of this afferent input into efferent outputs for the control of licking, mastication, and other movements related to ingestion, as well as efferent outputs to the autonomic and endocrine controls of digestion and metabolism ([Fig. 40.5](#)).

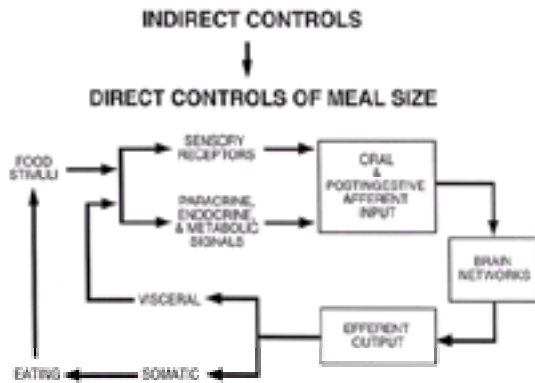

Figure 40.5. Flow diagram of the direct controls of meal size stimulated by ingested food acting on preabsorptive receptors of the gastrointestinal tract. Note that food stimuli activate afferent neurons directly and indirectly through effects on paracrine, endocrine, and metabolic signals and that the efferent output of the central networks for the control of eating is carried over visceral and somatic efferent fibers. Because some of the direct controls are stimulated by ingested food in every meal, indirect controls of meal size exert their effects by modulating direct controls. This is the reason for the unidirectional arrow between indirect and direct controls. (From Smith GP. *Neurosci Biobehav Rev* 1996;20:41–6, with permission.)

All other controls of meal size are indirect controls, which differ from the direct controls in not having preabsorptive, peripheral receptors that are stimulated by ingested food during a meal. In addition to distinction by the physical criterion of receptor site, the duration of action of indirect controls is longer than a single meal, which makes the mechanisms of indirect controls the likely source of the information required to close the gap between the meal and the scale.

Three conclusions can be deduced from this classification. First, direct controls must operate every time eating occurs, but a specific indirect control may not. Second, because indirect controls are, by definition, not activated by the preabsorptive, peripheral stimulation of ingested food, indirect controls must exert their effect on meal size by modulating some elements of the direct controls. This is the basis for the unidirectional arrow between indirect controls and direct controls at the top of [Figure 40.5](#). Indirect controls could modulate direct controls in a number of ways. The major modulation likely occurs in the brain networks that carry out the central processing of the afferent input of the direct controls and the comparator functions required to maintain the rate and duration of eating based on the relative potencies of the positive- and negative-feedback effects of ingested food (see above). It is also possible for indirect controls to modulate direct controls by changing the endocrine, metabolic, or paracrine responses to food stimuli; by changing the number or sensitivity of preabsorptive, afferent receptors; or by changing intracellular metabolism through effects on second messengers or genomic mechanisms. The site and kind of effect of a

specific indirect control can only be determined by further investigation.

Measurement of the Potency of Direct and Indirect Controls

Because indirect controls of meal size produce their effects by modulating the direct controls of meal size, measurement of meal size does not provide quantitative information about the separate contributions of the direct or indirect controls that determined the size of the meal. This very significant problem is complicated further by the fact that an indirect control could modulate the positive- or negative-feedback effects of the direct controls. Increased meal size, for example, could be due to changes in potency of positive feedback, negative feedback, or both ([Table 40.1](#)).

Positive Feedback	Negative Feedback
Increase	No change
No change	Decrease
Increase	Decrease

Table 40.1 Three Possible Combinations of Changes in Feedback Effects of Direct Controls Responsible for an Increase of Meal Size

The solution to this problem requires the following experimental sequence:

First, the change(s) in positive or negative feedback must be identified using measures listed in [Table 40.2](#). The specific measures used depend on the experimental setting, but all of the measurement techniques have been reported in humans as well as animals.

Positive Feedback	Negative Feedback
Sham feeding	Preload in stomach or small intestine
Initial rate of ingestion	Slope of the rate of decay of eating
"Sip and spit" psychophysics	

^aExcept for psychophysics involving linguistic reports of sensory and hedonic intensity, these measures can be made in animals and humans.

Table 40.2 Measures of Positive and Negative Feedbacks

After identifying the change(s) in feedback of the direct controls correlated with the abnormally large meal, curve-shift analysis is undertaken. This technique measures the potency of an indirect control by the amount that it shifts the potency of a direct control (Fig. 40.6) (see [20] for details). Examples of curve-shift analysis for the potency of indirect controls include (a) food deprivation for 17 hours shifted the eating-response functions for four carbohydrate solutions during sham feeding to the left by approximately one log in concentration (38) and (b) that the inhibitory potency of CCK was displaced to the left in the light compared with the dark in the rat (39), in a short photoperiod compared with a long one in hamsters (40), and by central administration of insulin in rats (41).

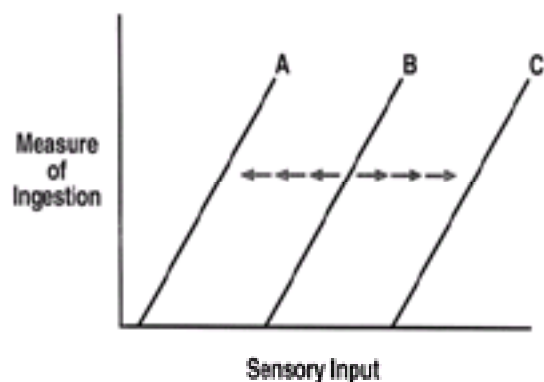

Figure 40.6. The method of curve-shift analysis used to measure the potency of a specific indirect control of meal size by measuring the displacement it causes of a direct control, preabsorptive sensory-eating response function (B). If the indirect control increases the potency of the direct control, B will be displaced to the left (A). If the indirect control decreases the potency of the direct control, B will be displaced to the right (C). Note that the slope of function B is arbitrary and that indirect controls could also change it. Sensory input is inferred from the intensity of adequate stimulus. In most

cases, this will be the load of the stimulus (concentration \times volume) because afferent receptors in the gut are distributed over a relatively large area of the mucosal surface. (From Smith GP. *Neurosci Biobehav Rev* 1996;20:41–6, with permission.)

Curve-shift analysis not only measures the potency of indirect controls, it also provides a framework for evaluating putative mechanisms of indirect controls, such as insulin, the OB protein secreted by adipose tissue, neuropeptide Y, and corticotropin-releasing factor.

MECHANISMS OF INDIRECT CONTROLS

Insulin

Kennedy (42) first suggested that a humoral signal proportional to fat mass and acting in the brain in a negative-feedback manner was necessary for coordination of intake, energy storage, and body weight. A sustained search for this humoral signal revealed that pancreatic insulin and OB protein (leptin) have this function. Insulin is discussed here and the OB protein below in the context of genetic hyperphagia.

Insulin was suggested as a negative-feedback signal proportional to fat mass (43) because the resting concentration of plasma insulin is tightly correlated with the mass of fat tissue in humans. Proposed by Woods, Porte, and their colleagues in 1979, this hypothesis has been investigated in rats and to a lesser extent in baboons and dogs. The following statements summarize the major evidence for this hypothesis (43):

1. Insulin enters the brain from the plasma by a transmembrane uptake mechanism in the walls of cerebral capillaries.
2. Insulin administered into the third ventricle or into the medial hypothalamic tissue adjacent to that ventricle decreases intake (and body weight). This is the site of the negative-feedback effect.
3. The effect of insulin is in the brain because it is produced by doses of insulin that are too small to affect plasma glucose levels in the periphery.

Neuropeptide Y

Neuropeptide Y (NPY), a member of the pancreatic polypeptide family, contains 36 amino acids. Originally isolated from the porcine brain by Tatemoto (44), it has also been found in the brain of rats, humans, and other mammals (45). NPY is widely distributed in the brain and is colocalized in catecholaminergic cells in the hindbrain, some of which project to the paraventricular nucleus (PVN) (46). Although injection of NPY into a number of hypothalamic sites increases intake, the PVN (Fig. 40.4) has received the most experimental attention for two reasons: (a) the PVN appears to be a site of integration for peptide and monoamine controls of eating, and (b) neurons of the

arcuate nucleus that synthesize NPY project to the PVN.

Injection of NPY into the PVN, lateral ventricle, or third ventricle increases food intake in a variety of situations (47). In fact, NPY is the most potent stimulant of food intake that has been discovered. Because rats do not show tolerance to its orexigenic effect, repetitive injections of NPY into the PVN produce sustained hyperphagia and obesity (48).

NPY has a major effect on initiation of eating and a variable effect on meal size. For example, Kalra et al. (49) noted that during a continuous infusion of NPY into the third ventricle, rats increased the number of meals, but meal size varied from small to large. The importance of the initiation of eating to the orexigenic effect of NPY was supported by the recent observation that bolus administration of NPY into the third ventricle increased intake when rats initiated eating by approaching liquid food and licking it, but NPY had no effect on intake when eating was passively initiated by infusing the same liquid food into the mouth through an intraoral catheter (50). Endogenous NPY is probably involved in the control of spontaneous eating, because NPY concentration and release in the PVN are correlated with eating (51, 52); injection of antibodies to NPY into the PVN decreased eating (53), and injection of antisense oligodeoxynucleotides into the arcuate nucleus to disrupt NPY synthesis also decreased eating (54).

Since NPY can increase intake, identification of the controls of its synthesis and release is crucial. There is evidence for a number of these controls, and most of them are inhibitory (55) (Table 40.3). Thus, disinhibition is the dominant process for stimulation of NPY (see below).

Stimulus	Effect on Food Intake	NPY	CRF
Insulin	↓	Decrease	? ^a
OB protein	↓	Decrease	Increase
Estrogen	↓	Decrease	Increase
Serotonin	↓	Decrease	Increase
Glucocorticoids	↑	Increase	Decrease
Exercise	↓	Increase	Increase

^aEffect of the stimulus is not clear or has not been reported.

Table 40.3 Reciprocal Effects of Stimuli That Control Food Intake on Hypothalamic NPY and CRF

The orexigenic action of NPY is attenuated by an α_2 -adrenergic antagonist (47), by haloperidol (a dopaminergic antagonist [56]), by fenfluramine (a 5-HT agonist and uptake blocker [57]), and by naloxone and naltrexone (58). The site of this opioid

mediation is in the hindbrain, not in the hypothalamus, because injections of naltrexone in the nucleus tractus solitarius (NTS) in the hindbrain blocked the effect of NPY, while injection of naltrexone in the PVN was much less effective. This is a good example of how a stimulus in the forebrain depends on hindbrain mechanisms for its effect on eating.

Corticotropin-Releasing Factor

Just as NPY is a peptide in the hypothalamus that stimulates eating under a variety of conditions, corticotropin-releasing factor (CRF) is a neuropeptide that inhibits eating under a variety of conditions (59). First purified in 1981, CRF is a 41-amino acid peptide named for its action of stimulating corticotropic cells in the anterior lobe of the pituitary gland after being released from nerve terminals into the hypophyseal portal veins. The neurons that secrete CRF into the portal system are in the parvocellular part of the PVN. Neurons containing CRF in the PVN also project to other neural sites including the NTS, the site where visceral afferent stimuli also project.

Because of its critical role in stimulating release of adrenocorticotropic hormone (ACTH), which then stimulates release of adrenal glucocorticoids, the neuroendocrine signature of stress responses, the anorectic action of CRF was originally demonstrated in that context (60). The parallel effect of CRF to increase the activity of the sympathetic nervous system was consistent with that view. But subsequent work demonstrated that CRF mediated at least part of the inhibitory effect on eating of acute exercise, estrogen, serotonin, and the satiating action of peripherally administered bombesin (59). The peptide also appeared to mediate the inhibitory effect of adrenalectomy on intake in lean rats and genetically obese rats (61, 62). Most recently, increased CRF has been implicated in the anorexia that results from involuntary overfeeding (63). From these various results, CRF is now viewed as exerting an important inhibitory control on eating in a number of circumstances that are not simply a reaction to stress.

A major site for this inhibitory action is the PVN. Injections of CRF into the PVN decreased eating (64), and injections of α -helical CRF₉₋₄₁, an antagonist of CRF, blocked this effect. Although CRF neurons project from the PVN to the hindbrain, their role in the inhibition of eating is not clear. Oxytocinergic projections (i.e., efferent fibers of neurons that synthesize, store, and release oxytocin at their terminals) from the PVN to the hindbrain may be more important, because an oxytocin antagonist abolished the inhibitory effect of CRF on eating (65).

When the controls of NPY and CRF are compared (Table 40.3), most controls (exercise is an interesting exception) have reciprocal effects on NPY and CRF activity, measured primarily by in situ hybridization, less often by protein content, and occasionally by peptide release. CRF can block the effect of NPY on intake, NPY decreases CRF mRNA in the PVN, and CRF decreases NPY mRNA in the arcuate nucleus. Such reciprocal actions are consistent with major roles for NPY and CRF in the indirect control of eating. Because NPY and CRF also decrease and increase sympathetic nervous activity, respectively, their reciprocal interactions on intake and sympathetic activity are consistent with their coordinating the frequently observed inverse correlation

between intake and sympathetic activity in lean and obese rodents ([55](#), [59](#)).

NPY, CRF, and the Eating Response to Food Deprivation

The importance of reciprocal changes in NPY and CRF has been tested in a situation of fundamental biologic interest—the increased eating that occurs after 24 to 48 hours of food deprivation. After deprivation, the eating response is robust and reproducible and, together with metabolic adjustments, restores body weight to normal with impressive precision. Such deprivation increases NPY mRNA in the arcuate nucleus and decreases CRF mRNA in the PVN ([66](#)). Food restriction, such as occurs in dieting, produces the same effect.

The changes in NPY and CRF are related to negative energy balance. Schwartz et al. ([67](#)) suggested that the low circulating insulin level (and resultant low level of central insulin) was the critical signal for the increase in NPY. Their idea predicted that the increased eating observed in insulin-deficient diabetes would be correlated with increased NPY levels, which proved to be the case ([68](#)). Furthermore, administration of insulin into the third ventricle in diabetic rats decreased NPY mRNA in the arcuate nucleus and decreased eating ([69](#)). Dallman has emphasized the importance of increased glucocorticoids in the eating response to deprivation ([70](#)). Glucocorticoids increase NPY and decrease CRF ([71](#)).

Further evidence for the reciprocal actions of NPY and CRF comes from involuntary overfeeding that produces increased body weight and decreased intake. The predicted effects occurred—NPY mRNA decreased and CRF mRNA increased ([63](#)). Although NPY appears to be important for the eating response to deprivation, it is not necessary, because mice with a knockout lesion of the NPY gene still show an eating response to deprivation ([72](#)). The non-NPY mechanisms and the changes of CRF that are involved in this mouse remain to be determined.

GENETICS OF HYPERPHAGIA

Increased eating is a characteristic phenotype of single gene mutations in rodents ([73](#)). These include four recessive mutations (*obese*, *diabetes*, *tubby*, and *fat*) and two dominant mutations (*yellow* and *Adipose*) in mice and the recessive Zucker *fatty* mutations in rats. Although there has been important progress in the molecular genetics of these mutations ([Table 40.4](#)), the functional analysis of how the gene products of these mutations result in increased eating is just beginning.

Gene	Mutation	Gene Product	Rodent Chromosome
OB	<i>ob</i>	OB protein	Mouse 6
OB-R	<i>db/fa</i>	OB receptor	Mouse 4, rat 5
Cpe	<i>fat</i>	Carboxypeptidase E	Mouse 8
Tub	<i>tub</i>	TUB protein	Mouse 7
agouti	<i>A^v</i>	Agouti signaling protein	Mouse 2

^aSee (73) for details.

Table 40.4 Rodent Obesity Mutations^a

The functional analysis began with the discovery that a protein synthesized and secreted by white adipose tissue in lean mice was not present in obese mice (*ob/ob*) because of a nonsense mutation at codon 105 (74). Peripheral or central injection of recombinant OB protein (leptin) into *ob/ob* mice decreased food intake and body weight (75). Thus, the abnormal OB protein from *ob/ob* mice lacks the inhibitory effect of the normal molecule. This deficiency of normal OB protein accounts for the hyperphagia and obesity in *ob/ob* mice.

Normal OB protein administered to mice with the diabetes mutation (*db/db*) had no effect (74). This suggested that the hyperphagia and obesity in *db/db* mice was due to a defect in the receptor (OB-R) for OB protein, which is the case. The *db* mutation results in an alternatively spliced transcript of the long intracellular domain form of the OB-R (76, 77). These recent results confirm the hypothesis that *ob* encodes a ligand for *db*, proposed by Coleman in 1973 on the basis of parabiosis experiments (78).

Because genetic mapping studies indicated that *fa* and *db* are homologous loci in the rat and mouse genomes, respectively, the hyperphagia and obesity in *fa/fa* rats was also hypothesized to be a defect in the OB-R, which was confirmed (79). The missense mutation consisted of a nucleotide substitution at position 880 (A @ C) that causes an amino acid substitution at position 269 (Glu-Pro). The mutant OB-R has greatly reduced binding of OB at the cell surface, which is correlated with a markedly reduced (80) or total lack of response (81) to OB in the *fa/fa* rat. The *fa/fa* rat also does not respond to central insulin (82). Thus, the hyperphagia of the *fa/fa* rat that is correlated with increased NPY (83) and can be reduced by increased CRF (84), is probably related to the lack of normal response to insulin and OB protein. The interaction between insulin and OB protein at the level of the hypothalamus will be interesting to define. In the periphery, insulin increases the synthesis of OB protein (85).

The inhibitory effect of OB protein on intake and body weight has now been extended to nondeprived and deprived rats (80, 81). The decreased intake after deprivation produced by OB protein is associated with decreased NPY mRNA and increased CRF

mRNA (86). This is identical to the central effect of insulin and reinforces the importance of the reciprocal changes of these peptides for the eating response to food deprivation.

These new relationships between a gene product (OB) secreted in proportion to adipose mass in mice (87) and humans (88, 89), a hormone (insulin) sensitive to energy balance, adipose mass, and metabolic state, and two neuropeptides (NPY and CRF) with reciprocal actions on eating are a major advance that provides a heuristic framework for further analysis of these single-mutation syndromes of hyperphagia and obesity. This problem will be more complicated in humans, in whom the genetics of the hyperphagia involved in obesity is oligogenic or polygenic, except in such unusual cases as the Prader-Willi syndrome (90).

LEARNING AND EATING

Successful omnivores, such as rats and people, learn to identify foods from the various stimuli provided by their environment. Having succeeded in distinguishing nutrients from water and poisons, omnivores develop preferences and aversions to different foods.

With the exception of the unconditioned preference for sweet taste and the unconditioned aversion to bitter taste, all identification and selection is accomplished by forming associations between olfactory and orosensory stimuli and postingestive stimuli. The olfactory and orosensory (gustatory and texture) stimuli serve as conditioned stimuli (CS), and postingestive stimuli serve as unconditioned stimuli (UCS), that is, stimuli that control intake independent of a prior association with eating or its consequences. Because every meal provides olfactory, orosensory, and postingestive stimuli, there is ample opportunity for such learning to occur. In fact, learning is so pervasive in eating that specific protocols are required to distinguish learned and unconditioned controls, which has not been done much (see "[Microstructure of a Meal and Feedback Effects](#)," above, for the distinction between conditioned and unconditioned satiation). There have been three kinds of explanation for conditioned preferences and aversions—deficiency, reinforcement, and molecular.

Beginning with Curt Richter's insight that eating could serve nutrient homeostasis (91), preferences have been commonly ascribed to nutrient deficiencies. Salt appetite is an example of an appetite elicited by a specific deficiency, but salt appetite is innate, not learned (92). Experimental vitamin deficiency proved to be a better paradigm for investigating learning about eating in response to a deficiency (93). Certainly this learning can be demonstrated during acute deficiencies of carbohydrates and protein (94, 95); however, the sites and mechanisms of the recognition of these deficits and their repletions have never been identified.

Such deficiency-dependent appetites could occur in an environment that was nutritionally marginal but not in a nutritionally adequate environment. Preferences and aversions observed under that condition must arise by differential reinforcements of orosensory, olfactory, and postingestive stimuli. Two major kinds of mechanisms underlie conditioned preferences flavor-flavor and flavor-postingestive (96). The flavor-postingestive mechanism is more potent and more interesting because it is clear that rats can distinguish among the postingestive stimuli of the type and quantity of

nutrients. Some of this detection may occur preabsorptively in the stomach and small intestine, but most probably occurs in postabsorptive metabolic events. The site, mechanism, and detection of those events is under active investigation. Conditioned preferences endure for relatively long times without periodic reinforcement, while the effect of these associations on intake extinguish when the CS occurs in the absence of postingestive nutrient effects (96).

Conditioned aversions are also formed by associations between olfactory, orosensory, and postingestive stimuli, but the postingestive stimuli are aversive (nausea is commonly reported in humans). This appears to be involved in the anorexia observed in amino acid imbalances (97). This anorexia (smaller and less frequent meals) depends on a serotonergic mechanism, because 5-HT₃ antagonists abolish it. The same 5-HT₃ mechanism operates in the conditioned aversion observed in cancer patients undergoing chemotherapy (98).

Recent work has used the *c-fos* technique to map changes in the neural network that underlies the expression of a conditioned taste aversion. These changes center on the NTS in the hindbrain and in the amygdala in the forebrain (99). The NTS changes depend on the forebrain because they are abolished ipsilateral to hemidecerebration (surgical procedure) at the level of the superior colliculus (100). This is another example of an eating response being organized by forebrain and hindbrain interactions.

Finally, there have been repeated suggestions that preferences can be the direct effect of central neurotransmitters and neuromodulators, and there is some evidence for this form of molecular determinism. For example, NPY produces a preference for carbohydrates, galanin and opioids produce a preference for fats, and serotonin mediates the alternating preference for carbohydrates and protein (101). This evidence, however, is fragile, because small changes in experimental protocols produce different results (101, 102), which argues against any strong form of molecular determinism. The action of synaptic transmitters and modulators in food preferences is more reasonably understood as influencing a complex, central neural network that is processing food stimuli in a specific context of environment and experience.

CONCLUSIONS

Although the control of eating involves reflexes stimulated by ingested food, metabolic states, and a variety of environmental and neuroendocrine stimuli, this reflex control is augmented by rapid learning of associations between orosensory stimuli, viscerosensory stimuli, and metabolic effects.

All of the recent progress in understanding the controls of eating has come from investigation of rats and mice. This is encouraging because these omnivores have previously proven to be good models of human nutrition. The progress in rodents sets the problem for new human investigation. We must now move beyond measures of meal size to mechanisms of direct and indirect controls of eating. Because most measurements involve peripheral manipulations and sampling that are feasible in humans, we can expect to make real progress in our understanding of the controls of

human eating and its contribution to normal nutrition.

ACKNOWLEDGMENTS

I thank Mr. Berkeley Cooley and Ms. Terri Popeil for expert processing of this manuscript. I am also grateful for the constructive criticism of Drs. J. Davis, N. Geary, R. Leibel, A. Sclafani, R. Seeley, K. Simansky, and S. Woods. This review was prepared while I was supported by a Research Scientist Award of the National Institutes of Mental Health (MH00149).

Starvation is the physiologic condition that develops when macronutrient intake is inadequate. The manifestations of the disease that results from chronic starvation are due to protein and energy deficiency, hence the term *protein-energy malnutrition* (1). Since this chapter emphasizes both normal and pathologic responses to macronutrient deprivation, the broad concept of starvation is retained in the discussion that follows. Most human starvation results from deprivation of food, not selected nutrients, so the clinical disease that results from it is usually associated with micronutrient and macronutrient deficiencies (2, 3 and 4).

The physiology of starvation is central to human nutrition and important for understanding many aspects of metabolism and medicine. [Chapter 59](#) deals with the clinical presentation and treatment of protein-energy malnutrition. This chapter summarizes what is known about the metabolic consequences of protein and energy deficiency, as studied, for the most part, in human metabolic laboratories. The aim is to establish links between basic nutritional physiology and areas of applied clinical nutrition covered in other chapters in the text, including, among others, protein and energy

metabolism, body composition, and nutritional assessment.

The chapter begins with an overview of water deprivation and describes metabolism during prolonged fasting and the effects of modifying a fast by selective carbohydrate or protein provision. There follows a description of the clinically more common forms of starvation in which protein or energy are consumed, but in deficient amounts. Finally, the metabolic effects of refeeding starving patients are discussed.

DEFINITIONS

Although detailed studies of human starvation physiology have been conducted for more than a century, there is little uniformity in the terminology used to describe it. In this chapter, *starvation* refers to prolonged inadequate intake of protein, energy, or both. A *fast* or a *total fast* is exclusion of all food energy. However, for other authors, starvation refers to complete deprivation of dietary energy (i.e., a fast), and *semistarvation* to the commoner condition of merely insufficient energy and protein provision. Yet other authors consider any diet restricted to only a few nutrients to be a fast, such as a “juice fast.” The term *fast* is also commonly applied to the normal condition of any person after the overnight sleep (i.e., the period before “breakfast”). Terms such as *starvation*, *inanition*, *wasting*, and *cachexia* have, in the past, been used synonymously to describe the malnourished condition of famine victims, underfed prisoners, or patients with chronic disease and serious weight loss. However, in recent years some authors have used the term *cachexia* to refer specifically to the wasting that results from metabolic stress, also termed *cytokine-induced malnutrition* (5), and the term *starvation* to refer to wasting that results from simple food deprivation in the absence of stress.

The different forms of starvation have much in common, but they are not identical. Thus, metabolism during a fast longer than 2 to 3 days is dominated by the low-insulin state that develops once the liver's limited glycogen store is exhausted, a state characterized by lipolysis, ketone body production, and, at least in its initial phase, increased protein catabolism (6). Provision of as little as 150 g carbohydrate per day fully abolishes ketosis (7), so only rarely are patients with even advanced protein-energy malnutrition ketotic, nor do they manifest the hormonal and metabolic profile of prolonged fasting. Thus, when interpreting the results of biochemical studies of starvation, it is important to know whether the nutritional manipulations resulted in an extremely low insulin state (as in fasting or diabetes), protein deficiency in the presence of adequate carbohydrate energy, or gradations between these extremes.

WATER DEPRIVATION

Fluid deprivation occurs as extracellular volume deficiency, pure water deficiency (dehydration), or a combination of the two (see [Chapter 6](#)). Volume deficiency occurs when a combination of sodium and water loss depletes the extracellular fluid volume. The clinical presentation includes weight loss, poor skin turgor, dry mucous membranes, diminished sweat, and postural hypotension. The diagnosis is confirmed by the patient's response to appropriate treatment. Typical (but not invariable) biochemical findings are hyponatremia and an increased serum urea concentration, the latter due to reduced

renal glomerular filtration and urea clearance. Thirst may be present or absent, and anorexia or even nausea are common (8).

Dehydration occurs when whole body water loss occurs with relative preservation of extracellular volume; its clinical hallmark is hypernatremia. The commonest cause of dehydration is failure to drink, and the earliest symptom is thirst (9). Symptoms of dehydration develop slowly when water is deprived, as long as urinary and insensible water losses are normal. In healthy persons denied food or water for 24 hours, plasma viscosity increases by about 15% (10), but serum sodium, albumin, and the hematocrit increase by only a few percent (9, 11). These small changes are predictable, since only about 4% of body water is normally lost in a day. With persistent water deprivation the serum sodium continues to rise, and the resulting hyperosmolality leads to confusion, weakness, lethargy, obtundation, coma, and ultimately death (12). The risk of dehydration is greater in elderly persons, who, for unknown reasons, have less appreciation of thirst during water deprivation than young adults (9).

It is common in hospice care not to supplement the voluntary fluid intake of dying patients (12, 13). As a result, dehydration commonly develops and is frequently the proximate cause of death. In one study, symptoms of thirst and hunger occurred in only a minority of such patients, and when it did occur, small amounts of food or fluid and moistening the mouth sufficed to alleviate it (13). Less commonly, dehydration may cause an agitated delirium that can be prevented or treated with rehydration (14).

From experiments in which a 40% depletion of body water caused death in animals, it has been estimated that a human adult could survive for 2 weeks if deprived of all water, while losing 1.3 L water daily from all sources (15). This calculation assumes that fat oxidation produces about 250 mL of water per day. It seems more likely that a 25% depletion would be fatal, since this would raise the serum sodium concentration from 140 to 180 mmol/L. If first-order kinetics are assumed and 4% of body water is lost per day, the predicted survival is 6 days. If 3% of body water is lost per day, survival is 8 days.

PROLONGED FASTING

Carbohydrate Metabolism

A lucid description of carbohydrate metabolism during prolonged fasting best proceeds from the last meal before the fast. Characteristic of the fed state are increased blood concentrations of glucose, fats, amino acids, and their metabolites. Insulin secretion is induced by the absorbed carbohydrates and amino acids, and it regulates their disposition within the tissues by stimulating glucose incorporation into glycogen in the liver, glucose transport and glycogen synthesis in muscle, triglyceride synthesis, and amino acid transport and synthesis into proteins in the insulin-sensitive peripheral tissues (mainly muscle). Glucagon levels are unchanged or decreased during meals containing carbohydrate, but a protein meal low in carbohydrate stimulates glucagon secretion (16). This directs the liver to continue glycogen breakdown and increase gluconeogenesis, thereby maintaining a normal blood glucose level despite the

concurrent insulin-mediated glucose uptake by the peripheral tissues.

The fed state ends after the last nutrient has been absorbed and the transition to endogenous fuel consumption begins. The condition that exists after an overnight fast has been found convenient for study and is termed the *basal* or *postabsorptive* state. It is characterized by the release, interorgan transfer, and oxidation of endogenous fatty acids and the net release of glucose from liver glycogen and amino acids from muscle, all of these the results of relatively low levels of circulating insulin. Even with high carbohydrate diets, the body's predominant postabsorptive fuel is fat. As indicated by the characteristic nonprotein respiratory quotient (NPRQ) of 0.8, fat oxidation accounts for two-thirds of the body's postabsorptive resting energy expenditure (17).

Under postabsorptive conditions, glucose disappears into the tissues at a rate of 8 to 10 g/h; the free glucose pool of the body (about 16 g) must therefore be replaced every 2 hours (18). Glucose is normally the brain's only metabolic fuel; any reduction in the blood glucose concentration below a critical value promptly impairs consciousness and, if prolonged, results in neurologic damage. Given the brain's fixed and high metabolic requirement (more than half the total glucose production rate) there is no room for error in the delivery of adequate amounts of glucose from the liver into the circulation. The blood glucose concentration of healthy individuals is tightly regulated by the action of several physiologic control systems, chief of which are the insulin and glucagon systems.

As the blood glucose concentration is progressively lowered by tissue uptake, insulin levels fall in parallel, slowing further blood glucose lowering by reducing the rate of glucose transport into muscle and fat and by stimulating glycogenolysis and inhibiting glycogen synthesis in the liver. As a result, glycogen gradually releases its store of glucose into the circulation, while new glucose molecules synthesized from lactate, glycerol, and amino acids pass directly into the circulation instead of being sequestered in glycogen.

There is now good evidence that hepatic gluconeogenesis is continuous, even in the fed state. Starting very early in the postabsorptive period, approximately one-half of the glucose appearing in the circulation originates from gluconeogenesis, and one-half from glycogen breakdown (18, 19, 20, 21 and 22). The precise amount of glucose each of these sources contributes to the circulating glucose pool in the early postprandial period must largely be determined by the carbohydrate and protein content of the preceding diet, for these would, respectively, determine the size of the liver's glycogen store and the amount of substrate presented to the liver for gluconeogenesis (23).

In a fast longer than 12 to 24 hours, the insulin concentration is further reduced, and this, together with an increasing glucagon concentration, results both in continuing gluconeogenesis and rapid mobilization of free fatty acids from adipose tissue triglyceride and of free amino acids from muscle (24), while the lowered insulin:glucagon ratio activates the liver for fatty acid oxidation. Once the liver is activated in this way, its rate of fatty acid oxidation is determined by the rate at which fatty acids are delivered to it (25). Thus, along with diminished conversion of glucose and glucose precursors to acetyl coenzyme A, the entry substrate for the Krebs cycle, acetyl coenzyme A

production due to fatty acid oxidation increases. Some of the acetyl coenzyme A produced from fatty acid oxidation is terminally oxidized through the intrahepatic Krebs cycle, thus serving as the predominant energy source for the liver (26), but most of it is oxidized only as far as the 4-carbon molecule acetoacetic acid, which in turn is reversibly converted to its oxidoreduction partner, b-hydroxybutyric acid, and, to a lesser extent, irreversibly decarboxylated to form acetone.

A fast longer than 2 to 3 days exhausts the liver's glycogen reserve (20, 27) and about half the glycogen in muscle (27, 28). All glucose oxidized thereafter must be synthesized from endogenous glycerol, the glucogenic amino acids, and lactate and pyruvate produced by glycolysis of preexisting glucose via the Cori cycle. Consequently, the NPRQ falls to 0.7. An NPRQ of 0.7 and appearance in the circulation of large amounts of acetoacetate, b-hydroxybutyrate, and acetone, collectively known as the "ketone bodies," are the hallmarks of the low insulin:glucagon ratio and rapid hepatic fatty acid oxidation that characterize a prolonged fast.

During the period of glycogen depletion, gluconeogenesis from glucogenic amino acids (chiefly alanine and glutamine) accounts for a progressively larger fraction of total glucose output during the first 2 days of fasting (20, 22). The absolute rate of gluconeogenesis does not appear to increase during this period; rather, total glucose release into the circulation decreases by 40 to 50% within the first few days of fasting (20, 29, 30 and 31).

The shortfall in glucose production during this period is matched by a corresponding reduction in glucose use. Only a part of this is due to a reduction in terminal glucose oxidation in muscle and fat or by reduced Cori cycle activity. Indeed, the Cori cycle seems not to change significantly even after a fast of several weeks (32). The reduction of plasma glucose disappearance that occurs both in the earliest phase and later, during prolonged fasting, can only be explained by a reduction in brain glucose metabolism, made possible by the concurrent availability of ketone bodies as an alternative fuel. This was recently confirmed in a study of short-term fasted humans that used a combination of positron emission tomography (to measure glucose metabolism) and arterial–internal jugular vein sampling (to measure b-hydroxybutyrate consumption). After a 3.5-day fast, brain glucose consumption was reduced by 25% (approximately 100 kcal/day), whereas ketone body consumption increased from approximately 16 to 160 kcal/day (33).

Ketosis

Even in the fed state, small amounts of acetoacetic acid are produced and oxidized in the liver (34), and under basal conditions, acetoacetic acid oxidation furnishes about 2 to 3% of the body's total energy requirement (26). Circulating ketone body concentrations are almost unmeasurably low under normal conditions (0.1 mmol/L or less), and ketone body export from the liver is negligible (35). Starvation ketosis is arbitrarily defined as being present when the blood acetoacetate concentration has risen to 1.0 mmol/L and b-hydroxybutyrate to 2 to 3 mmol/L, as typically occurs by day 2 or 3 of fasting (26). After an overnight fast, the urine of an adult is normally free of ketone bodies, but their appearance in the overnight urine of thin persons, especially women, is

not uncommon and indicates their relatively low basal insulin state (36).

After release into the blood, acetoacetic acid and β -hydroxybutyric acid dissociate to become water-soluble anions. Acetone is a volatile molecule soluble both in water and lipids. After 3 or 4 days of fasting it appears in small amounts in the breath, imparting a characteristic sweet odor.

The circulating concentration of free fatty acids (and consequently their rate of delivery to the liver) is a major determinant of the ketogenic rate and the level of ketonemia. Another factor is the maximum rate of hepatic fatty acid β -oxidation, which cannot exceed the upper limit set by the liver's rate of energy use. All tissues with mitochondria oxidize ketone bodies, and ketone body oxidation provides 30 to 40% of the body's total energy use in the first 4 to 7 days of fasting. After about 2 weeks, however, muscle ketone body oxidation decreases, and this tissue returns to oxidizing fatty acids as its main resting fuel (18). Ketogenesis is maximal by about 3 days of fasting, but since its uptake into muscle is reduced after 2 weeks and renal tubular reabsorption increases, blood ketone body levels continue to rise steadily and, after about 3 weeks, reach a steady state double that found after 3 to 5 days of fasting. The brain's rate of ketone body use is determined by the blood ketone body concentration, so brain ketone body oxidation steadily increases over this period, and glucose oxidation is further reduced. After 3 to 5 weeks of fasting, brain glucose metabolism is globally reduced by about 50% (37). Moreover, only 60% of glucose taken up by the brain is now fully oxidized to CO_2 and water; the other 40% of glucose carbon is recycled to the general circulation as pyruvate and lactate for use in gluconeogenesis (38). This combined adaptation of reduced terminal oxidation and Cori cycling reduces irreversible glucose oxidation in the brain by 75%, with an equivalent reduction in the requirement for gluconeogenesis from amino acids and glycerol.

Metabolic Significance of Ketosis

Mention of ketosis or ketoacidosis (ketosis sufficient to reduce the blood bicarbonate, but within its normal buffering capacity) brings diabetes mellitus to mind. In the most severe form of diabetes, destruction of the β cells of the pancreas produces virtually complete insulin deficiency. The result is increased mobilization of fatty acids and priming of the liver for ketone body production and gluconeogenesis, as in simple fasting (25, 39). However, when carbohydrate is ingested but insulin is lacking, little of the resulting blood glucose is removed by muscle and adipose tissue, and the blood glucose concentration rises to high levels, exceeding the renal threshold for glucose reabsorption. The resulting glycosuria creates an osmotic diuresis that depletes the body of water and extracellular fluid. In fasting nondiabetic persons, ketone body levels seldom rise higher than 6 to 8 mmol/L, whereas in untreated diabetes they may rise to 12 to 14 mmol/L, imposing an acid load too great for the body's buffering system to absorb and causing a dangerous fall in pH (ketoacidemia).

Why is severe ketoacidemia common in untreated insulin-dependent diabetes but almost unheard-of in fasting, nondiabetic persons? One possibility is that sufficiently high ketone body concentrations are normally self-regulated. In some studies, ketone body infusions slightly stimulated insulin secretion, and this in turn increased peripheral

ketone body use (35, 40). Against this, at least as a sole explanation, is the uncommon but well-recognized syndrome of “nondiabetic ketoacidosis.” This usually occurs in alcoholic persons who, following an alcoholic binge with little or no food consumption, subsequently develop recurrent vomiting (41). The resulting fasting ketoacidemia may be as severe as diabetic ketoacidosis, but the blood glucose concentration is low, not high; appropriate treatment involves volume replacement and glucose, without insulin. Nondiabetic ketoacidosis also occurs in pregnancy, although rarely. In pregnancy, fasting hypoglycemia and mild ketosis develop rapidly because of the high glucose demands of the fetus (18). As with alcoholic nondiabetic ketoacidosis, gestational nondiabetic ketoacidosis has been reported in a setting of fasting, hypoglycemia, and volume depletion or metabolic stress (42).

A feature that distinguishes all forms of severe ketoacidosis from the benign ketoacidosis of fasting is hypermetabolism. Uncontrolled diabetes is characterized by hyperglucagonemia and increased norepinephrine secretion. These increase gluconeogenesis and the metabolic rate, whereas fasting is normally a hypometabolic state. Metabolic stress also stimulates gluconeogenesis and the delivery of free fatty acids and gluconeogenic precursors to the liver (43, 44). These factors act together to increase the liver's energy consumption and hence its ketogenic capacity (45). For nondiabetic fasting persons, a stress-induced increase in blood glucose would, under most conditions, stimulate insulin release sufficiently to restrain lipolysis and gluconeogenesis, thereby limiting ketogenesis (35), but in exceptional circumstances, this does not happen. The occasional development of severe nondiabetic ketoacidosis in a setting of combined fasting and hypermetabolism thus becomes understandable, and indeed, it is consistent with observations made in the preinsulin era. Prior to 1922, the only treatment that extended the life of insulin-dependent diabetic patients was a diet low in glucose, to prevent hyperglycemia, and low in total energy, which reduced the metabolic rate and hence the liver's ketogenic capacity (46).

In summary, prolonged fasting is characterized by a low blood glucose concentration, which leads to physiologic hypoinsulinemia and ketosis, whereas uncontrolled insulin-dependent diabetes is characterized by a high blood glucose concentration, hypermetabolism, and ketosis, all of which are the direct or indirect result of a pathologic insulin lack. Unlike diabetic ketoacidosis, fasting ketosis is physiologic and a manifestation of proper metabolic regulation. It will not develop into a severe condition similar to diabetic ketoacidosis (18, 25), except, potentially, in a setting of severe volume depletion and/or metabolic stress.

Ketosis during Pregnancy

While normally benign, ketosis is to be avoided during pregnancy because of possible adverse consequences to the fetus. Maternal ketonemia in pregnancy has been associated with a reduction in the intelligence of the offspring (18). Thus, periods of fasting or carbohydrate restriction are to be avoided during pregnancy.

Protein and Energy Metabolism

After an overnight fast, insulin levels drop enough to stimulate mild net muscle

proteolysis, thereby releasing amino acids as an endogenous substrate for hepatic gluconeogenesis. In a fast longer than a day, insulin secretion drops yet further, muscle proteolysis is more strongly stimulated, and considerable skeletal muscle protein is lost. During the first 7 to 10 days of fasting, whole body N loss may be in the range of 10 to 12 g/day, excreted chiefly as urinary urea. Since mixed body protein is 16% N and the wet weight:dry weight ratio of lean tissue is about 3–4:1, this corresponds to the loss of 1 to 2 kg of lean tissue over this time (47, 48). If this rate of body N loss were to continue, the body's lean tissue reserve would be lethally depleted within 3 weeks of fasting. Instead, after 7 to 10 days an adaptation begins that, by the end of 2 to 3 weeks of fasting, has reduced the rate of body N loss to less than half of what it was during the first several days. This still incompletely understood adaptation is all the more remarkable since about 50% of urinary N by this time is in the form of ammonium excreted to buffer the protons generated by keto acid production, and it can be eliminated by simple bicarbonate administration (16, 49). Indeed, when ammonium excretion is reduced to normal by providing an exogenous buffer, the body N losses in late, “adapted” fasting are close to the “obligatory” rate of N loss considered to reflect the maximum attainable efficiency of body protein turnover (50, 51).

What accounts for the remarkable reduction in muscle protein catabolism that takes place in the face of the catabolic stimulus of persistent hypoinsulinemia? Metabolic investigations have, so far, been unable to explain this mystery.

In the first 1 to 3 days of fasting, plasma branched-chain amino acid concentrations double, and their release from whole-body proteins and subsequent oxidation increase by variable amounts from postabsorptive values (52, 53). Urinary 3-methylhistidine excretion, an indicator of myofibrillar protein breakdown, also increases in the first few days of fasting (52, 54). By 7 to 10 days, the early increase in amino acid turnover is superseded in most (52, 55) (although not all [53]) studies by a reduction of leucine or lysine (56) release due to proteolysis, in a setting of continued significant urinary N loss and leucine oxidation. By week 4, when N excretion has clearly diminished, protein turnover is reduced even further (57, 58), and 3-methylhistidine excretion is below the prefasting rate (57).

Even early in fasting, the liver is primed for gluconeogenesis (18), and its avidity for gluconeogenic precursors remains unchanged for the duration of the fast. The protein-sparing mechanism of prolonged fasting therefore resides in muscle, and indeed, muscle amino acid output, especially of alanine and glutamine, decreases at this time (18, 59). The reduced muscle protein synthesis and increased proteolysis that make free amino acids available for catabolism in early fasting are due to the combined effect of absent exogenous amino acids and insulin deficiency (24, 60). What reduces muscle proteolysis after 2 weeks of fasting? Most authorities regard the shift in muscle metabolism from ketone body oxidation to fatty acid oxidation and the resulting rise in blood ketone bodies and their delivery to the brain after 2 weeks of fasting as important factors. As ketone bodies increasingly displace glucose as the brain's oxidative fuel, the requirement for amino acid conversion to new glucose molecules is dramatically reduced.

Missing from this scheme, however, is the signal that “tells” muscle to reduce its

catabolic rate (61). Some evidence suggests that hyperketonemia has a direct protein-sparing effect on skeletal muscle (62, 63), but clear proof is still lacking (53). Another possibility is that the process by which muscle metabolism switches from ketone body oxidation to fatty acid oxidation after approximately 2 weeks of fasting is responsible, in some manner, for the reduction in muscle proteolysis. Perhaps increased fatty acid oxidation in muscle spares the branched-chain amino acids (which have structural similarity to fatty acids), and they (or their metabolites) are responsible for the diminished proteolysis (16). This possibility is attractive because of evidence that these molecules, particularly leucine, have protein-sparing effects (64). Finally, ketone bodies may stimulate a rise in peripheral insulin too slight to be detected with currently available methods (25, 35, 65) but which still exerts a protein-sparing effect.

Resting energy expenditure decreases by approximately 15% after 2 weeks of fasting (66) and is 25 to 35% below normal after 3 to 4 weeks (67). This reduction is too great to be entirely due to lean tissue loss, although lean tissue loss is plainly responsible for further reductions as the fast continues.

Other Metabolic Effects

The serum albumin concentration remains normal both in short-term and prolonged fasting, but concentrations of the rapidly turning over liver secretory proteins, transthyretin (thyroid-binding prealbumin) and retinol-binding protein, promptly decrease, as they do in response to any form of carbohydrate restriction (68, 69). Serum total bilirubin may increase by 50% after a 24-hour fast, doubling by the end of day 2 and remaining constant thereafter (70). Hyperuricemia invariably occurs, the consequence of inhibition of renal tubular excretion of urate by ketone bodies (18) and increased renal tubular urate reabsorption when the extracellular volume is depleted (71). Gastric emptying slows after only 4 days of fasting (72). In therapeutic fasts longer than 4 weeks, postural hypotension and nausea become prominent problems. Other metabolic effects and medical complications of prolonged fasting are described in clinical reviews (18, 73, 74).

Weight Loss

Weight and body N loss occur in roughly direct proportion to the existing body weight and lean body mass (73, 75), exhibiting the characteristics of a biexponential “decay” process. The pattern of weight loss is highly variable. Nonobese men with free access to water may lose 4 kg over the first 5 days of a fast and a further 3 kg over the next 5 days (48, 67), whereas obese men lose about 50% more than this. In one extreme case, a patient initially weighing 245 kg lost 32 kg in the first 30 days of fasting (73).

Water, not fat, accounts for most of the initial weight loss during fasting (76). This can be demonstrated by a simple calculation. If total energy expenditure is assumed to be 2400 kcal/day during the initial week of a fast and N loss is 10 g/day (equivalent to the catabolism of 62.5 g body protein, and hence, to the provision of 250 kcal of endogenous energy), negative energy balance is 2400 – 250 or 2150 kcal/day. Stored fat provides 9.4 kcal/g, so 2150/9.4 or 229 g of fat is oxidized per day to make up the energy balance. The adipose tissue lost during weight reduction is 85% fat by weight

(77, 78), so body weight loss directly due to fat loss will be $229/0.85$ or 269 g/day or 1.9 kg/week. This represents only one-third or less of the total weight loss during this period; the other two-thirds is water unrelated to adipose tissue. Of all the water lost in the first 3 days of fasting, approximately 65% is from the extracellular compartment (67). This rapid mobilization of extracellular water and sodium is due to a combination of absent dietary sodium and the low insulin level, since insulin has an antinatriuretic action on the kidneys (79). The dissolution of liver glycogen (2–3 g water/g glycogen [80]) and to a lesser extent muscle glycogen (3–4 g water/g glycogen [81]) contribute to intracellular water loss over the first 3 days, as does lean tissue dissolution, which persists at a rate of at least 10 g N/day (19–25 g water/g N [47]) during the first 7 to 10 days. After 2 weeks of fasting, extracellular fluid loss has almost completely ceased (73), and by the third week, weight loss slows substantially, a consequence of slower lean tissue loss, reduced metabolic rate, and stabilization of glycogen and extracellular water balance. During this phase of fasting, weight loss is due to continuing adipose and lean tissue loss and amounts to about 300 g/day in moderately obese persons (82).

Nutritional Modifications of Fasting Metabolism

It has been known for most of this century that carbohydrate, but not fat, reduces protein catabolism during fasting (17, 55, 83). As described 50 years ago in Gamble's famous "experiences on a life raft" lecture (15), 100 to 150 g of glucose per day prevents the ketonuria of fasting and reduces urea N excretion and extracellular volume loss by half. For these reasons, hospitalized patients who cannot eat or drink are customarily administered 2 to 3 L/day of intravenous fluids containing 50 g dextrose/L.

The important protein-sparing effect of carbohydrate occurs in the first 7 to 10 days of a fast. When given later, even large amounts of carbohydrate are only modestly more effective at limiting N loss than is accomplished by this time by natural adaptation (7, 84). Moreover, prolonged carbohydrate administration without protein can have adverse consequences. Hypoalbuminemia and immune system dysfunction have been observed in acutely ill, hospitalized patients maintained for prolonged periods on intravenous dextrose solutions, a syndrome reminiscent of kwashiorkor, the disease of protein-malnourished children with free access to carbohydrate. This syndrome is attributed to a carbohydrate-induced high peripheral insulin concentration that, in the setting of protein deficiency, drives scarce circulating amino acids into muscle tissue at the expense of the visceral protein store. For this reason, patients who cannot obtain normal oral nutrition for periods longer than 7 to 10 days require parenteral amino acids as well as energy.

The timing of the protein-sparing effect of dietary protein is the reverse of that of carbohydrate. When given in the first 7 to 10 days of fasting, protein has little effect on the rate of body protein loss, but after 2 or more weeks of continuous high-quality protein feeding in doses of 50 to 80 g/day, N balance gradually improves and may even return to zero after 3 or more weeks (85, 86). When protein is introduced during the adapted phase of a total fast, N balance abruptly becomes positive (57, 87).

Survival

Depletion of 50% or more of the body's lean tissues is said to be incompatible with survival (88) and has commonly been claimed to signal impending death due to fasting (3). However fat, not protein, may determine survival in this unique form of starvation (89, 90). Nonobese adults die after approximately 60 days of fasting, in reasonable agreement with the estimated time required to lose all their body fat, but only one-third of their lean tissues. Perhaps fat depletion is lethal in fasting humans because it reduces the availability of fatty acids, which are necessary both for hepatic ketone body synthesis and as the energy substrate that sustains gluconeogenesis (90). Fasting, therefore, should be avoided by individuals with depleted fat stores even if their lean tissue stores are ample (91).

Obese individuals have tolerated fasts of astonishing length (92, 93). The longest monitored fast on record was by a 27-year-old man whose starting weight was 207 kg. He lost 60% of his body weight after 382 days of uninterrupted fasting (94). Despite such spectacular experiences, total fasts longer than about 4 weeks are potentially dangerous, even for very obese persons. Although minimized, lean tissue loss does not cease in prolonged fasting. In cases of extremely prolonged fasting in which lean tissue loss was measured, critical levels of depletion were observed (93). Acute thiamin deficiency can be a devastating complication of fasting (95, 96 and 97) and could contribute to its lethality.

PROTEIN DEFICIENCY

Protein deficiency occurs when protein intake is chronically below the requirement level but energy intake is maintained. Severe protein deficiency has been relatively little studied in adults, since it rarely occurs without simultaneous energy deficiency. On the other hand, syndromes due to mild chronic protein deficiency are of considerable interest, for they have an important bearing on the definition of minimum protein or essential amino acid requirements. Considerable uncertainty continues to exist in this area (98, 99, 100, 101 and 102).

Adaptation and Accommodation

The normal response to a reduction in protein intake is an adaptive reduction of dietary and endogenous amino acid oxidation to match the new lower intake and, after a few days, restoration of N balance. Consumption of less protein than the minimum nutritional requirement exceeds the limit of this adaptation and results in sustained body protein loss (50). In most cases, a new steady state occurs later in which N equilibrium is restored after a variable amount of lean tissue loss. Waterlow has drawn attention to the difference, when assessing the nutritional value of diets, between *adaptation*, which is a normal physiologic response to variations within the acceptable range of protein intakes, and the protein-sacrificing response to an inadequate protein intake, which he termed *accommodation* (103, 104). Other terms, such as *normal adaptation* and *pathologic adaptation* would serve the same purpose; what is important is the distinction. Adaptation is understood to be an aspect of normal physiology, whereas

accommodation implies a physiologic compromise with adverse health consequences.

The phenomenon of accommodation is illustrated by the response of elderly but healthy women who were randomly assigned to diets that provided either surfeit (0.92 g/kg) or moderately inadequate (0.45 g/kg) protein, in the presence of adequate energy. After 9 weeks, the women consuming inadequate protein suffered no weight loss, and their N balance was only slightly negative, indicating approximate metabolic homeostasis. Moreover, their serum albumin (often considered a sensitive indicator of adequate protein nutrition) remained normal. Unlike the control subjects, however, their lean tissue mass was reduced, and muscle function and immune status were impaired (105). Similar abnormalities have been observed in patients with more severe or prolonged protein deficiency, but in these cases serum albumin is reduced (106), indicating more severe compromise. In all cases fat stores are normal.

When consumed by healthy persons for only a week or two, protein-free diets are without adverse effect; in fact, such diets were widely used in the past to estimate the minimum dietary protein requirement. When a normal adult is switched from a conventional diet high in protein (e.g., 100 g/day) to one that is protein free, urinary N decreases, and after about 7 days it reaches an apparent steady-state excretion of 37 mg N per kg body weight, accounting for almost 70% of total body N loss (the other sources of N loss, which do not change, are in the feces and secretions and from skin shedding) (50, 51, 107). This “obligatory” N loss indicates the lowest rate to which endogenous protein loss can be adaptively reduced and is considered to indicate the minimum dietary protein requirement (50, 108). The problem with this calculation of the minimum protein requirement is that it assumes no loss of dietary amino acids occurs during their absorption from the gut and resynthesis as new protein in the tissues. Gut absorption of amino acids is, in fact, normally highly efficient, but the biochemical steps leading to the conservation of dietary amino acids within newly synthesized endogenous proteins are not, and the degree of inefficiency varies under different conditions (109). When increasing amounts of high-quality protein are added to a protein-free diet, N balance improves steeply at low levels of intake (indicating highly efficient dietary protein retention) but more slowly at higher intakes (51). When the results of N balance studies that included many levels of dietary protein are analyzed and the lowest intake at which N equilibrium occurs is interpolated, the average daily intake of high-quality protein (0.6 g/kg) is substantially more than indicated from obligatory N loss (0.34 g/kg). Nevertheless, the precision of the protein-free diet method is such that it can still be useful for assessing the efficiency of basal protein metabolism in conditions in which only small numbers of subjects are available for study (110).

Protein and Energy Metabolism

Consumption of a severely protein deficient diet for 7 to 10 days reduces whole body protein turnover (110, 111 and 112) and also the rate of albumin synthesis, although the serum albumin concentration does not change (107, 113). Essential amino acid deficiency also promptly reduces whole body protein turnover (114). In animals, severe protein deficiency reduces liver protein synthesis (115, 116 and 117), consistent with the observation that protein synthesis in this organ fluctuates in close response to fluctuations in the amino acid supply comparable to those normally encountered during

the ingestion of protein meals ([118](#)). Increased protein synthesis by delivery of amino acids can even be evoked in the isolated perfused liver, showing that the hormonal responses evoked during meal absorption are not essential for liver protein synthesis ([118](#), [119](#)).

Less clear, in the human, are the effects of acute changes in protein intake within the normal adaptive range. As expected, most studies carried out in the fed state indicate that a low protein intake reduces amino acid catabolism and a high intake increases it, since these responses would act to keep N balance close to zero. Some ([120](#), [121](#) and [122](#)) but not all ([123](#), [124](#) and [125](#)) studies indicate that the increased or decreased leucine oxidation evoked by high or low leucine intakes is carried over into the basal period between meals. Basal protein turnover has been found insensitive to changes of protein intake within the normal physiologic range in most ([121](#), [122](#), [124](#), [125](#)) but not all ([111](#), [126](#), [126A](#)) human studies.

In the study of chronic protein deficiency described above, 9 weeks of moderate protein deficiency did not reduce fed-state whole body protein synthesis and breakdown nor urinary 3-methylhistidine excretion ([127](#)). This is a surprising result that challenges current concepts about the adaptation to protein deficiency. Regrettably, basal protein turnover, which may have been more reliable for detecting an adaptive reduction in protein turnover in this setting, was not measured ([105](#), [107](#)). Serum albumin and the concentrations of the liver secretory proteins, retinol-binding protein and transferrin, remained normal ([105](#)). Evidently, plasma concentrations of these proteins provide less insight into the adaptation to protein deficiency than would knowledge of their actual synthesis, secretion, and removal rates. It also provides further evidence that plasma transthyretin, retinol-binding protein, and transferrin concentrations, often taken as indicators of the adequacy of protein nutrition, are far more sensitive to carbohydrate and total energy intake than to protein nutrition per se ([68](#), [69](#)).

What are the health implications of reduced whole body protein turnover, as observed during severe protein or essential amino acid deficiency? Protein synthesis is energetically expensive ([128](#)), so the continuous recycling of body proteins in a seemingly "futile cycle" presumably confers a biologic advantage. Newsholme and Stanley showed that substrate cycles at regulation points in metabolic pathways permit finely tuned control of metabolite flow ([129](#)). Does recycling of entire proteins similarly allow rapid remodeling of body protein distribution and function in times of need? If so, then slowed rates of protein turnover characteristic of severe or prolonged protein or essential amino acid deficiency could be bad for the organism ([104](#)). It appears that the greater the protein intake, the coarser (and perhaps, therefore, less efficient) the regulation ([121](#), [122](#), [130](#)). When protein is consumed above the requirement level, dietary protein conservation is inefficient, as indeed it must be to eliminate the excessive amino acids provided by the diet. When protein intake is severely reduced below the requirement level, protein turnover rates are reduced to maximize amino acid reuse, a state manifested by low fluctuations in N excretion ([130](#), [131](#)). Thus, according to this view, adaptation to significant protein deficiency necessarily involves reduction in the rate of cellular protein turnover, because rapid flux through the free amino acid pools is incompatible with the finest regulation (and efficiency) of amino acid oxidation ([57](#), [114](#)).

There is little information on energy expenditure in pure protein deficiency. The resting metabolic rate appears to remain normal, either when measured after 7 to 10 days of a protein-free diet (132) or when related to the metabolic mass after prolonged, moderate protein deficiency (127).

Labile Protein

In 1866, Carl Voit first demonstrated the existence of a small protein store whose amount was determined by the dietary protein content and which was excreted during the first several days of fasting or upon changing from a higher to a lower protein intake. This protein store is now known to be an example of a general phenomenon of rapid body protein gain or loss in response to variations in protein intake (83, 133). When a normal adult consumes a low-protein diet, urinary N excretion remains higher than intake for 3 to 5 days before diminishing to a new steady state. When the former protein intake is resumed, N balance becomes positive until the previous losses are made up (Fig. 41.1). Labile protein is said to constitute about 3% of body protein in well-nourished rats or humans (133), an insignificant amount in terms of total body N economy, but of potential importance to understanding adaptation to starvation.

Figure 41.1. Labile protein. The *solid line* indicates the N excretion of a human subject abruptly changed to a low-protein diet. The *dashed line* indicates the level of N intake. Initially, N intake approximates its excretion, and the subject is close to N equilibrium. On switching to the lower N intake, N loss exceeds intake for several days until equilibrium is reestablished. The N lost from the body during this period is shown in the *first shaded area*. On resuming former intake, the subject stores N, as shown by the *second shaded area*. The two shaded areas are approximately equal. (From Munro HN. General aspects of the regulation of protein metabolism by diet and hormones. In: Munro HN, Allison JB, eds. Mammalian protein metabolism, vol 1. New York: Academic Press, 1964;381–481, with permission.)

Although small, the amount of labile protein in the body is larger than the free amino

acid pool, which makes up only about 0.5 to 1.0% of the body's amino acids and an even smaller percentage of the essential ones ([134](#), [135](#) and [136](#)). The free amino acid pool, because of its small size and rapid turnover, can be assumed to be essential to the regulation of tissue protein synthesis and breakdown ([136](#)). Since labile protein undergoes the most rapid exchange with the free amino acid pool, it is tempting to regard it as important in determining the extent of oxidation of amino acids, particularly those newly entering from the diet ([133](#)). In the protein-deficient or fasted rat, the greatest acute loss of protein is from the liver, with the other visceral organs making up large contributions as well, as might be predicted from the rapid turnover rates of proteins in these organs ([107](#), [117](#)).

A labile pool of rapidly turning over protein could help explain how the efficiency of dietary protein retention improves after reduction of protein intake within the normal adaptive range. To what extent does an increase or decrease in whole-body protein turnover represent a slight change in the rate of synthesis and breakdown of a large, slowly turning over protein pool of nearly constant mass, and to what extent a considerable increase or decrease in the size of a small, rapidly turning over pool, such as labile protein? The contributions of the different protein pools of the body to whole-body protein turnover are not well defined, so the notion that labile protein synthesis and breakdown contribute importantly to whole body protein turnover remains speculative ([52](#)). If a high protein intake increases the labile protein pool, then “basal” protein turnover ought to be more rapid in persons adapted to higher protein intakes and lower after they adapt to lower intakes within the normal range ([137](#)). The apparent insensitivity of basal whole-body protein turnover to variations in protein intake thus argues against a significant regulatory role for labile protein ([122](#)).

PROTEIN-ENERGY STARVATION

The commonest form of starvation results from a deficiency of all food, and hence represents the combined features of energy deficiency, protein deficiency, and, in all likelihood, deficiencies of certain micronutrients whose role in the pathogenesis of the clinical entity of protein-energy malnutrition is not yet elucidated ([98](#), [138](#)). In general, protein-energy starvation combines the hypometabolic adaptation of energy deficiency with the reduced whole-body protein turnover characteristic of severe or chronic protein deficiency; it is a far more variable entity than simple fasting or short-term protein deficiency. Metabolism during protein-energy starvation depends to a considerable degree on the composition and duration of the starvation diet, and it is frequently complicated by the medical or surgical condition that led to its development in the first place (see also [Chapter 59](#), [Chapter 96](#) and [Chapter 98](#)).

Weight Loss

The most detailed study of the effects of chronic energy and protein deficiency on human physiology was conducted between 1944 and 1946 by Keys and his coworkers, in an experiment in which 32 healthy young men volunteered to live on the campus of the University of Minnesota and consume a diet providing approximately 1600 kcal/day, about two-thirds of their normal energy requirement ([139](#)).

The Minnesota volunteers lost an average of 23% of their initial body weight. Body composition measurements indicated that they lost more than 70% of their body fat. Muscle was lost as well; in all, the volunteers lost 24% of their lean tissue mass (termed *active tissue mass* in the study), which accounted for 60% of their weight loss. Weight loss alone underestimated the sum of their fat and lean tissue losses, because their extracellular fluid volume increased. In extreme cases (and especially in the presence of other diseases associated with water retention), the increase in extracellular volume causes obvious fluid accumulation within the skin and interstitial tissues, called “hunger edema.” When present, edema makes assessment of the severity of lean tissue depletion more difficult (140); midarm circumference takes on special usefulness in this situation (141).

Adaptation

As in fasting, weight loss early in semistarvation is rapid, but it gradually slows, even if there is no change in the starvation diet. Whereas weight loss can never slow to zero during fasting, a pathologic adaptation is commonly achieved in less extreme states of energy deficiency by which body weight stabilizes at a lower steady-state value. This occurred for the Minnesota volunteers after 24 weeks. Evidently it involved cessation of losses both of fat (energy) and lean tissue (protein).

Energy Expenditure

The resting energy expenditure (REE) of the Minnesota volunteers decreased by 40% after 24 weeks of starvation, thus coming approximately into line with their energy intake. This decrease in REE was largely the result of a diminished lean tissue mass, which is responsible for most of the metabolic processes that determine energy expenditure (142). REE was also reduced per unit of remaining lean tissue (Fig. 41.2). Total energy expenditure also decreased substantially, because smaller meals evoke a smaller thermic effect of food, and a lower body weight demands less work in moving (143). Moreover, the volunteers reduced their level of voluntary physical activity by more than half, a form of adaptation shown in other studies of chronic starvation (144, 145) and in some (146) but not all (147) short-term starvation studies. Such adjustments, when successful, bring starving individuals back into energy equilibrium.

Figure 41.2. Mean basal metabolism for 32 men before and during 24 weeks of starvation. All values are expressed as percentage of the prestarvation values for the oxygen uptake per man, per square meter of body surface, and per kg of body weight. (From Keys A, Brozek J, Henschel A, et al. *The biology of human starvation*. Minneapolis, University of Minnesota Press, 1950, with permission.)

Lean Tissue Loss

The energy-restricted organism can restore energy balance by reducing its lean tissue mass, but it cannot lose so much lean tissue that the adverse metabolic consequences of protein deficiency become intolerable. Successful adaptation is a process of controlled protein loss that should cease when just enough has been sacrificed to permit zero energy balance to be reestablished. N equilibrium is reestablished by an adaptation that can be separated conceptually into two components: (a) decreased endogenous N loss and (b) increased efficiency of dietary protein retention ([Fig. 41.3](#)). As starvation proceeds, the rate of continuing lean tissue loss is roughly proportional to the amount of lean tissue remaining, and hence it automatically slows as the lean tissue mass decreases ([148](#)). Simultaneously, cellular metabolism adjusts to reduce the rate of endogenous amino acid oxidation ([149](#)) and increase the efficiency of exogenous (dietary) protein retention. The increased avidity of starving tissues for dietary protein has long been recognized ([150](#), [151](#) and [152](#)). Net body protein loss continues until the slowing of endogenous protein loss matches the increasing efficiency of dietary protein retention and a new state of protein equilibrium is established ([Fig. 41.3](#)).

Figure 41.3. A hypothetical scheme to account for adaptation to starvation in the adult. A first-order (linear) relationship exists between the amount of lean tissue and the rate at which it is depleted. This is indicated by the *solid line*. An *inverse* relationship exists between the amount of lean tissue and the efficiency of retention of protein in the diet. This relationship is affected by the concentration of protein in the diet, resulting in a family of curves (*dashed lines*). As starvation progresses and the lean tissue store diminishes, the rate of protein depletion slows as the amount of protein retained from

each meal increases. At the crossover point a new equilibrium is established and lean tissue loss ceases. The “price” paid to achieve this physiologic adaptation is a diminished lean tissue store. This scheme illustrates that a high-protein diet may permit protein equilibrium after only moderate lean tissue wasting; a low-protein diet may also be compatible with protein equilibrium, but the cost, in terms of protein wasting, will be greater.

Determinants of Lean Tissue Conservation

Because the starving individual must sacrifice a certain amount of protein to reestablish zero energy balance, protein loss can be regarded as a beneficial survival mechanism during prolonged starvation (153). However, energy intake is only one of several factors that affect the rate of N loss during starvation and the total amount of lean tissue that must be sacrificed to reestablish N equilibrium. These factors include energy balance, protein intake, protein-nutritional state, biologic individuality, and possibly obesity.

Energy Balance. The Minnesota volunteers consumed an amount of protein close to the amount regarded as safe for normal adults (0.75 g/kg body weight), but they still lost a large amount of body protein. Many studies have shown that N balance at a constant protein intake is improved by increased, and worsened by decreased, energy intake (133, 154). The energy effect is most potent in the modestly submaintenance range of both protein and energy intakes (155). Under most circumstances, the predominant energy source (carbohydrate or fat) is immaterial (156).

Kinney and Elwyn emphasized the importance of measuring the energy balance (the difference between exogenous energy ingested and energy expended), not simply energy intake (157, 158). Because it is the amount of dietary energy in surplus or in deficit after accounting for expenditure, energy balance is probably the specific physiologic variable that when negative worsens N balance and when positive improves it (159). Direct measurement of energy balance may be particularly important in hospitalized patients whose energy expenditure varies considerably (157).

Protein Intake. The combination of protein and energy deficiency results in a greater loss of body protein than is physiologically necessary to reduce energy expenditure. N balance is improved by increased protein intake over a wide range of energy intakes from deficient to maintenance (133); thus, increased protein intake may compensate for negative energy balance (133, 160, 161 and 162). This interaction is illustrated in [Figure 41.3](#). When the lean tissues are depleted, a greater fraction of the protein in a given meal is retained, so (over an appropriate range of protein intakes) a meal high in protein will be associated with greater absolute protein retention than one low in protein. This explains why a high-protein starvation diet may be associated with protein equilibrium after only moderate lean tissue wasting; a low-protein starvation diet may also be compatible with protein equilibrium, but the ultimate protein-wasting will be greater.

Thus, in the Minnesota study, fat-free mass (FFM, body weight minus pure fat)

accounted for 71% of the weight loss after 12 weeks of starvation (139), whereas, in a recent 10-week study of normal-weight men whose energy intake was reduced by a not dissimilar margin, but whose protein intake (94 g/day) was nearly twice that of the Minnesota volunteers, only 17% of the weight lost was from FFM. This is close to the amount of extracellular fluid associated with adipose tissue (77, 78). Urinary creatinine excretion (an indicator of skeletal muscle mass) remained constant, further evidence that the high-protein diet effectively spared body protein in these normal starving men (163).

The sparing effect of a high protein intake is also demonstrated in most N balance studies of obese persons on weight reduction diets. N losses tend to be greater in men than women, and some body N and FFM loss appears inevitable when severely obese persons are starved. This occurs because adipose tissue has nonfat components that are measured as FFM (164) and because there is a reduced need for muscles after significant weight reduction (85, 165, 166). Most, but not all (86), studies have shown that a high-protein diet (at least 1.5 g protein per kg of normal body weight) maintains N balance (85) or FFM (167) better than lower intakes. The failure to find a difference in N balance between diets providing 50 and 70 g protein per day in a recent study (86) may have been because the protein levels were not sufficiently different to detect it.

Stage of Starvation. The efficiency of N retention at any protein and energy intake is increased by prior protein depletion (57). In part, this occurs simply because a smaller mass of active body protein requires less amino acid replacement than a larger one. However, cellular adaptations also improve the efficiency of amino acid use; these are described below. The influence of protein-nutritional status is implicit in the scheme shown in Figure 41.3, in which a given lean tissue mass (indicated on the horizontal axis) has an important effect on both endogenous protein loss and dietary protein avidity.

Obesity. It has been suggested that obesity confers a sparing effect on protein loss during starvation (76). In my view this is not well established, especially considering differences in sex, protein intake in relation to FFM, and the greater physical activity level of obese, weight-reducing persons than of nonobese starving ones. Indeed, to the extent that lean tissue mass is increased in severely obese individuals, their absolute rate of N loss is faster than that of less obese persons during starvation (73, 168). An analysis of the composition of weight loss by weight-reducing patients did not show any slower loss of FFM in those more obese (169).

Other Factors. When weight loss continues in spite of conditions conducive to adaptation, attention should be directed to such correctable factors as malabsorption, the adequacy of micronutrient provision (170, 171), or supervening physiologic stress (5) (see also Chapter 59). These factors are considered in detail below, but even when they are all controlled or considered, the variation in individual responses to starvation is wide (172). This is consistent with the scope of biochemical individuality (173) and, specifically, with the wide variation in individual amino acid requirements of normal men (174).

Characteristics of Successful Adaptation

Pathologic adaptation has “succeeded” when energy equilibrium is reestablished through reduction of total energy expenditure and a process of controlled lean tissue wasting that is arrested before the adverse consequences of lean tissue depletion become insupportable. The organism survives, but a metabolic and functional price must be paid (107). The most apparent deficits are loss of insulating fat and loss of muscle mass with its associated reduction of physical power. A hypometabolic state of “unwellness” is induced, reminiscent of (but not identical to) hypothyroidism (175). Starving patients are hypothermic and do not mount an appropriate thermic response to environmental cold (176). The loss of muscle mass diminishes the body's protein reserve and, together with slower protein turnover in the remaining muscle (177), reduces the body's options for protein remodeling in response to changing metabolic needs. Thus, starving patients mount a blunted rise in protein turnover and a smaller catabolic response during metabolic stress (178). The physical appearance of patients with protein-energy malnutrition is reminiscent of advanced aging, and indeed, some similarities of body composition exist (179).

In addition to the loss of peripheral proteins, deficits in central protein occur as well. The anatomic and functional consequences of severe human starvation are covered in clinical depictions (139, 180, 181) and medical reviews (3, 165, 182, 183). These effects include anemia, altered heart muscle mass and function, decreased pulmonary mechanical function and a diminished response to stimuli to breathe, altered gut anatomy and mildly impaired absorptive function, altered drug metabolism (184, 185 and 186), and immunodeficiency (187, 188).

Immune competence is crucial for long-term survival, yet the precise nature of immune dysfunction in human starvation remains poorly understood. In both animals and humans, advanced protein-energy malnutrition results in a variety of immune deficits, especially of cell-mediated immunity (demonstrated clinically by anergy, the loss of delayed cutaneous hypersensitivity) (187, 188). However, the clinical importance of immune deficiency in moderate starvation and the possible additive effect of concurrent micronutrient deficiency have not been well studied (189). A potentially broad area of interaction is cytokine production or release, which is independently impaired in protein-energy malnutrition and in several micronutrient deficiencies (190).

Weight-stable anorexia nervosa in an otherwise healthy young individual is a useful clinical paradigm for well-adapted starvation (191). More complex examples can be observed daily in any outpatient chronic disease clinic and in segments of the population of many parts of the world. The defining features of successful adaptation are less-than-critical total lean tissue depletion, weight stability, normal plasma albumin level (in the absence of dehydration), normal peripheral blood total lymphocyte count, and intact delayed cutaneous hypersensitivity (192).

Central and Peripheral Protein Depletion

An important aspect of successful adaptation involves preferential visceral uptake of

amino acids released from muscle. This results in relative preservation of the mass and function of critical “central” proteins despite large losses of “peripheral” skeletal muscle protein (192). When adaptation is unsuccessful, either because the food restriction is too severe, because of micronutrient deficiency, or for other reasons, the peripheral lean tissue depletion becomes too great and proteins are lost from both the central and peripheral compartments (Fig. 41.4). Metabolic stress frequently precipitates central protein deficiency. The hyperglycemia induced by stress hormones stimulates insulin release, which drives scarce amino acids into the insulin-sensitive peripheral proteins at the expense of the insulin-insensitive central proteins (133, 192). By contrast, moderate stress in the well-nourished organism is characterized by mobilization of peripheral proteins to the center (193, 194).

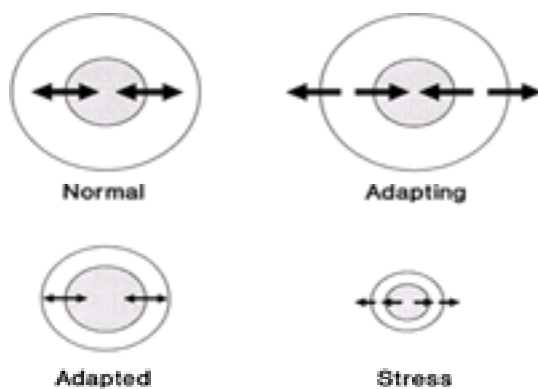

Figure 41.4. Adaptation to starvation. The *outer circles* represent the mass of peripheral, metabolically active proteins. The *inner circles* represent the central (visceral) proteins. The *arrows* represent N transfer. In normal life, protein equilibrium exists. During adaptation to starvation, N is lost from the body, but there is a relative sparing of the central proteins. When adaptation is successful, equilibrium is reestablished at a major cost to peripheral proteins but at a relatively minor cost to central proteins. Stress (or other reversal of adaptation) causes a loss of both central and peripheral N.

Development of central protein deficiency, as manifested by anergy and hypoalbuminemia (with resultant edema), indicates a dangerous condition (192). Parallels have been drawn between simple, adapted adult protein-energy malnutrition and childhood marasmus, on the one hand, and between central protein malnutrition in the adult and kwashiorkor (which may also be precipitated by stress or a high-energy, low-protein intake) on the other (195). However, starvation in the chronically ill adult is only approximately similar to childhood marasmus or kwashiorkor (176, 196), and there is uncertainty about the precise pathogenesis of kwashiorkor (195, 197, 198). Most often, advanced protein-energy malnutrition in the adult has a mixture of “central” and “peripheral” features that tends toward one end of a spectrum or the other (106, 199).

Failed Adaptation

Failed adaptation should be suspected when a starving patient develops metabolic stress, as indicated by fever or a rapid heart rate. However, these responses to stress may be blunted in starving patients, and their absence does not rule out stress nor does it exclude factors other than stress that reverse the adapted state. A more reliable sign of stress-induced protein wasting is an inappropriate rise in serum urea concentration and urinary urea excretion. By far, the simplest indicator of the reversal of accommodation from any cause is resumption of weight loss in a previously weight-stable, malnourished patient or the failure to gain weight despite development of edema. Either situation indicates new lean tissue loss. Factors that can impair adaptation and thus should alert the clinician to its possible failure, include further diminution of food intake, worsening of the primary disease or development of one of its complications, onset of a new disease that imposes a metabolic stress, or administration of a treatment that alters protein or energy metabolism.

Metabolic Stress. The hypermetabolic, protein-catabolic response to severe infection, trauma, or traumatic major surgery reverses the adaptation to starvation ([5](#), [192](#), [200](#)) (see also [Chapter 96](#) and [Chapter 98](#)). Food intake previously compatible with homeostasis is now inadequate. Starving, stressed patients move rapidly into a state of central protein deficiency because their peripheral protein reserves have previously been depleted.

Mineral Deficiency. Mineral deficiencies, particularly of potassium ([170](#), [171](#)), phosphorus ([170](#)), zinc ([201](#), [202](#)), and presumably magnesium, prevent maximal protein-sparing and an appropriate anabolic response to re-feeding.

Metabolic Disease or Administration of Hormones or Antimetabolites.

Hyperthyroidism, pheochromocytoma, glucagonoma, poorly controlled diabetes mellitus, and states of glucocorticoid excess ([203](#)) are all associated with protein wasting. The existence of any of these diseases or its new development in starving patients calls for attention to the patient's nutritional status. In any of these situations, protein-energy malnutrition may rapidly develop, or the previously successful adaptation to existing starvation may be reversed, resulting in rapid progression to an advanced stage. Some evidence reveals that the efficiency of protein metabolism remains abnormal even with appropriate insulin treatment of insulin-dependent diabetes ([204](#)). Diabetic patients may therefore be at increased risk of severe protein depletion during starvation.

Glucocorticoids or antimetabolites used to treat inflammatory conditions, or chemotherapeutic agents and extensive radiotherapy used in cancer therapy, may impair the adaptation to starvation. Anorexia is a systemic manifestation of certain malignancies, including those of the pancreas, stomach, and liver ([205](#)), and may add to the anorexia induced by many chemotherapeutic agents ([206](#)), abdominal radiation, and psychologic factors. The combination of reduced food intake and metabolic stress is common in these patients.

Food Restriction Too Severe. The most common maladaptation to starvation should not be described as maladaptation at all but is merely the consequence of food deprivation too severe to allow adaptation. The result is continuous weight loss until death.

Chronic Energy Deficiency

Starvation in a ward or clinic patient is easily recognized, requiring only physician or nutritionist awareness and confirmation of the diagnosis on the basis of a food-intake and body-weight history, physical examination, and a record of weight over time (207). However, in societies where scarcity and low body weight are common, it can be difficult to define the minimum acceptable food intake and corresponding nutritional state (88, 153, 208). To address this, a form of adapted protein-energy starvation, “adult chronic energy deficiency” (CED), has been described (209, 210). This stable but malnourished condition is compatible with gainful employment, pregnancy, and other aspects of daily life and is thus clearly distinct from “acute energy deficiency,” which corresponds to the weight-losing stage of poorly adapted starvation, or to the clinical condition of protein-energy malnutrition. CED is defined as a subnormal body mass index (BMI, body weight in kilograms divided by the square of height in meters), and classified into 3 grades of severity: grade I, 17.0–18.4; grade II, 16.0–16.9; and grade III, less than 16 (210).

BMI reflects the body's fat store both in obesity and underweight. A BMI between 20 and 25 is generally regarded as optimum (50). In the United States, Hungary, or Brazil, fewer than 5% of adults have a BMI below 18.5, whereas 10% of Chinese, 20% of Congolese, 25% of Pakistani or Philippino adults, and nearly 50% of Indian adults are in this category (209, 210). Only grades II and III CED have been associated with an increased probability of days of illness, reduced physical work capacity, poorer reproductive function, and poorer lactation performance. A measurable decrease in voluntary physical activity has been shown only in grade III CED. These observations suggest that a BMI of 17.0 to 18.5 may be compatible with normal health. Therefore, an appreciable number of normal persons (especially young adults) with BMIs in this range could be incorrectly diagnosed as malnourished (209, 210).

CED described in active young adults living in poor countries could well be the same condition as the successfully adapted protein-energy starvation of weight-stable anorexia nervosa patients or the wasting that commonly accompanies chronic disease. It is also possible that years or decades of CED induce long-term adaptations, including psychologic ones, that we do not yet understand (107, 199). The BMIs of the Minnesota volunteers fell from 21.4 to 16.3 after 6 months of starvation (139). If their 1.8 kg of extracellular fluid gain is subtracted, their BMI becomes 16.0, a value within the range associated with disability in CED. On the other hand, the BMI of patients described as severely malnourished in one detailed study (106) was 17.5. In that study, undernutrition was diagnosed on the basis of a combination of features that included serum albumin and urinary creatinine for height, as well as body weight for height.

In summary, it appears that young adults without intercurrent disease can tolerate a BMI

as low as 17 without apparent physiologic dysfunction, despite their lack of nutritional reserves. Even a BMI below 17, while associated with disability, can be tolerated in well-adapted CED. This is in marked contrast to much medical experience, which dictates that a weight loss of more than 10% is sufficient to identify malnutrition ([211](#), [212](#)). At the other extreme, a BMI above 18.5 does not rule out severe malnutrition, since fat and extracellular fluid mass can greatly affect body weight. Evidently, better criteria than body weight or BMI alone are required to identify dangerous protein or protein-energy starvation. The best clinical criteria currently available are ones that point to failed adaptation to starvation. These include continuing weight loss, functional disability, and hypoalbuminemia, especially in the presence of physiologic stress ([205](#), [213](#), [214](#) and [215](#)).

MECHANISMS GOVERNING ADAPTATION TO STARVATION

The above discussion highlighted nutritional factors that influence physiologic adaptation to starvation. This section deals with the biochemical mechanisms that could mediate this adaptation.

Energy Metabolism

The adaptive reduction in REE during energy restriction is caused by alterations in the peripheral metabolism of thyroxine (T_4), the hormone secreted by the thyroid gland, to its more active metabolite, triiodothyronine (T_3), and perhaps, to a lesser extent, by changes in sympathetic nervous system activity ([85](#), [148](#), [175](#), [216](#), [217](#)). Serum T_4 levels and those of thyrotropin (the pituitary hormone that regulates T_4 secretion) remain normal, but serum T_3 decreases within a few days (or even hours) of initiating a starvation diet. Serum levels of an inactive metabolite, reverse T_3 , rise. Both energy intake and, specifically, the amount of carbohydrate consumed affect this conversion process, apparently through their effect on insulin secretion ([175](#), [218](#)). Although an association clearly exists between decreased circulating T_3 and lowered REE during starvation, its precise nature is not well understood ([85](#), [175](#)), nor is T_3 the only modulating factor. Thus, a carbohydrate-free diet that provides maintenance energy reduces T_3 levels, but the resting metabolic rate does not decrease ([219](#)). Poorly controlled diabetes mellitus is associated with decreased serum T_3 levels, but the metabolic rate is increased ([220](#)).

In uncomplicated starvation, and especially if volume depletion has been prevented ([221](#)), catecholamine secretion and turnover decrease, as measured in the blood and urine of humans and in the organs of laboratory animals ([144](#), [153](#)). The blood pressure, heart rate, and core temperature of starving patients are reduced as is their thermic response to cold or to a norepinephrine infusion. Pupil size, an indicator of basal sympathetic tone, is diminished ([139](#), [144](#), [176](#)). As with T_4 to T_3 conversion, both energy balance and carbohydrate intake, at least in part because they stimulate insulin release, are important regulators of these effects. The thyroid and catecholamine effects are interconnected ([153](#)). T_3 increases the number of tissue norepinephrine receptors,

and in its absence, the number decreases ([222](#)).

It has been common, when attempting to identify the factors responsible for changes in energy metabolism, to divide the measured REE value by body weight or FFM, on the assumption that a change in REE/FFM implies a change in metabolism at the cellular level ([Fig. 41.2](#)). Unless FFM is constant, however, this procedure is prone to error. First, while normal resting (and total) energy expenditure can be accurately predicted from the FFM, the body's FFM is inhomogeneous with respect to its energy-producing elements ([223](#), [224](#)) and these are lost in different proportions in starvation ([225](#)). Secondly, even though FFM accurately predicts normal REE over a wide range of FFM, the equation is of the form $REE = E(0) + B \cdot FFM$, where $E(0)$ is a constant nonzero energy factor (the y intercept), and B is the proportionality factor relating increasing FFM and REE. Dividing REE by FFM incorrectly diminishes the effect of $E(0)$ on REE and does so in biased fashion, since larger values of FFM diminish this constant more. As a result, REE/FFM increases as FFM decreases, even when REE is in precise agreement with the predictive equation ([226](#), [227](#)). The importance of the error introduced by this incorrect normalizing technique depends on the relative sizes of $E(0)$ and B . In analyses in which FFM is appropriately adjusted for by use of covariate analysis, adjusted REE is reduced in adapted starving patients ([228](#), [229](#)).

Protein Metabolism

Tissue protein synthesis is regulated to a large extent by the supply of amino acids, whereas the kinetics of the enzymes that catabolize amino acids are such that transamination and oxidation increase linearly with increasing tissue concentrations. As a consequence, body protein synthesis is sensitive to amino acid intakes within the adaptation range of protein provision, while amino acids consumed in excess of synthesis are rapidly catabolized ([116](#), [149](#)). In confirmation, whole-body studies consistently find that leucine oxidation is roughly proportional to its plasma concentration when leucine or protein intakes are above the requirement level ([230](#)).

Few measurements of whole-body protein turnover have been carried out in chronically starved nonobese individuals. On the basis of these studies ([127](#), [178](#)), the results of animal experiments, and extrapolations from the literature on weight reduction and short-term protein deficiency, it may be concluded that adaptation to starvation reduces protein turnover in most body tissues ([107](#), [116](#), [231](#), [232](#)). It also appears that the major nutritional regulator of protein turnover is protein intake itself. Thus, very low energy (500 kcal) reducing diets that include generous amounts of high-quality protein ([58](#), [233](#), [234](#)) maintain protein turnover, whereas fasting ([57](#), [58](#)) or low-energy diets that are low in protein (or provide only low-quality protein) dramatically reduce it ([55](#), [233](#)).

As with energy expenditure, the contribution of a reduced lean tissue mass to slowing of whole-body protein turnover during starvation cannot be discerned simply by dividing a whole-body turnover parameter by body weight or FFM ([235](#)). Protein turnover proceeds at different rates in different lean tissue compartments ([236](#)), and these compartments are depleted to different extents during starvation ([3](#)). Also, as with energy expenditure, any equation relating body weight or FFM to basal protein turnover

is likely to have a nonzero y intercept (226, 227). Thus, in a recent study of adults with chronic energy deficiency, whole-body protein turnover per kilogram FFM was higher than that of normal adults. This was attributed to the markedly greater loss of slowly turning over skeletal muscle than of rapidly turning over central proteins in these adapted starving persons (225).

Many hormonal changes occur in starvation (218, 237), but our understanding of how these changes govern adaptive changes in protein metabolism remains incomplete. T_3 plays a role in the regulation of muscle metabolism, but its precise effects in starvation are not yet well defined (162, 175). T_3 levels decrease early in starvation, and T_3 administration to fasting obese subjects increases their body N losses (175), suggesting that the decreased T_3 is important (at least permissively) for successful adaptation. However, the doses of T_3 administered in those studies were physiologically excessive (85). Moreover, the relationship between T_3 and N balance apparent in total fasting studies is less clear when patients on hypocaloric diets are studied (85).

Insulin stimulates protein synthesis and inhibits its breakdown in muscle and in liver, and the absence of insulin reduces protein synthesis and increases proteolysis (24, 59, 238). Even in advanced protein-energy malnutrition, carbohydrate intake stimulates enough insulin release to prevent ketosis and the acute catabolic state characteristic of early fasting (7, 151). A milder reduction of insulin effect does occur, however (239), and this (in combination with reduced dietary amino acid delivery) curtails tissue protein synthesis (116) and, secondarily, proteolysis (162). The combination of reduced insulin and amino acid cellular action could be expressed both directly on the cells and indirectly, by diminishing the peripheral action of thyroid hormone (162).

It has been known for many years that protein or energy restriction and catabolic states reduce circulating concentrations of the protein anabolic peptide hormone, insulin-like growth factor-1 (IGF-1). This occurs despite increased serum concentrations of growth hormone, which normally stimulates IGF-1 release (240, 241). Structurally related to insulin, IGF-1 stimulates net protein synthesis in cultured cells and in isolated muscle in a manner similar to insulin (24). Much information about IGF-1 and its nutritional interactions has become available in recent years (242, 243, 244, 245 and 246). Despite the complexity implied by IGF-1's autocrine and paracrine functions and its six plasma binding proteins (IGFBP), IGF-1 is clearly important in the adaptation of protein metabolism to altered nutritional states, acting in combination with (and modulated by) insulin and thyroid hormone (247, 248).

IGF-1 is synthesized in many tissues, but most of the IGF-1 found in the bloodstream is released by the liver, where it circulates as part of a large ternary complex with IGFBP-3 (244, 245). Serum total IGF-1 thus corresponds closely to the serum IGFBP-3 concentration (245). The IGF-1–IGFBP-3 complex is too large to leave the circulation, but IGF-1 complexes with other binding proteins, notably IGFBP-1, which are much smaller and readily enter the extracellular space; presumably they deliver IGF-1 from the circulation to its tissue receptors (240, 245). The circulating half-life of the IGF-1–IGFBP-3 complex is more than 12 hours, and its plasma concentration changes only sluggishly, whereas IGFBP-1 turns over very rapidly in the circulation, and its

serum levels increase dynamically in humans by as much as seven-fold (249) in response to short-term fasting or pathologic insulin deficiency and rapidly decrease following glucose or food consumption or in response to insulin administration in diabetic persons. These changes are due to both changes in hepatic release and clearance from the circulation (245).

In human studies, both energy and protein intake affect IGF-1 levels. When dietary energy is severely restricted, the amount of carbohydrate eaten is a major determinant of the circulating IGF-1 response to growth hormone stimulation (240, 250). In the rat, short-term protein restriction reduces hepatic IGF-1 mRNA (251) and increases its clearance from the circulation (246); serum IGF-1 levels decrease and IGFBP-1 levels increase in protein-restricted humans (240, 252). A specific role for IGFBP-2 in the metabolic adaptation to protein restriction has been suggested (251, 252).

In summary, the level (and quality) of protein intake appears to be the key external regulator of adaptation of protein metabolism to starvation, since it provides the substrate (or lack of it) for protein synthesis. Both energy and protein restriction evoke an intricate, coordinated hormonal response, mediated by insulin, growth hormone, IGF-1, and thyroid hormone, that reorganizes amino acid traffic to bring about an orderly adaptation to the altered nutritional environment (253). Under favorable conditions, this adaptation progressively reduces the maintenance protein requirement until it matches protein intake. The adaptation is partly automatic (because the lean tissue mass has decreased) and partly regulated, since a lower rate of protein synthesis and breakdown in the remaining lean tissues allows more efficient processing of dietary protein and recycling of endogenous amino acids.

DEATH

Adult body protein content is normally about 12 kg, half of it being structural, and the other half intracellular lean tissue protein. Lean tissue loss in the range of 50% is considered incompatible with survival (88, 182, 187, 254). BMI is a better predictor than body weight of the certainty of death. Data analyzed by Henry (255) suggest that death is certain when the BMI falls below about 13 in men and 12 in women, but more recent experience in Somalia indicates that a BMI of 10 is compatible with life in mature adults, and even lower BMIs can be tolerated by young adults (199). One-fifth of starving adults over age 25 and nearly one-half of those under age 25 admitted to a medical unit for treatment of terminal starvation had BMIs below 12. Survival with a BMI this low is rare on hospital wards, where advanced starvation typically occurs in older persons as the consequence of a primary medical or surgical condition. This further confirms the importance of the interaction among malnutrition, age, and disease in causing starvation-related death.

In developed countries where severe malnutrition is almost always associated with a primary medical or surgical disease, the immediate causes of death are infectious pneumonia (related to decreased ventilatory mechanical function and drive, lung stasis, and ineffective cough); skin breakdown with local and systemic infection (related to inactivity, skin thinning, and edema); sepsis spreading from intravenous infusion catheters; diarrhea with dehydration; or synergistic worsening of the primary disease.

Contributing to all these causes is starvation-induced immunodeficiency, itself the result of decreased mobilizable protein stores, hypothermia, anemia, and any of several possible micronutrient deficiencies (2, 3). In some patients, death is attributed to a cardiac arrhythmia (139, 256).

In summary, the nature and tempo of the primary disease strongly, but not solely, determine death in moderate starvation. As lean tissue depletion approaches and exceeds about 40%, death directly due to starvation becomes increasingly more certain. This thermodynamic law is unaffected by the number of diagnostic procedures, operative interventions, or antibiotic combinations administered to the patient, unless they are combined with nutritional therapy (257).

Descriptions of needless death from starvation evoke dismay in most commentators. Particularly moving are the writings of Fliederbaum, whose observations in the Warsaw ghetto probably provide the best clinical description of the effects of severe starvation ever published (181):

Boys and girls from blooming like roses change into withered old people. One of the patients said, "Our strength is vanishing like a melting wax candle." Active, busy, energetic people are changed into apathetic, sleepy beings, always in bed, hardly able to get up to eat or to go to the toilet. Passage from life to death is slow and gradual, like death from physiological old age. There is nothing violent, no dyspnea, no pain, no obvious changes in breathing or circulation. Vital functions subside simultaneously. Pulse rate and respiratory rate get slower and it becomes more and more difficult to reach the patient's awareness, until life is gone. People fall asleep in bed or on the street and are dead in the morning. They die during physical effort, such as searching for food, and sometimes even with a piece of bread in their hands.

REFEEDING

The refeeding syndrome may develop in severely wasted patients during the first week of nutritional repletion (200, 258, 259, 260, 261 and 262). Expansion of the extracellular fluid volume is rapid and considerable, frequently producing dependent edema; it results from increased sodium intake combined with the antinatriuretic effect of insulin stimulated by the increased carbohydrate consumption. This aspect of the syndrome can be minimized by limiting sodium intake during refeeding (263). Refeeding (especially with carbohydrate) can stimulate enough glycogen synthesis to lower serum phosphate and potassium concentrations. Refeeding also increases REE and, when combined with protein, stimulates N retention, new cell synthesis, and cellular rehydration (263, 264). Depletions of phosphate, potassium, magnesium, and vitamins occur commonly in this setting (200, 258, 261), and unless mineral status is judiciously monitored during refeeding, acute deficiencies, especially of phosphorus or potassium, may occur. Less apparent deficiencies may merely prevent an anabolic response to refeeding (170, 171, 201). Left heart failure may occur, especially in predisposed patients. The ingredients for heart failure are an abrupt increase of the intravascular volume, increased REE (which increases demand for cardiac output), an atrophic left ventricle with a poor stroke volume (139, 265), and myocardial deficiencies of potassium, phosphorus, or magnesium. Cardiac arrhythmias may occur (266). Acute

thiamin deficiency is a potential hazard.

REE returns toward normal (and energy needs correspondingly increase) as the sum of two processes: (a) the hypometabolic state of adapted starvation reverses, causing an important increase in REE within the first week of refeeding (264, 267, 268), and (b) REE gradually increases as the lean tissue mass is rebuilt.

Circulating IGF-1 levels, which are reduced in all forms of starvation, increase rapidly within days to a week of refeeding in concert with improving N balance (240, 252, 269). Because T_3 potentiates growth hormone-induced expression of mRNA for IGF-1 (247) and stimulates IGF-1 release from the liver (270), the refeeding effect could be mediated by insulin-stimulated rises in T_3 (162).

The specific changes in body composition induced by refeeding are determined by the existing metabolic state and body composition and, importantly, by the composition of the refeeding diet (271, 272 and 273). A diet high in sodium and carbohydrate predisposes to large increases in extracellular volume and edema. A low-protein, high-energy refeeding diet brings about fat gain without an increase in the lean tissue mass (263). A high-protein diet (e.g., 2 g/kg body weight/day) can arrest ongoing N losses, even when energy balance is negative (160). A high-energy, high-protein diet will replete both fat and lean tissue stores at a rate that can be predicted with reasonable accuracy from the resulting energy and N balances, both of which can be measured or estimated. Activity is a factor because it increases energy needs and, more importantly, exercises muscles. Malnourished patients with limited mobility will increase their central protein stores, which confers an important benefit, but they cannot be expected to gain muscle mass unless their muscles are exercised (272, 274, 275). The catabolic effect of metabolic stress reduces or prevents protein accretion during protein and energy provision, even if energy balance is positive; the patient will simply gain fat (276). For severely stressed patients, the best attainable objective of nutritional intervention is often cessation of ongoing protein catabolism; but this in itself may be life saving.

Several features of the refeeding process are illustrated by a clinical trial in which various protein levels were fed sequentially to severely starved men (263). When the diet was generous in energy (2250 kcal/day) but low in protein (27 g/day), the patients' weight, body fat, and serum cholesterol increased, but N balance remained nearly zero; their serum albumin, blood hematocrit, and urinary creatinine excretion failed to increase even after 45 days of refeeding. When the low-protein diet was replaced by one providing 100 g protein, daily N balance became positive by 7 g (equivalent to a daily lean tissue accretion of 200 g). After 45 days on this diet, BMI had increased to normal, serum albumin was nearly normal, and creatinine excretion had increased by 40%. Ninety days of the 100-g protein diet were required before serum albumin, BMI, and blood hemoglobin were fully normalized.

In general, the steps in refeeding severely malnourished patients are as follows. After normalizing fluid and electrolyte parameters and maintaining them, if necessary, by continuing supplementation, a mixed diet is provided at the maintenance energy level to establish tolerance and avoid the refeeding syndrome. Even at this level of energy

provision N balance will become positive (157). Energy intake is then increased to create a positive energy balance to promote fat regain and accelerate protein accretion. A generous protein intake (1.5–2.0 g/kg of existing adult body weight) promotes the most rapid repletion of body protein at any energy level (157, 161). Protein intakes substantially greater than this confer no additional advantage to the adult and could be dangerous (199).

During the Paleolithic era, the perpetual search for sustenance regularly presented humans the daunting challenge of distinguishing food from nonfood or suffering dire consequences. With the cultivation of plants, domestication of animals, and control of fire, Neolithic peoples had the luxury of expressing their sensory preferences. Decisions about an item's wholesomeness and palatability were, and still are, aided by the human chemosensory systems of taste, smell, and chemesthesis (chemically stimulated somatosensory sensation).

Much of the early interest in olfaction focused on its functions (1). In many cultures (e.g., Egyptian, Greek, Arab) odors were ascribed religious significance, thought to sway sexual behavior, and believed to reflect and influence health status. Theophrastus, a student of Aristotle, recognized that olfaction was both a means of locating food in the

environment and a gatekeeper for its ingestion. Odors facilitate selection of nutritious and appealing items, prompt rejection of many others, and initiate digestive processes. Historically, Western interest in taste was primarily concerned with its physiology (e.g., the existence and number of taste primaries). The first treatise formally considering the mechanisms of taste dates back to the Greek physician Alcmaeon in the middle of the 6th century BC (2). It has long been recognized that taste is strictly a contact sense, with a limited repertoire of perceptual qualities (e.g., sweet, sour, salty, bitter) relative to olfaction, but it serves as the final checkpoint before a voluntary decision is made to internalize a substance.

U.S. interest in the sensory properties of foods expanded in the 1940s because of heightened concern about the morale and health of the military during the war effort as well as mounting complaints by consumers who indicated that changes in the food industry were compromising the sensory quality of products. Given the increased consumer demand for products with attributes (e.g., reduced fat, sugar, salt and/or energy) that facilitate attainment of various health goals without sacrificing sensory quality, there is an unprecedented level of activity in the fields of sensory evaluation (focus on the sensory properties of foods) and psychophysics (focus on the perceptual abilities of individuals). Nevertheless, understanding of the nutritional implications of the chemical senses remains wanting.

OVERVIEW OF THE ANATOMY AND PHYSIOLOGY OF THE CHEMICAL SENSES

The flavors of foods are an amalgam of input from all sensory systems. Each system is distinct anatomically, has different functional characteristics, and contributes unique information. Variations in any one source of input will alter the overall perceived flavor of a food, much as the loss of a single piece can alter the appearance of a jigsaw puzzle. Such variations may be innate or acquired. The prevalence of innate selective olfactory and gustatory deficits in individuals with otherwise normal senses of smell and taste is high (>50% of the population) (3). The incidence of acquired selective losses due to, for example, pathologies or medication use is not known. Temporary losses attributable to perceptual adaptation following exposure to selected sensory stimuli are common. These conditions contribute to individual perceptual variability and virtually ensure that no food is experienced in quite the same way by any two individuals. The mechanisms underlying these individual differences are not well characterized but probably involve alterations in the anatomy and/or physiology of the sensory systems as described below.

Gustation

In mammals, the gustatory system comprises specialized epithelial cells located on the tongue, soft palate, pharynx, epiglottis, larynx, and upper one-third of the esophagus, as well as the components of the peripheral and central nervous system (CNS) that transmit and decode electrical signals generated in the taste cells. On the tongue, taste cells coalesced in onion-shaped taste buds occur in fungiform, foliate, and circumvallate

papillae. Combined, taste cells represent less than 1% of the lingual epithelium.

The fungiform papillae are mushroom-shaped structures (appearing as red bumps) on the anterior two-thirds of the tongue. There are typically 100 to 200 fungiform papillae on a tongue, each containing 0 to 20 taste buds, with a mean of about 3. Taste cells in these structures receive innervation from the chorda tympani nerve (lingual branch of the facial nerve, cranial nerve VII). Foliate papillae appear as 2 to 9 folds on the posterior lateral margins of the tongue and contain an average of 120 taste buds per papilla. These structures are innervated anteriorly by the chorda tympani nerve and by the glossopharyngeal nerve (lingual branch of cranial nerve IX) posteriorly. Eight to 12 circumvallate papillae are arranged in a “V” configuration on the posterior dorsal tongue. Each papilla is surrounded by a trench where 200 to 250 taste buds are arranged in tiers on the lower two-thirds of the papillae. These taste cells are innervated by the glossopharyngeal nerve. Taste buds on the epiglottis are innervated by the superior laryngeal branch of the vagus nerve (cranial nerve X). The greater superficial petrosal nerve subserves taste buds on the soft palate (4, 5). All gustatory neurons initially synapse in the nucleus of the solitary tract. Projections to other sites where additional coding occurs remain poorly characterized in humans.

The responsivity of taste cells to sapid stimuli varies in different regions of the oral cavity. However, subjective reports and electrophysiologic recordings following stimulation of single taste cells with varying taste qualities demonstrate that individual cells and regions respond to multiple taste qualities (6). Consequently, damage to a specific region of the tongue or to a specific gustatory nerve does not result in loss of responsivity to a specific taste quality.

Whether taste is a synthetic or analytic sense has yet to be resolved. The former view holds that there are taste primaries, commonly identified as sweet, salty, sour, and bitter (although the Japanese include *umami*, or “meat flavor”), which in combination can account for the full range of taste sensations. Vision is an example of a synthetic sense where combinations of three primaries result in all possible colors. The analytical view is that there are multiple tastes that, even in combination, are distinguishable. Audition is an example of an analytic sense.

Chemosensory transduction mechanisms are just being elucidated in humans. Perception of saltiness probably involves passage of sodium through amiloride-sensitive ion channels in the apical end of taste cells and other channels in the basolateral membrane. A role for voltage-dependent ion channels in the apical membrane remains a possibility as well.

Organic and inorganic acids are perceived as sour. The most widely accepted mechanism involves proton inhibition of outward-going potassium channels. Protons can also pass through amiloride-sensitive channels.

Sweet taste is elicited by a wide array of substances including sugars, glycosides and modified sugars, D-amino acids, peptides, proteins, coumarins, dihydrochalcones, ureas and other nitrogenous compounds, substituted aromatic substances, and selected salts. Whether a single transduction mechanism can account for the common sensation

provided by this diversity of chemical structures is unresolved. The most widely accepted mechanism posits that all sweet compounds possess a hydrogen ion donor and a hydrogen ion acceptor group that form a double-hydrogen-bonded complex with a similarly configured system on the taste receptor. Amiloride-sensitive channels may also contribute to the sensation.

Multiple receptors and transduction mechanisms have been proposed for human bitter taste to account for the broad diversity of substances (e.g., quinine, urea, xanthines, divalent cations, certain amino acids and peptides, modified sugars) eliciting this sensation. Among the better substantiated mechanisms are (a) receptor-stimulated G-protein activation of phospholipase C leading to generation of inositol 1,4,5-triphosphate, which causes release of calcium from internal stores and subsequent neurotransmitter release, (b) gustducin activation of cAMP phosphodiesterase, which would lead to reduced intracellular cAMP and decreased phosphorylation of basolateral potassium channels, and (c) direct potassium-channel blockade (7).

Olfaction

A 2- to 4-cm² patch of olfactory epithelium is located at the apex of the superior turbinate. It contains approximately 10⁷ receptor cells. These receptor cells are first-order neurons that merge into the olfactory nerve (cranial nerve I), pass through the cribriform plate, and synapse directly with the olfactory bulb. These first-order neurons are unique in two respects: first, they are in direct contact with both the external environment and the CNS, and second, they are capable of regeneration. Given the primacy of their location and susceptibility to damage by volatile environmental toxins, the latter characteristic reflects the importance of the sense and undoubtedly accounts for the preservation of function over much of the life cycle.

Olfactory stimuli consist of volatile molecules, but the characteristics responsible for quality discrimination remain elusive. There are presently two predominant hypotheses. One holds that quality is determined by specificity of receptors for the physicochemical properties of the myriad ambient olfactory stimuli. Recent work has identified a family of genes that appear to code for a large number of putative receptor proteins located on the cilia of olfactory neurons that could provide the basis for quality coding. The other theory argues that physicochemical properties of olfactory stimuli determine their temporal and spatial distribution across the olfactory epithelium and that the pattern of activation of neurons in different areas provides quality information. These views are not mutually exclusive, and human perception may reflect a combination of these mechanisms. Transduction mechanisms are not well characterized but likely involve receptor binding and activation of second-messenger systems (e.g., G proteins, cAMP, cGMP, IP₃) (7).

Chemesthesis

Sensitivity to chemical irritants (e.g., capsaicin, the burning compound in chili peppers) in the oral and nasal cavities is mediated by elements of the somatosensory system.

This subpopulation of fibers is often referred to as the “common chemical sense.” The primary somatosensory pathway in the nose and mouth is the trigeminal nerve (cranial nerve V), although in the oral cavity the chorda tympani, glossopharyngeal, and vagus nerves also contain fibers that respond to temperature, touch, and/or irritancy. The chemosensitive afferent sensory neurons of this sensory system are believed to comprise subsets of fibers associated with the senses of pain and temperature (8). Input from chemical stimuli is primarily transduced by polymodal nociceptors. However, cold fibers also respond to some chemical irritants such as menthol. Presently, there is only suggestive evidence that warm-sensitive fibers respond to chemical stimuli. While there may be specific protein receptors for some compounds, stimulation probably occurs nonspecifically when irritants disturb neural membranes or act directly upon ion channels.

CHEMOSENSORY DISORDERS

Manifestations

Disorders may present as lost, diminished, distorted, or, rarely, heightened sensation. Losses are termed *ageusia* (taste) or *anosmia* (smell) and may be complete or quality specific. Approximately one-third of individuals reporting to taste and smell centers are anosmic. Ageusia is rare, accounting for less than 1% of patient complaints. Hypogeusia and hyposmia (the most common disorders) are diminutions of sensation that may be generalized or quality specific. Dysgeusia and dysosmia (parosmia) are taste and smell distortions in which individuals experience inappropriate and/or obnoxious sensations to common stimuli. A variant of this problem is phantom tastes or smells persistent and often unpleasant sensations in the absence of obvious stimuli. This type of problem may greatly affect quality of life. Olfactory and gustatory agnosia refer to an inability to identify or classify odor and taste stimuli, respectively. Hyperosmia and hypergeusia refer to heightened sensation and are rarely encountered.

These disorders may occur alone or in combination. Most patients with a primary chemosensory complaint report that both taste and smell are affected, but this is confirmed in less than 10% of cases. Most have only an olfactory disturbance. Patients are likely confused by their reduced ability to sense the odorous volatiles released from food in the oral cavity via retronasal stimulation. Since the oral cavity is the source of such stimuli, the sensation they evoke is often referred to as a “taste.”

Etiologies

Chemosensory disorders have multiple etiologies. Extensive lists and references of implicated pathologies, medications, and toxins have been published (9, 10, 11 and 12), but over half of patients presenting to taste and smell centers have disorders with one of three causes. The most frequent finding is a link with an upper respiratory tract infection. Presumably, this leads to viral invasion of peripheral nerves, although damage to central structures is also possible. Symptoms may appear suddenly and be persistent or manifest gradually and spontaneously remit. There is no known treatment for abnormalities attributable to viral infection. Damage to peripheral and/or central structures following head trauma accounts for approximately 15 to 20% of patient visits.

Aside from cases in which surgical reconstruction can eliminate mechanical barriers to odorant access to the olfactory epithelium, there are no known treatments for chemosensory abnormalities stemming from head trauma. Between 5 and 40% of patients recover olfactory function spontaneously, and the prognosis may be somewhat better for taste. Nasal or sinus disease resulting in obstruction of pathways for odorants to reach the olfactory epithelium accounts for another 15 to 20% of cases. Surgical procedures and steroid sprays to reduce swelling have proven effective in some patients (11). Another 15 to 20% of patient complaints are classified as idiopathic. Most chemosensory disturbances related to pathologies and medications resolve when the underlying illness is effectively treated or the offending medication is discontinued. Marked nutrient imbalances may adversely affect taste and smell but are rarely the primary cause of disorders.

Prevalence

The prevalence of chemosensory abnormalities in the general population is unknown. Data have not been systematically collected, in part due to a lack of standardized evaluation criteria, low awareness by health care workers who thus do not solicit information on these senses when evaluating patients, and incomplete reporting by many affected individuals who do not view the problem as life threatening. However, nearly everyone experiences at least a mild transient abnormality (e.g., reduced olfactory ability associated with a cold), and in some, the problem is severe and chronic.

Health Implications

Abnormalities of taste and/or smell can increase the risk of environmental toxin exposure (since the chemical senses provide an early warning system for such compounds), compromise quality of life, and adversely affect diet and nutritional status. Among individuals presenting at clinical taste and smell centers, approximately 75% report decreased enjoyment of food, and about half report a compensatory alteration of eating patterns. The latter response can be problematic if it involves less healthful dietary choices such as reliance on a limited array of foods or increased use of salt or fat. One recent study noted that elderly women with olfactory dysfunction adopted diets associated with increased cardiovascular risk (13). Fifteen to 20% experience an increase or decrease in body weight exceeding 10% of their predisorder weight (14). Approximately half gain weight owing to increased intake as a means of deriving the missed sensory pleasure foods provide or in an attempt to mask an unpleasant sensation. Others decrease intake, often because food has lost its appeal or is believed to exacerbate an unpleasant sensation. At present, no set of patient or symptom characteristics provides a reliable predictor of a specific dietary response. Thus, dietary intervention must be individualized.

ASSESSMENT OF CHEMOSENSORY FUNCTION

Threshold

The senses of taste and smell convey intensity and quality information about

appropriate stimuli. The most traditional measure of function is threshold sensitivity, which may be determined as the “detection” or the “recognition” threshold. The former is the lowest concentration of a stimulus that can be detected in a given medium, and the latter is the lowest concentration that can be recognized with respect to its quality (e.g., NaCl is salty). Taste and odor thresholds are not innate, invariant characteristics of an individual. Rather, they are statistical concepts in which one arbitrarily determines a criterion level of performance (typically 50%) on a task requiring individuals to detect or recognize a stimulus in a given medium. Thresholds are also strongly influenced by methodologic factors.

Intensity and Identification

Intensity ratings reflect the strength of sensation elicited by suprathreshold stimulus concentrations. Assessments of this facet of sensory responsiveness in the oral cavity may be made with whole-mouth stimulation (e.g., sipping and swishing a solution) or by regional stimulation to explore the functional status of the various gustatory nerves. It is argued that intensity ratings are more nutritionally relevant than thresholds, since stimuli are presented at levels more commonly encountered under normal eating conditions. However, attempts to demonstrate associations between intensity ratings and either food preferences or intake have generally been unsuccessful. Suprathreshold concentrations of stimuli are also used in identification tasks in which subjects are asked to indicate the quality of unlabeled simple compounds or foods. Each of these measures provides unique functional information. Correlations between the measures are generally weak.

Time-Intensity

The above measures represent integrated information and fail to recognize that the time course of sensation following chemosensory stimulation varies across stimuli and for a given stimulus in different media. Sensation parameters that vary include onset time, rate of appearance, time to maximal intensity, rate of extinction, and total duration. They can be measured by tracking intensity responses over time. Temporal properties can markedly influence the appeal of foods.

Hedonics

Assessments of food acceptability rely upon higher-order processing of intensity and quality information from the periphery. Commonly evaluated hedonic dimensions include, but are not limited to, the preferred frequency of stimulus intake, preferred concentration of the stimulus in a medium, and preference for stimuli with a characteristic quality.

Hedonic responses to the odors and tastes of foods reflect innate and acquired characteristics. Knowledge of innate taste and odor preferences is rudimentary. Compelling data indicate the appeal of sweetness and saltiness is congenital, although for the latter, there is a postnatal lag of about 6 months before it is apparent (15). Data are less clear for responses to sour and bitter but suggest each is viewed negatively at an early age. Human neonates consistently exhibit a preferential orientation to breast

odors from lactating females, suggesting early olfactory preferences. However, in light of recent evidence that maternal diet can influence the sensory qualities of amniotic fluid and breast milk (16), it is not clear whether such early preferences are congenital or attributable to fetal conditioning. The basis for the appeal of dietary fats has not been established. Differential sucking responses to formulas with varying fat content among newborns have been small and inconsistent (17, 18) as have heritability estimates for fat preferences and intake in children and adults (19, 20).

The resistance of immigrants to abandoning the flavor principles of their native diet underscores the importance of culture and learning on flavor preferences. Multiple mechanisms are likely involved, including exposure effects and associative learning. Studies with children and adults demonstrate a direct association between frequency of exposure to novel items and their acceptance ratings (21). However, the time course and magnitude of the effect may reflect an innate bias, predominantly sweet and salty novel foods gain in acceptability more readily than sour or bitter items (22). Exposure frequency can also modify responses to familiar foods. A reduction in sensory exposure to dietary salt and fat leads to a heightened preference for foods with lower salt and fat levels, respectively, compared with ratings from individuals with comparable total intake of each food constituent but higher sensory exposure (23, 24). Preliminary evidence suggests hedonic shifts based on restricted sensory exposure require about 8 to 12 weeks to develop. The extent to which desired shifts in preferred levels of dietary constituents facilitate long-term compliance with therapeutic diets (e.g., reduced sodium or fat) has not been determined.

The flavors of foods also acquire positive and negative properties due to their association with metabolic cues stemming from ingestion. Illness following ingestion of a food can lead to subsequent rejection of the food based on its sensory characteristics. Approximately one-third of the population has held such a food aversion (25). Conditioned preferences have been shown in animals but have been more difficult to demonstrate in humans.

Whether early hedonic responses are innate or learned, the limited available data do not indicate that they predict preferences later in life. This has been documented for selected food constituents such as salt (26) as well as diets. Changes in flavor preferences are marked over the life cycle, as exemplified by early rejection of bitter or spicy foods; yet items with bitter notes (e.g., coffee, alcohol) become highly preferred, and globally, chili peppers are one of the most commonly used flavor principals. Indeed, family studies of food preferences generally reveal a low-order association between parents and offspring and a stronger relationship between peers (27).

Chemesthesis

Perception of chemical irritancy in the oral and nasal cavities is not routinely evaluated in clinical research centers because of the rarity of complaints about this component of the chemical senses. The appeal of chemesthetic stimuli is acquired and a principal component in many cuisines. Although there is a tendency to report diminished taste sensation for foods with a strong chemesthetic stimulus (e.g., capsaicin, piperine)

psychophysical studies have yielded equivocal results.

RELATIONSHIPS BETWEEN NUTRIENT INTAKE AND THE CHEMICAL SENSES

There is a reciprocal relationship between nutrient intake and chemosensory function. Peripheral gustatory and olfactory tissues are composed of specialized epithelial cells with relatively high turnover rates (10–12 days for taste and 30–45 days for olfaction) and metabolic requirements. Provision of adequate nutrients is vital for proper function. At the same time, the functional status of these sensory systems can strongly influence food and nutrient intake. Despite longstanding recognition of this association, little is known about the nutrient requirements of these tissues (28).

Effects of Nutritional Status on Chemosensory Function

Vitamin A

Vitamin A deficiency leads to increased keratinization of the oral and nasal epithelia. In addition, decreased mucopolysaccharide synthesis leads to reduced cleansing of the perireceptor area and drying of the epithelia. Blockage of stimulus access to chemosensory receptors ensues (Fig. 42.1). Vitamin A depletion results in a gradual loss of taste in rats (29) that is reversible with vitamin repletion. Chemosensory deficits are not a common feature of vitamin A deficiency in areas where this problem is endemic. However, hypogeusia and hyposmia have been reported in normal adults made vitamin A deficient as well as in patients with cirrhosis, acute viral hepatitis, and malabsorption disorders who were depleted of the vitamin (30). Supplementation with vitamin A reverses these chemosensory losses. It is important to recognize the role of zinc in maintaining normal plasma vitamin A levels, especially among patients with liver disorders. Zinc administration may also reduce taste deficits in alcoholic cirrhosis patients (31). Given the potential toxicity of vitamin A, its probable etiologic role in a sensory disorder must be established before therapeutic supplementation is initiated.

Figure 42.1. **A.** Longitudinal section of single taste bud in a fungiform papilla from a vitamin A-replete rat. **B.** Comparable section from a vitamin A-deficient rat. The taste

bud pore is infiltrated with keratin. (From Bernard RA, Halpern BP. *J Gen Physiol* 1968;52:444–64, with permission.)

B Vitamins

Studies in dogs reveal that diet-induced deficiencies of niacin, riboflavin, pyridoxine, pantothenic acid, and folic acid result in noninflammatory lesions of the oral mucosa, especially on the dorsal tongue surface (32). Papillary atrophy and degeneration are also observed, particularly on the anterior tongue, although in niacin deficiency, the entire tongue surface may be involved (Fig. 42.2). Fungiform papillae are the most severely affected. No abnormalities have been noted in circumvallate papillae. Pathologic changes worsen progressively with successive deficiency trials. Replacement therapy results in prompt restoration of the epithelium. Improvement is apparent in 2 to 3 days and is complete within a week. Recovery of connective tissue is slower. Distinct lesions are apparent in animals with specific vitamin deficiencies, and these identifiable lesions are superimposed in animals with multiple deficiencies.

Figure 42.2. **A.** Longitudinal section of a canine normal fungiform papilla containing two taste buds. On either side of the fungiform papilla are filiform papillae. **B.** Papillary atrophy in a niacin-deficient dog. **C.** Late-stage papillary atrophy in a dog deficient in pyridoxine. **D.** Absence of filiform papillae and atrophied fungiform papillae of a dog made riboflavin deficient for the first time. (From Afonsky D. *Ann NY Acad Sci* 1960;85:362–7, with permission.)

Findings similar to those reported in dogs have been observed in humans (33). In addition, deficiencies of pyridoxine, riboflavin, and cobalamin may lead to peripheral neuropathies. However, this has only been reported in case studies involving severe deficiency (34). Importantly, while repletion of pyridoxine has reportedly corrected chemosensory disturbances in patients with subclinical pellagra (34), high levels of

pyridoxine have also been associated with peripheral neuropathy (35). In such patients, nonspecific axonal degeneration was observed, with a loss of sensory nerve action potentials in response to an electromyogram. Thus, indiscriminate use of high levels of B vitamins to treat chemosensory disorders is inappropriate.

Vitamin E

A direct association, but no causal relationship, between plasma vitamin E concentration and papillary atrophy was reported in one study of elderly patients with atrophic glossitis (36). There are no data linking vitamin E status to subjective reports of chemosensory function.

Copper

Reversible hypogeusia has been reported in humans with low ceruloplasmin levels during treatment with penicillamine (37). However, it is not clear that the effect of penicillamine is copper specific. The drug also binds zinc, nickel, and other cations, and zinc has also been reported to improve taste sensitivity in patients treated with this medication. Administration of penicillamine to patients with Wilson's disease does not lead to chemosensory complaints.

Iodine

Diminutions of taste and olfactory sensitivity, or dysgeusias, have been documented in hypothyroid patients (38). The reported incidence of sensory complaints in such patients ranges from a few percent to over 80%. This may be attributable to the generally slow onset of symptoms and consequent lack of subjective awareness. Replacement hormone therapy generally corrects the chemosensory disorder. Treatment of hyperthyroid patients with antithyroid agents (e.g., methimazole, methylthiouracil) has also led to partial or complete loss of taste and smell, which resolves upon cessation of drug use.

Iron

Hypogeusia has been reported in patients with iron deficiency anemia (39). Normalization of iron status with oral iron supplements (50 to 100 mg/day) led to restoration of taste within 2 weeks in most patients and improvement in others. Cravings and pica have been reported in iron-depleted individuals, but there is presently no evidence that this is related to shifts in chemosensory function.

Zinc

Marked zinc deficiency may lead to chemosensory abnormalities (i.e., hypogeusia, hyposmia, distortions) that resolve with zinc repletion (40). Whether sensory disturbances reported by patients with pathologies involving negative zinc balance or altered zinc metabolism (e.g., acute infectious hepatitis, chronic cirrhosis of the liver, Crohn's disease, chronic renal disease) are attributable to the change in zinc status or

other factors remains largely unresolved. Double-blind crossover studies (41, 42) have not supported a causal role for zinc in most patients with chemosensory complaints. Evidence that levels of zinc recommended for use with chemosensory disorders (i.e., 100 mg/day) may lead to anemia, neutropenia, and impaired immune function (43) indicate that this therapeutic approach must only be used with caution.

Heavy Metals

Case studies in humans indicate that accidental exposure to mercury or lead as well as parenteral administration of gold can produce taste abnormalities. The mechanisms in these cases remain unexplored.

The Chemical Senses and Nutrient Utilization

A potential role of sensory stimulation on the digestion, absorption, and utilization of nutrients has been recognized since the work of Pavlov but remains poorly characterized. Sensory, especially chemosensory, stimulation elicits digestive, thermogenic, cardiovascular, and renal responses that anticipate the arrival of food in the gut. They are termed *preabsorptive- or cephalic-phase responses* (44). Examples of such responses are listed in Table 42.1. They are typically small and transient, with unknown nutritional significance. They may play an important priming role that determines the extent of postabsorptive events and the efficacy of nutrient metabolism.

System	Ref	Increased Response
Salivary	(45)	Flow
Gastric	(46-48)	Acid, gastrin and gut peptide secretion, motility
Pancreatic exocrine	(49, 50)	Lipase, amylase, trypsin, chymotrypsin, total secretion
Pancreatic endocrine	(51-53)	Insulin, glucagon, pancreatic polypeptide
Thermogenic	(54)	Heat production
Cardiovascular	(55)	Heart rate, cardiac output, resistance of mesenteric vasculature
Renal	(56)	Urine volume (decreased osmolality) to hypotonic stimulus

Table 42.1 Cephalic Phase Responses

THE CHEMICAL SENSES AND DIET IN SELECTED POPULATIONS

Aging

Statistically significant declines in taste and especially smell sensitivity have been reported in many, but not all, studies of the elderly (57). However, the functional

significance of these changes is unclear because the absolute magnitude of decline is small. Data in [Figure 42.3](#), representing an age- and sex-stratified sample of healthy adults, reveal a statistically significant decline in salt taste and phenylethyl alcohol odor thresholds with age, but the more striking feature of these data is the number of elderly with normal function ([58](#)). To reconcile this observation with the high level of complaints of diminished sensory abilities by the elderly requires consideration of more subtle aspects of sensory function and testing.

Figure 42.3. *Top*, Scatterplot of sucrose taste-detection thresholds for healthy adults 19 to 87 years of age. *Bottom*, Scatterplot of olfactory detection thresholds of healthy adults 19 to 87 years of age for phenyl ethyl alcohol.

Elderly persons exhibit slower recovery following adaptation to a stimulus, reduced retronasal olfaction (a large component of food flavor), and compromised ability to discriminate stimuli in complex foods. None of these measures is included in standard chemosensory testing regimens. Increased use of medications and a higher prevalence of health disorders that may influence sensory function may also contribute to the belief that aging is associated with marked declines in chemosensory function. Finally, age-related decrements in memory, cognition, and testing skills can result in poorer testing. The decline in taste bud number with age is small, and the number of taste buds is not closely correlated with taste function, since only a small number of buds may provide the full range of sensory experience (much as a small patch of skin can convey temperature information as well as a larger area). Further, receptive structures in one area of the oral cavity compensate for losses of sensation in other areas ([59](#)).

The diversity of influences and variability of their effects on the different sensory systems preclude a standardized treatment approach. Flavor fortification may hold some benefit for individuals with sensory decrements (not loss or distortion), but it requires an individualized plan because changes are often quality-specific and a correct level of fortification for one individual will be excessive or inadequate for another.

Hypertension

The view that sodium intake is related to hypertension has prompted studies of salt taste in various high-risk populations including different classes of hypertensive patients (e.g., low vs. high renin, salt sensitive vs. salt insensitive) and normotensive offspring of hypertensive individuals. Small differences between some of these groups and control subjects on isolated measures of salt taste (i.e., recognition thresholds but not detection thresholds) have been noted. However, most work has failed to reveal any meaningful associations ([60](#), [61](#)). Further, there is no clear evidence for a heightened preference for salt by hypertensive patients. Normotensive and hypertensive individuals exhibit a comparable increment in hedonic responses to reduced-salt foods following adherence to a diet restricted in sensory exposure to the salty taste.

Diabetes

Disturbances of taste and smell have long been recognized in diabetics ([62](#)) and may affect over 60% of patients. The most consistent sensory changes involve alterations in glucose taste thresholds among non-insulin-dependent diabetics as well as their nondiabetic first-degree relatives. This suggests a general abnormality of glucose receptors. However, complications of hyperglycemia probably also contribute, since the severity of hypogeusia increases with progressing neuropathy ([63](#)). Macrovascular disease and peripheral neuropathy have also been implicated in olfactory disturbances ([64](#), [65](#)). The extent to which these chemosensory changes influence food selection and adherence to prescribed diets has not been established. Diabetic patients and healthy controls show similar decrements in hedonic responses to a sweet solution following a glucose load ([66](#)).

Cancer and Bone Marrow Transplantation

Changes of chemosensory function (sensitivity and preferences) are frequently reported by untreated patients with cancer. Systematic study of these complaints has failed to identify any consistent pattern of change with respect to the nature of the sensory complaint (e.g., quality specific vs. general loss, loss vs. distortion) and the site, severity, or duration of pathology. Similarly, no clear association between sensory function and anorexia has been established in this patient population ([67](#), [68](#)). Antineoplastic treatment may be more problematic for the sensory systems than the pathology. Radiotherapy involving gustatory and olfactory tissues results in a profound loss of function because of damage to sensory end organs as well as supporting tissues (e.g., salivary glands) ([69](#), [70](#)). Bitter and salty tastes are often more severely affected than sweet and sour. Impairment is first apparent following an accumulated dose of approximately 20 Gy. A total dose of 60 to 70 Gy may lead to elevated thresholds (i.e., decreased sensitivity) that persist for years ([69](#)), whereas suprathreshold function may be less severely affected ([71](#)). Among patients with head and neck cancer receiving radiotherapy, there is a strong association between loss of sensory function, anorexia, and weight loss. Altered chemosensory function may also result from chemotherapy regimens, but the impact of these changes on diet are less clear ([72](#)).

It is commonly argued that learned food aversions (LFA) contribute to anorexia and weight loss in cancer patients. In untreated cancer patients, the incidence of aversions is about 50%, but following the onset of either chemotherapy or radiotherapy, approximately 50 to 55% of patients form new LFAs. High-protein items are particularly problematic, but any item, including water, may be targeted (73). Typically, treatment-related aversions are specific (a mean of 3–4 items per individual) and transient (often less than 1 month duration); consequently, they hold little dietary significance. Several approaches aimed at preventing formation of LFAs have been explored. First, patients may be counseled to refrain from eating prior to treatments, but evidence that LFAs may form toward items consumed the day before or following treatment indicates such advice is often not practical. Antiemetics administered to reduce the adverse side effects of treatments (the purported conditioning stimulus) have also proven ineffective. One approach that appears promising involves exposing patients to a nutritionally inconsequential food just before their first treatment. This may interfere with formation of LFAs toward wholesome foods in the patient's customary diet. Such an approach has reduced the incidence of treatment-related LFAs by over 30% (74).

Taste sensitivity abnormalities have also been reported following allogeneic bone marrow transplantation (75, 76). Reports note quality-specific effects, with a salt hypogeusia being the most consistent finding. Abnormalities are most pronounced during the acute phase of graft-versus-host disease but may persist for months. The mechanism is not clear, since patients receiving autologous bone marrow transplants experience many of the same oral complications but have no gustatory complaints.

HIV Infection

The human immunodeficiency virus invades the CNS in a large number of infected individuals. This may lead to various neurophysiologic abnormalities, including disturbances of chemosensory function. Reported taste and smell complaints by infected individuals have led to speculation that such symptoms may provide an early index of CNS involvement and contribute to the anorexia often associated with advanced infection. However, assessments of olfactory ability reveal little or no decrement in patients who may or may not be immunocompromised but are otherwise healthy (77, 78). The severity of olfactory complications, most notably odor identification ability, is directly related to progression of disease. The most marked olfactory changes occur in patients with AIDS dementia complex (79). No changes of taste have been reported. Thus, chemosensory changes do not provide a reliable early hallmark of CNS infection. Further, the limited available data do not support a substantive role for chemosensory disturbances in the loss of appetite associated with infection, although this has not been systematically evaluated in patients with AIDS (77).

Obesity

While small differences in sensory responses to aqueous solutions of taste stimuli or experimentally prepared foods have been noted between obese and lean persons (80, 81), the preponderance of evidence fails to support an association between body weight

and chemosensory responses (82, 83 and 84). Differences in the importance and nature of food and flavor preferences are reported more consistently (85) and may lead to erroneous assumptions about sensory function. Few data indicate that sensory responses among the obese actually influence their eating behavior, so the assumption that sensory factors play an etiologic role in the onset or maintenance of obesity is not appropriate.

Chronic Renal Disease and Dialysis

Patient complaints of diminished chemosensory sensation are supported by evidence that taste detection and recognition thresholds are elevated in chronic renal disease (86) and worsen with advancing disease. Concomitant low levels of zinc in some studies and improved sensory function with zinc supplementation (87, 88) prompted hypotheses that this may be the underlying cause. However, additional data show no correlation between zinc status and sensory measures (86, 89, 90) and no therapeutic efficacy of zinc supplementation (91, 92). The conflicting observations may indicate that there is a subset of patients with compromised zinc status who will benefit from supplementation, but many will require alternative approaches. Dialysis typically has no effect on sensory deficits (89, 90, 93, 94). Chemosensory function may improve with renal transplantation but may require up to 1 year (95). The limited published data on hedonic shifts associated with uremia and dialysis are inconsistent (94, 96, 97). The influence of sensory changes on food selection and nutritional status remain poorly characterized.

Smoking

Most evidence indicates that smoking has little effect on taste. Studies of taste thresholds before and immediately after smoking a cigarette (98, 99) or following 2-week periods of enforced increased and decreased smoking frequency (100) reveal no significant differences. Comparisons of chronic smokers and nonsmokers, controlling for recent use, have yielded mixed findings (101, 102 and 103). Perceived intensity ratings also show little difference between smokers and nonsmokers (100). Studies of taste hedonics have focused on sweetness and have yielded mixed findings (104, 105).

Early work on olfaction showed no significant general elevation of thresholds (98, 106), although sensitivity to pyridine, a substance in tobacco smoke, was lower in smokers (106). Small but significant differences in perceived intensity ratings (107, 108) and odor identification (106) have been reported more recently. Interestingly, for pyridine, the difference was marked only at low concentrations and resolved after 5 days of smoking abstinence (106). These findings indicate that decreased perception of pyridine may be an adaptation effect. Whether the more general effects can be attributed to smoking is questioned by evidence that smokers have elevated thresholds for other sensory modalities (e.g., audition [109]) presumably unaffected by smoking status. Cigar and pipe smoking do not alter test performance. At present there is no evidence supporting a causal role for smoking-related chemosensory changes in the lower body weight of smokers or their weight gain upon cessation of smoking.

The Roman God Janus has two faces. Similarly, two opposing treatment strategies have been developed that involve modifying nutrient absorption from the gut. In the treatment of gastrointestinal disease, emphasis has been placed on improving absorption of nutrients in conditions such as Crohn's disease, celiac disease, short bowel and stagnant loop syndromes, radiation enteropathy, postgastrectomy disorders, and Whipple's disease. Other situations, however, involve attempts to reduce the rate or amount of nutrient absorption, including the treatment of diabetes, hyperlipidemia, or obesity with, for example, high-fiber diets, enzyme inhibitors, nonabsorbable food substitutes, or gastric stapling.

Manipulations that increase or decrease the rate of absorption are likely to have certain

physiologic consequences, as illustrated in [Figure 43.1](#) and [Figure 43.2](#). When the absorption rate is reduced, a larger length of small intestine is likely to be exposed to the nutrient, with an increased proportion absorbed more distally (see [Fig. 43.1A](#)). On the other hand, rapidly absorbed foods are likely to be taken up more proximally in the small intestine and over a shorter segment (see [Fig. 43.1B](#)).

Figure 43.1. Schematic representation of stomach and small intestine showing (A) slow digestion and absorption of energy-dilute food in a “fiber-rich” diet and (B) rapid digestion and absorption of energy-dense food from a low-fiber diet.

Figure 43.2. Schematic representation of the postprandial glycemia following (A) slow absorption of starchy fiber-rich meals and (B) rapid absorption with undershoot due to excessive insulin release following refined, fiber-depleted carbohydrate foods.

After oral intake, the consequences of a slower flux of nutrient into the system result in lower circulating nutrient levels and thus lower endocrine responses ([Fig. 43.2A](#)), as opposed to the sharper rises and falls seen with more rapid fluxes ([Fig. 43.2B](#)). In

addition, differences can be expected in nutrient absorption characteristics (e.g., chylomicra synthesis), depending on where in the bowel it takes place. Regional specialization also occurs in terms of gut endocrine responses to nutrients absorbed in different parts of the bowel. For example, more gastric inhibitory polypeptide (GIP) is secreted when carbohydrates are absorbed proximally, and more enteroglucagon is secreted when they are absorbed distally.

The food factors that influence the absorption of nutrients relate not only to the nature of the nutrients themselves, but also to their interaction with each other and with the nonabsorbable components of the food, the complex of substances referred to collectively as dietary fiber, and associated antinutrients. All these factors ([Table 43.1](#)) combined produce the form or physical state of the food, which itself exerts a major influence on the handling of a food by the gastrointestinal tract. Some of these effects are short term, but food constituents also have long-term effects. They may influence the absorptive capacity of the gut either by enzyme induction or by effects that may be stimulatory, inhibitory, or toxic to mucosal cell growth, turnover, and villus structure.

Classical Nomenclature	Solubility Characteristics	Classes of Polysaccharide
α -Cellulose Hemicelluloses	Water insoluble Insoluble in alkali Insoluble in water	Cellulose (glucan) Arabinoxylans Galactomannans
Lignin	Soluble in alkali Insoluble in 12 M H ₂ SO ₄ Water insoluble	Xyloglucans Polyphenolpropane Noncarbohydrate
Pectic substances	Water soluble	Galacturonans Arabinogalactans β -Glucans Arabinoxylans
Gums	Water soluble or dispersible	Galactomannans Arabinogalactans
Mucilages	Water soluble or dispersible	Wide range of branched and substituted galactans

Table 43.1 Dietary Fiber Components

EFFECTS OF MACRONUTRIENTS

Before discussing the effects of food form and so-called antinutrients on the absorbability of natural diets, it is useful to consider the similarities and differences within the three macronutrient groupings and their relationships to each other and to fiber.

Carbohydrates

Traditionally, it was held that “complex” carbohydrates (starches) are absorbed more slowly than “simple” carbohydrates (1). Meals containing a higher proportion of their carbohydrates as sugars were considered to result in more rapid absorption and higher

increases in blood glucose levels (2). This view was challenged by several studies. Using solutions of starch (a glucose polymer), caloreen (predominantly 5 glucose units), and glucose itself, Wahlquist et al. demonstrated similar glucose and insulin rises following consumption of 50-g carbohydrate loads of each of these glucose sources by healthy volunteers (3) (Table 43.2).

Food	Sugar Concentration (mg/L at 3 hr)	Percentage of Total as		
		Glucose	Maltose	Maltotriose
White bread standard	806	6.97	6.61	6.5
Whole wheat bread	811	6.21	7.21	7.2
Rice	652	3.97	1.72	4.4
Corn flakes	954	4.97	3.52	1.7

Table 43.2 Differences in Digestion Rates and Sugars Released from Common Foods^a

Starch

Such results should have been predictable because earlier work by Dahlquist and Borgstrom and Fogel and Gray showed that luminal hydrolysis of starch is not rate limiting for starch digestion (4, 5). Fogel and Gray found that even patients with chronic pancreatitis and significant exocrine pancreatic insufficiency (amylase secretion rate 10% of normal) hydrolyzed starch *in vivo* at a rate similar to that of normal subjects (5). Their studies involved feeding 50-g starch loads and aspirating the residual hydrolytic contents at the ligament of Treitz (duodenojejunal junction). This finding does not indicate that luminal events are unimportant in the digestion of foods of complex composition but that differences in absorption are unlikely among meals containing sugars or highly processed, low-amylose, or soluble starches (25–30% amylose and 70–75% amylopectin) (6).

Still, differences in food form or indigestible food components may profoundly affect the rate of luminal digestion. If proportions of amylose (1–4 linked straight-chain starch) and amylopectin (1–6 linked branched starch) vary in a food, alterations in digestibility may be seen. Traditionally, such branching was considered nutritionally significant because α -amylase has poor specificity for 1–6 branch points and produces α -limit dextrins (7). Digestion was considered to proceed more slowly for this reason. However, the brush border α -glucosidases are so efficient that it makes no difference in terms of rates of uptake whether the substrate for absorption is glucose, maltose, or α -limit dextrins (8). Some evidence even indicates that absorption rate increases with chain length up to 10

glucose units (8). Part of the explanation may be related to a reduced osmotic effect.

Differences do exist between amylose and amylopectin, but opposite to those originally expected, perhaps because of the more compact structure and hydrogen bonding of the glucose chains in amylose, which render it physically less accessible to amylolytic attack than the more open and branched amylopectin (9). Raw legume starch (higher in amylose) is less digestible in rats than cornstarch (higher in amylopectin), and the rate of hydrolysis of legume starch in vitro is less than that of cornstarch (10, 11). Possible differences in the nature of starches from different foods have been emphasized by Crapo and coworkers (12, 13, 14 and 15). In vivo studies of whole legumes (30–40% amylose) show lower glycemic responses than those with cereals (25 to 30% amylose) (16, 17). They are also digested less rapidly in vitro than other starchy foods (18, 19). As expected from their higher amylose content, they produce more glucose and less maltotriose on digestion. Studies with high-amylose long-grain rice demonstrated that the amylose content is related to the glycemic effect of the rice. The greater the amylose content, the flatter the response (20). High-amylose diets reduce insulin secretion and serum lipids in healthy volunteers (21).

The degree of hydration of the starch is a major determinant of digestibility (22), and hydration is a function of both cooking and other forms of processing. Cooked starch produced higher blood glucose responses than raw starch (Fig. 43.3) (23); perhaps because of the degree of gelatinization of starch. Uptake of water by the starch molecule may render it more accessible to enzymatic digestion. In addition, processing (milling) legumes prior to cooking increased digestibility more effectively than grinding after cooking (24), and damp heat was more effective than dry heat in making both the carbohydrate (24, 25 and 26) and protein (27, 28) more easily absorbed.

Figure 43.3. Mean serum insulin and glucose concentrations after ingestion of glucose monohydrate (1.1 g/kg body weight) and cooked and raw cornstarch (0.91 g/kg body weight) in healthy volunteers. Conversion (SI to traditional units): glucose, 1 mmol/L » 18 mg/dL. (From Collings P, Williams C, MacDonald I. Br Med J 1981;282:1032.)

Comparisons of legumes and cereal foods illustrate many facets of foods that influence absorbability. Studies have clearly demonstrated the slower digestibility of legumes by comparison with cereal products and the relationship of digestibility with the glycemic response in both normal and diabetic volunteers ([19](#), [29](#)). Such studies also highlight other factors of possible importance, including food form, fiber, and nonnutritive food factors (including the so-called antinutrients) in determining absorbability of carbohydrate from foods.

Today, it is probably useful to divide the starches that are resistant to digestion into three broad classes according to Cummings and Englyst ([29a](#)): RS1, RS2, and RS3. RS1 starches may increase starch malabsorption and may be produced by coarse milling or large particle size of cereal grains (e.g., whole-grain pumpernickel bread or bulgar). RS2 starches, resistant starches that are crystalline and resist hydration, are found in green bananas, high-amylose corn, and relatively high amylose legumes (peas, beans, and lentils). Starches, especially high-amylose starches that are cooked and allowed to cool, undergo retrogradation with more-crystalline realignment. These starches are produced in common foods such as potato, rice, and bread and are termed RS3 starches. Resistant starches in this category are produced commercially from high-amylose corn starch (e.g., Novelose) by enzymatically debranching the remaining 1,4-linkages and allowing the resulting 1,6-linked starch to “retrograde” into a highly crystalline, digestion-resistant starch.

Sugars

Efficient transport systems exist for maltose, maltotriose, α -limit dextrans, sucrose, lactose, glucose, and galactose. Fructose absorption is less efficient, and the transport maxima may be exceeded with large amounts of this sugar. The pentose D-xylose is only approximately 50% absorbed, and considerable malabsorption is found with the sugar alcohols, or polyols, sorbitol and xylitol ([30](#)). Therefore, great differences exist among sugars in absorption rate and proportions.

The comparative effects of sugars and starches on metabolic responses have generated much interest. Contrary to many previous assumptions, numerous studies showed a lower response to sucrose than to an equivalent amount of starch in both normal and diabetic volunteers ([16](#), [31](#)). Nevertheless, different sugars raise the blood glucose concentration to markedly different degrees: fructose causes a comparatively small rise, lactose and sucrose are intermediate, and glucose and maltose cause the highest rises ([16](#), [32](#), [33](#), [34](#) and [35](#)). This effect is apparently related to the proportion of glucose in the sugar molecule, with nonglucose components raising the blood glucose minimally. On the other hand, fructose may raise serum lipids higher than starch does, which may offset the advantage of slower absorption and flatter glycemic response ([36](#)).

Fats

Much work has been done on the absorption of fatty acids, but most fat in the human diet is in the form of triglycerides. Studies by Calloway et al. indicated comparable

digestibility of many edible fats including butter, lard, and soybean, coconut, corn, and cottonseed oils (37). Butter, lard, shortening, and cod liver and corn oils appeared to be absorbed to the same extent, with maximum absorption occurring within 6 to 8 hours, at a time when the chylomicra rise would also have peaked (16, 31, 32, 33, 34, 35, 37, 38, 39, 40 and 41). It was estimated that 24 to 41% of the fat was absorbed by 2 hours, 53 to 71% by 4 hours, 68 to 86% by 6 hours, and 97 to 99% after 12 hours (38). Comparing lymphatic absorption of long-chain fatty acids, including palmitic, oleic, linoleic, and stearic acids in man, showed a slight discrimination against triglyceride synthesis from stearic acid and favored cholesterol ester synthesis from oleic acid (42). Other studies suggest that triglycerides composed of the saturated dietary fatty acids (palmitic and stearic) are less well absorbed in the presence of high calcium, whereas triglycerides containing the unsaturated fats with lower melting points (oleic and linoleic) are unaffected (43, 44). Investigators have suggested that in general, either palmitic or stearic acid in the 1,3 positions of the triglyceride molecule reduced the absorption of that fat (45, 46).

Medium-chain triglycerides (MCTs) are being used in drinks, baked foods, and enteral feedings, however, in an attempt to increase the absorption of dietary fat. Their advantage lies in their direct absorption without micelle formation, with uptake as the fatty acid into the portal vein and clearance by the liver. They can therefore be absorbed even in the absence of bile salts or when lipoprotein synthesis necessary for chylomicra production is impaired or absent. Animal studies suggest that MCTs are absorbed four times as efficiently as long-chain triglycerides (47).

MCT use has been advocated in various situations, including small intestinal disease or damage, short bowel syndrome, pancreatic and biliary insufficiency (biliary atresia), and a-b-lipoproteinemia (Tangier disease); but they do not stimulate chylomicra formation, and fat-soluble vitamins are thus not transported out of the enterocyte (48). In addition, in rats, dietary substitution of MCTs for corn oil resulted in 20% less weight gain, largely through lack of deposition of carcass fat. In man, weight gain has been variable (42), and the early clinical use of MCTs was in the control of obesity (49, 50). The increased absorptive efficiency of the gut for MCTs was questioned on the grounds that the widely used solvent system for stool lipid extraction in the Van de Kamer method (51) only extracts up to 68% of the medium- to short-chain fatty acids (SCFAs) (52); however, the titrimetric determination assumes a mean molecular weight of 284 for fatty acids while MCTs have a mean molecular weight of 144, so the conversion factor used to derive the grams of fat malabsorbed is twice the number that should be applied to the MCTs. Thus, the two errors should balance out (53). However, cramping abdominal pain and increased diarrhea, together with increased steatorrhea, have been reported in the short bowel syndrome following MCT use (54). In addition, MCT should not be used in decompensated cirrhosis because poor clearance of short- and medium-chain fatty acids may exacerbate encephalopathy (55, 56). Further, in two instances, cirrhosis evolved in young patients with a-b-lipoproteinemia who were fed diets high in MCT on a long-term basis (57).

Thus, in terms of dietary fats, foods containing oleic or linoleic acid appear to be well absorbed. MCT may have an advantage in specific states, but it should be monitored

cautiously. As dietary fat load is increased, fecal fat decreases proportionately (58).

Protein

Comparatively little is known about the intrinsic digestibility of proteins from different food sources independent of other factors in the food such as inhibitors. Some data suggest differences among common protein foods such as eggs, meats, poultry, fish, and cheeses that might favor their specific incorporation into the therapeutic diets of patients with limited absorptive capacity. In general, evidence indicates that animal proteins are more rapidly absorbed and metabolized than vegetable proteins (59). Surprisingly, in patients with cirrhosis, nitrogen balance studies showed no advantage of conventional animal protein foods over protein from cereal and legumes (60, 61 and 62).

Although foods may be processed in ways that may influence the digestibility of their constituent proteins, studies have focused on the total amount absorbed or retained, rather than on how the rate of absorption may be modified. When protein foods are heated, cross-linking may occur among amino acids or between amino acid side chains and sugars. In the latter reaction, the free NH₂ groups on the lysine chains combine with the reducing groups of sugars, especially in the presence of heat, as in the baking of breads or cereal products and the manufacture of breakfast cereals. This synthesis (Maillard reaction) reduces the effectiveness of tryptic digestion and reduces the biologic value of the protein in experiments in animals. The effect on blood amino acid responses in man remains to be assessed.

In addition, much work is being done on modifying proteins such as those of soy (63), fish (64), casein, and whey (65) to improve such functional properties as solubility, emulsifying capacity, and heat stability, so they may be used in human foods. Their nutritional and digestibility properties will be reduced, however, because common methods involve succinylation or acetylation of the ε-amino group of lysine, the hydroxyl group of serine and threonine, the sulfhydryl group of cysteine, the phenol group of tyrosine, or the imidazole group of histidine (66). In vitro, succinylated proteins have low digestibility, owing to resistance of the succinyl-lysyl bonds to pancreatic digestion (66, 67).

Thus, processing generally reduces the digestibility of proteins. Nevertheless, these processes (e.g., heat) may be essential to remove the antinutrients from other food sources (e.g., legumes, cereals, and tubers) and to enhance digestibility, so that use of heat is likely to have a net positive nutritional impact.

DIETARY FIBER

Many of the differences in the digestibility of foods that cannot be explained by intrinsic differences in their macronutrient components are due to differences in their non-nutrient constituents, the plant materials that are resistant to small intestinal digestion, collectively known as dietary fiber.

Large differences exist in the physical form and the physiologic effect of various classes

of dietary fiber. In general, purified viscous fibers such as gums, gels, and mucilages reduce the rate of nutrient absorption, whereas particulate fibers (e.g., cereal brans) have little effect on nutrient absorption in the small intestine but have a major impact on colonic function (see below in this section).

Definition

The definition of dietary fiber has always been controversial, and some feel the term is obsolete. One of the most widely accepted definitions is that of Trowell et al. (67a): “Fiber is composed of the plant polysaccharides and lignin which are resistant to digestion by the digestive enzymes of man.” This is a physiologic rather than a chemical definition. Those who feel the term is obsolete favor such terms as plant cell wall nonstarch polysaccharides (NSPs) (67b), since dietary fibers were originally thought to be the structural elements responsible for maintaining the shape of plant cells via a cellulose-lignin lattice “waterproofed” with other NSP molecules. Cell wall NSPs can be directly measured, but focus on cell wall material exclusively may be deceptive, since nonstarch storage polysaccharides in foods such as legumes (e.g., galactomannan [guar] in the cluster bean [*Cyamopsis tatarongaloba*]), though analyzed as NSP, are not necessarily cell wall materials.

Classification

Dietary fiber was originally called crude fiber, a term from ruminant nutrition that referred to the fraction of plant material (forage) that was resistant to ruminant digestion and therefore of no nutritional value. It constituted the very resistant cellulose lignin fraction of what is now called dietary fiber. Van Soerst later developed analyses that gave greater definition to dietary fiber and classified fiber fractions as acid or neutral detergent fiber. Acid detergent fiber (ADF) was closer to the original crude fiber, and neutral detergent fiber (NDF) was closer to what we now term dietary fiber but without some of the water-soluble fiber fraction. These terms are still the standards used in animal nutrition. The chief dietary fiber components of interest are the water-insoluble celluloses, hemicelluloses, and lignins, and the water-soluble pectic substances, gums, and mucilages (Table 43.1). In general, dietary fiber and its components of interest are polymers of glucose or other sugars; the exception is lignin, which is polyphenol propane.

Dietary Fiber Hypothesis

The health benefits of eating cereal fiber and high-fiber plant foods in general were promoted in the 19th century by the well-known health advocates Graham and Kellogg in America and Allinson in Britain. However, much of the interest generated in the latter half of this century is the result of the work of Denis Burkitt and Hugh Trowell. From their experience of over 30 years, medical and surgical practice in Uganda, and subsequent studies of disease incidence in other countries, they proposed that many Western diseases resulted from maladaptation to low-fiber diets. Diseases they attributed to a lack of dietary fiber included colonic disorders, constipation, diverticular disease, colon cancer, and such systemic disorders as hyperlipidemia, cardiovascular disease, diabetes, and obesity. Their theory, known as the dietary fiber hypothesis (67c), has

been the stimulus for physiologic, clinical, and epidemiologic research since. A major focus of this research has been how fiber alters the absorption of macro- and micronutrients and bile acids along the length of the gastrointestinal tract and the biochemical consequences of these alterations.

Physiologic and Metabolic Effects (See Also [Chapter 86](#))

Although dietary fibers have been divided into those that are water soluble (soluble fiber) and those that are not (insoluble fiber), there is concern that these terms should be discarded. Most foods contain both soluble and insoluble components in varying ratios, with the average for Western diets being about 1:3 soluble:insoluble fiber. They have, however, proved useful conceptually. Insoluble fibers are considered to be those with the greatest effect on fecal bulk ([68](#), [68a](#), [68b](#), [68c](#), [68d](#) and [68e](#)) (e.g., cereal brans from wheat, rye, and rice). The soluble fibers, most importantly the viscous fibers, have metabolic effects (e.g., pectins from fruit and vegetables; β -glucan from oats and barley, gums from legumes, roots such as konjac, mucilages from the outer surface of plants such as sea weeds). They tend to flatten blood glucose and insulin levels postprandially ([69](#)) and reduce serum cholesterol in association with increased fecal bile acid losses ([70](#), [71](#), [71a](#) and [71b](#)). The effects are related to viscosity, and in general, these fibers have little fecal bulking effect since they are rapidly fermented to gases and SCFAs by the colonic microflora. In fact, pectin may have a constipating effect. The fecal bulking and metabolic effects are therefore usually dissociated. A notable exception is psyllium husk, which has a high viscosity but is not well fermented by colonic microflora and thus also has a fecal bulking effect. The mechanisms of action for the metabolic effects of fibers in the small intestine and colon are discussed below.

Viscous Fibers and the Upper Gastrointestinal Tract

Dietary fibers of the viscous type, such as gums and pectic substances, delay gastric emptying ([72](#), [73](#), [74](#) and [75](#)) and slow small intestinal uptake of sugars, amino acids, ([69](#), [76](#)) and drugs such as acetaminophen and digoxin. Fiber is also associated with increased small intestinal (ileostomy) ([71b](#)) and fecal losses of bile acids ([70](#), [71](#) and [71a](#)). As a result, increases in bile acid synthesis rates (especially of chenodeoxycholate) are seen ([76a](#), [76b](#) and [76c](#)). The effect of fiber on the small intestine is thought to be due to its ability to increase the thickness of the unstirred water layer, which acts as a barrier to diffusion of nutrients to the enterocyte brush border. Studies using pectin have supported this concept ([77](#)). It has also been suggested, however, that viscous fibers slow absorption simply by impeding diffusion in the bulk phase. The mechanism may also differ along the length of the small intestine as water is absorbed. Use of a triple-tube lumen and balloon tamponade to isolate a segment of human small intestine in vivo showed that adding guar to the perfusate reduces the rate of small intestinal absorption of glucose ([78](#)). Nevertheless, although slow absorption has been observed, malabsorption has not resulted, as judged by urinary recovery of xylose ([69](#)) and acetaminophen ([72](#)) and the lack of breath H_2 evolution ([80](#)). In addition, fat and protein losses increased minimally, as judged by the marginally increased output of protein and fat from the terminal ileum ([80](#)) after bran supplementation. Viscous fiber preparations are associated with enhanced chylomicronemia and higher postprandial fat-soluble vitamin levels, possibly because they stabilize lipid emulsions ([81](#), [82](#)).

Similar enhanced vitamin A absorption has been seen with cholestyramine at a low level (74) but not at high levels at which fat absorption is depressed (84). Viscous fiber preparations have been used in the management of diabetes (85, 86, 87 and 88), as well as to reduce serum cholesterol levels in hyperlipidemia (89, 90 and 91). These preparations also improve symptoms in the dumping syndrome following gastric surgery (70, 92, 93). Detailed studies demonstrated that added viscous fiber in test meals blunted the glucose, insulin, and GIP responses when taken with a glucose load (73) and decreased both the undershoot in blood glucose (72) and hemoconcentration, assessed by hematocrit (74a).

The viscosity of the fiber appears to determine its metabolic effects, especially in terms of postprandial glycemia. Hydrolysis of the viscous fibers guar or oat β -glucan renders them ineffective (69, 94a). The effects of hydrolysis on the cholesterol-lowering effect are less clear, since the one study reported with guar gum still used an hydrolyzed guar gum with significant residual viscosity (94b). Low-viscosity fibers (e.g., acacia gum) have proved ineffective in lowering serum cholesterol, as have some oat β -glucans, presumably related to their low viscosity (94c, 94d and 94e). Indeed, standardization of oat β -glucan solubility and viscosity in foods may be of great importance now that health claims are permitted by the Food and Drug Administration (FDA) for foods containing more than 1 g β -glucan per serving, without requiring assessment of product efficacy (94f).

Indeed the effectiveness of fiber in foods in reducing the rate of absorption and altering associated metabolic events is generally less clear. No significant differences in glycemic response or digestibility were found between white bread, pasta, and rice and their wholemeal or bran equivalents (94, 95) (Fig. 43.4) (19). In addition, when over 50 foods of equivalent carbohydrate content were compared, the flattening in postprandial glycemia was significantly negatively related to their fat and protein contents, but not to fiber (Fig. 43.5) (16). This may have been due to the large number of high-cereal fiber foods examined. Because cereal fiber of medium-to-large particle size (500–1200 μ m) appears to have little effect on small intestinal absorption, the effect of other types of fiber may have been obscured. The selection of particle size and fiber sources may be all important because this debate continues, with some (96), but not all (97), workers finding a fiber-glycemic index relationship.

Figure 43.4. Effect of fiber depletion on the mean blood glucose curves after eating

50-g carbohydrate portions of bread, rice, and spaghetti compared with 50-g glucose tolerance tests. (From Jenkins DJA, Wolever TMS, Taylor RH, et al. *Diabetes Care* 1981;4:509–513.)

Figure 43.5. Relationship of fat, protein, and fiber content of 62 foods and sugars with the glycemic index of 50-g carbohydrate portions. (From Jenkins DJA, Wolever TMS, Taylor RH. *Am J Clin Nutr* 1981;34:362–366.)

Studies with purified fibers therefore indicate that certain types of fiber may affect the absorbability of foods. Fiber in unprocessed foods is also likely to influence the absorption of the macronutrient components in a Western diet through its effect on food form (discussed below).

NUTRIENT-NUTRIENT INTERACTIONS IN FOODS

Nutrient-nutrient interactions have a significant effect on the digestibility of foods. Studies using breath hydrogen measurement to assess carbohydrate malabsorption indicate significant (10–20%) malabsorption from white bread and other farinaceous products (98). When gluten-free flour was used, no malabsorption was seen, nor was malabsorption produced by adding back purified gluten to the same level as found originally in the white bread (Fig. 43.6). The investigators concluded that the natural physical interaction of the starch and protein in wheat limited its rate of digestion, resulting in some malabsorption (98). The implication is that patients without definite evidence of celiac disease who are placed on a gluten-free diet and appear to improve may do so because of the enhanced availability of dietary starch rather than elimination of the gliadin component of wheat protein. Such a measure may thus be generally applicable therapeutically when malabsorption of carbohydrate (starch) is a problem. Furthermore, the *in vitro* digestion rate of gluten-free or gluten-reconstituted bread was more rapid than that of regular bread and the *in vivo* glycemic response to feeding

breads made of these flours (gluten reduced) was also higher (99).

Figure 43.6. Breath hydrogen concentration as a measure of carbohydrate malabsorption in healthy volunteers during a 10-hour fast (A) and after ingestion of 100 g carbohydrate (B through G). (From Anderson IH, Levine AS, Levitt MD. N Engl J Med 1981;304:891–892, by permission of the New England Journal of Medicine.)

Conversely, the presence of protein in the small intestine helps to stabilize fat emulsions and enhances micelle formation and fatty acid uptake (39, 100). This was demonstrated with casein given with olive oil to dogs (39, 100), in mixtures of proteins (bovine albumin and bovine hemaglobin/ovalbumin mixture), and in various digests of these administered to rats (100). In addition, the effect of fiber in reducing the glycemic response to carbohydrate was reported to diminish as dietary protein levels increased (101).

Fat, on the other hand, delays gastric emptying (102) and thus slows digestion and absorption of other nutrients. However, the extent of this delay may depend on the stability of the fat-food mixture, because separation of fat into an upper lipid phase may cause the fat to have little effect on the gastric emptying of the carbohydrate and protein lying below.

A starch-lipid interaction has been described in which the hydrocarbon chain of a monoglyceride becomes embedded within the relatively hydrophobic internal portion of the amylose α -helical structure (103). Investigators suggested that starch-lipid interactions may form in the upper part of the small intestine during fat ingestion and may slow the rate of starch digestion and reduce the glycemic response.

Lipid-lipid interactions are also important. For example, lecithin may enhance triglyceride absorption by facilitating micelle formation (39, 104). Similarly, owing to their effect in stimulating chylomicron formation, long-chain fatty acids increase cholesterol

absorption (105) and, most importantly, absorption of fat-soluble vitamins (106).

MICRONUTRIENT INTERACTIONS

Our discussion has so far focused on the factors affecting absorption of the so-called macronutrients from foods, rather than the minerals, trace elements, and vitamins. This level has another series of interrelationships. Evidence indicates that fiber binds minerals in vitro (107). Various types of fiber to reduce the absorbability of calcium (Ca^{2+}), iron (Fe^{2+}), and magnesium (Mg^{2+}) (108, 109, 110 and 111). Phytate, a fiber-associated antinutrient, may also be important, although its relationship to deficiency states is not clear. Results are affected by the kind of fiber and by the presence of other agents in foods. Responses to test meals given to human subjects indicate that fiber may decrease absorption of iron and zinc (112). Responses were affected by amounts of fiber and minerals and by the presence of protein and phytate in test meals. Although fiber intakes by vegetarians have been reported to be higher than those for omnivores, studies reveal no differences in blood mineral levels between the two groups (112).

Results of human balance studies involving fiber and mineral bioavailability are controversial. Many factors influence the outcome of such studies, making them difficult to evaluate. Phytate and oxalate in food can also bind minerals and may contribute to decreased mineral balances (113). The relative levels of fiber, minerals, protein, and other substances in the diet are important and contribute to the confusion in attempts to compare different studies. The type of fiber is also a variable, and indications are that insoluble fibers are more likely than soluble fibers to have an adverse effect on mineral bioavailability.

The length of the study period is important in evaluating the results of human balance studies (114). Adaptation to a different level of mineral intake or to a different level of availability may take considerable time, depending on the magnitude of the change. Thus, study subjects fed a lower level of a mineral than in their usual diets may develop negative mineral balance at the beginning of the study but become adapted to the new level if sufficient time is allowed. From reports of balance studies in the literature, it appears that an intake of 25 g per day of insoluble fiber does not adversely affect mineral nutrition if adequate mineral intake is maintained.

Consumption of long-chain fatty acids facilitates fat-soluble vitamin uptake. High levels of fat in the diet may increase Ca^{2+} losses in the feces (115). Raising dietary protein intake may diminish the absorption of zinc (Zn^{2+}), copper (Cu^{2+}), and Ca^{2+} , all in the presence of modest amounts of fiber (101). In the colon, reduction of pH by carbohydrate fermentation favors absorption of Mg^{2+} (116) and vitamin K (117). Many other such interrelationships are discussed in their respective sections of this book.

INFLUENCE OF FOOD FORM AND NONNUTRIENT FOOD COMPONENTS

Many of the studies showing differences in the absorbability of natural diets were carried

out in relation to factors concerned with absorption of carbohydrate from foods; thus, much of the present discussion uses carbohydrate digestibility to illustrate general principles. Factors include food form, fiber content, and the presence of lectins, tannins, saponins, and phytates. The possible role of fiber is discussed above.

Food Form

The form in which a food is eaten is a major determinant of its rate of digestion and absorption. Apples eaten whole rather than blended produced flatter blood glucose and insulin responses, indicating a slower rate of absorption (118). Crapo and coworkers demonstrated differences in glucose and insulin responses to a range of starchy foods including baked potato, boiled rice, bread, and corn, which in part might be attributed to food form (12, 13). Maize and rice (whole seeds) produced the least response, whereas baked potato, a less “compact” food, approximated the blood glucose rise seen when the equivalent amount of carbohydrate was given as glucose (12, 13 and 14). Furthermore, rice that was ground and then cooked evoked rises in blood glucose and insulin approximating those for glucose (119) and a more rapid rate of in vitro digestion than whole rice.

Particle size, an important aspect of food, is not detected by assessing the chemical composition of the diet. Many traditional foods with low glycemic indices have large particle sizes, including whole-grain barley, as used in traditional soups; cracked wheat or tabouli, a staple food in North Africa and throughout the Middle East; and pumpernickel bread with 80% whole rye grains, as commonly used in northern Europe. The proportion of whole grain (wheat or barley) in a bread mix determines the glycemic effect and the in vitro rate of digestion; more whole grain in the bread produces slower absorption and a flatter glycemic response (120). Heaton et al. used this concept to explain possible health benefits of traditionally milled flours, independent of their fiber content. Their studies showed that traditional coarse-milled flours with large particle sizes produce flatter postprandial glucose and insulin responses (121).

The digestibility of cereal grains also appears to be influenced by “parboiling,” i.e., precooking a grain in its husk before dehusking. Possibly because of prevention of swelling and hence a reorganization of the starch molecule, subsequent cooking fails to hydrate the dehulled grain, which, although perfectly acceptable for consumption, produces a lower glycemic response (122). This is a traditional way of processing rice.

Although food form is a determinant of digestibility, application of this principle may not be universal. Studies with lentils indicated that blending to a smooth paste after cooking did not affect the in vitro digestion rate or the glycemic response (123), nor did boiling for an additional 40 minutes. Heat treatment for 12 hours was required to increase the digestibility of the lentils (123).

Enzyme Inhibitors

Enzyme inhibitors in foods, although common in storage organs such as seeds, cereal grains, and beans, are usually effectively destroyed by the heat treatment of conventional cooking practices (124). Their relevance to human nutrition is therefore

likely to be limited. In terms of animal nutrition, however, the antitryptic activity of uncooked bean meal has attracted attention because it limits the protein quality of animal feeds. In rats, it was associated with impaired growth and pancreatic hypertrophy ([102](#)).

On the positive side, purified enzyme inhibitors are beginning to find a use in modifying small intestinal absorption. Inhibitors of carbohydrate absorption have been developed specifically to control the rate of carbohydrate absorption. An anti- α -amylase isolated from wheat was shown to reduce the rate of starch digestion and the glycemic response to a starch meal in rats, dogs, and man ([125](#)). Subsequently, a commercially developed α -glycoside hydrolase inhibitor with antisucrase, antimaltase, and anti-amylase activity found application in the treatment of diabetes ([126](#), [126a](#)) and the dumping syndrome ([127](#)). In the dumping syndrome, relief was obtained despite enhanced carbohydrate losses ([127](#)). Presumably, the reduced glycemic excursions caused by dampening the carbohydrate flux offered a large measure of relief to patients and outweighed the discomfort of carbohydrate malabsorption to which they were already accustomed. Thus, although enzyme inhibitors may be of little relevance in the context of commonly eaten foods and dietetic manipulations, pharmacologic development of these agents may in the future provide a further means of modifying small intestinal absorption.

Saponins

Saponins, steroidal or triterpenoid amphiphilic glycosides with surface-active and emulsion-stabilizing properties, are relatively heat resistant; thus, their levels are maintained in fat-containing plant foods and oils. Under normal circumstances, they are not absorbed. They have attracted attention by possibly precipitating cholesterol and interfering with micelle formation in the small intestine by enhancing the binding of bile acids to fiber ([128](#)). There is no suggestion that they would induce major changes in fat absorption, but in view of their effects on cholesterol absorption, they may possibly interfere with fat-soluble vitamin uptake. The exact effect of these surface-active agents on the enterocyte or digestive enzymes is unknown.

Tannins

Tannins, large, condensed polyphenols, are powerful reducing agents widely distributed in plant food. Because they are heat stable, however, they survive cooking procedures and can complex with dietary proteins and reduce protein digestibility ([129](#)). They also reduce the activity of the digestive enzymes trypsin and amylase ([130](#), [131](#)). Tannins may therefore reduce the rate or total absorption of both dietary starch and protein from foods. Although tannins occur in high concentrations in certain natural diets, their effects have not been studied directly in man; however, their concentration in foods is inversely related to the digestibility and glycemic response of a wide range of foods tested ([132](#)).

Phytates

The most important phytate is *myo*-inositol 1,2,3,4,5,6 hexakis dihydrogen phosphate, which is found in relatively high concentrations in many high-fiber foods (cereals, legumes, and vegetables). Its levels are reduced by the action of yeast in the leavening

of bread. Nevertheless, phytates can bind metal ions and bind to protein (133, 134) and possibly to starch, thereby reducing macro- and micronutrient digestibility. As a consequence, phytates were implicated in calcium and zinc deficiency in man (135). Their exact role in macronutrient absorption, however, seems to be less important than that of fiber (136). Nevertheless, phytates reduce carbohydrate digestibility when they are added to white bread in the same concentration as found in legumes (Fig. 43.7) (137). This effect is probably due to the binding of Ca^{2+} , which catalyzes the action of amylase (138), because addition of excess Ca^{2+} minimizes the effect (137).

Figure 43.7. Rate of digestion of starch in unleavened breads with and without addition of sodium phytate (PA). (From Yoon JH, Thompson LU, Jenkins DJA. *Am J Clin Nutr* 1983;38:835–842.)

Although phytate may also bind to proteins and so reduce protein digestibility (133, 134), the significance of this effect in commonly eaten foods is not clear. Phytates may possibly play a major role in determining starch digestibility in foods, because they have a highly significant negative relationship with digestibility and glycemic response to many foods tested in man (137). Their levels are especially high in legumes, which show some of the slowest rates of in vitro digestion (19).

Lectins

These substances are a diverse family of proteins and glycoproteins found ubiquitously in plant foods (139). Lectins bind to carbohydrate receptors on cell surfaces and, in extremely high concentrations, have caused small intestinal mucosal damage in rats (140). Apart from retrospective studies by Noah et al. concerning raw kidney bean consumption (141), no toxic effects have been reported in man at levels commonly found in the diet; however, preliminary studies indicate that, as with many antinutrients, the lectin content of a food and its digestibility both in vitro and in vivo are related (142). The exact significance of this finding awaits further elaboration.

Rate of Food Ingestion and Meal Frequency

Finally, the rate of nutrient delivery to the organism can be slowed simply by reducing the rate and prolonging the time over which food is ingested ([Fig. 43.8](#)). In many ways, this also provides the least complicated model for examining the physiologic effects of reducing the rate of absorption. In short-term studies of glucose or mixed meals, possibly the most notable effect is the reduction in postprandial insulin levels ([143](#), [144](#) and [145](#)). The possible benefits of increased meal frequency discussed here refer to isocaloric redistribution of food so that absorption of a defined material load is spread over a longer time. It is not intended to imply a benefit from ingesting more food. Lack of emphasis of this point has often resulted in a negative connotation for “snacking” or “eating between meals” when associated with increased caloric intake.

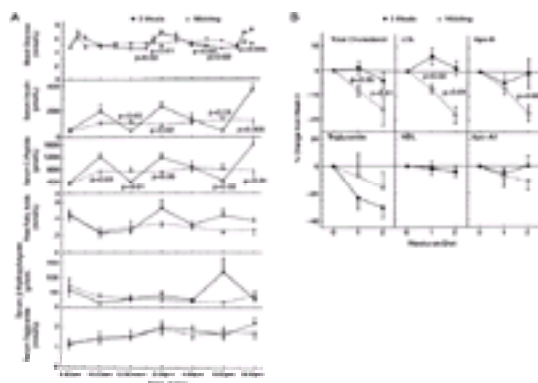

Figure 43.8. A. Mean (\pm SE) blood glucose levels and serum concentrations of insulin, C-peptide, free fatty acids, 3-hydroxybutyrate, and triglyceride in seven men on day 13. During the nibbling diet, meals were eaten hourly from 8 am onward, and during the three-meal diet, 8 am, 1 pm, and 7 pm. **B.** Mean (\pm SE) percentage of change from time 0 in serum lipid and apolipoprotein (apo) concentrations in seven men during the nibbling diet and the three-meal diet. (From Jenkins DJA, Wolever TMS, Vuksan V, et al. *N Engl J Med* 1989;321:929–34, with permission.)

Over 50 years ago, Ellis noted the beneficial effect of frequent oral glucose administration in the management of insulin-dependent diabetes ([145a](#)). More recently, studies showed benefits on glycemia and insulinemia in non-insulin-dependent diabetes over the day from increased meal frequency ([145](#), [145b](#)). The most recent nutrition recommendations of the American Diabetes Association also draw attention to the possible advantages of increased meal frequency ([145c](#)).

Economy in insulin secretion has been seen in longer-term studies ([Fig. 43.8A](#)) and has been associated with reduced serum lipid and lipoprotein levels, notably LDL cholesterol and apolipoprotein B ([Fig. 43.8B](#)). Indeed, for over a quarter of a century, evidence has

accumulated on the beneficial effect of meal frequency on serum lipids ([146](#), [147](#), [148](#), [148a](#) and [148b](#)). Stable isotope studies in man showed that increased meal frequency reduced cholesterol synthesis; reduced insulin levels were also noted ([148c](#)). In addition to reduced insulin levels and hence lower stimulation of hydroxymethylglutaryl coenzyme A (HMGCoA) reductase, ([149](#), [150](#)) the rate-limiting step in cholesterol synthesis, alteration or expansion of the bile salt pool, secondary to more frequent enterohepatic cycling, may also be a factor in lowering serum lipid levels. These benefits of increased meal frequency on serum lipids and coronary heart disease ([151](#)) were not seen in relation to cancer; increased cancer incidence has been noted ([152](#), [153](#)). In the cancer studies, the determining factor may be the nature of the snack foods used (high fat, high salt, etc.) in uncontrolled diets. These findings highlight the need for more research into the physiologic and pathologic consequences of alterations in food frequency and, by inference, factors that prolong absorption time in general.

DIFFERENCES IN DIGESTIBILITY OF FOODS AND PHYSIOLOGIC IMPLICATIONS

General Considerations

Because many factors may alter the digestion and absorption of foods, we cannot predict the rate at which a food will be digested simply by knowing its constituents. Nevertheless, as illustrated by starch-containing foods, large differences are seen among different foods ([Table 43.1](#)) ([28](#)). Predictably, the legumes that are relatively high in soluble fiber and antinutrients are digested more slowly than cereal foods and potato ([28](#)). In addition, they release a greater proportion of glucose and maltose and a smaller proportion of maltotriose. As mentioned above, this effect may reflect their higher content of the less readily digested amylose form of starch. On the other hand, the content of cereal fiber in white and wholemeal bread demonstrates clearly that this form of fiber does not reduce the rate of digestion of bread.

Again, by contrast, foods of similar composition (e.g., white bread and white spaghetti) differ markedly, presumably because of differences in food form. Because the rate of digestion relates well to the glycemic response to foods ([19](#)), the physiologic implications of these differences are great. Flatter glycemic responses are seen (expressed as a glycemic index) in response to foods that are digested less rapidly ([Fig. 43.9](#)) ([19](#)). As data accumulate, it should be possible to select diets on the basis of rates of digestion to achieve the desired physiologic and metabolic effects.

Figure 43.9. Relationship between the mean glycemic index and mean digestibility index for each of the 10 foods studied. The glycemic and digestibility indices were calculated by ascribing to white bread a value of 100, both for the glycemic response areas observed over 3 hours after consumption of the test foods and for the total sugars liberated at 3 hours during in vitro digestion (descending order of digestibility: cornflakes, white and wholemeal breads, rice, potato, spaghetti, porridge, kidney beans, chick peas, and lentils). (From Jenkins DJA, Ghafari H, Wolever TMS. *Diabetologia* 1982;22: 450–455.)

Glycemic Index (See Also [Chapter 86](#))

Because many factors in foods may influence their rates of digestion and glycemic responses and because most of these factors are not listed in food tables and many have nothing to do with food composition, it is not possible to predict the physiologic effect of a food on the basis of its chemical composition. The glycemic index was developed as an index of the physiologic effect of foods to supplement information on chemical composition (16). It was reasoned that such information might allow a better understanding of the effects of carbohydrate foods and aid in the selection of appropriate foods for therapeutic diets. The glycemic index is defined as the blood glucose response to a 50-g available carbohydrate portion of a food expressed as a percentage of the response to the same amount of carbohydrate from a standard food, which has been either glucose or white bread. Bread is the preferred standard and gives glycemic index values 1.38 times greater than glucose (because glucose produces a glycemic response 138% that of white bread). The glycemic index value obtained also depends on the method of calculating the area under the glycemic response curve and, to a lesser extent, on other methodologic variables, discussed fully elsewhere (154). Relatively comprehensive tables of the glycemic indices of foods are now becoming available (154a).

A compilation of over 75 different foods tested in various centers is provided in Appendix [Table IV-A-26-a](#) (155). For most foods tested more than once in different centers there is reasonable agreement, with an average coefficient of variation of the mean glycemic index values of 16% (154). The variability of certain foods in many cases

has been found subsequently to be due to subtle differences among foods, such as the method of rice processing (parboiled vs. polished) (122), different varieties of potato (154), and the ripeness of banana (156). Different individuals may have vastly different absolute glycemic responses to a food, depending upon their glucose tolerance status. The glycemic index normalizes each subject's response to that of a standard food, however, so differences among individuals are removed (157). Thus, the glycemic index values of foods are the same in normal and diabetic subjects.

In individual subjects, blood glucose responses vary from day to day. For this reason, the glycemic index cannot be applied quantitatively in individual subjects who test foods only once. One can predict the ranking of glycemic responses, however, with the chance of a correct prediction determined by the variation of glycemic responses within the subject tested, the expected glycemic index difference, and the number of times the subject repeats the tests (158). The glycemic index can be applied to mixed meals if appropriate methods are used (154, 159). Briefly, the meal glycemic index is the weighted average of the glycemic index value of all the individual carbohydrate foods in the meal, with the weighting based on the proportion of the total meal carbohydrate contributed by each food. The percentage differences among meal glycemic index values accurately predicts the percentage differences among the mean incremental glycemic response areas of mixed meals taken by groups of subjects, provided accurate glycemic index values are known for the individual foods. A reasonable correlation exists between the glycemic and insulinemic indices of different foods (159a).

The clinical relevance of the glycemic index was demonstrated in studies in which the types of starchy carbohydrate foods in the diet were altered without changing the overall dietary composition in terms of fat, protein, carbohydrate, and dietary fiber (see Chapter 85). A low-glycemic-index diet reduced blood lipids in hypertriglyceridemic subjects (160, 161); reduced insulin secretion (162); improved overall blood glucose control in insulin-dependent and non-insulin-dependent diabetic subjects (163, 164, 165 and 166); reduced abnormal blood glucose, insulin, and amino acid levels in patients with cirrhosis (167); and reduced urinary urea excretion, presumably by increasing nitrogen trapping by colonic bacteria (162). In addition, some evidence indicates that low-glycemic-index foods enhance satiety (168) and increase athletic endurance (169).

Studies appear to be confirming that low-glycemic-index foods may offer protection from development of non-insulin-dependent diabetes. Studies of 65,174 nurses (women) (169a) and 42,759 health professionals (men) (169b) followed up for more than 5 years, found that diabetes was less common in both sexes in those with low-glycemic-index and higher-cereal-fiber diets (Fig. 43.10).

Figure 43.10. Relative risk of NIDDM by different levels of cereal fiber and glycemic load. (From Salmeron J, Stampfer MJ, Colditz GA, et al. JAMA 1997;277:472–77, with permission.)

Colonic Absorption

Food residues not completely absorbed in the small intestine may be absorbed in the colon. In terms of overall protein metabolism, ammonia and the bacterial metabolites of amino acids may have little impact apart from their deleterious effects in the genesis of encephalopathy in liver disease. In the case of malabsorbed carbohydrate, however, the situation differs. A small proportion of the starch in many commonly consumed foods escapes absorption in the small intestine and enters the colon. This is especially true for foods that are absorbed slowly. Breath H_2 (105, 123) and ileostomy studies (170, 171) indicate that 7 to 20% of the starch in bread enters the colon. With other foods, such as legumes, the percentage lost may be higher. Although these losses relate to the in vitro rate of digestion, the differences in the percentage of carbohydrate malabsorbed among foods are much smaller than the percentage differences in their glycemic responses (16, 17, 172). Carbohydrate losses thus do not appear to account for the flatter glycemic responses of starchy foods of low glycemic index.

In terms of energy losses from carbohydrate foods (starch, sugars, and fiber), much may be salvaged by colonic absorption of the resulting volatile fatty acids (173, 174), which have been estimated to contribute 10% or more of dietary calories (174). Therefore, factors that alter the rate of carbohydrate digestion may not be reflected in malabsorption so much as in an altered balance of nutrient absorption from different parts of the gut, including the colon.

Short-Chain Fatty Acids: Local and Systemic Metabolism

The major products of carbohydrate fermentation in the colon are the SCFAs, acetate, propionate, and butyrate. These anions are taken up rapidly from the colonic lumen and may exert local and systemic effects on metabolism. Studies indicate that SCFAs may

enhance the uptake of divalent metal ions (175), and investigators have suggested that the colon may be a major organ for salvaging minerals and trace elements trapped by fiber fermented in the colon (176). In man, colonic Ca^{2+} absorption is enhanced by incorporating acetate and propionate into the perfusate. SCFAs are also considered valuable energy sources for the host. Butyrate is a preferred substrate for the colonocyte and has been suggested to have antineoplastic properties (177). Butyrate has been used in enemas to treat exclusion (diversion) colitis (178). Propionate is largely extracted by the liver. It is gluconeogenic and may have an inhibitory effect on cholesterol synthesis (179). Acetate is taken up by both liver and peripheral tissues. Of the three SCFAs mentioned, only acetate appears in significant quantities in the peripheral circulation.

Colonic SCFAs may influence systemic carbohydrate and lipid metabolism, but the exact effects are not fully known, and this is an area of current research. Acetate has no effect on intravenous or oral glucose tolerance or glucose turnover rates (180, 181). It may influence glucose use indirectly, however, by reducing serum free fatty acid levels. This effect was first described in studies suggesting that acetate accounted for the free fatty acid-lowering effect of alcohol (182). Recently, investigators have demonstrated that colonic acetate also has the same effect in reducing serum free fatty acids (183). Propionate has direct effects on carbohydrate metabolism. Evidence indicates that as in ruminants, propionate is gluconeogenic in humans (183). Feeding propionate improves carbohydrate tolerance, which may be related, in part, to an inhibitory effect of propionate on starch digestion (184).

The potential effects of colonic SCFAs on lipid metabolism have been of major interest, especially as a mechanism for the lipid-lowering effect of soluble fiber. In vitro, propionate inhibits cholesterol synthesis in slices of hepatic tissue (185); however, the concentration of propionate required may exceed that ever reached in the portal vein (186). In human feeding studies, propionate has no effect on serum cholesterol (184, 187). Nevertheless, propionate can inhibit incorporation of acetate into cholesterol and triglyceride by isolated hepatocytes (188). This may be significant in humans, because rectal infusion of acetate results in increased serum cholesterol within 1 hour, an effect partly blocked by addition of a physiologic amount of propionate (183). The serum cholesterol-raising effect of acetate was further suggested by the finding that feeding lactulose for 2 weeks to healthy subjects increased serum total and LDL cholesterol, apolipoprotein B, and triglyceride concentrations (Fig. 43.11) (189). Therefore, the influence of propionate on lipid metabolism cannot be determined until the importance of colonic acetate as a substrate for cholesterol synthesis is known.

Figure 43.11. Mean 2-week lactulose values for blood lipids and apolipoproteins expressed as the percentage difference from the corresponding control values. Bars represent the mean \pm SE of the lipid and lipoprotein categories for subjects. (Adapted from Jenkins DJA, Wolever TMS, Jenkins AL, et al. *Am J Clin Nutr* 1991;54:141–147.)

Recent interest has focused on substrates that produce specific SCFA spectra. One goal has been to enhance butyrate synthesis to improve colonic health ([189a](#), [189b](#), [189c](#) and [189d](#)). There is growing evidence that colonic fermentation of resistant starches increases intracolonic levels of butyrate and propionate, depending on the starch source and the butyrate:SCFA ratio ([189e](#), [189f](#)). These findings raise the question of the possible use of resistant starches in the treatment of ulcerative colitis and in polyp and colonic cancer prevention.

Long-Term Effects of Dietary Components

Not only can specific foods or food processes be identified with specific short-term effects in gastrointestinal function and absorption, important long-term effects may also be associated with specific diets and dietary components. For example, diets high in carbohydrate induce sucrase-isomaltase and enhance the absorption of sucrose, whereas removal of carbohydrate from the diet rapidly reverses this trend ([190](#)). Diets high in specific dietary fibers reduce sucrase levels in rats ([191](#)); pectin reduced sucrase and lactase, tannin and galactomannan reduced lactase, and cellulose was without effect ([191](#)). Other studies have demonstrated that increasing protein or carbohydrate in the diets of diabetic rats decreased or increased absorption of cholesterol, respectively ([192](#)).

Changes in small intestinal morphology may also be produced by diet. The broad, leaflike jejunal villi seen in inhabitants of areas where high-fiber diets are common but not associated with tropical sprue made researchers wonder what effect unprocessed vegetable material had on villous structure. Studies in rats showed that standard chow and pectin feeding resulted in a flattened villous structure not seen when cellulose or cholestyramine were the only unabsorbable component of the diet ([193](#)). An unexplored but possibly analogous situation might exist in subjects habitually consuming diets high

in the glycoproteins (lectins). Certainly, this is evident in extreme form in susceptible individuals (with celiac) exposed to gliadin, the glycoprotein of wheat.

Dietary components apparently may be used to induce changes not only in morphology, enzyme levels, and absorptive function of the upper gastrointestinal tract but also in motor activity. After 4 weeks of pectin supplementation, gastric emptying of a pectin-free meal in healthy volunteers was half that of the original control. This, too, may have important nutritional and metabolic consequences. Cellulose supplementation was without effect (194).

In summary, the nature of dietary carbohydrates, fats, and proteins has an acutely important influence on the absorption of natural diets. Perhaps less well recognized is the role of food form and food preparation procedures, especially those that alter either the absolute amount of fiber and antinutrients within a food or their relationship with the macronutrients. Increasingly, factors that alter carbohydrate absorption can be viewed not simply as causing or reducing malabsorption, but as altering the rate of absorption. Thus, factors that reduce the rate of absorption result in absorption at sites further along the small intestine. Finally, carbohydrate that is not absorbed in the small intestine may still be salvaged as SCFAs in the colon. The endocrine and metabolic effects of these changes can be considerable, as are the effects on absorption of other nutrients. In addition, long-term adaptation of small intestinal and, indeed, colonic function to the maneuvers described is only beginning to be explored. Active modification of small intestinal absorption probably has the potential to become an important therapeutic technique in the future (195).

This chapter examines the effects of various hormones on the metabolism of macronutrients. Defining hormones in a broad sense, the chapter examines the effects of humoral factors from classic endocrine organs such as pancreatic islets, thyroid, pituitary, gonads, and adrenals as well as from tissues not traditionally characterized as regulators of metabolic homeostasis. In particular, the chapter examines cytokine and eicosanoid elaboration by immune cells and growth factor production by a variety of tissues that contribute to nutrient disposition and mobilization during illness and tissue repair. The chapter examines the *endocrine* actions of hormones, in which hormones act at sites distant from their tissues of origin, generally traversing the circulation to reach their target tissues. It reports the *paracrine* actions of hormones, in which hormones act on neighboring cells within their tissues of origin. Finally, it identifies

occasions in which a given hormone acts as an *autocrine* factor, acting to affect the cell from which it was secreted.

The chapter creates a context for understanding hormone-nutrient interactions that underscores the role of hormones in determining availability of nutritional substrates for immediate needs or long-term storage. There is interindividual variability in the response of tissues to hormones, and nutritional substrates may partially regulate their own use. [Figure 44.1](#) and [Table 44.1](#) distinguish the effects of hormones primarily affecting nutrient storage ([Fig. 44.1](#)) and those mediating nutrient mobilization ([Fig. 44.2](#)). [Table 44.2](#) summarizes the influence of various hormones on circulating concentrations of glucose, free fatty acids, and amino acids.

Table 44.2 Effects of Hormones on Circulating Concentrations of Metabolites

PANCREATIC ISLET HORMONES (INSULIN, GLUCAGON, AND SOMATOSTATIN)

Carbohydrate Metabolism

Carbohydrate metabolism is finely regulated by interactions between insulin, the hormone promoting fuel storage, and the counterregulatory hormones such as

glucagon, epinephrine, cortisol, growth hormone, and immune cell cytokines. Glucose homeostasis is maintained in the presence of widely varying quantities and compositions of food intake. Because the brain has a limited ability to vary its extraction of glucose with variation in glucose supply (1), the importance of these homeostatic mechanisms is apparent.

Insulin

Insulin has a central role in promoting glucose disposal into peripheral tissues and storage as glycogen, a characteristic of the fed state. Like other peptide hormones, insulin initiates its metabolic effects by binding to a cell-surface receptor. These effects depend on the activation of a tyrosine-specific protein kinase, which is contained in the β -subunit of the receptor (2, 3). After binding to the receptor, insulin accelerates membrane transport of sugars following initiation of a cascade of intracellular enzyme phosphorylation events (4). Increases in maximal glucose transport rates in response to insulin vary from 3.2-fold in skeletal muscle to 30-fold in adipocytes (5, 6 and 7). This effect is produced by insulin-mediated translocation of glucose transporter proteins from intracellular membrane pools to plasma membrane in insulin-sensitive tissues (8, 9). Transporters located in the insulin-sensitive tissues (e.g., adipose tissue, skeletal muscle, and heart muscle) are sodium-independent, facilitative transporters named GLUT1 and GLUT4 (10). GLUT4 is the primary protein involved in insulin-stimulated translocation (11). Despite the pivotal role of GLUT4 in insulin-stimulated glucose transport, clinical resistance to the metabolic effects of insulin on glucose disposal, as seen in non-insulin-dependent diabetes, does not appear to be due to disorders of GLUT4 expression but is more likely due to impaired communication between the insulin receptor and GLUT4-containing intracellular vesicles (12).

Insulin rapidly increases membrane glucose transport, within 1 to 2 minutes, with a maximal effect in 15 to 20 minutes. Many tissues, including brain and liver, maintain glucose uptake independent of insulin concentrations (13). This ability corresponds to the predominance in those tissues of glucose transporters such as GLUT1 (a ubiquitous transporter) and GLUT3 (brain) or GLUT2 (liver), respectively, which have plasma membrane activities known to be independent of insulin concentrations (14). The hypothalamus may represent a brain region with some dependence on insulin for glucose use, particularly in the glucose-sensitive areas of the ventromedial and lateral nuclei (15, 16). Conversely, skeletal muscle (generally an "insulin-sensitive" tissue) may take up glucose without insulin stimulation under circumstances of contractile stimulation (17).

In addition to increasing glucose transport, insulin also has major effects on intracellular glucose metabolism (Fig. 44.3). In experimentally induced diabetes, activities of enzymes involved in glycolysis and glucose oxidation, such as glucokinase, phosphofructokinase, and pyruvate kinase, are decreased, and activities of gluconeogenic enzymes, such as glucose-6-phosphatase, fructose 1,6-bisphosphatase, phosphoenolpyruvate carboxykinase, and pyruvate carboxylase, are increased. These abnormalities are corrected by insulin replacement. Insulin also promotes glycogen synthesis, by promoting the conversion of glycogen synthase to its active, glucose-6-phosphate-independent ("I") form and by decreasing the activity of

phosphorylase. Insulin causes rapid decreases in phosphorylase activity and more gradual increases in synthase I activity, although the hormonal effect is brief in vivo (18).

Figure 44.3. A. Enhancement of gluconeogenesis and glycogenolysis by glucagon in diabetes and starvation. Both processes are activated by increases in cyclic adenosine monophosphate (*cAMP*) in the hepatocyte. Phosphofructokinase-1 (*PFK-1*) catalyzes formation of fructose 1,6-bisphosphate (*F-1,6-P₂*) in the glycolytic pathway, whereas *PFK-2* synthesizes fructose-2,6 biphosphate (*F-2,6-P₂*), a regulator of *PFK-1* activity; *cAMP*-induced phosphorylation of the enzyme decreases *PFK-1* and increases *PFK-2*. Decreased *F-2,6-P₂* decreases glycolysis and increases gluconeogenesis. **B.** Inhibition of gluconeogenesis and activation of glycogen synthesis and lipogenesis by insulin. Insulin decreases *cAMP*, deactivates protein kinase, and reverses changes in *F-2,6-P₂* and substrate flux over the glycolytic-gluconeogenic pathway produced by glucagon. Glycogen synthesis and lipogenesis are also increased. (From Unger RH, Foster DW. In: Wilson J, Foster DW. Williams textbook of endocrinology. 7th ed. Philadelphia: WB Saunders, 1985.)

Insulin generates an enzymatic profile that decreases glucose carbon recycling (seen during insulin deficiency) and promotes glucose use for energy storage (19). It stimulates glycolysis and lipogenesis in adipose tissue and both glycolysis and glycogen synthesis in skeletal muscle tissue and inhibits gluconeogenesis in the renal cortex and liver (20). Skeletal muscle glycogenolysis is very sensitive to inhibition by insulin according to studies in rats; it is inhibited by concentrations of insulin that inhibit hepatic glucose output—concentrations much lower than those required to stimulate circulating glucose uptake (21). Studies in humans suggest that both direct, hepatic effects of insulin (most potent when insulin is delivered in a typical manner through the portal vein) and indirect effects (from the influence of insulin on gluconeogenic substrate availability) operate in regulating hepatic glucose production (22). Some may be more important than insulin concentrations in activating glycogen synthase and glycogen deposition in the liver, whereas insulin has a key role in regulation of skeletal muscle glycogen metabolism (23). However, results of studies with cultured hepatocytes indicate that glucose-stimulated glycogen deposition plateaus within 2 hours of exposure to

high-glucose medium, and insulin is required to continue glycogen accumulation beyond that time (24).

Ingestion of carbohydrate produces a prompt increase in plasma insulin and a decrease in glucagon concentrations (25). The rise in insulin occurs before the rise in arterial glucose concentrations comprising the so-called enteroinsular axis and cephalic-phase insulin release, which are mediated through hormonal (26, 27) and parasympathetic (28, 29) mechanisms. This early insulin release creates a “priming effect” in which the action of insulin begins concurrently with the absorption of glucose to minimize the extent of hyperglycemia after a meal. As glucose is absorbed, hepatic production of glucose is decreased through the hormonal changes mentioned above, and glucose uptake by the liver, muscle, and adipose tissues increases. Approximately 75% of glucose taken orally bypasses hepatic metabolism and is taken up peripherally (30). Skeletal muscle is the predominant tissue for disposal of an oral glucose load.

During periods of starvation, maintenance of euglycemia is critically important to the organism (see Chapter 41). In the nonketotic state, the energy needs of the brain can only be met by glucose, and its absence results in death of central nervous system tissues. Because the glucose pool can provide only 15 to 20 g in the adult, and glycogen that can be mobilized to provide circulating glucose (i.e., hepatic glycogen) averages 70 g, preformed glucose can provide less than an 8-h supply of glucose on average. Thus, gluconeogenesis is important for maintenance of postabsorptive plasma glucose concentrations and becomes the sole source of glucose production beyond a 24- to 48-h fast. Only the liver and kidneys contain glucose-6-phosphatase, the enzyme necessary for release of glucose into the circulation. The liver and kidneys also contain the enzymes necessary for gluconeogenesis (pyruvate carboxylase, PEP carboxykinase, and fructose 1,6-bisphosphatase). Except after prolonged starvation when renal gluconeogenesis becomes important, the liver is the sole source of *endogenous glucose production* (EGP). Starvation is associated with a decline in insulin and a rise in glucagon concentrations (31), which result in increased rates of gluconeogenesis. Decreased plasma insulin concentrations allow decreased glucose use by peripheral tissues and enhanced lipolysis; free fatty acids are thus more available for use as an oxidative fuel during starvation. These changes in serum insulin and glucagon concentrations also result in increased conversion of free fatty acids to the ketone bodies, acetoacetate and β -hydroxybutyrate, which can substitute for glucose as an energy supply for the brain (32). The change from a glucose- to a lipid-based (free fatty acids and ketone bodies) energy supply in prolonged starvation helps minimize skeletal muscle protein catabolism by reducing the need for amino acid-derived gluconeogenesis (33). β -Hydroxybutyrate also directly increases skeletal muscle protein synthesis in humans while simultaneously decreasing leucine oxidation (34). Similarly, studies in dogs demonstrated that increased free fatty acid availability decreases the whole-body leucine oxidation rate and leucine carbon flux (an estimate of protein degradation rate) (35).

The effects of insulin deficiency are exemplified by type 1, insulin-dependent diabetes mellitus (IDDM). As stated above, this disorder is associated with increased activities of enzymes involved in gluconeogenesis, and decreased activities of glycolytic and oxidative enzymes. In addition, IDDM often is associated with relative or absolute hyperglucagonemia (36, 37), resulting from loss of the restraining influence of insulin

(38) on the secretion of glucagon by the pancreatic α cell (39). An increase in glucose concentration also fails to inhibit glucagon secretion (40, 41) as it normally does and may paradoxically increase glucagon release (42). Glucagon responses to protein are also excessive in association with IDDM (20) and are not blunted by hyperglycemia (43). Control of the plasma glucose concentration to near normal levels with insulin therapy corrects the basal hyperglucagonemia (44) and the exaggerated response to protein ingestion (42).

Inappropriate hyperinsulinemia, as seen in insulin-producing islet cell adenomas or hyperplasia, results in postabsorptive hypoglycemia. In this condition, insulin secretion probably does not decrease as the plasma glucose declines in the postabsorptive state. The result is a low rate of EGP, with rates of glucose uptake that are not high in the absolute sense but are inappropriately high relative to the plasma glucose concentration. The hypoglycemic effect of insulin is potent. When insulin is present in sufficient quantity, it can cause hypoglycemia despite the actions of all known counterregulatory factors. Postabsorptive hypoglycemia may also occur when both glucagon and epinephrine are deficient and insulin is present (45). This situation occurs in some patients with IDDM (46, 47) but has not been demonstrated convincingly in other conditions.

Glucagon

Glucagon is secreted from the α cells of the pancreatic islets into the hepatic portal circulation and is thought to act predominantly on the liver under physiologic conditions. It exerts its effects through activation of adenylate cyclase (48) (Fig. 44.3A). Cyclic adenosine monophosphate (AMP) concentrations in liver rise within seconds after administration of glucagon. Glucagon is a potent activator of glycogenolysis and gluconeogenesis and is able to increase EGP within minutes, although the effect is transient. Glucagon decreases levels of fructose-2,6-bisphosphate, a key regulator of gluconeogenesis and glycolysis. Despite ongoing hyperglucagonemia, EGP decreases toward basal levels within 90 minutes. Glucagon-induced hyperglycemia is transient because the increase in glycogenolysis does not persist. This transient response is not the result of glycogen depletion, but more likely of glucagon-induced insulin secretion coupled with an autoregulatory effect of hyperglycemia to inhibit EGP. (See Chapter 37 for a more detailed discussion of cell signaling.)

During fasting in humans, about 75% of EGP is mediated by glucagon (49). In circumstances of combined glucagon and insulin deficiency, the decreased glucose production may not be balanced by decreased insulin-mediated glucose use because only about 40% of glucose use occurs in insulin-sensitive tissues. Therefore, plasma glucose concentrations would remain constant or even fall. The effect of insulin on the liver is to oppose the effect of glucagon (50). Insulin deficiency has a minimal influence on hepatic glucose and ketone metabolism in the absence of glucagon, and significant overproduction of glucose and ketones by the liver does not occur without glucagon (51).

Glucagon deficiency, produced experimentally by infusion of somatostatin with partial insulin replacement, reduces nadir glucose concentrations after glucose ingestion by

approximately 30%. Patients who have glucagon deficiency from pancreatectomy manifest decreased rates of glucose “recycling” (measured as the difference between 6-³H-glucose and 1-¹⁴C- glucose turnover rates, an index of gluconeogenesis) and increased serum concentrations of gluconeogenic precursors such as alanine and lactate (52). However, prolonged hypoglycemia does not occur because it is prevented by epinephrine secretion. As noted above, combined glucagon and epinephrine deficiency, as seen in some longstanding IDDM subjects, totally disrupts the counterregulatory process and results in hypoglycemia late after glucose ingestion. Diminished glucagon response to insulin-induced hypoglycemia is in part related to concomitant insulin-induced hypoaminoacidemia (53).

Exercise requires increased glucose production to counterbalance the increased glucose use that occurs with muscular work. Approximately 60 to 70% of the increased glucose production is mediated by increased glucagon secretion coupled with inhibited insulin release; another 30 to 40% is the result of epinephrine secretion (54, 55). The changes in glucagon and insulin are associated with decreased fructose-2,6-bisphosphate concentration in liver with resultant increased gluconeogenesis; simultaneous increases in epinephrine concentration produce increased concentrations of fructose-2,6-bisphosphate in nonexercising muscle with resultant stimulation of glycolysis and lactate production for use in gluconeogenesis (56). Combined glucagon deficiency and adrenergic blockade during exercise at 60% of maximal oxygen consumption produce profound hypoglycemia between 30 and 60 minutes of the exercise bout (54).

Glucagon excess, as seen in islet-cell glucagonoma, is associated with glucose intolerance, hypoaminoacidemia, and a characteristic rash, “necrolytic migratory erythema,” thought to result from either the hyperglucagonemia or the decreased plasma amino acid levels (57, 58). The glycogenolytic and gluconeogenic actions of glucagon result in mild hyperglycemia that can usually be controlled by dietary therapy. The syndrome is also characterized by increased resting energy expenditure that is blunted by insulin infusion (59). The cause of the hypermetabolism is unknown.

Somatostatin

Somatostatin is a peptide hormone of 14 amino acids that originates from the d cells of pancreatic islets. Its general effect is to inhibit cellular secretion of other peptides, particularly peptide hormones. In the somatostatinoma syndrome (60), seen in somatostatin-producing islet cell adenomas, suppression of both insulin and glucagon causes mild diabetes mellitus. Neither the hyperglycemia nor the hyperketonemia is severe, most likely because of glucagon and growth hormone suppression. The somatostatin analogue octreotide can similarly blunt postprandial glycemic excursions in IDDM patients and decrease prandial insulin requirements (61).

Lipid Metabolism

Insulin and glucagon also play important roles in lipid metabolism; increased insulin concentrations stimulate lipogenesis and lipid storage, and the decreased insulin and increased glucagon levels seen in fasting promote lipolysis and lipid oxidation (62). The

major function of stored triglyceride in adipose tissue is to act as an efficient energy reserve. Triglyceride stores can serve as fuel to support many weeks of fasting, whereas stored carbohydrate can support a fast of only several hours. Stored triglyceride yields over twice as many calories per gram as either carbohydrate or protein and requires less than half as much intracellular water for storage.

In the fed state, insulin and glucose are required for lipogenesis. Glucose use is needed for fatty acid synthesis and esterification and supplies the following: (a) acetyl coenzyme A (CoA) as a precursor of long-chain fatty acids, (b) α-glycerophosphate for esterification to fatty acids to form triglycerides, and (c) nicotinamide adenine dinucleotide phosphate (NADPH). Insulin stimulates carrier-mediated glucose transport, and (a) activates pyruvate dehydrogenase for conversion of glucose to acetyl-CoA (63), and (b) inhibits lipolysis, thereby reducing concentrations of palmitoyl-CoA, an inhibitor of lipogenesis (64). In humans, however, less than 1% of ingested carbohydrate is converted to lipid (65). The mixed fat and carbohydrate intake of humans allows dietary fat to supply lipid for storage in a more energy efficient process than would be achieved if significant lipogenesis from carbohydrate occurred (i.e., 2 vs. 23% of ingested calories, the cost of storing these nutrients as lipid) (66). Nonetheless, recent studies suggest that consumption of a diet with very high carbohydrate and low fat content stimulates lipogenesis from carbohydrate in humans. Very low density lipoprotein (VLDL)-triglyceride produced from de novo synthesis increases from 0% on a high-fat diet (40% fat) to 44% on a very low fat, high-carbohydrate diet (10% fat) (67).

Fatty acids stored in adipose tissue as triglycerides are derived from either dietary (chylomicrons) or endogenous (hepatic VLDL) sources. Preformed triglycerides are transported from the gastrointestinal tract and liver to adipose tissue, where they are hydrolyzed by the enzyme lipoprotein lipase (LPL) on the cell surface of the capillary endothelium. Insulin has an important role in maintaining and stimulating the activity of LPL (68). In addition, insulin has a direct stimulatory effect on free fatty acid uptake by adipose tissue. During insulin deficiency, LPL activity is reduced, and uptake of free fatty acids by adipose tissue is diminished (69).

In humans, liver as well as adipose tissue is a major site of lipid synthesis, occurring when dietary fat is replaced by carbohydrate. The liver removes a large proportion of circulating free fatty acids delivered from adipose tissue in a concentration-dependent manner. Fatty acids synthesized in the liver are converted mainly to VLDLs, which are secreted into plasma and then cleared from the circulation within minutes to hours by mechanisms similar to those involved in the removal of chylomicron triglycerides (see [Chapter 4](#) and [Chapter 74](#)). During insulin deficiency, hexose monophosphate shunt activity is impaired, and NADPH is not provided for fatty acid synthesis (70). In addition, decreased glucose use reduces the availability of acetyl-CoA and citrate, which retards lipogenesis.

Lipolysis, with a net release of free fatty acids and glycerol from adipose tissue, occurs during fasting, exercise, stress, and uncontrolled diabetes mellitus. Low levels of insulin and perhaps increased glucagon concentrations enhance this mobilization of lipid from adipose tissue (62). The latter effect of glucagon to increase lipolysis has been variable, may be influenced by the effect of glucagon to increase inhibitory insulin levels, and

remains somewhat controversial (71). Insulin reduces catecholamine-stimulated cAMP concentrations in adipose tissue (72), by either decreasing adenylate cyclase and/or increasing phosphodiesterase activity (73). With lipolysis, glycerol diffuses out of the adipocyte, because adipose tissue lacks the enzyme glycerolkinase and cannot reuse glycerol. Free fatty acids can either be released into the circulation or reesterified with glycerol phosphates into triglycerides in adipose tissue. Part of the antilipolytic action of insulin is to stimulate reesterification of fatty acids.

After release from adipose tissue, glycerol and free fatty acids circulate briefly in the plasma. Glycerol is metabolized primarily in the liver and kidney, where it is phosphorylated and either reesterified to triglyceride or used for gluconeogenesis. Free fatty acids are taken up by tissues in proportion to local blood flow and plasma concentrations. The potential fate of those taken up by the liver includes reesterification to triglyceride, oxidation, or conversion to ketone bodies, depending on the hormonal milieu. In the absence of either glucose or insulin and in the presence of glucagon, only a small proportion of the free fatty acids taken up by the liver is reesterified to triglyceride and released as VLDL. The insulin:glucagon ratio (74) appears to be critical in regulating hepatic metabolism of free fatty acids.

Activated fatty acids must be transported into the mitochondria for oxidation or conversion to ketone bodies, and neither free fatty acids nor their CoA derivatives can penetrate the inner mitochondrial membrane. Carnitine palmitoyl transferase I, an enzyme present on the inner mitochondrial membrane, reversibly transfers fatty acyl groups from CoA to carnitine and allows entry into the mitochondria. A second enzyme, carnitine palmitoyl transferase II, irreversibly transfers the fatty acyl groups to mitochondrial CoA, allowing them to undergo either β -oxidation or conversion to the ketone bodies acetoacetate and β -hydroxybutyrate. The activity of the key enzyme, carnitine palmitoyl transferase I, is regulated via the effects of insulin and glucagon on malonyl-CoA concentrations (75). In addition to their effects on carnitine palmitoyl transferase I activity, low insulin and high glucagon concentrations also contribute to increased lipid oxidation and ketogenesis by increasing adipose tissue lipolysis and free fatty acid delivery. Ketone bodies circulate in plasma and are metabolized in skeletal muscle and heart and brain tissues.

Alterations in lipid metabolism are frequently present in subjects with diabetes mellitus, with hypertriglyceridemia occurring in approximately one-third of patients. This finding is related to the key role insulin plays in both hepatic triglyceride production and removal of triglyceride-rich lipoproteins (76). Insulin is essential for the normal function of LPL; in severe insulin deficiency, hypertriglyceridemia is secondary to acquired LPL deficiency. "Diabetic lipemia," with milky plasma and eruptive xanthoma, may result from coexistent poorly controlled IDDM and a familial form of hypertriglyceridemia (77). This defect is promptly reversed with appropriate insulin replacement. Withdrawal of insulin from subjects with IDDM can produce decreased LPL activity and hypertriglyceridemia within 48 hours.

Obese subjects, both with and without diabetes, have higher than normal rates of VLDL triglyceride production (78, 79), probably related to an increased flow of glucose and free fatty acids to the liver as part of an insulin resistance syndrome (80). Free fatty acid

delivery to the liver is enhanced when adipose tissue is deposited in an intraabdominal depot. This form of hypertriglyceridemia responds dramatically to weight reduction (81).

The predominant insulin deficiency of IDDM and the predominant insulin resistance of NIDDM have other widespread effects on lipoprotein metabolism (82). In IDDM, this may include increased low-density lipoprotein (LDL) from decreased insulin-stimulated LDL-receptor activity. However, no consistent abnormalities are noted in the physicochemical properties of LDL or VLDL lipoproteins in IDDM patients (83). In NIDDM, abnormalities include (a) low levels of high-density lipoprotein (HDL) from decreased transfer of surface components of triglyceride-rich lipoproteins to HDL, (b) triglyceride enrichment of LDL and VLDL particles, and (c) accumulation of VLDL remnant particles, related perhaps in part to an increased ratio of apoprotein CIII to CII. Nonenzymatic glycosylation of lipoproteins in both forms of diabetes may further alter their clearance characteristics such that LDL catabolism is decreased and HDL catabolism is increased (84).

The effect of dietary composition on lipoprotein metabolism in diabetes remains controversial. Current recommendations maintain that less than 10% of energy should be consumed as saturated fat. The remaining nonprotein energy should be tailored to the patient's individual response to dietary carbohydrate (85). Some patients experience exacerbation of hypertriglyceridemia with high intake of dietary carbohydrate. Some investigators suggest that a moderate carbohydrate intake with expanded use of monounsaturated fats provides the most effective control of the VLDL elevation and low HDL of type 2 diabetes (81, 86, 87).

Protein Metabolism

Insulin and other hormones play an important role in protein metabolism. Within several hours of starvation, protein catabolism is increased to provide amino acids for gluconeogenesis. With more prolonged starvation, metabolic adjustments occur that spare muscle protein, such as increased reliance by the central nervous system on ketone bodies as an oxidative fuel (see Chapter 41). Nonetheless, muscle continues to yield a net release of amino acids as plasma insulin levels fall during prolonged starvation; the phenomenon can be reversed completely when insulin delivery is increased (88). When fuel supplies become plentiful, protein synthesis is restored.

Insulin lowers blood concentrations of several amino acids in both normal and diabetic subjects in a time pattern resembling that for glucose concentration. The serum insulin concentrations required to produce half-maximal suppression of plasma amino acid concentrations are similar to those required for half-maximal stimulation of peripheral glucose disposal (89). Plasma levels of the essential amino acids are lowered in a pattern that corresponds to their relative concentrations in muscle protein. Isolated muscle preparations incubated in vitro liberate amino acids; the rate of release is depressed by addition of insulin. The presence of glucose may be necessary for insulin-mediated inhibition of heart muscle proteolysis (90). Insulin also inhibits intracellular protein degradation in isolated hepatocytes, an effect that depends on internalization of insulin by the cells (90). In addition to inhibiting release, insulin also stimulates accumulation of amino acids in skeletal muscle. Of the seven identified

amino acid transport systems, insulin most potently stimulates two, the A and the X_{sc} systems (transporters for neutral amino acids and long-chain anionic amino acids, respectively) (91). System A is similarly regulated by insulin in hepatocytes (92). The primary effect of insulin is to increase the V_{max} of transport, felt to represent an increase in plasma membrane transporter number. Other studies have shown that the ASC and N^m systems (system ASC shows preference for alanine, serine, and cysteine and is relatively pH insensitive; system N^m is a sodium-dependent transport system for amino acids with N-containing side chains, like Gln, His, Asn) are also stimulated by insulin, the latter more potently (93, 94). Though circulating concentrations of branched-chain amino acids such as leucine, isoleucine, and valine are dramatically decreased by insulin and their muscle uptake is stimulated, there is no evidence that insulin stimulates the branched-chain amino acid transport system (system L) (95). It is possible that the effect of insulin to decrease branched-chain amino acid concentrations is related to its ability to inhibit protein degradation, thereby decreasing intracellular concentrations of these essential amino acids and promoting their movement into cells down a concentration gradient.

Prior exercise may potentiate the ability of insulin to increase amino acid uptake by muscle tissues (96). Exercise additionally inhibits amino acid release from skeletal muscle protein, but the effect appears limited to nonmyofibrillar proteins (97). When added to isolated muscle preparations, insulin promotes incorporation of labeled amino acids into tissue protein (98). At the subcellular level, protein synthesis appears to be stimulated in both cytoplasm and mitochondria (99).

Insulin stimulates incorporation of labeled precursors into nucleic acid (100). Although insulin increases RNA synthesis in muscle, the increase does not appear requisite for hormone-mediated stimulation of protein synthesis; actinomycin, an inhibitor of RNA synthesis, does not impair the ability of insulin to increase protein synthesis (101). To the extent that insulin promotes protein synthesis, it appears to do so by stimulating translation rather than transcription. Specifically, insulin, through insulin-receptor-substrate-1 (IRS-1) and phosphatidylinositol-3-kinase (PI3K), dissociates regulatory peptides from eukaryotic initiation factor eIF-4E and phosphorylates eIF-4E itself, allowing it to initiate translation (102, 103).

The importance of insulin in regulation of protein balance was demonstrated most clearly in subjects with IDDM who rapidly develop negative nitrogen balance with cessation of insulin therapy. In heart and most skeletal muscles studied, the absolute protein content (i.e., the quantity of protein per tissue or organ) was significantly lower in diabetic, than in control, animals. In contrast, the protein content of liver was unaffected in those with diabetes (104). The most significant loss of protein in vivo, as the result of insulin deficiency, occurs in muscle. Studies using stable isotopes of amino acids to examine rates of whole-body protein turnover and oxidation demonstrated increased rates of protein degradation and leucine oxidation in insulin-deprived IDDM subjects, which could be decreased by insulin infusions (105). In vitro (106) and animal (107) studies have demonstrated decreased rates of protein synthesis in diabetes. In contrast, increased rates of protein synthesis were found in insulin-deprived IDDM human subjects, although protein breakdown was more accelerated (108). The postulated mechanism for this increase in protein synthesis in vivo, not found in vitro, is that

accelerated protein degradation provides increased intracellular free amino acid concentrations as precursors for protein synthesis. Conversely, insulin administration to insulin-dependent diabetic patients decreases intracellular free amino acid concentrations through inhibition of protein degradation in skeletal muscle, resulting in an inability of insulin to increase muscle protein synthesis in vivo ([109](#), [110](#)).

A persistent theme in all of these hypotheses about the effects of insulin on protein metabolism in vivo in humans is that amino acid concentrations in the circulation are important for maintenance of protein synthesis, particularly in muscle, and that the effect of insulin to decrease amino acid concentrations may blunt its effect to stimulate protein synthesis. Recent reports indicate that local infusion of insulin into the legs of human subjects at rates that do not affect systemic amino acid concentrations augments extraction of several amino acids from the circulation by leg tissues and stimulates muscle protein synthesis ([111](#)).

Given the importance of insulin in maintaining nitrogen balance, inhibiting protein degradation, and stimulating protein synthesis, it is reasonable to speculate that the dietary protein requirements of patients with insulin-dependent diabetes might be increased to counterbalance the abnormal regulation of insulin as an anabolic hormone. Some authors have reported resistance to insulin-mediated suppression of branched-chain amino acid (BCAA) plasma concentrations ([112](#)), and rates of BCAA turnover and oxidation ([113](#)) in IDDM. Others have shown that IDDM patients following a diet containing the mean minimum adult requirement for protein experience decreases in muscle strength, persistently negative nitrogen balance, and increased adiposity ([114](#)). However, close examination of amino acid metabolism in IDDM patients consuming the minimum protein requirement reveals a normal adaptation to the dietary protein restriction as long as the subjects are euglycemic ([115](#)). Indeed, investigators have reported normalization of whole-body amino acid metabolism in IDDM with prolonged tight glycemic control ([116](#)). Protein requirements in IDDM appear to be determined by the chronic level of glycemic control ([117](#)).

Glucagon has three effects on amino acid metabolism: (a) increased membrane transport of amino acids, (b) decreased protein synthesis and increased catabolism (when accompanied by insulin deficiency, both protein degradation and amino acid oxidation rates increase), and (c) increased amino acid conversion into glucose (gluconeogenesis) ([118](#), [119](#)). Glucagon increases gluconeogenesis in perfused liver, an effect that can be reproduced by perfusion with cyclic AMP. Glucagon increases hepatic use of glycine, alanine, glutamate, and phenylalanine for gluconeogenesis. In addition, glucagon increases the rate of ureagenesis.

During early starvation, plasma glucagon and insulin concentrations increase and decrease, respectively, resulting in increased rates of gluconeogenesis and ureagenesis. Splanchnic extraction of alanine is increased from 43% in the postabsorptive state to 71% after 3 days of fasting, but this value decreases to 53% after 6 weeks of fasting ([120](#)). These effects of fasting are mimicked by glucagon infusion ([121](#)). With prolonged starvation, the brain adapts by developing the capacity to use ketone bodies as an energy source, thereby decreasing the need for increased

rates of gluconeogenesis.

Glucagon can increase liver protein catabolism in the intact animal; liver protein content is decreased and branched-chain amino acid release from the liver is increased. This increased protein catabolism can be suppressed by administration of insulin or a mixture of amino acids. When protein is ingested without accompanying carbohydrate, insulin concentrations increase slightly, allowing skeletal muscle protein retention, with a parallel rise in glucagon (25) that prevents hypoglycemia (122).

As mentioned above, patients with glucagonoma syndrome commonly exhibit hypoaminoacidemia. When similar degrees of hyperglucagonemia are produced by infusions of glucagon in normal volunteers, reductions in blood amino acid concentrations are similar (123). High-protein diets can normalize the plasma amino acid profile and result in a positive nitrogen balance in patients with glucagonoma syndrome (124). When glucagon deficiency is produced by infusions of somatostatin with insulin replacement, amino acid concentrations increase (125). Urinary urea nitrogen and total nitrogen excretion rates are lower during glucagon deficiency than during glucagon excess, suggesting that alterations in the rate of gluconeogenesis constitute one mechanism by which glucagon influences blood amino acid levels.

GUT PEPTIDES: GLP-1, GIP, CCK

It is reasonable that the first organ to encounter nutritional substrate, the gut, should initiate anabolic stimuli for nutrient storage (see [Chapter 39](#)). Certain peptide hormones produced by the gut clearly contribute to general body anabolism. In particular, glucose-dependent insulinotropic peptide (GIP; previously known as gastric inhibitory polypeptide), cholecystokinin C-terminal octapeptide (CCK-8), and glucagon-like peptide 1 (GLP-1) enhance anabolism through their stimulation of insulin secretion in response to meal ingestion. GLP-1 is several times more potent as an insulin secretagogue than GIP (126). Its antagonism results in an important disturbance in glucose tolerance in baboons (127), and its supplementation results in improved glucose control in humans with type 2 diabetes (128).

Other gut hormones are likely to contribute to trophic phenomena specific to the gut itself; examples include peptide YY that is trophic for gut mucosa. Peptide YY preserves gut mass in rats receiving total parenteral nutrition, a circumstance that generally results in gut atrophy (129). Additionally, pentagastrin, neurotensin, and bombesin provide trophic stimuli to the intestine of rats, particularly the jejunum, during an atrophy-inducing elemental diet (130).

THYROID HORMONES

Carbohydrate Metabolism

Thyroid hormones exert multiple effects on carbohydrate metabolism. Patients with hyperthyroidism frequently (30–50%) display mild-to-moderate glucose intolerance (131, 132 and 133). Part of this abnormality is due to more-rapid gastric emptying and

intestinal absorption of glucose in hyperthyroidism (134), whereas glucose absorption is delayed in hypothyroidism. Additionally, insulin secretion is reduced in hyperthyroidism in response to oral, but not intravenous, administration of glucose (135) and may be accompanied by impaired processing of proinsulin to insulin (136).

Rates of hepatic glucose production are increased by 20% in the fasting state, and the liver is less sensitive to insulin infusions in hyperthyroid human subjects (137). Hepatic glycogen stores are reduced in states of thyroid hormone excess. Thyroid hormones appear to modulate the magnitude of the glycogenolytic and hyperglycemic actions of epinephrine and norepinephrine, possibly by enhancing the responsiveness of the adenylate cyclase–cyclic AMP system. In rats, thyroid hormone exerts a biphasic effect on liver glycogen. Small doses of thyroid hormone increase glycogen synthesis in the presence of insulin, whereas large doses augment hepatic glycogenolysis. Small doses of thyroid hormone enhance, and large doses depress, the glycogenolytic response to epinephrine (138). The glycogen content of liver and muscle tissues is decreased in hypothyroidism, possibly reflecting a new balance between simultaneously decreased rates of glycogen synthesis and degradation (139).

Rates of gluconeogenesis are also increased in hyperthyroidism, in part because of an increase in substrate supply from protein breakdown and lipolysis. Splanchnic uptake of gluconeogenic precursors is increased by 20 to 120% in hyperthyroidism (137). Gluconeogenesis is suppressed in hypothyroidism. In vitro, addition of T₃ to hypothyroid hepatocytes stimulates hepatic gluconeogenesis by approximately 80 to 90% within 30 to 40 minutes (139).

Rates of total glucose disposal during euglycemic, hyperinsulinemic clamp studies were normal, suggesting that skeletal muscle is not insulin resistant in hyperthyroidism (140). However, in vitro skeletal muscle preparations from hyperthyroid rats display rates of insulin-stimulated glucose oxidation that are significantly (twofold) increased, whereas rates of glycogen synthesis are reduced (141). Oxidative glucose use appears to be synergistically stimulated by exercise and thyroid hormones.

Total-body-glucose turnover rates are increased in thyrotoxicosis. Most of the increased glucose turnover is accounted for by increased glucose recycling. Recycling through both the Cori (glucose-lactate) and the glucose-alanine cycles increases in hyperthyroidism and decreases in hypothyroidism (138). In addition, patients with hyperthyroidism form hexose intermediates of both glycolysis and gluconeogenesis simultaneously at increased rates (i.e., glucose \rightleftharpoons glucose-6-P and fructose-6-P \rightleftharpoons fructose-1,6-di-P) (142). In part, thyroid hormone facilitates these cycling phenomena by stimulating glucose-transporter gene expression and enhancing glucose transport across the plasma membrane in muscle and liver cells (143, 144). Likewise, thyroid hormone increases insulin-stimulated glucose transport in skeletal muscle by increasing GLUT4 content (145) but produces a simultaneous increase in GLUT2 in the liver to facilitate hepatic glucose output (146).

Lipid Metabolism

Thyroid hormones also have an impact on multiple aspects of lipid metabolism,

including lipid synthesis, mobilization, and degradation. Degradation is affected more than synthesis, so the net effect of excess thyroid hormone is decreased total body lipid stores and plasma concentrations. Thyroid hormones increase lipolysis in adipose tissue by both directly stimulating cyclic AMP production and increasing the sensitivity to other lipolytic agents (catecholamines, TSH, ACTH, growth hormone, glucocorticoids, and glucagon). Conversely, lipolysis is impaired in hypothyroidism.

Delivery of free fatty acids to peripheral tissues and the liver is increased in hyperthyroidism. Free fatty acid turnover rates are approximately doubled in thyrotoxicosis (147). Lipid oxidation rates are also increased in thyrotoxicosis, which may contribute to the calorogenic action of thyroid hormones.

Hepatic triglyceride synthesis increases in hyperthyroidism, in large part because of increased delivery of free fatty acids and glycerol to the liver. Synthesis and clearance of cholesterol and triglyceride are accelerated in hyperthyroidism, with the latter effect predominating. Serum cholesterol and triglyceride levels are usually modestly reduced (148). Conversely, serum lipid levels may increase in hypothyroidism because of impaired clearance. HDL-cholesterol levels decrease in hypothyroidism, even at a subclinical stage, and revert to normal with thyroxine therapy (149). Both hepatic and adipose tissue LPL activity has been reported to be low in hypothyroidism (150, 151).

At a cellular level, lipid transfer into and out of membranes is altered by thyroid hormone. Cholesterol is transferred out of erythrocyte plasma membranes into plasma in hyperthyroidism, resulting in a higher relative phospholipid content in the erythrocyte membrane (152). The hyperthyroidism-induced change in the lipid content of mitochondrial membranes allows increased phosphate transport (153)—teleologically, a favorable compensation for partially uncoupled electron transport in this condition.

Protein Metabolism

Short-term administration of thyroid hormones produces increases in liver protein and RNA content, with a concomitant decrease in muscle protein. With more prolonged administration, both liver and peripheral tissues decrease in size (154). Thyroid hormone increases amino acid uptake by the liver and increases incorporation of amino acids into protein by isolated liver microsomes and mitochondria (155). The latter does not occur in the presence of actinomycin, suggesting that these effects of thyroid hormone are mediated by DNA transcription and RNA translation (156).

Clinically, a great excess of thyroid hormone appears to have the opposite effect, with suppressed rates of protein synthesis (157), increased catabolism of collagen (158), and increased forearm amino acid release (159) in human subjects. Nitrogen excretion increases in thyrotoxicosis, and nitrogen balance may be normal or negative depending on whether intake meets the increased demand.

In hypothyroidism, rates of protein synthesis and degradation both decrease. Patients are usually in positive nitrogen balance. Treatment of myxedema is accompanied by mobilization of extracellular protein and a significant temporary negative nitrogen

balance. Total serum protein concentrations are usually normal in hypothyroidism.

Thyroid hormone, particularly T_3 in the intracellular environment, regulates production of a wide range of proteins through its interaction with its nuclear receptor—a member of a family of hormone-responsive nuclear receptors. The interaction of thyroid hormone with its receptor and its actions on particular tissues has been reviewed in detail (160). Proteins that exhibit increased production and expression of their respective genes include myosin a-chain, Na^+ - K^+ ATPase, Ca^{2+} -ATPase, malate dehydrogenase, glucose 6-phosphate dehydrogenase, fatty acid synthase, hepatic lipase, and LDL receptor of certain genotypes.

Taken together, the metabolic effects of thyroid hormone can be interpreted as indicating a role for thyroid hormone in maintaining substrate turnover. Maintaining activity in metabolic pathways that simultaneously produce and consume metabolic substrates, though energetically costly, may be beneficial in allowing the organism to produce or degrade a particular product rapidly in response to urgent need. The need may be particularly frequent during growth and development, when tissue remodeling might be expected. The role of thyroid hormone in simultaneously stimulating glycogen synthesis and glycogenolysis, lipogenesis and lipolysis, and protein synthesis and proteolysis is consistent with its importance for normal growth and development.

GLUCOCORTICOIDS

Carbohydrate Metabolism

Corticosteroids in excess produce increases in plasma insulin and glucose concentrations, i.e., a state of insulin resistance. This resistance is out of proportion to the degree of obesity seen in patients with Cushing's syndrome (161, 162 and 163). Glucose intolerance in association with Cushing's syndrome has been reported in 80 to 90% of patients, although overt diabetes occurs in only 15 to 20% of subjects (164, 165).

Glucocorticoids counteract the effects of insulin at numerous steps in glucose homeostasis. First, rates of gluconeogenesis may be augmented by several mechanisms: (a) increased release of gluconeogenic precursors, i.e., amino acids (166) and lactate (167), from peripheral tissues; (b) increased activity of key gluconeogenic enzymes (168), including pyruvate carboxylase and phosphoenolpyruvate (PEP) carboxykinase, the unidirectional, rate-limiting enzyme in the initiation of the gluconeogenic cascade from pyruvate; and (c) stimulation of glucagon secretion by pancreatic α cells (166, 169). The latter effect may be the result of increased proteolysis and hyperaminoacidemia. Corticosteroids act in conjunction with glucagon to increase rates of gluconeogenesis in perfused rat liver (170).

The physiologic nocturnal increase in cortisol in humans contributes to maintenance of gluconeogenesis postprandially (171), perhaps in part due to increased lipolysis and fatty acid delivery to the liver as well as decreased insulin secretion with increased glucagon production during hypercortisolemia (172). However, other in vivo human

studies implicate increased glucose-6-phosphatase activity rather than gluconeogenesis as the cause of increased hepatic glucose output in response to dexamethasone (173). Likewise, studies in insulin-deficient dogs indicate that cortisol does not increase gluconeogenesis (174), whereas insulin deficiency itself and epinephrine are potent promoters of gluconeogenesis. Thus, the subject remains controversial.

The second way in which glucocorticoids may affect glucose tolerance is by decreasing production of glucose transporters and promoting their sequestration in intracellular pools rather than at the plasma membrane, an effect reported in rat adipocytes (175) and fibroblasts (176). Third, glucocorticoids decrease insulin binding to its receptor through decreases in receptor affinity (177, 178) and number (175). Finally, glucocorticoids may induce postreceptor defects in insulin action that remain to be characterized (162, 179). The hyperglycemic action of glucocorticoids is amplified if increases in glucagon, catecholamines, or growth hormone exist (180, 181). However, in regard to epinephrine, this synergism may only occur when epinephrine levels are elevated briefly in the presence of increased cortisol and not during prolonged (72-h) elevation of levels of both hormones (182).

Glucocorticoids stimulate hepatic glycogen deposition and in this regard resemble insulin. The carbon for this new liver glycogen is derived from breakdown of muscle protein with release of amino acids. The activity of glycogen synthase, the rate-limiting enzyme for glycogen synthesis, is decreased in adrenalectomized rats and restored to normal by corticosteroid treatment.

Lipid Metabolism

Glucocorticoids appear to exert a permissive effect on lipolysis through activation of cyclic AMP–dependent hormone-sensitive lipase in the adipocyte. Epinephrine-induced lipolysis is promoted by cortisol (183), which appears necessary for full stimulation of lipolysis by catecholamines (184). Glucocorticoids are similarly required for maximal lipolytic action of growth hormone. The lipolytic action of cortisol is prevented by inhibitors of protein synthesis (185).

Prolonged treatment with glucocorticoids may result in increased plasma triglyceride concentrations (186). This effect is seen most often in the presence of diabetes mellitus and primarily reflects impaired triglyceride removal. However, hepatocytes in culture increase triglyceride production and VLDL-apoprotein synthesis when incubated with glucocorticoids (187). LDL uptake and degradation by cultured fibroblasts and smooth muscle cells are also impaired by high doses of glucocorticoids (188). Chronic glucocorticoid treatment may result in a “fatty liver,” because of increased lipolysis and free fatty acid delivery associated with enhanced hepatic uptake of free fatty acids.

A chronic excess of corticosteroids also increases total body fat in humans and in laboratory animals. Pair-feeding experiments suggest that increased food intake is the major factor contributing to obesity in steroid-treated rats (189). Changes in body fat distribution are also characteristic of Cushing's syndrome, with accumulations of fat in the supraclavicular, truncal, and facial areas (190). Increased energy intake in excess of a small increase in energy expenditure has been confirmed as the cause of excess

energy storage during glucocorticoid administration in humans (191). The mechanism by which this occurs is unknown but is speculated to be partly related to inhibition of corticotropin-releasing hormone (CRH)-stimulated neuropeptide Y (NPY) secretion in the hypothalamus. The altered fat distribution in humans with Cushing's syndrome is associated with enhanced adipocyte LPL activity and diminished lipolytic response to catecholamines in abdominal fat, compared with femoral-region fat (192). In addition, glucocorticoid receptor number and its mRNA are increased in abdominal region subcutaneous fat, compared with femoral region subcutaneous fat, and they are increased even more in omental adipose tissue (193).

Administration of ACTH stimulates lipolysis through cyclic AMP-mediated activation of adipose tissue hormone-sensitive lipase. This is a direct action of ACTH, because it is demonstrable in adrenalectomized animals (194).

Protein Metabolism

One of the major metabolic effects of glucocorticoids is to stimulate skeletal muscle protein breakdown. Many of the clinical features of Cushing's syndrome, such as loss of bone density, increased capillary fragility and dermal atrophy, muscle wasting, and growth retardation in children, are attributable in part to this augmented proteolysis. In addition to increasing protein breakdown, corticosteroids also appear to inhibit incorporation of amino acids into muscle protein (195, 196). Elevations of cortisol levels within the physiologic range increase muscle proteolysis, with increased activation of muscle branched-chain ketoacid dehydrogenase and BCAA oxidation (197, 198), de novo alanine synthesis (199), and muscle glutamine release (200). Corticosteroid inhibition of muscle protein synthesis is sustained during prolonged elevation of glucocorticoid levels in the rat, whereas muscle proteolysis shows adaptation toward normal levels within a few days (201). Thus, diminished protein synthesis rather than proteolysis may account for long-term effects of glucocorticoids that produce muscle wasting. The mechanism of adaptation of muscle myofibrillar protein breakdown is unknown; nonmyofibrillar muscle proteins may be spared by adaptive increases in insulin (202).

Administration of glucocorticoids results in increased protein and RNA content in liver and other viscera (203). Amino acids delivered as a result of enhanced muscle proteolysis and decreased peripheral use for protein synthesis are transported to the liver where they can be used for protein synthesis. Administration of cortisol to rats results in enhanced hepatic uptake of α -aminoisobutyric acid (196) and increased free amino nitrogen concentrations in the liver (204). These effects of glucocorticoids depend on the diet, with increased protein synthesis occurring when the caloric and protein contents of the diet are adequate. Under circumstances of systemic inflammatory processes, glucocorticoids increase hepatocyte receptors for interleukin 6, a potent stimulator of synthesis of acute-phase proteins such as C-reactive protein and fibrinogen (205).

The pattern of metabolic effects induced by cortisol (and other hormones with glucocorticoid effect) substantiates its role as a "stress hormone." Glucocorticoids produce not only catabolism with dissipation of nutritional substrate but also anabolism

such that substrate is rearranged. The simultaneous stimulation of gluconeogenesis and glycogen deposition, lipolysis and abdominal lipid deposition, muscle proteolysis and visceral (e.g., hepatic) protein synthesis increases resting energy expenditure during glucocorticoid excess (206). One may speculate teleologically that the energy is well spent in rearranging substrate into depots most accessible during stress—liver glycogen, abdominal fat, and hepatic protein.

GROWTH HORMONE AND INSULIN-LIKE GROWTH FACTOR–1 (IGF-1)

In considering the metabolic effects of growth hormone, it is important to distinguish the direct effects of growth hormone from those of IGF-1. IGF-1 is synthesized by liver and other tissues in response to stimulation by growth hormone, although nutritional intake appears to have a direct effect on IGF-1 production. In normal human volunteers, IGF-1 levels decline 60 to 70% during a 5-day fast (207). Studies in the rat have shown that both adequate dietary protein and total energy content are necessary to produce IGF-1-stimulated cartilage growth (208). The “somatomedin hypothesis” states that many of the anabolic, growth-promoting effects of growth hormone are mediated by IGF-1 (previously known as somatomedin C), whereas growth hormone has direct catabolic effects on glucose and lipid metabolism. The somatomedin hypothesis may not be entirely correct, as evidence is accumulating that growth hormone may have direct, specific anabolic actions.

Carbohydrate Metabolism

Acute administration of growth hormone elicits a biphasic response. During the initial 2 hours after administration, growth hormone exhibits an insulin-like effect, lowering plasma glucose levels by directly stimulating β -cell insulin secretion (209) and also by stimulating glucose use in peripheral tissues. Nonetheless, growth hormone does not produce hypoglycemia in normal subjects. It does have such an effect, however, in hypophysectomized animals that also have an impaired pituitary-adrenal axis (210). From 2 to 12 hours after acute administration, growth hormone exhibits antiinsulin effects. This state of insulin resistance results from a postreceptor defect in peripheral glucose use, coupled with hepatic insulin resistance (211, 212).

With chronic administration in animals and humans, growth hormone results in an insulin-resistant state. Glucose intolerance in association with acromegaly has been reported in 60 to 70% of patients, although elevated fasting plasma glucose concentrations are reported to occur in only 6 to 25% of acromegalic patients (213, 214, 215 and 216). Even more striking than glucose intolerance is the hyperinsulinemia and resistance to insulin that occur in acromegaly (214) and in patients receiving growth hormone by injection (217). In most patients, increased insulin secretion can compensate for the insulin-resistant state. Chronic excess of growth hormone results in increased rates of hepatic glucose production and decreased glucose use by peripheral tissues (218, 219), largely the result of decreased glucose oxidation (220). Whether the insulin resistance of acromegaly derives from defects at the level of the insulin receptor or is entirely postreceptor is controversial. Decreased peripheral glucose use in acromegaly is associated with a decreased number of insulin receptors on peripheral blood monocytes (221). However, the defect is not reproduced by incubation of

monocytes with acromegalic plasma or growth hormone. Furthermore, porcine adipocytes show no defects in insulin binding or insulin receptor tyrosine kinase activity with chronic growth hormone treatment (222). Elevations in the concentration of plasma free fatty acids and ketone bodies inhibit glucose use by muscle tissue and may in part explain the postreceptor defect seen in acromegaly (223). Successful treatment of acromegaly results in improved glucose tolerance and lower serum insulin concentrations in most patients (214, 224, 225). In contrast to acromegaly, chronic growth hormone deficiency produces increased insulin sensitivity.

Whereas chronic elevations in growth hormone concentrations produce antiinsulin effects, many of the actions of IGF-1 mimic those of insulin. This is not surprising given the structural similarities in tertiary configuration between IGF-1 and proinsulin (226). IGF-1 acts through a specific cell-surface receptor with substantial homology to the insulin receptor but can also stimulate the insulin receptor itself (227). IGF-1 increases glucose transport (228) and rates of glycolysis and glycogen synthesis (229) in heart and skeletal muscle tissues.

Lipid Metabolism

The acute effects of growth hormone administration on lipid metabolism are similar in their insulin-like nature to those described for glucose. Within the first few hours after growth hormone is given, plasma free fatty acid concentrations drop. In addition, reduced rates of epinephrine-stimulated lipolysis have been described in hypophysectomized rats during this early period after growth hormone administration (230).

Free fatty acid and ketone body levels increase as the result of longer-term growth hormone administration. Increased glycerol concentrations after in vivo administration of biosynthetic growth hormone in humans suggest stimulation of lipolysis (215). Growth hormone-mediated lipolysis is similar to that induced by glucocorticoids in that a lag time of at least 1 hour is required before the effect can be observed, and the lipolytic actions can be blocked by inhibitors of protein synthesis (231). Some investigators have shown significant growth hormone-mediated lipolysis to occur only in the presence of insulin deficiency (232, 233, 234 and 235). No lipolytic response to growth hormone is seen in vivo or in vitro in the growth hormone-deficient mouse (236). Rather, fatty acid synthesis is inhibited by growth hormone, suggesting a primary role for blunted lipogenesis in the deranged fat metabolism in this model. Ketogenesis occurs in response to increased free fatty acid delivery to the liver and as the result of a direct hepatic effect of growth hormone on ketone production (237).

Humans exhibit regional differences in the response of adipocyte lipolysis and lipogenesis to growth hormone: abdominal cells are more affected than are peripheral (e.g., gluteal) cells. This variation results in fat redistribution from “android” (truncal) to “gynoid” (hip/thigh) deposition in patients treated with growth hormone (238).

In contrast to the effects of growth hormone on lipid metabolism, IGF-1 increases lipogenesis and inhibits epinephrine-stimulated lipolysis in adipose tissue (239). IGF-1 infusion in humans decreases serum triglyceride levels and the ratio of total to HDL

cholesterol (240).

Protein Metabolism

One of the major effects of growth hormone is promotion of linear growth and skeletal maturation. IGF-1 is responsible for these effects, producing increased synthesis of DNA, RNA, and protein in fibroblasts and chondrocytes (241). While circulating IGF-1, responsible for linear skeletal growth, depends on the presence of growth hormone, IGF-1 secretion occurs in multiple tissues and may serve as an anabolic factor independent of growth hormone in tissue hypertrophy and repair by autocrine and paracrine actions (242, 243).

The exact physiologic roles for the anabolic actions of growth hormone and IGF-1 and their physiologic interdependence are not yet completely defined. Growth hormone administration stimulates amino acid uptake and incorporation into protein in both liver and skeletal muscle tissues (244). The effect on muscle is underscored by the absence of an effect of systemically administered growth hormone on whole-body protein synthesis in humans, even while forearm (largely composed of muscle) protein synthesis is stimulated (245). In humans, local administration of growth hormone to forearm skeletal muscle stimulates amino acid uptake (246). This response may occur without increases in systemic IGF-1 levels, suggesting that growth hormone effects in muscle are not necessarily mediated by IGF-1. However, the extent to which growth hormone can stimulate protein anabolism directly and independently of IGF-1 paracrine or autocrine actions remains controversial. Recent studies in rats support an independent role for growth hormone on muscle anabolism. Comparing the effects of growth hormone and IGF-1 administration on organ-specific protein synthesis indicated that growth hormone specifically promotes protein synthesis in skeletal muscle, while IGF-1 specifically promotes protein synthesis in gut (247) but not muscle. However, to complicate matters, the importance of each hormone for anabolism may depend on how anabolic responses are defined under given study conditions. For example, certain investigators have noted that while IGF-1 does not stimulate muscle protein synthesis in fed rats, anti-IGF-1 antibody decreases it below control values, suggesting that IGF-1 serves a permissive or facilitative role for skeletal muscle protein synthesis rather than a stimulatory role (248)—a function that may be considered anabolic by some and not others.

Despite the data suggesting a specific role for growth hormone in promoting skeletal muscle anabolism, there appears to be an absence of growth hormone effect on muscle strength in healthy adults, suggesting that the effect of growth hormone supplementation may be to stimulate production of noncontractile muscle proteins in this group (249, 250). However, growth hormone may have a modest effect in increasing muscle protein synthesis and strength in growth hormone-deficient patients, implying that growth hormone may facilitate maintenance of normal rates of muscle contractile protein synthesis (251).

What may be most obvious about the effects of growth hormone and IGF-1 on protein metabolism is that the current understanding of their actions is inadequate and that their functions and interdependence are likely to be complex. This is particularly true because

their actions vary with nutritional state and physiologic stress, circumstances in which growth hormone concentrations are often elevated in the face of catabolism.

INSULIN-LIKE GROWTH FACTOR–BINDING PROTEINS

Insulin-like growth factor–1 actions on nutrient substrates and nutrient stores cannot be completely understood without an examination of the binding proteins that largely sequester the growth factor. The biologic actions of these binding proteins and IGFs themselves have been reviewed in depth ([252](#), [253](#)). This section summarizes issues relevant to nutrient metabolism.

IGF-1 circulates with a high-molecular-weight (~150,000) binding complex consisting of a 46- to 53-kDa protein termed *insulin-like growth factor–binding protein–3* (IGFBP-3) complexed with an 88-kDa glycoprotein that does not bind IGF, called the acid labile subunit (ALS). IGFBP-3 production, like that of IGF-1, is stimulated by insulin. Its functions other than that of a carrier protein for IGF-1 are controversial. It is speculated to assist in delivery of circulating IGF-1 to the interstitium of peripheral tissues and to serve as a reservoir for IGFs during stress. The latter function may be activated by degradation of IGFBP-3 by specific proteases. The ability of IGFBP-3 to both stimulate and inhibit cellular functions independent of binding IGFs has been noted in cell culture, depending on the prevailing culture conditions. The physiologic relevance of these findings remains in question.

Another binding protein for IGF-1, IGFBP-1, is believed to either inhibit or stimulate its actions, depending upon whether it is phosphorylated (inhibitory) or nonphosphorylated (stimulatory). Its predominant action is believed to be inhibitory, which is consistent with the findings that IGFBP-1 is increased in the circulation during catabolic states such as uremia, insulinopenia, and starvation. IGFBP-1 may act directly to stimulate cellular anabolism (apart from IGF) by binding to a fibronectin-binding cellular integrin. The functional significance of integrin binding remains poorly described.

Other binding proteins believed to inhibit IGF-1 actions include IGFBP-2 and IGFBP-4. In contrast, IGFBP-5, largely associated with extracellular matrix, appears to potentiate IGF-1's actions. A sixth binding protein, IGFBP-6, remains poorly characterized in terms of its physiologic activity.

In summary, physiologic phenomena that raise or lower IGF-1 concentrations must be viewed in the context of the effect on the array of IGF-binding proteins. This may be particularly true when the effect of IGF-1 on a particular tissue is being examined, as the ability of IGFBPs to sequester IGFs and either inhibit or potentiate their actions may be particularly important within a local tissue milieu.

CATECHOLAMINES

The catecholamines are epinephrine, norepinephrine, and dopamine. Norepinephrine is secreted from the sympathetic neurons throughout the body and to a limited extent from the adrenal medulla. The principal secretory product of the adrenal medulla is

epinephrine. Both epinephrine and norepinephrine have α - and β -agonist activities, although norepinephrine predominantly produces α -adrenergic effects. The major stimuli to sympathetic nervous system stimulation and adrenomedullary secretion are physical exercise, circulatory dysfunction, trauma, cold exposure, pain, emotional stress, and hypoglycemia. Although combined increases in epinephrine and norepinephrine secretion occur with most stresses, hypoglycemia predominantly augments epinephrine secretion (254). However, epinephrine appears to be critical for recovery from hypoglycemia only in the absence of glucagon (255).

Carbohydrate Metabolism

Catecholamines have multiple effects on carbohydrate metabolism. α -Adrenergic stimulation inhibits insulin secretion, whereas β -adrenergic stimulation augments insulin release. The α -adrenergic inhibitory effects on pancreatic β -cell function generally prevail under conditions of stress or sympathetic nerve stimulation. Both α - and β -adrenergic stimulation appear to augment pancreatic glucagon secretion (256, 257).

Catecholamines increase glycogen breakdown in liver and muscle tissues. β -Adrenergic stimulation activates phosphorylase and inhibits glycogen synthase through a cAMP-dependent mechanism. In addition, the α -adrenergic system can activate phosphorylase and inhibit glycogen synthase through a cAMP-independent mechanism involving membrane calcium transport (258, 259, 260 and 261). Liver glycogenolysis appears to be mediated predominantly through α -adrenergic, cAMP-independent mechanisms. This conclusion derives from in vitro data showing inhibition of catecholamine-mediated hepatic glycogenolysis (and gluconeogenesis) by α -adrenergic, but not β -adrenergic, blocking drugs (260, 261 and 262). A study in conscious dogs, however, yielded contradictory findings (263). In contrast, skeletal muscle glycogenolysis is mediated by β -adrenergic stimulation of adenylate cyclase (264) and does not appear to be affected by α -adrenergic mechanisms (258, 265). The effects of catecholamines on muscle glycogen metabolism are antagonized by insulin and depend on glucocorticoids (266, 267 and 268).

As mentioned, catecholamines also stimulate hepatic gluconeogenesis through α -adrenergic mechanisms. Catecholamines increase delivery of gluconeogenic precursors to the liver through their lipolytic (glycerol) and muscle glycogenolytic (lactate and pyruvate) actions. In addition, α -adrenergic agonists increase hepatic uptake of amino acids and possibly lactate (269, 270). The decreases in circulating insulin and increases in glucagon concentrations after sympathetic stimulation also promote glycogenolysis and gluconeogenesis. However, dose-related increases in such activity occur as the result of direct hepatic effects of epinephrine when plasma insulin and glucagon are maintained at fixed concentrations (271).

Infusions of epinephrine resulting in physiologic elevations of plasma concentrations inhibit insulin-stimulated glucose uptake by peripheral tissues, even when plasma glucose and insulin concentrations are controlled by use of the insulin clamp technique (272, 273). This effect is primarily associated with diminished insulin-stimulated glycogen deposition as glucose oxidation is slightly increased (274). In contrast to these acute responses, chronic administration of terbutaline, a β_2 -adrenergic agonist,

significantly increased peripheral insulin sensitivity through increased nonoxidative glucose use (glycogen deposition) during insulin clamp studies (275). Chronic infusion of norepinephrine, an α - and β_1 -agonist, produces similar increases in peripheral insulin sensitivity in the rat (276). Finally, the argument that catecholamines promote insulin sensitivity as part of their chronic, long-term action is bolstered by the recent finding that people with mutations in the β_3 -adrenergic receptor have reduced insulin sensitivity (277, 278 and 279), increased capacity for weight gain (280), and earlier onset of non-insulin-dependent diabetes (281).

Taken together, the *acute* actions of catecholamines on carbohydrate metabolism promote increased availability of glucose in the circulation. The most common physiologic circumstance in which these functions are evident is in exercise, in which catecholamines are primarily responsible for the hepatic production of glucose to compensate for the increased glucose use during the exercise bout (282). The effect of catecholamines to inhibit glucose clearance during exercise seems counterintuitive when fuel is required for mechanical work, but it is an important protection that ensures adequate circulating glucose for brain function when muscle fuel needs are high. Following the end of a bout of exercise, glucose clearance remains impaired because of catecholamine effects and hyperglycemia develops (e.g., as may occur in insulin-deficient diabetic persons following exercise) unless there is an acute increase in insulin concentration (the normal physiologic response) to counteract the catecholamine effect (283). The *chronic* effect of catecholamines may be to promote glucose storage in the periphery.

Lipid Metabolism

The major effect of catecholamines on lipid metabolism is augmentation of lipolysis. Both epinephrine and norepinephrine activate hormone-sensitive lipase in adipose tissue, liver, heart, and skeletal muscle. Some studies have reported that stimulation of lipolysis is cAMP dependent and mediated through β_1 -adrenergic stimulation of adenylate cyclase (284, 285). Other authors studying the increased lipolysis in burn patients have reported that it can be inhibited only by medications that antagonize the β_2 -adrenergic receptor (286). Still others have reported that both β_1 and/or β_2 receptors in dogs may be involved in lipolysis, with β_3 receptors recruited only when catecholamines are present in very high concentration (287, 288). α_2 -Adrenergic stimulation has an antilipolytic effect (284), although this may not be of physiologic importance. Many other hormonal factors affect catecholamine-induced lipolysis, with insulin producing a major opposing role. Thus, catecholamine inhibition of insulin secretion is important in promoting lipolysis.

Catecholamines increase lipogenesis and ketogenesis. Hepatic triglyceride synthesis is increased by adrenergic stimulation, although this effect is predominantly related to increased free fatty acid delivery resulting from enhanced lipolysis (264). Augmented ketogenesis is also partly the result of increased free fatty acid delivery to the liver, although other mechanism(s) coexist. Norepinephrine produces dose-dependent increases in ketogenesis in isolated rat hepatocytes, without increasing free fatty acid

uptake (289).

Catecholamines increase in plasma lipid levels. Cholesterol synthesis and plasma levels increase after epinephrine administration, through activation of the rate-limiting enzyme controlling cholesterol synthesis, 3-hydroxy-3-methylglutaryl CoA reductase (290, 291 and 292). Triglyceride levels increase acutely during catecholamine infusions (293) but are not elevated after chronic administration.

Thus, the combined effects of catecholamines on lipid metabolism increase the availability of lipids and ketones for peripheral use. This is accomplished through mobilization of lipids from storage sites and stimulation of triglyceride and ketone production.

Protein Metabolism

Catecholamines have insulin-like effects on plasma amino acid levels. Infusing epinephrine to produce plasma concentrations similar to those seen during acute stress result in a decrease in total amino acid levels, although alanine concentrations are unchanged (294). This effect occurs in the absence of insulin secretion (in type 1 diabetics) and can be prevented by b-adrenergic blockade with propranolol. Drugs with b₂ agonist activity increase body weight, body protein content, and weight of certain skeletal muscles (but not cardiac muscle weight) in guinea pigs with burn injuries (295). Likewise, lambs given b-agonists experience increased muscle protein content accompanying decreased rates of protein degradation while fat content decreases (296).

In contrast to insulin, epinephrine increases both splanchnic uptake of gluconeogenic amino acids and peripheral de novo alanine synthesis and hepatic alanine delivery (297, 298). As dogs recover from insulin-induced hypoglycemia, amino acids are released from the gut into the portal circulation, providing gluconeogenic precursors (299); the amino acid release is suppressed by a-adrenergic blockade and is associated with release of endogenous opioids, suggesting involvement of catecholamines and opioids in the response (300, 301). Stimulation of lactate uptake by liver during hypoglycemia occurs after a-adrenergic blockade and is inhibited by b-adrenergic blockade (302). Perhaps consistent with evidence suggesting a protein anabolic role for catecholamines, epinephrine has not been shown to increase nitrogen excretion despite the enhancement of gluconeogenesis.

SEX STEROIDS AND PROLACTIN

Carbohydrate Metabolism

Estrogen therapy as used in oral contraceptive preparations has been reported to exacerbate mild diabetes mellitus. However, some reports suggest that it is the progestogen component, specifically the 19-nortestosterone derivatives, of oral contraceptives that alters glucose tolerance. The effect is only seen with some of these compounds and is less prominent in low-dose formulations (303, 304). Administration of

testosterone to female rats decreased insulin-stimulated glucose transport, increased plasma insulin levels, decreased muscle glycogen synthesis, and decreased capillarization and number of type 1 muscle fibers (associated with insulin resistance) (305).

Lipid Metabolism

Pharmacologic doses of estrogens influence the production and removal rates of plasma lipoproteins. Plasma concentrations of VLDL-cholesterol increase because of enhanced hepatic production rates (306). Certain estrogen-responsive apolipoproteins in avian models markedly elevate VLDL triglyceride levels in the presence of estrogen when overexpressed in transgenic mice, suggesting that estrogen may specifically stimulate production and secretion of certain hepatic VLDL proteins (307). These effects may be counterbalanced slightly by an effect of estrogen to produce a minor inhibition of lipolysis (308). However, estrogen also inhibits LPL activity and so estrogen may, on balance, reduce fat mass. The clinical importance of these effects and the particular adipose tissue depots most affected have not been determined.

Testosterone has biphasic effects on fat tissue. High concentrations of testosterone increase lipolysis, particularly in the abdominal fat depot, and inhibit LPL and fat deposition into the abdominal repository (309). The decrease in LPL activity may be due to production of estrogen from testosterone through testosterone aromatization (310). The summed effects of high levels of testosterone decrease the waist:hip ratio in testosterone-supplemented obese men and concomitantly increase insulin-induced glucose disposal (311). However, low levels of testosterone increase LPL activity (312). The dual effects of testosterone to promote fat storage at low concentration and inhibit fat accretion (particularly abdominal fat) at high concentrations may be related to the seeming paradox that men (and women displaying androgen excess) accumulate fat in the abdominal region from which originates the term “androgenic” obesity (i.e., male pattern, upper-body adiposity). The former effect may dominate at usual male and elevated female testosterone concentrations, while the latter effect may become manifest during androgen supplementation.

In contrast to the effect of estrogen in increasing VLDL, clearance of LDL is enhanced by estrogens, in part because of increased hepatic excretion of cholesterol in the bile (313). This effect has led to the therapeutic use of estrogens in some types of familial hypercholesterolemia, with the most striking results seen in women with familial dysbetalipoproteinemia (type III) and in some postmenopausal women with heterozygous familial hypercholesterolemia (type II) (314). Oral, but not transdermal, estrogen increases HDL apo-A1 production (315). Whereas oral estrogens produce significant increases in plasma HDL-cholesterol levels, the progestogens of the 19-nortestosterone series, often combined with estrogen in oral contraceptives, may lower HDL concentrations (316). A large-scale clinical study of the use of combined estrogen/progestin oral contraceptives indicated that levonogestrel produced a dose-dependent increase in LDL-cholesterol and a decrease in HDL-cholesterol (particularly the HDL2 subfraction) (317). In contrast, norethindrone had opposite effects, indicating that lipoprotein changes related to progestogens may vary with their molecular side-chain configurations. Testosterone lowers HDL-cholesterol

concentrations during supplementation and at physiologically relevant levels, possibly because of enhanced HDL clearance by hepatic endothelial triglyceride lipase (312).

Despite the pharmacologic effects of sex hormones on plasma lipids, epidemiologic evidence does not support a major role for sex hormones as the cause of abnormalities of lipoprotein levels in otherwise healthy people (318, 319). However, relationships between sex hormones and lipids may be obscured by the fact that hyperinsulinemia and upper-body obesity, commonly associated with syndromes of hyperlipidemia, tend to decrease levels of sex hormone-binding globulin (SHBG), thereby decreasing the ratio of total to free hormone (320, 321 and 322). An interesting corollary to this observation is that Western-style refined carbohydrate, low-fiber, high-fat diets, also associated with hyperlipidemia, appear to increase the availability of sex hormones, raising total concentrations while decreasing SHBG (323).

Protein Metabolism

Testosterone administration to hypogonadal or castrated men decreases urinary nitrogen excretion and results in weight gain (324) and increased body density (325, 326). The weight gain is largely composed of fat-free mass when testosterone is given in supraphysiologic doses to healthy, young men (327, 328) or to reproduce youthful doses in elderly men (329). Testosterone replacement in hypogonadal men increases fat-free mass in large part by producing increased muscle mass that results from increased rates of skeletal muscle protein synthesis (330). Attempts to use androgens to improve the rate of nitrogen repletion in patients suffering from catabolic illness have had little or no therapeutic benefit (331).

Estrogens in pharmacologic doses inhibit somatic growth. This effect may be mediated through suppression of IGF-1 generation, which has been demonstrated in growth hormone-treated hypopituitary subjects (332).

Prolactin has a weak stimulatory effect on IGF-1 generation in patients with prolactin-secreting pituitary tumors (333). Prolactin administration to growth hormone-deficient human subjects mimics many of the actions of growth hormone, producing nitrogen retention, lipid mobilization, glucose intolerance, and modest skeletal growth.

VASOACTIVE FACTORS (ANGIOTENSIN II AND BRADYKININ)

Hormones such as insulin that are known to stimulate certain patterns of intracellular nutrient metabolism may also be vasoactive. It is reasonable to think that delivery of nutrients to sites of potential use or storage may be nearly as important for substrate metabolism as processing the substrate once it arrives at the site. Indeed, the decreased ability of insulin in obese persons and those with non-insulin-dependent diabetes to dispose of glucose in peripheral tissues such as skeletal muscle is partially due to inhibition of an insulin-stimulated vasodilatory response (334). Angiotensin II, a vasoactive hormone, promotes insulin-stimulated glucose disposal in healthy humans. Some authors suggest that the angiotensin effect is independent of its effect on blood

flow (335), but others state that the hemodynamic effects of angiotensin II to redirect blood flow to insulin-sensitive tissues may contribute to its metabolic actions (336).

The converse may also be true. It is now recognized that hormones typically considered important for maintenance of the circulation are also important for regulation of intracellular substrate metabolism. Angiotensin II stimulates glucose uptake into many cells including astroglia, cardiac muscle, and skeletal muscle of rats. It appears to mediate this effect in part by stimulating production of GLUT1 and GLUT4 glucose transporters (337, 338).

Though angiotensin II appears to stimulate glucose use, administration of angiotensin-converting-enzyme (ACE) inhibitors improves glucose disposal despite lowering angiotensin II levels. It has been hypothesized that bradykinin, a hormone degraded by ACE, may have even more potent effects on glucose disposal than angiotensin and that its accumulation during the use of ACE inhibitors may account for this increased glucose disposal. Bradykinin increases glucose transporter (GLUT1 and GLUT4) translocation to the plasma membrane of cardiac muscle (339). Antagonism of bradykinin-B2 receptors abolishes the effect of ACE inhibitors in enhancing insulin-mediated glucose transport in muscle. However, some authors have reported no effect of bradykinin in enhancing in vivo glucose disposal in humans (340), bringing into question the relevant mechanism for the effects of ACE inhibitors.

CYTOKINES AND EICOSANOIDS

The severely injured or infected patient shows dramatic metabolic responses characterized by mobilization of stored carbohydrate, fat, and protein substrates. Additionally, an “acute-phase” response is initiated in which certain, largely fast-turnover, proteins are created at the expense of other structural and functional proteins such as muscle, for reasons that are unknown but are expected to account for homeostasis of vital tissues during injury and infectious stress. As mentioned above, these phenomena occur in part because of elaboration of classic “stress hormones” such as cortisol and catecholamines from endocrine organs such as the adrenal. It is now recognized that cells of immune origin such as macrophages, monocytes, and lymphocytes, well known to mediate tissue repair and elimination of infecting organisms, also mediate some of the metabolic responses to injury and infection. (See [Chapter 35](#), [Chapter 37](#), [Chapter 45](#) and [Chapter 96](#) for more information on cytokines and growth factors.)

Carbohydrate Metabolism

Thromboxane A₂ (TXA₂) and prostaglandins F_{2a} (PGF_{2a}) and PGE₂, derivatives of arachidonic acid (see [Chapter 4](#)), increase glycogenolysis when secreted by Kupffer cells in the liver (205). These prostanoids are released in response to stimulation by phagocytosis and bacterial lipopolysaccharide, explaining in part the glucose intolerance and insulin resistance associated with infection and inflammation. Likewise, interleukin-6 (IL-6) stimulates glucose production from the liver but appears to do so by increasing secondarily secretion of glucocorticoids and glucagon (341). Interleukin 1-a (IL-1-a)

increases hepatic glucose production when infused peripherally in rats, an effect that can be blocked by IL-1 receptor antagonists (342). IL-1- α may provide another example of indirect effects of a cytokine on metabolism. IL-1- α acts on the central nervous system to enhance hepatic glucose production in excess of a smaller increase in peripheral glucose use, thus elevating plasma glucose. The effect is mediated by stimulation of the central nervous system adrenergic system that in turn stimulates peripheral secretion of both glucagon and insulin (343).

Tumor necrosis factor- α (TNF- α), also known as cachectin, promotes energy depletion in muscle by stimulating substrate cycling within the glycolytic pathway. Phosphofructokinase and fructose biphosphate phosphatase activities are simultaneously enhanced in myocytes exposed to TNF- α , depleting ATP so that glycolysis and its resulting elevated glucose utilization, increased lactate production, decreased oxygen consumption, and decreased CO₂ production from glucose can continue unabated (344). However, these effects on cultured muscle cells may not be relevant to the in vivo situation in which TNF- α appears to produce insulin resistance with attendant decreased glucose use in rats and humans (345, 346). Some authors have concluded that the decreased glucose use and insulin sensitivity effected by TNF- α may represent either direct effects of TNF- α on tissues (i.e., TNF- α inhibits insulin receptor and/or insulin receptor substrate-1 phosphorylation in part by stimulating phosphotyrosine phosphatases) or indirect effects of TNF- α -induced increases in circulating free fatty acids (347, 348). Even such equivocating conclusions must be interpreted with caution, however, given the rudimentary current understanding of cytokine and stress hormone responses and actions.

It is becoming clear that conclusions based on models of injury or infections are clouded by the large array of hormones and cytokines elaborated in these conditions, and the metabolic effects of any one factor, such as TNF- α , are difficult to elucidate. Additionally, each factor may in turn stimulate production of others (Fig. 44.4). Models based on infusion of a given cytokine may attribute metabolic effects to the cytokine that in fact belong to a secondary hormone. Such is likely the case with TNF- α ; those concluding that it decreases glucose use and increases lipolysis during physical stress may be mistakenly attributing the effects of simultaneously secreted catecholamines to TNF- α . Those concluding that TNF- α increases glucose production and lipolysis may be mistakenly attributing these responses to TNF when in fact they are due to TNF-stimulated production of glucagon (349). Even though some effects may be mediated indirectly by agents such as glucagon, this should not diminish the importance of TNF- α . The fact that glucagon concentrations can remain elevated for weeks during sepsis or severe injury and not be suppressed by glucose-related feedback may underscore the importance of TNF.

Figure 44.4. The stress response elicited by generation of immune cytokines: hormones induced by cytokines. *Arrows from an immune cell (IL-1: macrophages, NK cells, T cells, tumors such as lung malignancy, IL-6: macrophages, fibroblasts, tumors such as melanoma and lung, TNF-a: macrophages, T cells, tumors such as breast) indicate cytokine stimulation of a secondary hormone from the indicated glands. Arrows intersecting parallel lines indicate inhibition of secretion of factors from the indicated organ. Arrows from target glands indicate stimulated secretion of the designated hormones. Dotted lines/arrows indicate decreased secretion of the designated factor. In some cases, immune cells may stimulate or inhibit other immune cells as indicated by arrows directed toward the immune cell representation.*

Lipid Metabolism

TNF-a has been implicated as the cytokine producing many of the metabolic and nutritional perturbations associated with the critically ill patient (346). Specifically with regard to lipid metabolism, it induces anorexia and lipolysis while inhibiting lipogenesis. These effects have been attributed to the ability of TNF-a to stimulate adipocyte hormone-sensitive lipase while suppressing expression of LPL, fatty acid-binding protein, and glycerol-3-phosphate dehydrogenase (350). As stated above, however, some of these apparent actions of TNF have not been reproduced by other authors. It should be assumed that apart from obvious differences among studies (e.g., species differences in recipients of TNF-a), other differences in study conditions (e.g., duration of anorexia and starvation allowed during TNF administration or inhibition of secondary hormones such as glucagon and insulin) may account for differing interpretations of the effect of TNF-a on lipids. For the present, it suffices to say that TNF-a is at the center of a cytokine and hormonal response to severe stress that results in elevated free fatty acids. The elevation in fatty acids identified with increased concentrations of TNF-a may be accompanied by increased serum cholesterol and decreased HDL-cholesterol concentrations that in hamsters have been shown to result from increased transcription of HMG CoA reductase and decreased transcription of apo A-1 genes, respectively (351). The cholesterol effects are also induced by IL-1 and are additive to those of TNF-a.

Other cytokines have been implicated in the metabolic (lipid and glucose) effects of inflammatory stress in addition to TNF- α , most notably IL-6. Administration of IL-6 to humans increases energy expenditure, fatty acid and ketone production, fat oxidation, glucose production, lactate production, and glucose oxidation (352). Such effects account for many of the manifestations of inflammatory stress, implicating IL-6 as the direct cause of them, perhaps the mediator of some of the effects of TNF- α , which secondarily stimulates IL-6 production. However, like TNF, IL-6 in turn stimulates production of catecholamines, glucagon, and cortisol, which may mediate some or all of the effects of IL-6. In a fashion that resembles classic endocrine hormones, IL-6 provides feedback inhibition of the cytokine cascade that erupts during physical stress by inhibiting TNF- α and IL-1 production (353). Interestingly, IL-6 levels also increase during exercise, another circumstance beside injury in which nutrient mobilization is essential, and are inhibited by glucocorticoids, underscoring feedback on the cytokine cascade by the adrenal axis, which is potently stimulated by IL-6 (354).

Finally, two other cytokines described in the past decade and elaborated during sepsis have been shown to affect lipid metabolism. Ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF) both produce hypertriglyceridemia and hepatic triglyceride synthesis (from free fatty acids released by lipolysis and produced de novo) through stimulation of a signal transducer, gp130, that is shared with IL-6 (355). The effects of CNTF and LIF to produce hypertriglyceridemia are only noted during the fasting state, but this may be common given that these cytokines produce anorexia in the same fashion as TNF.

The bulk of the effects of cytokines on lipid metabolism increase free fatty acid availability and induce the production of triglycerides. Some authors have concluded that the increase in circulating lipids is beneficial during stress because lipids are delivered to cells involved in the stress response or tissue repair and because lipoproteins, including VLDL, may bind endotoxin (356).

Protein Metabolism

TNF- α promotes catabolism of skeletal muscle protein, in large part by promoting anorexia with resultant starvation. TNF- α stimulates skeletal muscle proteolysis in vivo independent of starvation, an effect that may be mediated by another, undefined factor, as it does not occur when skeletal muscle is incubated with TNF- α in vitro (357). A similar effect is seen in rats in response to IL-1. The proteolysis and concomitantly decreased protein synthesis appear to be confined to fast-twitch muscle rather than slow-twitch or cardiac muscle (358, 359). The impaired protein synthesis induced by sepsis and particularly IL-1 in skeletal muscle and the seromuscular layer of the intestine, kidney, and potentially other organs (360) is likely due to poor availability of eukaryotic initiation factor-2B (eIF-2B) with impairment of peptide chain initiation (361, 362).

In contrast to skeletal muscle, visceral protein content and cell proliferation are enhanced by TNF- α such that liver, heart, and lung weight are all increased (363). Production of circulating proteins such as albumin and transferrin is depressed by

TNF- α . Albumin gene transcription and steady-state albumin mRNA levels are decreased by TNF- α (364). However, acute-phase circulating proteins may be increased by TNF- α , probably resulting in large part from stimulation of IL-6 formation. IL-6 is the most potent stimulator of hepatic acute-phase protein synthesis currently known (365). IL-1 does not appear to be involved in stimulation of hepatic protein synthesis during the acute-phase reaction, as its receptor antagonist, known to preserve muscle protein synthesis from an acute-phase decrease, has no effect on hepatic proteins (360). Thus, elaboration of cytokines from immune cells helps to explain further the peripheral wasting and visceral preservation noted after prolonged critical illness. The effects are opposite to those seen during adequate nutrition and health, when insulin and IGF-1 promote peripheral storage of nutrients. Interestingly, some investigators have found that administration of insulin to TNF- α -treated rats may reverse the catabolic effects of that cytokine (366), and others have noted that IL-1 may mediate some of its effects in decreasing somatic protein synthesis via decreasing circulating and tissue levels of IGF-1 and increasing levels of the inhibitory IGF-binding protein IGFBP-1 (367) (Fig. 44.5).

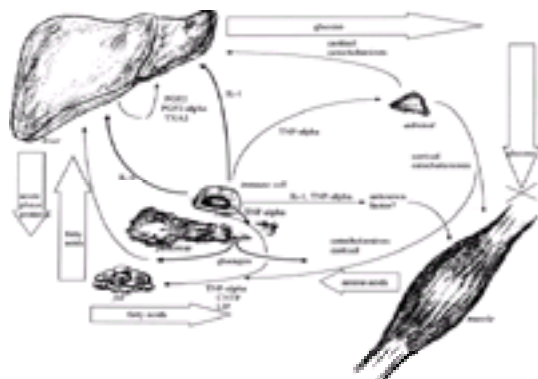

Figure 44.5. The stress response elicited by generation of immune cytokines: alteration in substrate release and use by cytokines. *Large arrows* indicate the net directional movement of the substrate noted within the arrow. *Large arrows intersecting crossed lines* indicate impaired disposal/use of the indicated substrate. *Small arrows* indicate relevant cytokine and hormone effectors of substrate release and use.

Cytokines, in summary, are elaborated in a cascade in response to severe physical stress such as infection or injury. The accelerating cascade of interdependent immune factors such as IL-1 and TNF- α and hormones such as catecholamines and glucagon produces a redistribution of nutrients that largely sacrifices peripheral nutrient stores. Protein stores in muscle and fat stores in adipose tissue are mobilized in favor of circulating proteins and lipids that may protect the organism from infectious agents or assist in the repair of tissue. Some elements of the cascade that assist in the nutrient redistribution, such as IL-6 and glucocorticoids, also feed back to calm the inflammatory events. Indeed, macrophages that are integral components of many inflammatory phenomena secrete an IL-1 receptor antagonist so that the same cell simultaneously

stimulates and retards inflammation ([368](#)).

[Selected Readings](#)

The fundamental concept underlying the function of the immune system is the ability to distinguish, at the molecular level, the host from foreign materials. This “self/nonself discrimination” is responsible for selective destruction of microbial infectious agents, neutralization of chemical toxicants, rejection of foreign tissue grafts, and allergic responses to certain xenobiotics. Thus, the immune system has been deemed a sensory tissue that develops a sense of identity.

The study of nutritional influences on the immune system represents an area of growing concern to nutritionists, food scientists, and immunologists. This chapter summarizes basic information on the structure and function of the immune system. A brief section on the evolution of the immune system is followed by overviews of the two basic forms of immune defenses: the innate/natural and acquired/adaptive/specific immune systems. Subsequent sections provide more details on topics such as the cellular interactions necessary for generation and regulation of immune responses. These are followed by discussions of some of the known associations between nutrition and immunity.

FUNDAMENTALS OF IMMUNOLOGY

Innate Immunity

Innate, as opposed to acquired, immune responses are defined as those that are not qualitatively and quantitatively affected by repeated contacts with the same specific immunologic stimulus. Such responses are not customized for the offending stimulus, and there is no enhanced response following another exposure to the stimulus (there is no immunologic memory of past contacts). Thus, innate immunity is considered a more primitive, basal, or constitutional form of defense. On this foundation developed the more flexible acquired immune system that exhibits aspects of learning and memory (discussed below).

Phagocytes

The major phagocytes are the polymorphonuclear (PMN) leukocytes, or neutrophils, and the macrophages. Neutrophils are produced in the bone marrow and released into the blood where they constitute between one-half and two-thirds of all leukocytes. A typical adult human has about 50 billion neutrophils in the circulation, with a life span of 1 to 2 days; thus, the bone marrow uses much of its hematopoietic capacity for neutrophil production. A mature PMN is characterized by a multilobed nucleus and a large reservoir of cytoplasmic granules containing enzymes and other proteins used to degrade and digest phagocytosed particles. Sizable glycogen stores also support glycolytic anaerobic activity among PMNs.

Macrophages are produced in the bone marrow and circulate in the blood as monocytes (1). Although macrophages constitute a relatively minor (1–6%) percentage of circulating leukocytes, their frequency often increases during infections. Blood monocytes further mature to tissue macrophages or histiocytes. Collectively, these macrophages are widely distributed in the host as the mononuclear phagocyte system. Tissue macrophages attain distinct morphologic characteristics as Kupffer cells (liver), microglia (brain), mesangial cells (glomerulus), and osteoclasts (bone). Macrophages also reach substantial numbers in connective tissues and the lung (alveolar macrophages). The life span of tissue macrophages can extend into months.

A typical phagocytic event is initiated by adherence of a microbe to the phagocyte. Adherence mechanisms range from nonspecific hydrophobicity to specific receptor–ligand interactions. Intracellular contractile systems then extend pseudopods around the particle, followed by a “zippering” effect and encasement of the particle in a cellular vacuole called the phagosome. Cytoplasmic granules consisting of proteolytic enzymes then fuse with the phagosome and release their active constituents to begin bacterial digestion (Fig. 45.1).

Figure 45.1. Three methods of killing cells by the immune system. (A) Both cytolytic T lymphocytes and NK cells induce apoptosis in their targets. Although apoptosis is illustrated by nuclear degradation, not all apoptotic cells exhibit DNA fragmentation. In addition to apoptosis, the plasma membrane is perforated by attack membrane complexes similar to complement-mediated lysis. (B) Phagocytes wholly engulf items and degrade them intracellularly with a variety of enzymes. If foreign materials are too large to phagocytize, enzymes and reactive oxygen species are released extracellularly. (C) The complement cascade activated by antibodies forms membrane attack complexes that result in cell membrane damage.

There are two main granule types in the PMN: the primary azurophilic granules that contain myeloperoxidase, defensins, bactericidal/permeability increasing factor and cathepsin G and the secondary specific granules containing lactoferrin, lysozyme, alkaline phosphatase, and cytochrome b_{558} . The preformed antimicrobials of PMN granules perform a variety of functions depending on intraphagosomal conditions. Increased vacuolar pH, following the dismutation of superoxide anion and the consumption of hydrogen ions, activates peptides such as the defensins, which form voltage-regulated ion channels in bacteria, fungi, and some enveloped viruses. The neutral proteinase, cathepsin G, also increases bacterial permeability. Lysozyme degrades the peptidoglycan wall of certain bacteria, while lactoferrin chelates iron. Acidification of phagosomes promotes target hydrolysis and increases the activities of other enzymes (2).

Following phagocytosis by macrophages, phagosomes migrate to the perinuclear region where they fuse with lysosomes. These lysosomes contain acid hydrolases (proteases, nucleases, glycosidases, phosphatases, lipases, etc.) that are potentiated by the acidic environment produced by proton pumps located in the phagosome. The digested materials are then stored as “dense bodies” or expelled by exocytosis. Importantly, some macrophage phagosomes (endosomes) can be recycled to the cell surface, a process that is important in antigen presentation (see below).

Phagocytes also generate reactive oxygen molecules for killing microorganisms in a process called the respiratory, oxidative, or metabolic burst because of the

characteristic increase in oxygen consumption (3). An increase in the hexose monophosphate shunt results in enhanced NADPH synthesis, consuming glucose and producing lactate. Electron transfer leads to reduction of molecular oxygen to superoxide anion. Superoxide dismutase then catalyzes the conversion of superoxide anion to hydrogen peroxide. Neutrophilic myeloperoxidase combines with peroxides and halide ions (e.g., Cl^- , Br^- , I^-) to form hypohalites (e.g., HOCl), which oxidize a wide range of biomolecules, including thiols, nucleic acids, and proteins. The relative stability of H_2O_2 allows its diffusion to more distal sites and extends the range of antimicrobial action. Hydrogen peroxide may be further processed to form the highly reactive hydroxyl radicals that bind to targets more proximal to the phagocyte. Phagocytes are protected from their reactive oxygen by the sulfhydryl-containing tripeptide reduced glutathione and catalase, which enzymatically converts H_2O_2 to water and oxygen. Although release of these toxic materials to the extracellular space allows phagocytes to eliminate large parasites that cannot be ingested, this process can cause considerable damage to surrounding host tissues.

Nitric oxide (NO), a reactive nitrogen radical, is toxic to bacteria and tumor cells. The enzymatic activity of NO synthase on molecular oxygen and L-arginine generates citrulline and NO. The antibacterial mechanism of NO may involve degradation of Fe-S prosthetic groups of electron transport enzymes and the generation of hydroxyl radicals.

In general, phagocytosis by macrophages tends to be slower than that by PMNs, and the metabolic burst is less intense. In addition, the longer life span of macrophages is reflected in their more gradual and extended degradation of engulfed materials, compared with PMNs. This is partly a function of the relatively lower density of lysosomes present in macrophages. But unlike neutrophils, macrophages can synthesize new lysosomes and hydrolytic enzymes. Together, PMNs and macrophages provide both short- and longer-term phagocytic function for elimination of microbes and other particulate foreign materials.

Complement

Complement is a term for approximately 25 plasma proteins and protein fragments that are important in host defense (4). The functional roles of the complement system include lysis of cells and enveloped viruses, facilitation of phagocytosis, and phagocyte activation and chemotaxis. Many of these proteins are zymogens or proenzymes that require proteolytic cleavage to become active. The complement cascade is a series of such cleavages mediated in large part by the complement proteins themselves. There are two major cascade pathways; the innate alternative pathway and the antibody-dependent classical pathway have different initiation conditions, but eventually converge to a common series of reactions (Fig. 45.2). The alternative pathway is directly activated by the cell walls of certain microorganisms, while the classical pathway is initiated by antibodies.

Figure 45.2. Schematic diagram of the classic and alternate complement pathways. The complement pathway is regulated by the instability of C3 convertase and the displacement of factor B by factor H. iC3b can be further degraded, or can act as an opsonin. C3 convertase is able to catalyze the cleavage of C3 to C3a and C3b.

The Acute-Phase Response

The acute-phase response is a rapid reaction to tissue damage that integrates the elimination of microbes, the control of further tissue damage, the cleanup of debris, and the initiation of repair processes (5). For example, microbial endotoxins induce macrophages to release cytokines interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF). These are followed by changes in the concentrations of many plasma proteins, such as increased production of C-reactive protein (CRP) by the liver. CRP then attaches to the phosphorylcholine-containing membranes of certain microorganisms and activates the complement cascade. In addition, the binding of CRP to necrotic host tissues may protect against autoimmune responses by promoting the rapid removal of self molecules from the circulation. Other proteins that increase in the plasma include complement components B, C3, and C4; ceruloplasmin, the major copper-binding protein, which removes iron from inflammatory sites and may act as an oxygen radical scavenger; fibrinogen, a protein involved in coagulation and bacterial clumping; serum amyloid A and P, proteins that bind to the extracellular matrix and are possible components of amyloid deposits; and α_1 -PI, a protease inhibitor important in modulating tissue damage.

Some plasma proteins decrease in concentration during the acute-phase response. The role of albumin as a “metabolic compensator” in maintaining an overall constant rate of protein synthesis is suggested by its decreased production during the acute-phase response. Albumin is also a transport protein and its sequestration may be important in minimizing nutrient delivery to microbes. In addition, decreases in circulating transferrin, concomitant with increased activity of intrahepatic ferritin, decreases iron availability at peripheral sites of infection.

Cytotoxic Cells

The process of cell killing by another cell type is termed *cytotoxicity*. One proposed function of the immune system is elimination of abnormal host cells that are thought to constantly appear throughout an individual's life. This process of immune surveillance is thought to be the prime function of the natural killer (NK) cell (6).

Morphologically, NK cells are categorized as large granular lymphocytes. Relative to other lymphocytes, they are large, are granular in appearance, and have low nuclear:cytoplasmic ratios. NK cells normally constitute about 15% of circulating lymphocytes and 4% of splenic lymphocytes. These cells are distinct from T and B lymphocyte lineages. For example, certain immunodeficiency states are characterized by a lack of T and B cells but not NK cells. However, NK cells do share certain characteristics with T lymphocytes. NK cells, cytotoxic T (T_c) cells, and T cells that possess the α T-cell receptor (TCR) exhibit similar cytotoxic activities and target cell specificities, surface protein markers, and cytokine production.

Although the means by which NK cells recognize their choice of target cells is controversial, binding of lectinlike NK receptors to carbohydrate ligands on target cells appears important (7). NK cells are known to kill syngeneic (genetically identical), allogeneic (same species but different genotype), and xenogeneic (different species) tumor cells. There is evidence that the expression of major histocompatibility complex (MHC) class I molecules on target cells is inversely related to susceptibility to killing.

NK cells can kill their chosen targets by cytolysis and/or by inducing apoptosis. Fragmentation of target cell DNA occurs early, suggesting that apoptosis is the principal mode of target cell destruction. Additionally, within minutes of NK–target cell contact, NK cell granules migrate to the regions of contact and release their contents (e.g., perforin or cytolysin, which are structurally and functionally similar to C9) to form transmembrane pores in the target cell's plasma membrane (Fig. 45.1). Other granule constituents include a family of serine proteases (granzymes) that function as perforin activators, and ionized ATP, which may initiate apoptosis. NK cells are protected from their own armaments by a lack of cell surface ATP receptors and the presence in their granules of chondroitin sulfate A, a protease-resistant, negatively charged proteoglycan that inhibits autolysis.

The eosinophil, another component of the innate immune system, is associated with allergic reactions and antihelminthic responses (8). Eosinophils normally constitute about 1 to 3% of circulating leukocytes, a frequency that may increase in atopic situations. The vast majority of eosinophils are sequestered in the bone marrow and connective tissues. Most helminths activate the alternate complement pathway and production of C3b, an eosinophil opsonin and activator. Activated eosinophils release a variety of bioactive materials such as eosinophil peroxidase to generate reactive oxygen intermediates, the lysophosphatase Charcot-Leyden crystal protein, major basic protein that induces release of histamine from mast cells and basophils, a C9-like amphipathic molecule, and the helminthotoxic eosinophil cationic protein. Eosinophils also release regulators of inflammatory mediators. Histaminase inactivates histamine, while

arylsulfatase A antagonizes the slow reactive substance of anaphylaxis (SRS-A) and leukotrienes C4, D4, and E4.

In summary, the innate immune system is composed of a network of cellular and humoral immune components that are able to respond to numerous microbial and cellular challenges. However, a constantly evolving infectious environment requires a more adaptable form of defense. This type of flexibility is provided by the adaptive immune system.

Adaptive Immunity

To generate effective responses to unique microbial challenges, the immune system developed the ability to recognize a large array of molecular shapes. Central to this recognition system are the antigen receptors of leukocytes: the cell surface-bound immunoglobulins of B cells and their soluble counterparts and the T-cell receptors.

Secreted Antibodies/Immunoglobulins

The monomeric antibody molecule (immunoglobulin, Ig) is a covalently linked complex of four polypeptide subunits: two smaller light chains and two larger heavy chains. Monomeric antibodies may be covalently linked to form dimeric or multimeric antibodies. The Ig molecule contains three major functional regions. The first is the antigen-binding site, the region with high interclonal variability that allows recognition of different antigens. An antigen-binding site is created from one heavy and one light chain; because of the presence of two identical heavy-light chain sets, each monomeric antibody has two identical antigen-binding sites for a specific epitope configuration. At the other end is the Fc region that binds to Fc receptors present on the surfaces of many leukocytes. This spatial arrangement gives immune cells an added form of antigen recognition through the use of antibodies as bridges or adaptors. Between these ends is a portion of the antibody that activates the classic complement pathway. Both Fc and complement-activating regions are functions of the heavy Ig chains. The antibody molecule is also separated into constant and variable regions. The antigen-binding site is contained within the variable region, while the complement-fixing and Fc portions are in the constant region.

There are five isotypes, or classes, of antibodies as defined by the structure of the constant region of the heavy chain: IgM, IgG, IgA, IgE, and IgD. Structural differences among heavy chain isotypes are limited to the constant regions where they influence the non-antigen-binding characteristics of antibodies. For example, secreted antibodies are not necessarily monomeric. IgM is released as a pentamer, and IgA may be secreted as a dimer. Functionally, only IgG crosses the placenta, while IgM is the most efficient activator of the classic complement pathway, and IgA is the major isotype found in mucosal secretions. As for the functions of antibodies as cellular bridges, mast cells and basophils have Fc receptors for IgE (Fce) only, while neutrophils and macrophages express Fc receptors for IgG (Fcg). Since the constant regions of the heavy and light chains are selected independently from the variable regions (more on this with the descriptions of generation of antibody diversity and isotype switching), antibodies that differ by isotype could have the same light and heavy chain variable regions and thus

the same epitope specificity. As a result, different immunologic effector mechanisms could be mobilized to respond to the same antigen.

Heavy and light chain isotypes are coded for by distinct genetic loci, and these loci exist in different allelic forms within the population. These allotypes are relatively minor polymorphisms due to, at most, a few amino acid substitutions. In humans, allotypes have been found for the heavy chains g, a, and e, and the k light chain. People may be allotypically heterozygous or homozygous; in heterozygous allotypes, the markers are expressed codominantly. Allotypic patterns have no significant effect on antibody function and are of interest primarily because of their immunogenicity in certain situations, such as blood transfusion and pregnancy. Additionally, patients with rheumatoid arthritis may produce rheumatoid factor or antibodies that recognize allotypic epitopes of IgG.

Idiotypic characteristics are determined by the variable regions of the antibody. The ability of an individual to produce specific immune responses to a large number of antigens requires an equally large number of antigen-binding sites. Therefore, idiotypic variations are quantitatively greater than isotype and allotype differences. Antiidiotypic antibodies (antibodies that bind to the antigen-binding sites of other antibodies) have been useful reagents in characterizing the antigen-binding sites of immunoglobulins. Antiidiotype antibodies are also important in the regulation of the immune system, as they are normal constituents in the pool of circulating antibodies.

B- and T-Cell Receptors

The B-cell antigen receptor is similar in structure to a secreted antibody (9). But there are important differences between secreted and membrane-bound Igs (slg and mlg). Unlike slgM and slgA, mlg is monomeric. Also, an mlg has a hydrophobic transmembrane region that allows the antibody to sit on the membrane as a receptor. The production of slg or mlg is determined by the differential splicing of the exon for the membrane-spanning region in the Ig transcript. The slg molecule is coexpressed in association with a set of membrane-bound molecules that are involved in signal transduction.

The TCR is a heterodimer composed of disulfide-linked α and β chains (9, 10). The TCR is similar to the B-cell receptor in several respects. The amino-terminal antigen-binding regions of the TCRs are highly polymorphic, and an individual T cell expresses TCRs of only one antigenic specificity. Also, the TCR is associated with a set of nonpolymorphic accessory proteins, the CD3 complex, which is required for TCR expression and function. Aside from the $\alpha\beta$ isotype, there is also the $\gamma\delta$ TCR (11). These TCR isotypes differ in antigen specificity, MHC restriction, and appearance during ontogeny. T cells that express $\alpha\beta$ TCRs also differ in effector functions and anatomic locations from those with $\gamma\delta$ TCRs.

The most striking differences between Igs and TCRs are the nature of antigens they recognize. Receptors of both types bind to antigens via noncovalent molecular interactions: electrostatic, hydrogen bond, hydrophobic, and Van der Waals. While some Igs recognize linear sequences of amino acids within protein antigens, most

immunoglobulins bind to native, as opposed to denatured or degraded, antigens. Thus, most antibodies recognize discontinuous or conformational molecular structures that are lost through denaturation. On the other hand, TCRs recognize linear epitopes, and quite unlike antibodies that bind ligands without the involvement of accessory molecules, TCRs only recognize antigen-derived peptide fragments in conjunction with MHC molecules on the surfaces of antigen-presenting cells.

Clonal Selection of Lymphocytes

Constitutive production of antibodies to every possible foreign antigen would be an inefficient use of resources. Instead, selected immune responses are generated in response to antigens via the activation and proliferation of lymphocyte clones that possess antigen receptors capable of recognizing these antigens. Antigens are responsible for the clonal selection of antigen-specific lymphocytes.

As described in more detail below, each B lymphocyte synthesizes antibodies with one antigen-binding specificity ([12](#)). The host is essentially a carrier of a large population of resting B-cell clones capable of responding to a wide range of immunogenic stimuli. Upon entering the host, a microbe encounters these B lymphocytes and activates those with the appropriate antigen-specific slgs. A similar strategy is used in the clonal selection of antigen-specific T lymphocytes.

Affinity Maturation and Isotype Switching

During an antibody response, two properties of the secreted antibodies change ([12](#), [13](#)). First, the affinity, or strength of binding, of the antibodies to their antigens increases. Following B-cell activation and during their proliferation, the immunoglobulin genes undergo somatic hypermutation. Point mutations accumulate to alter the antigen specificity of the synthesized Igs. Concurrently, as antigens become limiting, B-cell clones with higher binding affinities for antigens are preferentially reactivated by antigens, compared with clones with lower affinities. Second, antibody isotypes switch from IgM to other isotypes (e.g., IgG, IgA, IgE) as directed by T-cell signals. This isotype switching increases the functional diversity of slgs. IgE will bind to its respective Fc receptors on granulocytes, IgA is released into mucosal sites, and IgG passes through the placenta. Isotype switching is accomplished by alternate splicing of immunoglobulin primary RNA transcripts.

Classic Complement Pathway

Unlike the alternate pathway, the classic pathway is initiated by secreted antibodies ([Fig. 45.2](#)). C1q-binding sites within the constant regions of aggregated IgG or a single IgM are activated following antigen binding. As with the alternate pathway, opsonins are situated on the cell membrane to facilitate phagocytosis, chemotactic substances are released, and membrane attack complexes are formed.

Cell-Mediated Immunity

Many infectious microbes live within host cells, including immune cells, and thus are inaccessible for elimination by host humoral immune mechanisms. The inability of humoral immune components such as Ig and complement to neutralize intracellular parasites efficiently necessitates another strategy for their elimination. T lymphocytes are important in this respect because their antigen receptors can recognize foreign antigens present on the surfaces of host cells. For example, T helper (Th) cells of the type 1 variety (Th1) activated via the TCR-dependent recognition of infected cells release a variety of soluble signaling molecules, or cytokines (especially interferon- γ [IFN- γ]), into their immediate environment (1). These cytokines include those that are chemotactic for macrophages and activate their microbicidal processes. If macrophages themselves are the hosts of intracellular parasites, T cell-derived cytokines stimulate these phagocytes to kill their parasites.

Cytotoxic T cells (Tc) can kill infected cells directly (14). The mechanism of killing requires direct contact of Tc cells and their targets, recognition of target antigens by TCRs, and release of cytoplasmic granules in the vicinity of the target cell. The granular constituents of Tc cells are similar to those of NK cells, and cytotoxicity is also accomplished by apoptosis and lysis (Fig. 45.1). Release of IFN- γ also aids in reducing the spread of virus particles to neighboring host cells.

Antibody/Cell Interactions

An effector mechanism exists that combines both humoral and cellular components, termed *antibody-dependent cell-mediated cytotoxicity* (ADCC). Unlike opsonization, in which immune cells recognize antigen-bound antibodies via their FcRs, ADCC denotes the “arming” of leukocytes with antibodies via Fc-FcR interactions. This facilitates leukocyte binding to antigen. Both macrophages and NK cells possess FcRs that can presumably link with antigen-specific IgG. Cellular contact with antigens expressed on the surface of an infected cell then results in phagocytosis and/or cytotoxic killing of the target cell.

Antibodies also enable granulocytes to recognize foreign antigens. FcRs for IgG and especially IgA are present on neutrophils. Of particular importance to those with immediate hypersensitivities are the Fc ϵ receptors for IgE expressed by basophils and mast cells (15). IgE is the primary humoral mediator of anaphylaxis (16). The anaphylactic phenomenon is characterized by vasodilation and smooth muscle contraction and in its most severe form includes bronchiole/bronchi constriction and hypotension. Atopic people are prone to produce IgE to a variety of noninfectious xenobiotics (e.g., foods, pollen, drugs), which then arm circulating basophils and tissue mast cells via Fc ϵ receptors. Contacts with these allergens result in the cross-linking of Fc ϵ receptors by IgE and antigens, release of inflammatory mediators, and allergic responses such as anaphylaxis, asthma, gastrointestinal responses, and dermatitis.

Immunologic Memory

Immunologic memory distinguishes the adaptive immune system from innate immunity. This memory (enhanced secondary response) is evidenced by the protective effects of

vaccination and the improbability of recurrence of certain diseases (e.g., measles) in normal individuals. The enhanced secondary response is based on the clonal expansion of lymphocytes by antigen and the subsequent generation of memory cells (17). When an individual first comes in contact with an immunogen (e.g., tetanus toxoid, inactivated virus), a primary immune response is initiated in which specific antibodies appear in several days to clear the foreign material. A second contact, even some time later, results in a reaction that is quantitatively and qualitatively different. Among other things, this secondary response is characterized by a shorter lag time, and a much higher concentration of antigen-specific immunoglobulin in the circulation is ultimately reached. Clonal selection of immunogen-specific lymphocytes occurs during the primary response, and this enlarged population of cells is responsible for the stronger second reaction. Memory of a specific immunogenic stimulus may be long-lived, on the order of years if not decades. Two hypotheses have been forwarded to define the means by which immunologic memory is retained: (a) long-lived memory cells are preserved in a dormant state until reactivated by antigen or (b) the antigen responsible for immunologic memory persists for the duration of the memory response, and/or restimulation is induced by subclinical infections or by cross-reactive antigens. The last stimulus set refers to close mimics of the original immunogen, which may not be able to activate naive or previously unstimulated cells but can reactivate these clones following prior stimulation with the original immunogen.

Phenotypic and functional differences readily distinguish memory from naive lymphocytes. In general, memory T and B lymphocytes are more easily stimulated by succeeding contact with antigens, principally through antigen receptors with higher affinity for the antigen. Among B cells, this is due to somatic hypermutation of antigen-receptor genes; an isotype switch (e.g., from mIgM to mIgG) is also considered a marker of memory B cells. For T cells, TCR affinity changes are probably due to a form of clonal selection for T-cell clones that bind the antigen efficiently. There are also changes in the expression of various T-cell surface markers, such as an increase in the relative density of adhesion molecules. Also, there is a change in the isoform of the leukocyte common antigen, CD45. Naive T cells are defined by the presence of CD45RA, while memory cells express the lower-molecular-weight CD45RO. Although these changes in surface molecules suggest an activated status and support the notion that memory cells are in a constant state of activity, there is the possibility that in the absence of antigenic stimulation, CD45RO⁺ cells may revert to the CD45RA phenotype and join a resting pool of memory cells.

Inflammation

Inflammation is a complex and coordinated response by the host to eliminate foreign materials and enact tissue repair. It encompasses aspects of both innate and adaptive immunity and has traditionally been described as a progression from acute to chronic stages followed by healing and reconstruction. Chronic inflammation also accompanies a large number of pathologic states such as autoimmune diseases and allergies, although their etiologies are for the most part unclear. What is certain is that in these cases, inflammatory reactions become destructive to the host.

The overall function of the inflammatory response is to bring humoral and cellular

defense and repair components to the area of injury. Following tissue injury, inflammation is initiated by release of soluble mediators from tissue mast cells and vascular cells. These signals contribute to an initial vasoconstriction of several seconds followed by dilation of precapillary arterioles. The observed redness is due to increased blood flow to the site. There is also an associated increase in the permeability of postcapillary venules because of retraction of endothelial cells and formation of intercellular gaps. This leads to leakage of plasma into the interstitial space and resultant swelling and edema. The combined directed channeling of blood and fluid leakage results in a decreased blood flow and accumulation of blood cells at the affected site. This facilitates adherence of leukocytes (particularly neutrophils and macrophages) to the vascular walls and their migration into the interstitial space. Thus, the classic symptoms of inflammation are localized redness or erythema, warmth, and swelling.

In addition to the phagocytes and granulocytes already mentioned, two other cell types are important in inflammation: endothelial cells and platelets. Endothelial cells (ECs) provide the boundary between the intra- and extravascular spaces and, under normal conditions, provide a nonsticky, impermeable conduit for the passage of blood components. ECs also contribute to the regulation of vascular tone via the release of vasodilators (prostaglandin I_2 , adenosine, nitric oxide) and vasoconstrictors (endothelin). Disruption of EC function or integrity leads to alterations in mediator release, exposure of the basement membrane, eventual aggregation of platelets and leukocytes, and changes in blood flow patterns. Activation of ECs increases their surface expression of adhesion molecules that bind to counterparts on leukocytes and aids in the localized accumulation of inflammatory cells. Once this initial localization of leukocytes is accomplished, chemotactic factors guide the migration of leukocytes closer to the affected area.

Platelets provide several functions in the inflammatory reaction. In conjunction with the coagulation cascade, platelet aggregation forms plugs at sites of vessel damage. Platelet aggregation is promoted by contact with the extracellular matrix following vascular injury, as well as exposure to adenosine diphosphate (ADP), thromboxane A_2 , or the coagulation cascade. Coagulation, in return, can be activated by the aggregation of platelets, the surfaces of ECs and monocytes, and various tissue-derived factors. These processes result in construction of a fibrin and platelet network that inhibits the outflow of blood from injured vessels. Aggregated platelets also release a number of primarily proinflammatory cytokines (eicosanoids, proteases, and ADP) that regulate the activities of ECs and leukocytes. In addition, platelet-derived growth factors are important in mobilizing fibroblasts and smooth muscle cells toward wound healing and scar formation.

The noncellular plasma components that infiltrate the inflammatory site include the immunoglobulins, complement, and acute-phase proteins discussed above. In addition, molecules of the “contact-activation system” function to generate bradykinin and activate the coagulation cascade. The proinflammatory consequences of bradykinin include increased vascular permeability, smooth muscle contraction, and with prostaglandins, induction of soluble mediator–induced pain. This system integrates with platelets and other cells and coagulation and inflammatory mediators to produce the

fibrin thrombus.

Many pro- and antiinflammatory soluble factors are associated with the metabolism of arachidonic acid (AA) (18). Incidentally, these 20-carbon oxygenation products of AA, the “eicosanoids,” may form only a fraction of existing “oxylipins,” or signaling molecules, that can be derived from oxygenated polyunsaturated fatty acids (PUFAs); AA is one of many known PUFAs. (See Chapter 4 for AA metabolism and eicosanoid function.) The three classes of enzymes that use AA as a substrate for formation of eicosanoids are the cyclooxygenases (prostaglandins [PGs]), the lipoxygenases (leukotrienes [LTs], lipoxins [LXs], hydroxyeicosatetraenoic acids [HETEs]), and the epoxygenases (epoxyeicosatrienoic acids). There are two forms of cyclooxygenase (COX): COX1 is constitutively active, while COX2 is an inducible enzyme. Cyclooxygenase can catalyze two distinct reactions: the cyclization of AA and the hydroperoxidation of the cyclopentane ring, forming short-lived lipid hydroperoxide intermediates. Lipid hydroperoxides and hydroperoxyeicosatetraenoic acids (HPETEs) are the precursors of the various PGs and TXs and the array of LTs and LXs, respectively.

Platelet-activating factor (PAF), a term for a group of bioactive molecules that share the structure 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine, is produced by a large number of cells including phagocytes, granulocytes, and platelets, as well as endothelial and epithelial cells.

Histamine is an inflammatory mediator that composes up to 10% of the granule contents of basophils and mast cells. The consequences of histamine release are due to its binding to tissue histamine receptors.

Lymphocyte Development

As mentioned above, all leukocytes develop from a unique, self-renewing, pluripotential hematopoietic stem cell (19). From this cell type, different developmental signals and tissue microenvironments give rise to the known white blood cells.

T (thymus-dependent) lymphocytes develop from self-renewing progenitors that migrate from the bone marrow to become situated in the thymus (20, 21). Maturation of thymocytes is manifested by changes in the expression of cell surface molecules and the locations of these cells within the thymus. The surface markers most commonly used in staging the thymocytes are CD3, CD4, and CD8. The progenitors are initially CD3⁻CD4⁻CD8⁻. In the thymic cortex, prothymocytes rearrange their TCR genes and express TCR and CD3. gd TCR⁺ cells tend to remain CD4⁻CD8⁻ (doubly negative) while ab TCR⁺ cells convert to a CD4⁺CD8⁺ (doubly positive) phenotype. Clonal selection through TCR binding with MHC results in positive selection of clones that are capable of MHC-restricted interactions. Doubly positive ab TCR⁺ cells then develop into CD4⁻CD8⁺ or CD4⁺CD8⁻ (singly positive) cells. These thymocytes migrate to the thymic medulla where negative selection occurs. At this junction, clones that can recognize self-antigen–MHC complexes are eliminated to minimize the potential for autoreactivity. These mature cells are then released into the peripheral circulation. More than 90% of thymocytes initially produced are eliminated through the positive and negative selection

processes, primarily by apoptosis (22).

Since the mammalian thymus begins to involute during puberty, there is much interest in the status of T-cell development in postpubertal years. Studies suggest that with age, T-cell development shifts to other tissues, in particular, the intestines (23, 24). These age-dependent changes in T-cell development are possibly related to increased susceptibility to various immunopathologic states. For example, the onset of most forms of autoimmune diseases occurs during or after puberty (25). Also, graft-versus-host disease is more frequent in adults than in children, which suggests that following bone marrow transplantation, the absence of a thymus in the adult results in abnormal redevelopment of the immune system.

Unlike the T cell, mammalian B cells are produced primarily in the bone marrow. Although the fetal liver is a source of B cells early in life, B-cell production eventually shifts to the bone marrow. As with T-cell development, the stages of B-cell lineage are noted by the rearrangement and expression of antibody genes, as well as by other cell surface markers. An interesting surface marker that distinguishes two separate B-cell lineages is CD5. As with ab and gd TCR⁺ T cells, CD5⁺ (B1) and CD5⁻ (B2) B lymphocytes are separable by phenotype, appearance in ontogeny, distribution, and antigen specificity. Indeed, there is the notion of the existence of a two-layered immune system composed of evolutionarily older B1 cells and gd TCR⁺ T cells and the more recently evolved B2 cells and ab TCR⁺ T cells (26).

Generation of antibody diversity begins with the random combination of V, D, H, and J constant-region immunoglobulin genes. In a developing B cell, an immunoglobulin heavy-chain variable (V) region gene (of which there are hundreds) recombines with one diversity (D) region and one joining (J) region by excision of intervening genomic DNA. In addition, the terminal deoxyribonucleotidyl transferase enzyme inserts random nucleotides at these junctions prior to splicing. Diversity is increased through V-region exchange and transcription of D regions from one of three different reading frames. At the protein level, functional variation at the antigen-binding site is further enhanced by random combination of heavy and light chains. Finally, as mentioned above, somatic hypermutation in rapidly dividing B cells creates genetic variation. Except for the inability of T cells to undergo somatic hypermutation, these concepts apply to the TCR. The inhibition of T-cell, but not B-cell, somatic hypermutation is rationalized as the need to limit the random appearance of autoreactive T cells that could promote undesirable autoimmune reactions.

Cellular Interactions in Adaptive Immune Responses

Secondary Lymphoid Tissues

The adaptive immune response is generated from a network of cellular and subcellular components that are called into play following host contact with foreign material. These processes occur in specialized lymphoid tissues that provide the necessary environment for full expression of an adaptive response. In contrast, innate and inflammatory responses can be initiated and maintained in potentially any site in the body. The separation of primary and secondary lymphoid tissues is based on function. The bone

marrow and thymus are the primary lymphoid tissues responsible for leukocyte production, whereas secondary sites (e.g., lymph nodes, spleen, mucosal tissues) generate adaptive immune responses.

The lymphatic and circulatory systems facilitate translocation of leukocytes and immunoactive molecules and the immunologic protection of tissues distant from the actual site of immunogen contact. There are numerous examples of this process: activated immune cells migrate from the gut to the lungs; following contact with microbial antigens, macrophage-like cells of the skin migrate to lymphatic tissues to initiate an antimicrobial response; systemic infections result in the trapping of microbes as they pass through the filtering activity of lymphoid tissues.

In lymph nodes, activity is noted by the appearance of lymphoid follicles—aggregations of lymphocytes and supporting follicular dendritic cells. Primary follicles contain mature resting B cells, suggesting a minimum of immune activity. Following an immunogenic challenge, a secondary follicle containing a germinal center of rapidly proliferating B cells is formed. T lymphocytes and antigen-presenting cells are found in the paracortex, an adjacent region downstream of the follicles. Lymph node swelling or lymphadenopathy indicates increased lymph node activity following immune stimulation.

The spleen is the major lymphoid tissue that filters the blood. Blood enters the spleen via the splenic artery and branches into finer arterioles, whereupon it contacts T cells, B cell-containing lymphoid follicles, and a spongy network of reticular cells and macrophages. Approximately half of the total blood volume passes through the spleen daily, where it is monitored for infectious agents and damaged red and white blood cells.

The mucosa is an ideal entry point for infectious microbes since it provides sites for transfer of materials between the internal and external environments. Lymphoid tissues lining mucosal regions are collectively termed the *mucosa-associated lymphoid tissues* (MALT) (27, 28). Unlike their systemic counterparts (e.g., spleen), these mucosal lymphoid regions are somewhat distinct in their lack of well-defined tissues. Instead, the mucosal epithelia of the lungs and gut are lined primarily by diffused masses of lymphocytes and phagocytes, with occasional lymphoid follicles. More-organized structures, such as the tonsils of the upper respiratory tract and the Peyer's patches of the gut, are constituents of the MALT. However, these structures are not composed of distinct capsules nor vessels, as are lymph nodes and spleens. The MALT also differs from the systemic immune system in the preferential formation of IgA and IgE, as well as the limited circulation of mucosa-derived lymphocytes to mucosal regions.

Antigen Processing and Presentation

Antigens must be processed and presented by antigen-presenting cells (APCs) to facilitate their recognition by lymphocytes (29). There are several such APCs, which differ in antigen-processing characteristics, anatomic location, the types of lymphocytes they interact with, and the stages of the immune response at which they are employed. There are two characteristics common to the process of antigen presentation. First, T cells recognize antigens in the form of 9- to 25–amino acid stretches of linear short peptides. Second, these peptides must be complexed to MHC molecules on the APC

surface.

Major Histocompatibility Complex. The MHC is a set of genes whose extreme polymorphism accounts for much of the immunogenetic difference between individuals of the same species as well as problems associated with tissue allograft rejection. However, they are indispensable for generation of antigen-specific immune responses. Indeed, the survival of populations or species facing constantly evolving infectious challenges has been attributed to this polymorphism (30). The human MHC is termed the *human leukocyte antigen (HLA) system*. Other vertebrate species have genes analogous to the human MHC; for example, the murine counterpart is designated the H-2 system.

There are three major classes of MHC molecules encoded by the HLA genes: MHC-class I, II, and III. The cell-surface histocompatibility molecules are found in the class I and II loci, whereas class III codes for complement and other soluble proteins. Both MHC class I and II molecules are transmembrane heterodimers that contain structural domains formed by disulfide bridging. Similar domains are found in other molecules, and thus the MHC is included in the “immunoglobulin gene superfamily.” However, there are very clear differences in the structure and function of these two classes of MHC molecules. These differences translate into interactions between class II molecules with CD4⁺ “helper/inducer” T cells, and class I molecules with CD8⁺ “cytotoxic/suppressor” T cells. MHC class I antigens are found on most, if not all, somatic nucleated cells, have recognition sites for CD8, and present endogenously processed (e.g., peptide products of viral proteins expressed by the host's cells) antigens. Thus, CD8⁺ T cells are considered MHC class I restricted, and their immune responses constitute major defenses against virus-infected and tumor cells. MHC class II antigens are expressed by a more limited range of cell types; they are found primarily on macrophages, B and T lymphocytes, dendritic cells, and ECs. The density of the MHC class II molecules increases following cell stimulation. Class II⁺ APCs activate CD4⁺ T cells (class II restriction) and present exogenous antigens (e.g., phagocytosed bacteria). Class II-restricted responses promote antibacterial immunity and immunity to other exogenous protein antigens. These interactions involve the $\alpha\beta$ TCR. Other “nonclassic” MHC forms are less polymorphic and appear to activate T cells with the $\gamma\delta$ TCR (11).

Antigen-Presenting Cells. Since virtually all cells express MHC class I molecules, most cells can present endogenous antigens to CD8⁺ T cells. Specialization among class II–restricted APCs implies a need to direct immune responses to exogenous antigens and not self antigens. Among APCs, macrophages historically received the most attention. The phagocytic activity of this ubiquitous scavenger cell is found among blood monocytes, liver Kupffer cells, brain glia, and macrophages in systemic and mucosal lymphoid tissues. Macrophages are especially important in generating primary immune responses, as their relatively non-antigen-specific phagocytic activity allows the processing and presentation of many types of exogenous antigens. Similarly, dendritic cells such as skin Langerhans' cells and blood dendritic cells are important APCs in the initiation of a primary response. B cells, on the other hand, are important APCs in secondary immune responses. Following a primary response, expanded populations of antigen-specific B cells capture and endocytose antigens via their slg. These antigens

are then processed and presented. Antigen uptake in the gut is accomplished by M cells, which are specialized transport cells with no MHC class II expression. These cells are interspersed among the gut epithelial cells and pass antigens to the underlying macrophage and dendritic APCs (31).

Adhesion and Accessory Molecules. There is a constantly growing list of receptor-ligand interactions that involve cell surface molecules known collectively as adhesion molecules (32, 33). Relevant interactions include those involving MHC, CD4, CD8, and surface-antigen receptors. Adhesion molecules bind cells together to mediate a number of different activities, including cell killing, phagocytosis, signal transmission, and cell migration. The expression of adhesion molecules often depends on the activation state of the cell and its microenvironment. For example, the density of lymphocyte function-associated antigen-1 (LFA-1) on T cells increases following contact with macrophages (Table 45.1).

Family/Species	Distribution	Target Cell/Ligand Distribution
Immunoglobulin superfamily		
CD2	NK cells, T cells	LFA-3 (CD58)
CD4	T cell subset	MHC class II
CD8	T cell subset	MHC class I
CD28	T cells	B7
ICAM-1	EC, lymphocytes	LFA-1, Mac-1
ICAM-2	EC, lymphocytes	LFA-1
VCAM-1	EC, macrophages	VLA-4
Integrins		
VLA-4 (α4β1)	Eosinophils, lymphocytes	FN, VCAM-1
LFA-1 (CD11a/CD18)	PMNs, lymphocytes	ICAM-1, ICAM-2
Mac-1 (CD11b/CD18)	PMNs	ICAM-1, iC3b
gp 150.95	Myeloid cells	iC3b
Selectins		
E-Selectin (ELAM-1)	EC	Sialyl Lewis ^x , others
L-Selectin (LAM-1)	Lymphocytes, PMNs	CD34, GlyCAM-1
P-Selectin	EC, platelets	Sialyl Lewis ^x , PSGL-1

^a I indicate alternate designations.
^b EC, endothelial cells; FN, fibronectin; PSGL-1, P-selectin glycoprotein ligand.

Table 45.1 Selected Adhesion Molecules^{a,b}

Cell-surface accessory molecules also direct T-cell activation during antigen presentation (34). During generation of a primary immune response, the activation of T cells requires costimulatory signals in addition to that derived from the TCR-MHC binding. This costimulation is provided by the ligation of the T-cell CD28 molecule and the APCs B7 molecule. Interaction of the TCR with its cognate peptide–MHC molecule in the absence of CD28/B7 interaction renders the T cell anergic and unresponsive to further stimulatory signals. However, unlike a requirement for costimulation by resting T cells, T cells previously activated by antigens do not need costimulatory signals to be reactivated.

Cytokines. Cytokines are protein molecules, most of which have pleiotropic effects. They are produced by virtually all nucleated cells and include lymphocyte-derived lymphokines, monocyte-derived monokines, hematopoietic colony-stimulating factors, and connective tissue growth factors (35). Individual cytokine species may be secreted by more than one cell type, and the functional activity of a cytokine is mediated by

typical ligand/receptor binding events. These factors differ from hormones in that they operate at short distances within tissues for paracrine and/or autocrine communication. Generally, cytokines are induced by infectious challenge or other stressors and are not constitutively released. The understanding of cytokine networks is complicated by their numerous cellular sources, their pleiotropic effects, synergisms and antagonisms engendered by cytokine mixtures, and their ability to alter the production of other cytokines and their receptors. This communication network is an important aspect of immune system regulation. Information on the major cytokines is summarized in [Table 45.2](#).

Table 45.2 Cytokines

Regulating the Immune System

Since the function of the immune response is the elimination of foreign parasites and abnormal host cells, regulatory mechanisms are needed to minimize destruction of normal host cells. These devices, most of which are not well understood because of the complexity of their interactions, are crucial to the maintenance of human health. Indeed, problems in immune regulation result in chronic autoimmune, allergic, and other inflammatory conditions.

Clonal Deletion and Anergy

T cells can be deleted (i.e., certain lymphocyte clones are physically eliminated) or anergized (i.e., clones are insensitive to stimulation, although they may still be present) (34). Several factors contribute to the selection of T cells for deletion or anergy, including the stage of development or activation; differences in the type of APCs, cytokines, and other signals; the affinity of TCR-antigen-MHC binding; and the presence of costimulatory signals. Costimulatory signals, exclusive of TCR-MHC interactions, include cytokines and other receptor-ligand interactions. Without such associated signals, TCR-MHC interactions tend to result in T-cell anergy rather than activation. The principles governing B-cell tolerance are similar to those of T cells, such as

antigen-binding affinity and the developmental state of the B cell.

CD8⁺ T Cytotoxic/Suppressor Cells

Mature CD4⁻CD8⁺, ab TCR⁺ T cells are generally MHC class I restricted and traditionally fall into two major categories. Cytotoxic (Tc) CD8⁺ T cells, which are well-described, are important in the killing of virus-infected and tumor cells. Suppressor T (Ts) CD8⁺ cells, although less well characterized, are thought to inhibit the activation phase of immune responses ([36](#), [37](#) and [38](#)).

Cytokines and Eicosanoids

Cytokines as promoters of cell growth and differentiation were described above. Cytokines may also inhibit immune responses or concurrently activate one immune component while downregulating another. For example, transforming growth factor- β (TGF- β) is produced by many hematopoietic cell types, including Ts cells, and is involved in embryonic development, tumorigenesis, inflammation, and immunoregulation. The functions of TGF- β include inhibition of T-cell proliferation and the cytotoxic activity of Tc and NK cells.

Distinctions between the cytokine-release profiles of type 1 and type 2 T helper (Th1, Th2) cells are noteworthy ([39](#)). Although these Th cells cannot be distinguished phenotypically (they are both CD4⁺CD8⁻), they are separable by cytokine production. Th1 cells release IFN- γ and induce cell-mediated immune responses. Th2 cells typically produce IL-4, IL-5, IL-6, and IL-10 and are primarily involved in stimulating antibody production. These cell types and the immune networks they promote can be mutually antagonistic. For example, IFN- γ blocks the growth of Th2 cells, while IL-4 inhibits some of the functions of macrophages activated by IFN- γ . In addition, CD5⁺ B-1 cells release IL-10 and are activated by IL-5 ([40](#)). Another example of selective inhibitory function is shown by prostaglandin E₂ (PGE₂). Studies on Th1 and Th2 cells demonstrate the ability of PGE₂ to arrest the function of Th1, but not Th2, cells ([41](#), [42](#)).

Antibody Feedback

Antibodies can provide negative feedback to limit antibody responses. By eliminating or neutralizing immunogens that stimulate the immune system, antigen-specific antibodies contribute to limiting the extent of the immune response.

Of particular interest to researchers studying the relationships between immune networks and ontogeny are natural autoantibodies (NAs), their ligands, and the cells that produce NAs ([43](#)). NAs, their ligands, and NA-producing CD5⁺ B-1 cells are thought to represent a phylogenetically ancient immune recognition system ([26](#)). Although the function of NAs is controversial, they may be important in clearing cellular debris from the circulation. Their unusually broad antigen specificity could provide a constitutive immune defense against infectious agents, probably through recognition of common or ubiquitous antigenic structures. NAs may also be important for self-nonself

discrimination and the generation of self-tolerance by the immune system.

Laboratory Tests of Immune Function

A large number of immunologic tests are routinely available to assess the immunologic status of any individual's immune system. This section summarizes representative assays.

Antibodies and Antigens

Enzyme-linked immunosorbent assays, or ELISAs, constitute one of the most commonly used techniques in immunology. There is often a need to quantify the levels of circulating antibodies and their antigen specificity and isotype. This assay is based on the binding of plasma/serum antibodies with defined antigens on a solid phase (typically plastic or glass) and the commercial availability of antibodies linked to reporter molecules.

Immunoblotting is a useful technique for detection of antibodies to relatively ill-defined antigens, such as antigens from a tissue homogenate. After separation by gel electrophoresis, antigens are transferred to a matrix (blotting strips) and incubated with patient sera. Antigen-specific antibodies can then be detected by a color reaction. The location and intensity of the color change provide information on the relative amounts of antibody and the molecular mass of its ligand.

Enumerating Antigen-Specific B Cells

The ELISPOT is used to quantify the number of antigen-specific B cells in a fashion similar to the ELISA. In this case, B cells are added to the wells of ELISA plates previously coated with a particular antigen; these B cells are then nonspecifically activated to produce antibodies. B cells that recognize the antigen will then bind to the solid phase and can be detected by a subsequent color reaction. These cells show as visible spots, representing individual antibody-producing B cells, which can be counted.

Leukocyte Function

The extent of proliferation following exposure to activation signals is frequently used as a general measure of lymphocyte health. Briefly, a predetermined number of purified lymphocytes in a cell culture medium are stimulated by mitogens or agents that activate cells in an antigen-nonspecific (non-sIg and -TCR) fashion. After a short period of culture (approximately 3 days), the cells are pulsed with ^3H -thymidine, which is incorporated into the newly synthesized DNA of the proliferating cells and detected by scintillation counting.

Proliferation is also induced by mixing leukocytes from genetically different sources. This form of activation is induced by TCR-MHC interactions and is thus antigen (MHC) specific. This test is used as one functional measure of MHC differences (histocompatibility) between individuals and is considered an in vitro counterpart to

tissue mixing (e.g., tissue grafts, bone marrow transplants).

Cytotoxicity Assays

Cytotoxicity assays are used to determine the killing activity of cytotoxic cells, such as Tc and NK cells. Traditionally, tumor cell lines provide the sources of genetically consistent indicator or “target” cells used to measure NK cell function. Target cells are loaded with ^{51}Cr and incubated with their appropriate effector lymphocytes; release of this radiolabel is then used as a measure of target cell killing. More-recent innovations include the use of fluorescent, rather than radioactive, markers. DNA fragmentation (apoptosis) is also used as an endpoint.

Hypersensitivity Skin Tests

Hypersensitivity to exogenous antigens or allergens is a common problem in humans. The strategy of avoiding contact with allergens to minimize the frequency or intensity of allergic reactions first requires identification of these environmental agents. Skin tests are often used in this regard. Basically, samples of allergens are injected subcutaneously and a measure of reactivity is based on the size of the inflammatory skin reaction. Immediate hypersensitivities mediated by IgE (e.g., pollen extract) become evident in minutes. Delayed-type hypersensitivity (DTH) reactions (e.g., tuberculin test), which are due to T-cell recruitment of phagocytes to the injection site, require 24 to 48 hours.

Identification and Quantification of Leukocyte Subpopulations

Flow cytometry is the most reliable way to determine the frequencies of different leukocyte types in a sample. Flow cytometers use a hydraulic system to pass a single-cell suspension before a laser source. Information, in the form of light scatter and fluorescence, is collected to measure a variety of cell characteristics that serve to identify leukocytes as lymphocytes, macrophages, etc. The flexibility of the flow cytometer is greatly enhanced by the use of monoclonal antibodies that recognize specific cellular markers. These antibodies, which bind to specific cell-surface epitopes, are conjugated to fluoresceinated materials that, when excited by the laser, serve to identify cell types (e.g., CD4^+ vs. CD8^+ T cells). Flow cytometry is also used to measure other cellular parameters such as membrane fluidity, DNA content, and intracellular Ca^{2+} .

Cytokine Assays

Cytokines released by cells in vitro or present in plasma may be measurable by ELISA. However, because cytokines such as the interleukins tend to operate at very short intercellular distances, have very short half-lives, and/or are produced in minute quantities, ELISA detection may be impractical. Alternatively, Northern blot analysis or the polymerase chain reaction may be used to measure the levels of cytokine mRNA in cells, or intracellular cytokines may be detected by fluorescent anticytokine antibodies

and quantified by flow cytometry.

EFFECTS OF NUTRITION ON IMMUNE RESPONSES

A survey of the literature shows that most nutritional deficits lead to suppressed immune responses. This is not surprising, since anabolic and catabolic pathways in the immune system require the same sort of building blocks and energy sources as other physiologic activities. Lipids seem to diverge from this generalization in that excess fatty acids and certain shifts in the balance of lipid species also lead to immunosuppressed states. Caloric restriction is another area of emerging interest, with important implications for human health. In general, moderate caloric restriction appears to have beneficial effects on longevity and disease resistance. However, these trends and generalizations must be approached with some care. Dietary manipulation can have selective effects on one portion of the immune system and not others. Also, factors such as ongoing chronic infections, gender, and age add more complexity to the study of immunonutrition.

Protein-Calorie Malnutrition

Protein-calorie malnutrition (PCM) is a major cause of immunodeficiency. Kwashiorkor (protein deficiency) and marasmus (generalized undernutrition or starvation) are the two clinical manifestations of PCM. Consequently, the immunologic manifestations of PCM are broad and include lymphoid tissue atrophy, decreases in lymphocyte numbers, and abnormally low cellular and humoral immune responses. As a result, PCM is associated with a high incidence of morbidity and mortality from infections ([44](#), [45](#)). Deficits in protein and energy may be accompanied by other nutrient deficits. The following sections focus on the better-defined forms of nutritional deficits.

Caloric Intake

Unlike the immunodeficiencies observed in severe PCM, moderate deprivation is associated with increased T-cell functions ([46](#), [47](#) and [48](#)). Palmblad ([49](#)) showed that short-term starvation lowered T-cell responses to mitogens and reduced the levels of acute-phase reactants but had little effect on circulating leukocyte numbers or resistance to infection. In experimentally induced dietary fasts in mice, the ability of T cells to proliferate in vitro increased ([50](#)), while food restriction inhibited the progression of disease in a mouse model of systemic lupus erythematosus ([51](#)). These observations are of interest within the context of life span extension, improved immune function, and caloric restriction ([Table 45.3](#)).

Effects of food restriction	
Mice:	Increases T-cell proliferative responses Inhibits progression of systemic lupus erythematosus
Humans:	Decreases immunocompetence when body weight drops below 60% of ideal weight Decreases CD4 ⁺ T cells, but not CD8 ⁺ T cells Increases frequency of circulating B cells Normal to enhanced plasma antibodies Decreases plasma complement Following weight reduction in obese people, increases mitogenic responses by peripheral blood leukocytes
Effects of caloric restriction	
Mice:	Inhibits immune-mediated diseases, tumor virus expression, and malignancies Decreases the proliferative ability of autoreactive B1 cells Decreases inflammatory cytokines IL-6 and TNF- α Decreases immunosuppressive cytokine TGF- β Increases T-cell proliferation to mitogens Decreases PGE2 release by spleen cells
Proposed mechanisms of these effects	
Reduction in accumulation of oxidant and radical damage Alterations in fat deposition, obesity, and hormones	

Table 45.3 Moderate Food or Caloric Restriction and the Immune System

The balance of energy intake relative to expenditure partially determines body weight and composition, which in turn influence immune characteristics. Indeed, leanness is associated with tumor and infection resistance. The diets of anorexics (anorexia and bulimia nervosa) are low in energy but may contain sufficient protein, vitamins, and minerals. Bowers and Eckert (52) reported that although patients with anorexia nervosa were leukopenic, they did not appear to be more susceptible to infectious disease than control subjects. Increased immunocompetence during mild anorexia was observed by Pertschuk et al. (53). Immunocompetence decreased when body weight dropped below 60% of ideal body weight.

Patients with bulimia nervosa consume large quantities of food, followed by fasting, vomiting, or laxative use. Generally, they are not severely emaciated and are considered in relatively good physical health. A study of bulimics by Marcos et al. (54) reported a 40% incidence of leukopenia. Decreases in circulating CD4⁺ T cells without alteration in CD8⁺ populations resulted in lowered CD4:CD8 ratios. Bulimics also had more circulating B lymphocytes and low complement but normal immunoglobulin levels. These authors hypothesized that cell-mediated immunity is selectively compromised (54). Similarly, PCM was associated with increased plasma immunoglobulin levels and complement deficiency (55). In addition, both CD4⁺ and CD8⁺ T-cell levels were depressed. Chronic infections or decreases in T-suppressor cells were suggested to be responsible for the elevations in antibodies.

A primary consideration among claims of enhanced immune responses with caloric restriction or mild malnutrition is the accurate determination of the nutritional intake of the subjects under study. Defining the sources of calories is important, since lipids provide functions other than energy (e.g., eicosanoid signaling), while certain amino acids (e.g., glutamine) are important energy sources for leukocytes. Subtle changes in other nutrients such as zinc may offset any gains produced by caloric restriction (56). Such changes could result in the reported declines in immune function associated with mild or moderate malnutrition (57). Opportunistic infections may also result from anorexia nervosa (58). Therefore, the alleged benefits of caloric restriction should be

evaluated with care.

To address these issues, the effects of individual nutrients were studied in animal models of regulated caloric restriction without severe alteration of protein, vitamin, and mineral levels. Studies by Good et al. (56, 59) demonstrated that a 40% decrease in caloric intake, relative to ad libitum feeding, increased the life spans of several strains of mice. Such chronic energy restriction also inhibited or delayed development of immune-mediated renal disease, vasculitis, lymphoproliferative disease, tumor virus expression, and malignancies. Furthermore, some of these effects depended on the relative contributions of fat and carbohydrate to the caloric content; a high-carbohydrate component was more conducive to good health than high fat. Caloric restriction also downregulated the proliferative ability of lymphocytes, including CD5⁺ B1 cells. More recently, caloric restriction in a mouse model of Sjögren's syndrome decreased the inflammatory cytokines IL-6 and TNF- α while enhancing the level of immunosuppressive TGF- β 1.

Others also support the association of caloric moderation and immunologic benefits. A review of the literature by Newberne and Locniskar (44) shows general improvements in longevity and immune function with experimental caloric restriction in mice. Heightened T-cell proliferative responses to mitogen stimulation (with less effect on B cells) and increased splenic T-cell numbers were among the benefits.

Obesity is associated with a variety of immunologic disorders (44). Increased incidence of infections and abnormalities in cellular and humoral immune components are characteristic of obesity. In a study of obese humans, mitogenic responses among peripheral blood leukocytes increased following weight reduction (60). However, strong genetic influences in obesity are not easily attenuated by diet modification. In a study of genetically obese (*ob/ob*) C57Bl/6 mice, food restriction had no effect on the proliferative ability of spleen cells (61). However, food restriction reduced B-cell frequencies and increased CD4 and CD8 T-cell frequencies in both obese and lean mice. Although food restriction did not change the CD4:CD8 T-cell ratio in obese mice, this ratio was reduced in lean mice.

Proteins and Amino Acids

Inadequacies in generalized protein intake lead to suboptimal tissue repair and decreased resistance to infections and tumors. Studies on T lymphocytes do indicate that protein malnutrition can have selective effects on immune function (62). Chronic protein deprivation in mice resulted in diminished IgG and DTH responses after 3 weeks, followed by reinstatement of normal responses by 11 weeks. Perhaps this is another example of delayed maturation of immune function, as suggested for caloric restriction (44). Additionally, protein deprivation affects oral tolerance to ovalbumin. Increased humoral immune tolerance to ovalbumin was manifested by a decrease in antiovalbumin antibody synthesis. However, increases in DTH inflammatory responses suggested impaired T-cell suppression of the cell-mediated response (63).

Arginine. Arginine, a semiessential amino acid important to the urea cycle, supports the synthesis of other amino acids and of polyamines, urea, and NO (64, 65). Arginine is

important for cell-mediated immunity, and exogenous sources are often required during sepsis. The growth and function of T lymphocytes in culture requires L-arginine. In vivo, arginine has the effect of retarding thymic involution by encouraging production of thymic hormones and thymocyte proliferation. The thymotropic effect of arginine depends on an intact hypothalamic-thymic axis, suggesting that the thymus is a target organ for growth hormone and prolactin release induced by arginine.

Arginine also promotes leukocyte-mediated cytotoxicity in a number of ways. Growth hormone receptors are widespread in the immune system, and arginine may increase the cytotoxic activities of macrophages, NK cells, cytotoxic T cells, and neutrophils by releasing growth hormone. A product of arginine metabolism, NO, has tumoricidal and microbicidal activities, induces blood vessel dilation, and influences leukocyte-endothelial cell adhesion.

Glutamine. Glutamine is the most abundant amino acid in the blood and in the body's free amino acid pool (66). Lymphocytes and macrophages use glutamine as a source of energy and molecular intermediates for purine and pyrimidine synthesis. As with arginine, glutamine is an essential component of leukocyte cell culture media. Following cellular uptake, a glutaminase in the inner mitochondrial membrane converts glutamine to glutamate and ammonia. Further processing results in production of aspartate and oxidation of about 25% of the glutamine to carbon dioxide. This "glutaminolysis" pathway works in conjunction with the glycolytic pathway to allow the combined use of glucose and glutamine as energy sources in lymphocytes and macrophages.

Infection and inflammation release glutamine from large (20 mM in normal humans) intracellular stores in skeletal muscles. An additional response is de novo production of glutamine by the lungs. The observation that glutamine transport from tissue stores to leukocytes, and not glutamine metabolism, is rate limiting suggests a role for skeletal muscle in regulating leukocyte metabolism. Thus, a deficiency in glutamine stores or nutritional support is likely to lead to poor immune responses.

The integrity of the intestinal immune system also relies heavily on sufficient glutamine intake. In animals, addition of glutamine to total parenteral nutrition inhibited the mucosal atrophy and leukocyte depletion normally associated with intravenous feedings, reduced bacterial translocation across the gut epithelium, and increased secretory IgA production.

In all, information on arginine and glutamine point to their potential uses in food supplementation to enhance wound healing, increase resistance to tumorigenesis and infections, and improve immune function in aged and immunocompromised persons (Table 45.4).

Moderate protein deficiency	
Mice:	Temporary reduction in DTH and plasma IgG in oval tolerance to ovalbumin, increases humoral (Th2?) tolerance, but decreases DTH (Th1?) tolerance
	Generalized decrease in tissue repair
Severe protein deficiency (kwashiorkor)	
Humans:	Depresses both humoral and cell-mediated immune parameters
	Oxidant stress
Arginine	
	Important in the urea cycle and the synthesis of other amino acids, polyamines, urea, and nitric oxide
	Secretagogue for pituitary, pancreatic, and adrenal hormones
	Promotes T-cell development and growth and thymic integrity
	Deficiency leads to decrease in immune competence
	Exogenous sources important during sepsis
Glutamine	
	Important energy source for lymphocytes and macrophages
	Deficiency leads to poor immune responses
	Skeletal muscles store glutamine
	Supplementation in experimental parenteral feeding reduces gut mucosal atrophy and leukopenia

Table 45.4 Proteins, Amino Acids and the Immune System

Nucleic Acids

Preformed purines and pyrimidines in the diet appear necessary to maintain a number of cell-mediated immunologic mechanisms (67). A variety of T cell-associated processes declined when mice were fed nucleotide-free diets, including DTH responses, graft rejection, IL-2 and IFN-g production, T-cell proliferation, splenic NK cell cytotoxicity, and impairments of PMN functions. Dietary restriction of nucleotides also slowed the maturation of T lymphocytes. On the other hand, nucleotide supplementation altered human immune responses by increasing NK cell activity in human infants (68). Among septic or critically ill patients, feeding commercial diets containing nucleotides resulted in shorter hospitalization than with a nucleotide-free diet (69).

Elements

Copper

In animal and human studies, copper (Cu) deficiency is associated with increased susceptibility to infections. Copper deficiency may impair phagocyte functions, decrease T lymphocyte numbers and activities, lower IL-2 production, and increase B cell numbers (44, 70, 71). Bala et al. (72) reported increased IL-2 receptor and transferrin receptor expression by T cells from Cu-deficient rats. A report on human responses to experimental Cu deficiency described a decrease in T-cell proliferation and increased numbers of B cells (73). Excess dietary Cu also results in reductions in phagocyte numbers and performance. Explanations for these effects include copper's involvement in complement function, cell membrane integrity, immunoglobulin structure, Cu-Zn superoxide dismutase, and interactions with iron (Fe).

Following observations that Cu-deficient male rats tended to show a more marked depression in lymphocyte proliferation and more severe anemia than their female counterparts, Kramer and Johnson (70) studied the interaction of Cu with Fe. Better Fe

utilization in female rats was hypothesized. Indeed, Fe supplementation did not alleviate the anemia of Cu-deficient male rats. However, interestingly, spleen cells mitogenesis was greater in male rats deficient in both Cu and Fe.

Iron

A reduction in the concentration of plasma iron is considered an important host response to microbial infection. However, a number of T-cell and phagocyte abnormalities follow Fe deficiencies (45). Characteristic changes include reduced inflammatory responses such as the DTH reaction; impairments in neutrophil and macrophage cytotoxic activity; reductions in lymphocyte proliferation, T-cell numbers, cytokine release, and antibody production; and lymphoid tissue atrophy. Whitley et al. (74) noted decreased allograft rejection and changes in the migration patterns of T lymphocytes. Other parameters of immune function increase in activity (44, 75). These seeming inconsistencies may be due to complexities in Fe metabolism and its interactions with other nutrients.

The effects of Fe in immune function may be related to its involvement in folate metabolism, mitochondrial energy production, the respiratory burst, and/or its function as a component of many metalloenzymes including NO synthase, COX, lipoxygenase, and catalase (76). In addition, Fe metabolism and immune function are considerations in the “anemia of chronic disease” (77). Indeed, chronic inflammation is often associated with low serum Fe concentrations and increased Fe stores. There appear to be unique Th1-macrophage interactions in Fe metabolism; Th1, and not Th2, cells show hypoferrremia-induced inhibition of DNA synthesis (78). Th1 cytokines such as IFN-g and IL-2, as well as the inflammatory mediators IL-1 and TNF, induce NO synthesis in macrophages. Apparently, IFN-g activity is inversely related to the availability of low-molecular-weight and transferrin-bound Fe, perhaps because of direct physical interactions between Fe and IFN-g (79). Thus, high Fe levels tend to correlate with lower IFN-g and NO production.

In cells, Fe and NO levels regulate translation of mRNA containing iron-responsive elements (IREs) posttranscriptionally, as high Fe and low NO interfere with the binding of Fe-regulatory protein (IRP) to IREs situated on the 5' untranslated region of ferritin and erythroid 5-aminolevulinic acid synthase (e-ALAS) mRNA and on the 3' untranslated region of the transferrin receptor mRNA. Thus, depressed IRP-IRE binding encourages degradation of transferrin receptor mRNA and translation of ferritin and e-ALAS mRNAs. Consequently, Fe is stored by the formation of Fe-ferritin complexes and heme synthesis. Conversely, lower Fe and higher IFN-g, IL-2, and NO levels enhance transferrin-mediated Fe uptake by macrophages and lower Fe storage and erythropoiesis. Thus, activation of Th1 cells increases Fe storage, limits Fe availability for microbial agents, and promotes the antimicrobial and antitumor effects of NO. Because Fe consumption is but one of numerous factors that influence Fe status, the overt inconsistencies noted in the relationship of Fe status and immune function (44, 75) are, in hindsight, not surprising.

Magnesium

Animal studies have associated magnesium (Mg) deficiency with increases in thymic cellularity and inflammatory cells (especially eosinophils). Guinea pigs fed a Mg-deficient diet were at increased risk of anaphylactic shock, perhaps because of increased levels of tissue histamine. Also, release of histamine by mast cells may be regulated in part by the actions of Ca and Mg on cAMP formation. Magnesium deficits also elevate plasma concentrations of inflammatory cytokines such as IL-1, IL-6, and TNF- α . Conversely, Mg deficiency decreased concentrations of acute-phase molecules (45, 80). Relatedly, complement activity depends on an optimum Mg concentration range.

In vitro Tc cell-mediated lysis of target cells is directly proportional to Mg concentration, an effect possibly mediated via interactions with adhesion molecules (81). Since Tc cells may also induce target cell death by release of ATP, low Mg levels enhanced ATP-mediated killing of target cells. Maurois et al. (82) reported that experimental Mg deficiency in mice reduced parasitemia. Apparently, the increased oxidative environment caused by low Mg levels in red blood cells decreased the infectivity of these parasites for erythrocytes (82).

Manganese

Information on manganese (Mn) and immunity is relatively limited (44, 45). Manganese induces macrophages to spread on glass surfaces. Phagocytes incubated in medium supplemented with Mn salts showed reduced chemotaxis and uptake of amino acids. Manganese is also a constituent of the T-cell mitogen concanavalin A (con A). Manganese is a component of several metalloenzymes that may participate in immune functions, including arginase, peroxidases, catalase, and Mn superoxide dismutase (76).

Selenium.

Selenium (Se) deficiency is associated with suppression of a large number of immunologic endpoints including resistance to infection, antibody synthesis, cytotoxicity, cytokine secretion, and lymphocyte proliferation; chronic Se deficiency in human populations is also associated with a high incidence of cancer. Conversely, experimental Se supplementation increases most immune parameters, suggesting that this element has adjuvant properties.

Selenium is an essential component of glutathione peroxidase (GPx), an antioxidant enzyme that, in conjunction with vitamin E, prevents peroxidation of cellular and membrane lipids (45, 57). As an example of their interaction, lowered antibody production caused by Se deficiency is reversible by vitamin E supplementation. Since phagocytes produce reactive oxygen species, limiting the potential for lipid peroxidation during immune and inflammatory processes is important to prevent autoxidation as well as damage to surrounding tissue. Indeed, excess H₂O₂ is neutralized by phagocyte-produced GPx. In addition, Taylor (83) reported that Se could mediate posttranslational modifications of important immune system proteins. A study of human mRNA sequences coding for CD4, CD8, and HLA-R suggested alternate reading

frames that could code for selenoproteins. Taylor hypothesized that redox reactions and selenium availability at these selenocysteine sites may alter the conformation of these proteins.

Zinc

Insufficient zinc (Zn) intake may be the most common form of mineral deficiency, particularly among people consuming diets high in cereal and low in animal products (see [Chapter 106](#)). The best-documented immunologic consequences of Zn deficiency are low thymic weights and T-cell defects ([44](#), [45](#), [84](#)). Several T-cell abnormalities are related to Zn deficiency, including reductions in T-cell numbers and responsiveness to mitogenic stimuli, T-cell help toward antibody production, DTH reactions, thymic hormone production, Tc cell activity, and T-cell maturation. Interestingly, Zn deprivation does not affect T-cell responses to con A while the responses to phytohemagglutinin and pokeweed mitogen are reduced, suggesting differences in Zn dependency among T-cell subpopulations. Zinc-deprivation increases corticosteroid production and enlarges adrenal glands, which may be of interest in relation to corticosteroid-induced T-cell apoptosis. However, adrenalectomy does not prevent thymic involution. B-cell functions are relatively intact as tested by mitogen-induced proliferation. Other immune parameters such as NK cell activity and cytokine production have shown mixed results.

Zinc supplementation produces beneficial effects on thymic and T-cell characteristics. Zinc induces secretion of thymulin from cultured human thymic epithelial cells ([85](#)). In addition, in vitro Zn concentration is inversely related to susceptibility to apoptosis induced by dexamethasone or serum starvation ([86](#)).

The presence of Zn in many (>300) proteins ([87](#)) (see [Chapter 11](#)) complicates the understanding of Zn-related immune effects. Zn is a widely used structural component; Zn-finger structures are found in transcription factors and nuclear hormone receptors ([88](#)). Zn is known to influence endocrine function. Recently, prolactin was shown to bind Zn ([89](#)). The activity of thymulin is Zn dependent ([90](#)), as is the respiratory burst of macrophages ([91](#)). Obviously, a deficiency of Zn may cause numerous irregularities in the immune system.

Mineral Interactions

Studies of single-nutrient deficiencies face difficulties in interpretation because of the physiologic interactions among nutrients. Apart from those reported herein (Fe and Cu; Zn and other metals), numerous other examples were reviewed by Couzy et al. ([92](#)).

Vitamins

Taken as a whole, vitamins are important factors in a wide variety of metabolic processes such as gene transcription, enzymatic reactions, and redox reactions. Reviews of the literature present a correspondingly broad range of immunologic effects related to vitamin deficiencies and excesses ([44](#), [45](#), [57](#), [93](#)).

Vitamin A

A deficiency of vitamin A is associated with increased morbidity and mortality, most likely because of increased severity of infections (94). Vitamin A and related retinoids maintain the integrity of epithelial boundaries and the production of mucosal secretions. Some of the immunologic abnormalities that follow vitamin A inadequacies include a reduced number of leukocytes (except PMNs, which may increase), reduced lymphoid organ weights, reduced circulating levels of complement, impaired T-cell functions, and decreased resistance to immunogenic tumors. Vitamin A-deficient rats showed significant decreases in NK cell functions compared with controls (95). Vitamin A deficiency also decreased antigen-specific IgG responses and induced generalized hypergammaglobulinemia (96). Relatedly, vitamin A deficiency in rats somewhat increased IFN-g production by leukocytes, lowered resistance to helminth infections, and decreased IgE synthesis (97). Studies confirm that Th1 cell activity precedes that of Th2 cells and that vitamin A supports Th2 development (98). Thus, vitamin A deficiency may lead to elevated Th1:Th2 ratios during an immune response.

Vitamin A supplementation studies showed decreases in respiratory infections and neutrophil counts and increases in reticuloendothelial system function, lymphocyte proliferation, tumor resistance, graft rejection, and cytotoxic T-cell activities. Supplementation above that required to maintain normal vitamin A stores results in adjuvant effects. Excess vitamin A increases antibody and cell-mediated immune responses, stimulates Kupffer cells, and potentiates some types of liver toxicity and gouty arthritis (99, 100). The inhibition of T-cell apoptosis by retinoic acid (101) may possibly contribute to its adjuvant effect. The use of vitamin A as an immunologic adjuvant was recently tested (102). Because of a high prevalence of subclinical vitamin A deficiency, some infants vaccinated for measles also received 100,000 IU of vitamin A. Infants who had at least a 1:8 titer of maternally transmitted antimeasles antibodies and received vitamin A showed a significantly lower frequency of seroconversion. The researchers hypothesized that vitamin A inhibited the replication of the measles virus which was necessary to provoke a protective immune response.

The vitamin A precursor β -carotene is generally considered an antioxidant with activities that are independent of its provitamin A function. Some of its reported benefits include protecting host cells and tissues from oxidation by the respiratory burst and promoting lymphocyte proliferation, T-cell functions, cytokine production, and cell-mediated cytotoxicity. However, Bates (103) cautioned that carotenoids can exhibit prooxidant as well as antioxidant activity. Also, their record in ameliorating chronic and degenerative diseases is not consistent. Bates suggested that in addition to antioxidant activity, beneficial carotenoids may also function by promoting gap junction communication and connexin synthesis.

B Complex Vitamins

Pyridoxine or vitamin B₆ deficiency induces lymphocytopenia with decreases in lymphoid tissue weights and reduced proliferative responses to mitogens. There are general deficiencies in cell-mediated immunity, including allograft rejection, IL-2

production, and the DTH response (93). Humoral immunity is also affected, as seen by lowered antibody responses and depressions in antigen-specific secondary responses. Macrophage and NK cell cytotoxicity toward target cell lines was unchanged by pyridoxine deficiencies. The pyridoxine requirement for nucleic acid and protein synthesis during lymphocyte proliferation is probably responsible for the greater effect on lymphocytes than on macrophages or NK cells. Appropriate vitamin B₆ supplementation readily restores these immunologic endpoints. Pyridoxine supplementation also protects mice from the immunosuppressive effects of UV-B radiation (104). Pyridoxine may compete with *cis*-urocanic acid, a mediator of photoimmunosuppression, for binding on histamine-like receptors on T cells.

Cyanocobalamin (vitamin B₁₂) deficiency and folate deficiency are clinically indistinguishable since they are both required for synthesis of thymidylate. They depress a number of immunologic parameters including the respiratory burst, phagocytosis by PMNs, DTH responses, and T-cell proliferation to phytohemagglutinin. Proliferating T cells from patients with pernicious anemia are "megaloblastoid" in character, being larger in size and with an abnormal chromatin pattern. The defect in nuclear maturation results from inadequate thymidylate synthesis.

Biotin deficiency is associated with humoral and cell-mediated immune deficiencies. Depressions in thymic weights, antigen-specific antibody responses, and reduced lymphocyte-mediated suppressor activity have been noted.

Deficiencies in pantothenic acid commonly lead to decreased antibody responses. The biochemical lesion may be an inability to secrete newly synthesized proteins to the extracellular space.

Immunologic abnormalities associated with thiamin deficiency include increased susceptibility to infectious disease agents, premature thymic atrophy, decreased antibody responses, and reduced PMN mobility.

Riboflavin deficiency in dogs increased PMNs with concurrent decreases in peripheral blood lymphocytes. In other animal studies, decreased antibody responses and thymic weights and increased susceptibility to challenge with infectious disease agents were observed.

Vitamin C

Vitamin C, another antioxidant vitamin, functions as a biologic reductant in regeneration of oxidized vitamin E (105). Apart from a sparing effect on Se, interactions between vitamin C and glutathione may be important for phagocyte microtubule function. Scavenging of extracellular superoxide anion and hydroxyl radicals by ascorbic acid minimizes autoxidation of phagocytes and damage to bystander host cells without compromising intracellular oxidant capacity. Immunologic problems associated with vitamin C deficits include decreases in resistance to infections and cancer, phagocyte mobility and phagocytosis, the DTH response, skin allograft rejection, and wound repair. Studies on people of various age groups demonstrated the ability of vitamin C

supplementation to enhance many of these immunologic parameters, including the DTH and antibody responses (106). However, research does not support the use of megadoses (>1 g/day) of vitamin C to prevent common colds, although low doses may have minor prophylactic effects or reduce their symptoms. Indeed, high ascorbic acid levels arrested in vitro lymphocyte proliferation by mitogens (105).

Vitamin D

Vitamin D has both stimulatory and suppressive effects on immune responses because of its influence on mineral metabolism and its hormonal nature. For example, vitamin D stimulates maturation of normal and neoplastic myelomonocytic cells to more differentiated monocytes and macrophages. Certain tumors also reinforce myelopoiesis through the production of granulocyte-macrophage colony-stimulating factor (GM-CSF). Vitamin D₃ reduces tumor growth and its associated immunosuppression by blocking release of GM-CSF (107). The potential autocrine nature of vitamin D is suggested by its synthesis by activated macrophages and the presence of vitamin D receptors in mononuclear phagocytes. Tokuda and Levy (108) compared the effects of 1,25-dihydroxyvitamin D₃ (1,25(OH)₂D₃) and PGE₂ on monocyte function. While both cytokines increased phagocytosis, 1,25(OH)₂D₃ also reduced HLA-DR expression. This suggests that both cytokines activate innate responses (phagocytosis) while 1,25(OH)₂D₃ also inhibits an acquired immune response by downregulating MHC molecule expression required for antigen presentation.

Receptors for vitamin D, which are present on the surface of activated lymphocytes, probably mediate vitamin D's influence on lymphocyte proliferation and function. 1,25(OH)₂D₃ inhibits CD4⁺ T-cell activities such as IL-2 and IFN-g production, Tc activation in mixed leukocyte reactions, and T-cell promotion of immunoglobulin production by B cells. NK cell generation is also reduced. However, 1,25(OH)₂D₃ does not interfere with the cytotoxic function of already established T and NK cells (109). Interestingly, 1,25(OH)₂D₃ preferentially inhibits Th1 functions and not those of Th2 (110) or CD8⁺ T cells (111). This overall promotion of immunosuppression may be important in the reported modulation of autoimmune diseases (109, 112).

Vitamin E

Vitamin E deficiency is relatively rare in human populations and controversy exists about recommended intakes. However, its essential nature derives from its function as a radical scavenger to limit cell membrane peroxidation and its interactions with other antioxidants (113). Experimentally induced deficiency leads to depressed leukocyte proliferation, lower chemotaxis and phagocytosis by PMNs and macrophages, and decreased tumor resistance while leaving NK cell cytotoxicity either unchanged or enhanced. Vitamin E supplementation increased a number of immune parameters including lymphocyte proliferation, antibody levels, the DTH reaction, IL-2 and 6-keto PGF_{1a} production, and phagocytosis. Supplementation also reduced PGE₂ synthesis, levels of plasma lipid hydroperoxides, and oxidant damage induced by burns in lung tissues. The inverse relationship of PGE₂ and 6-keto PGF_{1a} production to changes in

vitamin E level is evidence for redox influences on arachidonic acid metabolism and, consequently, immune function. Vitamin E supplementation also restored Th1 activity and IL-2 and IFN-g production in murine AIDS (114). Finally, in human populations, high vitamin E intake increases resistance to infections among the elderly.

Lipids

FAs function as energy sources, as cell membrane components, and as mediators of cell signaling. Among the PUFAs, the most important dietary PUFAs are in the n-3 and n-6 classes. Since cell membrane composition is partially dependent on the FA species taken in through the diet (115), dietary lipids are an important influence on cell function.

Arachidonic acid (20:4 n-6) is an important constituent of plasma membrane phospholipids and a precursor of cell-derived eicosanoids (18). Eicosanoids are members of a family of 20-carbon PUFAs derived from oxygenation of arachidonic acid. Collectively, they contribute to an enormous range of physiologic and stress responses including inflammation, immunity, reproduction, blood flow, and temperature regulation. The evolution of signaling by eicosanoids may have its roots in the oxidation of membrane FAs during cellular damage. The disassembly and oxygenation of membrane components are an aspect of the stress response of cells and, indeed, the extent of membrane alterations may be proportional to the level of stress placed on a cell. The development of mechanisms to use these cellular responses to stress as cell signals could conceivably have driven the evolution of eicosanoid production. Within the context of the immune response, such signals are used in activation of immune cells during periods of host stress, such as microbial infection.

PGE₂ exhibits selective inhibitory function. Studies on Th1 and Th2 cells demonstrated the ability of PGE₂ to arrest the function of Th1, but not Th2, cells (41, 42, 116). The previously prescribed thesis of PGE₂ as an immunosuppressor was apparently based on studies of primarily cell-mediated not humoral immune functions. Thus, the downregulation of Th1 cells and the promotion of Th2 cells by PGE₂ may enhance antibody production.

The contribution of dietary lipids toward autoimmune disease is highlighted by the beneficial effects of experimental essential fatty acid (EFA) deficiency in animal models of diabetes and lupus (117). An important outcome of EFA deficiency is altered macrophage function related to arachidonic acid metabolism and eicosanoid synthesis (118, 119). As a result, there is interest in reducing the arachidonic acid content in the cell membranes of humans. Manipulation of eicosanoid synthesis often means replacing conventional vegetable oils with fish oils that are relatively rich in n-3 FAs, which can supplant membrane n-6 FAs and alter the eicosanoid species produced. As a result, ingesting fish oil leads to lower production of PGE₂ by spleen cells than an n-6-rich corn oil diet (120). Clinical studies demonstrated the effectiveness of fish oils in reducing autoimmune and other immunopathologic parameters. Fish oil supplementation on a mouse model of systemic lupus erythematosus, the NZB/NZW F1 strain, reduced levels of IL-1b, IL-6, and TNF-a and increased antioxidant enzyme activities (121). Sanderson et al. (122) reported that feeding rats fish oils increased graft survival while decreasing

popliteal lymph node NK cells and CD8⁺ T cells. Relative to safflower oil, fish oils decreased the frequency of gdTCR⁺ splenic T cells and the activity of lymphokine-activated killer (LAK) cells (123). Fish oil supplementation of multiple sclerosis patients similarly decreased IL-1, TNF- α , IL-2, and IFN- γ levels (124). However, fish oils from different sources possess different characteristics. Unlike menhaden and sardine oils, feeding rats cod liver oil decreased α -tocopherol levels in spleen cells (125), possibly because of antagonistic interactions between vitamin E and the vitamin A found in fish liver oil.

In addition, n-3 PUFAs are directly obtained from plant sources. Wu et al. (126) demonstrated the ability of plant-derived α -linolenic acid to reduce PGE₂ production by the peripheral blood leukocytes of cynomolgus monkeys. In this study, consumption of either marine- or plant-derived n-3 PUFAs led to a drop in the absolute numbers of circulating T cells but not B cells. Collectively, studies such as these demonstrate attenuation of a number of inflammatory states and immune-mediated diseases by dietary FA manipulation.

An alternative to both the n-3 and n-6 PUFAs are the monounsaturates. The monounsaturated FA, oleic acid (18:1 n-9), is abundant in olive and rapeseed oils, is not converted to eicosanoids, and is highly resistant to oxidation compared with PUFAs. These factors contribute to the widespread reputation of olive, and now canola, oil in minimizing coronary heart disease and possibly other chronic ailments. In experimental studies on the effects of edible oils on inflammation, olive and rapeseed oils are sometimes used as control or placebo oils (127). As caveats, the spectrum of biologic effects, particularly negative effects, that could result from the dominant use of these oils and the cellular enrichment of oleic acid is probably not known. Also, oleic acid is not highly competitive with arachidonic acid for incorporation into phospholipids.

Studies on experimental animals demonstrated associations between increasing consumption of dietary fats and immunosuppression (44, 45). High-PUFA diets decreased the proliferative capacity of mouse lymphocytes, while low-PUFA diets enhanced cell division. In addition, an examination of in vitro macrophage activity showed that supplementation of culture medium with saturated FAs decreased phagocytosis of zymosan particles (128). By comparison, PUFAs increased phagocytosis, with arachidonic acid giving the greatest response. Of practical concern, increased susceptibility to bacterial and tumor challenges may result from the immunosuppression caused by high-fat diets. Of course, the caveats to such studies include the extrapolation of in vitro studies to in vivo situations and the multiple effects of dietary fats (e.g., energy considerations vs. signaling).

This is not to say that a low-lipid diet is unequivocally advantageous. Enhancements in certain parameters of immune function with reductions in dietary fats may depend on the duration of food restriction. Long-term deficiency in EFAs (especially linoleic acid) in mice can result in reduced cell-mediated immune responses rather than enhancements. Unsaturated FAs are also not necessarily of better quality than saturates. In a study of hairless mice, dietary butter fat was more effective than vegetable oil or margarine in preventing the immunosuppression induced by UV-B radiation (129). The mechanism of protection may be related to differences in dietary FAs and the FA composition of the

skin. Additionally, studies showed that mice on high-fat diets had prolonged tissue graft survival, while EFA-deficient diets accelerated skin graft rejection (44, 45). The latter observation coincides with the association of increased PGE₂ production by liver Kupffer cells with decreased heart allografts (130, 131). The downregulation of Th1 cells and cell-mediated immune responses is probably responsible for the PGE₂ effect.

The lipid composition of foods given to patients is a target of research and development (132, 133). Modification of the FA composition of medical foods is seen as one means of increasing resistance to infection following surgery. Triglycerides are fat molecules formed from the covalent attachment of three FAs to a glycerol moiety. Triglycerides in the enteral and parenteral diets of medical patients provide calories and linoleic acid and carry fat-soluble vitamins. Long-chain triglycerides, which generally contain FAs of 14 carbons or longer, were initially used in medical foods. Unfortunately, intravenously administered long-chain triglycerides tended to impair macrophage and neutrophil functions. Indeed, experiments in animals demonstrated that long-chain triglycerides reduced the efficiency of their livers to clear injected bacteria and increased their risk of lung infections. More-recent innovations include medium-chain triglycerides with FAs of 8 to 10 carbons, and structured lipids prepared by the hydrolysis and reesterification of FAs to form mixed-length triglycerides. Medium-chain triglycerides and structured lipids appear to avoid the negative side effects of long-chain triglycerides.

Collectively, such studies show that dietary lipids are important factors that influence the characteristics of an immune response. However, stronger immune responses are not advantageous in all situations. Allergies and autoimmune diseases are examples of hyperactive or misdirected immune reactions. Also, since the immune system is responsible for rejection of tissue grafts, an ability to selectively suppress this aspect of an immune response would be useful. Therefore, the specific manipulation of dietary lipids in response to one health problem may not be appropriate for other situations.

Antioxidants

Nutrition interfaces with oxidant balance and immunity through antioxidant vitamins, trace elements and superoxide dismutase, the effects of caloric restriction on life span, and the endogenous production of reactive oxygen and radical species by leukocytes (134, 135 and 136). Of special interest to the present discussion are oxidized lipids, dietary antioxidants, and the effects of redox-related events on different lymphocyte subsets.

In terms of oxidant balance and the regulation of the immune system, some information is available from studies on inflammatory rheumatic diseases (137, 138) and allergies (139). Of more defined interest are the immunoregulatory effects of oxidants and associated signaling molecules on T-cell subpopulations. This is of immense importance as phagocytes are endogenous producers of reactive oxygen and T lymphocytes are central to the activation of specific immune reactions. There is evidence to suggest that CD8⁺ T cells are more susceptible to prooxidant inhibition than CD4⁺ T cells. Droge et al. (140) demonstrated the ability of an inhibitor of glutathione synthesis to lower in vitro proliferation of CD8⁺ T cells without a similar effect on CD4⁺ cells. In addition, human

peripheral blood CD8⁺ T cells have less intra-cellular superoxide dismutase than CD4⁺ T cells, and this quantitative difference increases with age (141). These observations are relevant within the context of selective prooxidant-mediated apoptosis of T lymphocytes.

The selective inhibition of Th1 cells also suggests that this T helper subset may be an important site for feedback inhibition of cell-mediated immune responses. PGE₂ inhibits Th1 function without a similar reduction in Th2 activity (41, 42, 116). Relatedly, inflammatory signals, including reactive oxygen, activate cyclooxygenase (142). As mentioned above, interactions between circulating Fe and Th1 cells affect iron storage (77), DNA synthesis in Th1 cells (78), and IFN- γ activity (79). Iron sequestration also lowers Fe-mediated catalysis of hydroxyl radicals from H₂O₂ substrates. Furthermore, UV-B radiation mediates the conversion of provitamin D₃ to previtamin D₃. Interestingly, 1,25-dihydroxyvitamin D₃ preferentially inhibits Th1 functions and not Th 2 (121) or CD8⁺ T cells (111). Of possible related interest, UV-B radiation causes release of Fe from transferrin (143). In addition, vitamin A downregulates the activity of Th1 and actively promotes development of Th2 cells (98, 144). Conversely, the antioxidant vitamin E is able to restore Th1 activity (113, 114). There is sufficient information to suggest that prooxidants and associated molecules and processes provide negative feedback signals to Th1 cells as a means of balancing cell (Th1)- and antibody (Th2)-mediated effector mechanisms. The rationale or significance of preferentially inhibiting Th1 cells is the modulation of cell-mediated immune responses. Cell-mediated reactions are responsible for the endogenous production of much of the reactive oxygen and radical effectors and, relatedly, the collateral tissue damage during inflammation.

Intracellular signaling pathways responsive to pro- or antioxidants are being defined and are likely to explain the effects of oxidant balance on T cells. Prooxidants are generally associated with the activation of the NF- κ B transcription protein through dissociation of its inhibitor, I κ B. Likewise, a response to antioxidants is the binding of fos-jun dimers to AP-1 binding sites that are found upstream of several T-cell interleukin genes (145). Promoter/enhancer regions often have sites for the cooperative binding of NF- κ B, AP-1, and other transcription regulators, and the interactions among these transcription factors are yet to be resolved.

As mentioned above, Th1 cells are more sensitive to hypoferrremia-induced inhibition of DNA synthesis than are Th2 cells (78). Thus, iron levels could be one component in an overall strategy toward managing the relative levels of different T-cell subpopulations in health and disease. Dietary manipulation of iron can affect the health of autoimmune mice (146); iron supplementation of MRL-lpr/lpr mice increased morbidity and mortality, possibly by enhancing the Fenton reaction and oxidant stress. Conversely, moderate iron deficiency improved the health status of these mice. Since autoimmune diseases are associated with Th1 and Th2 imbalances (147, 148), manipulation of dietary Fe may partially normalize T-cell functions.

Lipid oxidation is of immunologic interest because of the potential for oxidant-induced immune activation and cell apoptosis. Vitamin E is an important radical quencher that limits the peroxidation cascade among phospholipid FAs. However, cell membranes are

also sites of reactive oxygen and radical production, including formation of lipid hydroperoxides via metabolism of arachidonic acid (149, 150) and synthesis of reactive oxygen during the respiratory burst (151). Metals such as Fe are also implicated in the oxidation of lipids by catalyzing the formation of hydroxyl radicals (152). In addition, scavenger receptors on phagocytes act as receptors for oxidized low-density lipoproteins that have platelet activating factor–like activity (153). Foods constitute a potentially major source of oxidized lipids that act to compromise the antioxidant capabilities of the consumer (152, 154).

Foods are an important source of antioxidant activity, which varies as a function of the quality of the diet. Apart from the vitamins and trace minerals already mentioned, plant sources contain other nutritional antioxidants; of particular significance are the polyphenolics (155, 156). However, the antioxidant nature of a compound depends highly on its chemical environment, and indeed many plant-derived antioxidants that inhibit lipid oxidation promote carbohydrate oxidation (155). Finding oxidant stress in kwashiorkor (157) and the use of glutathione and other cysteine-containing antioxidants in the treatment of protein-energy malnutrition (158) show that dietary antioxidants and adequate energy sources help to maintain antioxidant defenses.

Age

Schandler (159) recently reviewed the contributions of human milk toward immunologic defense in infants. In particular, comparisons between human and bovine milks indicate a higher quality of the former for infant development. Human milk passively transfers immunoglobulin, antibacterial proteins such as lactoferrin and lysozyme, and oligosaccharides with bacteria-binding activity. Additionally, the composition of protein and fat from human milk is more conducive for absorption. Lahov and Regelson (160) also described casein-derived proteins, caseidins, with antibacterial properties. A purified polypeptide of casein, isracidin, increases the survival of mice during bacterial challenge. Although its mechanism of action is not clear, it does increase phagocyte activity.

Immune function in the elderly undergoes immunosenescence. During this period, decreases in antigen-specific immune responses to infections and cell-mediated immunity and increases in autoantibodies and autoimmune conditions are common (25, 161, 162). A focus of much interest in immunosenescence is the T cell (24, 163, 164). The start of thymic involution during puberty results in alterations in the developmental environment of T lymphocytes. Therefore, extrathymic sites for T-cell development, such as the gut, may become more important with increasing age. Changes in T-cell populations include declining IL-2 production, Th1/Th2 ratios, CD8⁺ T cells, and lymphocyte mitogenic responses. Increases are noted in the proportion of memory T cells, in PGE₂ production, and in NK cell numbers. Age-related changes in membrane composition and function also accompany declines in leukocyte activity.

Nutrition is useful in delaying or partially reversing the progression of immunosenescence. Nutritional status in the elderly is often compromised by a combination of physiologic and environmental factors. Thus, caloric restriction is generally not considered a viable option, as malnutrition is of concern in the elderly

(161). On the other hand, vitamin-mineral supplements do improve cell-mediated immune responses in older people (165). Most of the data on supplementation with specific nutrients are related to antioxidants, and the proposed mechanism by which caloric restriction appears to affect human health and aging (by limiting oxidant damage) is also considered important as a remedy for immunosenescence.

Several studies focused on the relationship of dietary Zn to immunocompetence. At least in aged mice that exhibited a negative Zn balance, supplementary Zn partially restored thymic architecture and function, as well as a number of immunologic parameters (166, 167). These authors noted normalization of the thymic epithelial cell network and increases in thymic hormone production and thymocyte numbers. Also enhanced were mitogen responses to phytohemagglutinin and concanavalin A, splenic T-cell numbers (particularly CD8⁺ T cells), and target-cell killing by NK cells.

Meydani et al. (168) recently summarized the benefits of dietary antioxidants on immune function in the aged. Vitamin E supplementation has its greatest effect on cell-mediated Th1 immune responses as manifested by increases in DTH responses and IL-2 production and decreases in PGE₂ synthesis. However, antigen-specific antibody responses to influenza virus and killing of *Candida albicans* by PMNs were unchanged. Vitamin E also decreased plasma lipid peroxidation. β-Carotene supplementation increased NK cell cytotoxicity and DTH responses to recall antigens, probably as results of alterations in cytokine production.

Cellular and tissue levels of glutathione decline with age, a condition that is partially reversible in mice by dietary glutathione (168). In this situation, improvements in DTH reactions and mitogen responses were associated with increased tissue levels of glutathione. In vitro addition of glutathione to cultures of human peripheral blood leukocytes showed a curious biphasic effect on mitogen-induced proliferation. The designated optimum concentration (5 mmol/L) for proliferation was slightly higher than that found in vivo. Compared with controls with no added glutathione, 5 mmol/L enhanced IL-2 production and inhibited PGE₂ and LTB₄. However, 0.5 and 1.0 mmol/L glutathione significantly decreased cell proliferation in comparison to controls. Meydani et al. (168) suggest that the lower levels (<1.5 mmol/L) of glutathione present in the extracellular medium actually enhanced hydroxyl radical production above that of controls. Therefore, glutathione, like other dietary antioxidants, can alter the release of cell metabolites as well as markers of oxidant stress.

EPILOGUE

This review supports the view that nutrients are an important environmental influence on the immune system. Advances in dietary and nutritional practices will contribute to an enhanced quality of life and, in particular, the prevention and improvement of immune-mediated degenerative conditions. Oxidant and radical balances appear to be important focal points for regulating the immune system, especially since the immune response is a major source of reactive oxygen species. In addition, the information suggests that nutrients may be useful tools for manipulating the proportions of T-cell subpopulations that are central to immune regulation. Food and nutritional sciences will

continue to provide interesting insights into the working of the immune system as well as identify practical dietary applications for the enjoyment of life.

Oxidative stress has been implicated in human disease by a growing body of scientific evidence. However, cells have multiple protective mechanisms against oxidative stress and succeed in preventing cell damage to the extent that these protective mechanisms are effective. Many dietary constituents are important sources of protective agents that range from antioxidant vitamins and minerals to food additives that might enhance the action of natural antioxidants. Indeed, at least part of the benefit of a high fruit and vegetable diet is thought to derive from the variety of plant antioxidants that might act as beneficial supplements in humans. On the other hand, materials such as pesticides, polyunsaturated lipids, and a variety of plant and microorganism-derived toxins might produce prooxidant effects in man. This chapter deals with our current understanding of the molecules that cause oxidative stress at the cellular level, the antioxidant systems that function at the cellular and organismal level, and the role of dietary materials in oxidative stress and human disease. Other chapters in this volume present more detailed information about individual vitamins and minerals and their potential participation in oxidative stress.

Oxidative stress has been defined as a disturbance in the equilibrium status of prooxidant/antioxidant systems in intact cells (1). This definition implies that cells have intact prooxidant/antioxidant systems that continuously generate and detoxify oxidants

during normal aerobic metabolism. When additional oxidative events occur, the prooxidant systems may outbalance the antioxidant, resulting in oxidative damage to lipids, proteins, carbohydrates, and nucleic acids, ultimately leading to cell death in severe oxidative stress. Oxidative stress may induce an alteration in the antioxidant systems by inducing or repressing proteins that participate in these systems and by depleting cellular stores of antioxidant materials such as glutathione and vitamin E.

A disturbance in prooxidant/antioxidant systems results from many different oxidative challenges, including radiation, xenobiotic metabolism of environmental pollutants and administered drugs, and challenges to the immune system in human disease or abnormal immune function. Clear evidence for the role of a variety of radical species in these processes has led to considerable interest in the reactions of partially reduced oxygen species and radical and nonradical species derived from them. Recently, it has also become clear that a variety of reactive nitrogen species derived from the reactions of nitric oxide play important roles as well. A radical species is specifically understood to be any atom that contains one or more orbital electrons with unpaired spin states. The radical may be a very small molecule, such as oxygen or nitric oxide, or part of a large biomolecule such as a protein, carbohydrate, lipid, or nucleic acid. Some radical species are very reactive with other biomolecules, and others, like the normal triplet state of molecular oxygen, are relatively inert.

RADICALS AND NONRADICALS IN OXIDATIVE STRESS

Oxygen Species

Radicals of oxygen (superoxide anion, hydroxyl radical, and peroxy radicals), reactive nonradical oxygen species such as hydrogen peroxide and singlet oxygen, as well as carbon, nitrogen, and sulfur radicals make up the variety of reactive molecules that can constitute an oxidative stress to cells (2, 3). It has been estimated that a maximum of 5% of the total oxygen metabolism of liver tissue results in production of partially reduced oxygen species such as those shown in [Figure 46.1](#). This represents a significant stress by itself, but extracellular sources of these molecules may be even more significant sources of oxidative stress. Therefore, considerable attention centers on identification of oxyradical-generating processes.

Electron-Accepting Orbitals

Triplet Oxygen	O_2	\uparrow	\uparrow
Superoxide Anion	$\bullet O_2^-$	$\uparrow\downarrow$	\uparrow
Hydrogen Peroxide	H_2O_2	$\uparrow\downarrow$	$\uparrow\downarrow$
Hydroxyl Radical	$\bullet OH$	$\uparrow\downarrow$	\uparrow
Water	H_2O	$\uparrow\downarrow$	$\uparrow\downarrow$
Singlet Oxygen	O_2	$\uparrow\downarrow$	

Figure 46.1. Molecular species of oxygen in oxidative stress. Each relevant orbital electron is indicated by an *arrow* showing its spin state. Each molecular species (except for singlet oxygen) is obtained by a one-electron reduction of the one above it in the table. In intact cells, singlet oxygen is formed by oxidation of one of the partially reduced states of oxygen.

Atmospheric oxygen, although a radical, is not particularly reactive with biologic molecules because the two orbital electrons participating in oxidation reactions have the same spin state. Thus, electrons that might be added to these orbitals during reduction of oxygen must be added singly rather than as a pair of electrons with paired spins. This spin restriction prevents rapid reactions with compounds that could easily react without the spin restriction. Any process that produces a one-electron reduction of oxygen produces the more reactive radical called superoxide anion. A second form of oxygen, singlet oxygen, is a much more reactive form with paired electrons. Reduction of this form of oxygen does not have the same spin state restriction. Singlet oxygen is formed by oxidation of the other reactive oxygen intermediates in [Figure 46.1](#). It has been identified in tissues under oxidative stress and may be an important reactant in oxidative stress.

Superoxide anion is generated continuously by several cellular processes including the microsomal and mitochondrial electron transport systems. In addition, xanthine dehydrogenase/oxidase and other cellular oxidases may be important sources of this molecule. Myeloid cells have a special role in production of superoxide anion since they contain a plasma membrane-bound electron-transfer complex, NADPH oxidase, that reduces oxygen with NADPH to produce copious amounts of superoxide anion (4). The products of this reaction are essential for effective bacterial killing. Absence of this enzyme activity is responsible for an inherited human condition, chronic granulomatous disease, characterized by recurrent infections.

The universal presence of superoxide dismutase in both cytoplasm and mitochondria ensures that much superoxide anion is rapidly converted into hydrogen peroxide. Superoxide anion is not particularly reactive, and it can diffuse considerable distances from its site of production. It may combine with other reactive species such as nitric oxide, produced by macrophages, to yield a more reactive species. It must be transported across membranes (by an anion transport mechanism), and in the vicinity of membranes, it may be protonated to $\text{HO}_2\cdot$ a much more reactive substance.

Hydrogen peroxide is generated by the same sources that produce superoxide anion since both enzymatic (superoxide dismutase) and nonenzymatic destruction of superoxide anion produces hydrogen peroxide. A number of other specific enzymes produce hydrogen peroxide directly. These include peroxisomal enzymes associated with fatty acid metabolism and cytoplasmic enzymes responsible for oxidation of a variety of cell metabolites. Hydrogen peroxide can diffuse over considerable distances and may pass membranes readily in this process. Thus, pools of hydrogen peroxide

equilibrate rapidly.

Hydrogen peroxide and superoxide anion can occur in the extracellular space and in blood plasma as a result of the membrane-associated reaction in myeloid cells such as neutrophils and macrophages (4). The membrane-associated NADPH-oxidase produces superoxide anion that rapidly dismutates to hydrogen peroxide as well.

In the presence of a transition cation such as iron or copper, superoxide anion can give rise to the highly reactive hydroxyl radical species (HO·) by the Haber-Weiss reaction (see below) (5, 6). Some forms of bound iron are more efficient than free iron in this process. Other complexes of iron prevent its participation in these reactions.

Haber-Weiss reaction

Iron-catalyzed Haber-Weiss reaction

Hydroxyl radical is considered a principal actor in the toxicity of partially reduced oxygen species since it is very reactive with all kinds of biologic macromolecules, producing products that cannot be regenerated by cell metabolism (Fig. 46.2). The rate of reaction of hydroxyl radical is diffusion controlled, and it reacts very close to its site of production. Therefore, damage by this radical is very site specific.

HYDROGEN ABSTRACTION

ADDITION TO AROMATIC RINGS

ELECTRON TRANSFER WITH IONS

Figure 46.2. Reaction of hydroxyl radicals with biologic molecules.

Peroxyl radicals occur during oxidation of lipids in oxidative stress and they are associated with the action of prostaglandin H synthase in prostaglandin synthesis (7). These radicals are formed by a one-electron transfer from a carbon-centered radical to oxygen (reaction 1 below). The peroxyl radical species, which are not very reactive, may diffuse a considerable distance. They react avidly with sulfhydryl groups (thiols) to generate the thiyl radical (reaction 2 below) (8).

Singlet oxygen is formed by oxidation of other partially reduced oxygen species, resulting in an oxygen with paired electrons in the reactive orbital (2).

The variety of oxygen species described above indicates the complexity of the reactions that can result from oxidative stress. Factors such as the site of production, the availability of transition metals, and the action of enzymes determine the fate of each radical species and its availability for reaction with cellular molecules. The H₂O₂ concentration under steady-state conditions in liver has been estimated to be 10⁻² to 10⁻⁹ M, while superoxide anion may be 10⁻¹¹ M.

Nitrogen Species

Nitric oxide (NO·) is an abundant reactive radical that acts as an important oxidative biologic signal in a large variety of diverse physiologic processes, including smooth muscle relaxation, neurotransmission, and immune regulation (9). The nitric oxide synthase enzyme generates this nitrogen-based radical species by a five-electron oxidative reaction that uses arginine as its substrate. This enzyme is found in both constitutive and inducible forms in many different cell types, and its activity is highly regulated by Ca²⁺ and other factors. The reaction is a complex one that involves flavin and pterin molecules. Calcium sensitivity is dependent on calmodulin (Fig. 46.3A). Nitric oxide synthase is especially active in macrophages and neutrophils. Thus, these cells produce both superoxide anion and nitric oxide during the oxidative burst triggered during inflammatory processes. Under these conditions, nitric oxide and superoxide anion may react together to produce significant amounts of a much more oxidatively active molecule, peroxynitrite (10) (Fig. 46.3B). Peroxynitrite is a strong oxidant that attacks protein cysteines and methionines. It also adds an NO₂ to the ring of protein tyrosines. The protein modifications that result from peroxynitrite production may explain some of the observed biologic effects of NO·. Additionally, NO· adds to thiols to form S-nitrosothiols (11) (Fig. 46.3B). The sulfhydryl is formally oxidized by one electron in

this reaction, and subsequent reaction with a reduced thiol leads to formation of a disulfide. S-Nitrosothiols may provide a mechanism for transport of NO· in the blood plasma where the low concentration of reduced thiol compounds prevents further reaction of the NO·/thiol adduct.

Figure 46.3. Formation and reactions of nitric oxide. *A.* The reaction catalyzed by nitric oxide synthase. The exact stoichiometry of the reaction is not known. The five-electron reaction generates nitric oxide and oxidizes NADPH in the process. *B.* Two important byproducts of nitric oxide generation are shown. In the *top reaction*, peroxyntirite is a simple addition product of superoxide anion and nitric oxide. No oxidation or reduction is necessary. In the *lower reaction*, S-nitrosothiols are formed by a reaction between thiols and nitric oxide that involves a one-electron oxidation. The reaction requires some electron-accepting species.

Production of nitric oxide can (a) trigger the production of cGMP through NO·-mediated stimulation of the guanylate cyclase enzyme; (b) produce adducts with thiols of various types (e.g., glutathione and protein thiols), generating S-nitrosothiols (Fig. 46.3B) as intermediates on the way to disulfide formation; (c) cause nitration of protein tyrosine residues through direct nitration reactions; and (d) increase oxidative stress through generation of peroxyntirite.

EFFECTS OF OXIDANTS ON MACROMOLECULES

Carbohydrates

Hydroxyl radicals react with carbohydrates by randomly abstracting a hydrogen atom from one of the carbon atoms, producing a carbon-centered radical (12). This leads to chain breaks in important molecules such as hyaluronic acid (Fig. 46.4) in a process that involves such intermediates as peroxy radicals. In the synovial fluid surrounding joints, accumulation and activation of neutrophils during inflammation produces significant amounts of oxyradicals. This phenomenon apparently accounts for a

significant decrease in the synovial fluid of affected joints.

Figure 46.4. Reaction of hydroxyl radicals with polysaccharides (hyaluronic acid).

Nucleic Acids

Nucleic acids are pentose-phosphate polymers that can undergo reactions with hydroxyl radical like those depicted for hyaluronic acid (Fig. 46.4) (13). There are also several important examples of modifications to the base portion of the polymer (Fig. 46.5). In fact these base modifications may be responsible for genetic defects produced by oxidative stress. Recently, 8-hydroxyguanosine has generated considerable interest as a product of hydroxyl radical attack on DNA that can be used to estimate DNA damage in humans (14, 15). Oxidative damage to DNA in humans has been estimated as 104 hits per cell per day. Estimation of modified bases in urine is a useful means of assessing the amount of DNA damage in an animal. Products such as 8-hydroxyguanosine, thymidine glycol, and uric acid are used for these estimates. DNA damage has also been estimated by chain breaks and base modifications in cultured cells under oxidative stress. An important metabolic effect of DNA damage is rapid induction of polyadenosine diphosphate ribose synthesis (ADP-ribosylation) in nuclei, resulting in extensive depletion of cellular NADH pools. ADP-ribosylation has been associated with repair of damaged DNA.

Figure 46.5. Selected modified bases found in DNA after oxidative stress.

Proteins

Proteins have many reactive sites that can be damaged during oxidative stress, but interest has centered on three measurable events. First, aggressive radicals such as hydroxyl radical can fragment proteins in plasma, and the fragmented products of specific proteins, if known, can be detected (16). This fragmenting is associated with reactions at specific amino acids such as proline (Fig. 46.6A) and histidine (17). Second, proteins may contain metal-binding sites that are especially susceptible to oxidative events through interaction with the metals. These reactions usually produce irreversible modifications in amino acids that might be involved in metal ion binding (e.g., histidine). These modifications may produce signal sequences that are recognized by specific cellular proteases that degrade such proteins (18, 19). Finally, many intracellular proteins have “reactive” sulfhydryl groups on specific cysteine residues (see “Cellular Antioxidants”) that can be modified (oxidized) to specific forms (disulfides) that can be reduced again metabolically (20). Similarly, some proteins have a “reactive” methionine that can undergo reversible modification to methionine sulfoxide (Fig. 46.6B) (21, 22). The disulfide and sulfoxide forms of these two amino acids may actually serve a protective role, since metabolic reversibility of the protein modification effectually detoxifies the oxidative species that caused the modification. The reversible nature of the modifications of cysteine and methionine also suggests that oxidative modifications of this type may have a role in regulating metabolic events in cells under oxidative stress.

Figure 46.6. Methionine and proline oxidation. *A.* Irreversible oxidation of proline in a peptide. The result is a break in the polypeptide chain and introduction of new carboxyl groups that can be measured to quantitate these events. *B.* Reversible oxidation/reduction of methionine as it occurs in several proteins. The reduction is an enzymatic process that requires a reduced thiol such as glutathione.

Lipids

Lipid peroxidation of polyunsaturated lipids is a facile process. This oxidation affects materials prevalent in dietary constituents and seriously affects the flavor of foods. In intact cells, these materials are major constituents of cellular membranes (23, 24), where peroxidation of membrane lipid seriously impairs membrane function. Most peroxidized membrane lipid results from oxidative stress in intact cells, but some dietary material may be directly incorporated into cell structures (25). Lipid peroxidation is a radical-initiated chain reaction that is self-propagating in cellular membranes. As a result, isolated oxidative events may have profound effects on membrane function. The reactions of this process are depicted in [Figure 46.7](#).

Figure 46.7. Reactions of lipid peroxidation.

The products of lipid peroxidation are easily detected in blood plasma and have been used as a measure of oxidative stress. The most commonly measured product is malondialdehyde ([Fig. 46.7](#)). In addition, the unsaturated aldehydes produced from these reactions have been implicated in modification of cellular proteins and other materials ([26](#)). The peroxidized lipid can produce peroxy radicals and singlet oxygen by reactions discussed above. Vitamin E is a particularly effective antioxidant in lipid-peroxidizing systems.

CELLULAR ANTIOXIDANTS

The most effective antioxidant in oxidative stress depends on the specific molecules causing the stress (i.e., superoxide anion, lipid peroxides, iron-generated hydroxyl radical, etc.) and the cellular or extracellular location of the source of these molecules. For example, cell membrane damage occurs from both internally and externally generated oxidative stress. This damage is most effectively prevented by vitamin E, which reacts with peroxy and hydroxyl radicals; carotenoids, which react with singlet oxygen; and possibly membrane-bound proteins. The chain-breaking antioxidant function of vitamin E in membranes results from its close association with polyunsaturated components of the membrane ([27](#)). It can be regenerated by reaction with cytoplasmic vitamin C and glutathione or by membrane-bound quinols. Vitamin C is subsequently reduced by glutathione through the glutathione cycle, described below. Thus, a specific attack on membranes results in participation of at least three different antioxidants. Similarly, when oxidative stress occurs in plasma, a variety of different antioxidants participates in the response. Many plasma proteins are affected by the process, causing either irreversible or reversible loss of functional protein activity. A good example is the oxidation of methionine residues in α -1-protease inhibitor (an inhibitor of elastase). The modification can be reversed by a specific reductase enzyme that restores the activity of the inhibitor ([21](#)) ([Fig. 46.6](#)).

Glutathione Redox Cycle and the Protein S-Thiolation Cycle

The low-molecular-weight thiol, glutathione, and “reactive” protein sulfhydryls (exposed cysteines in many proteins) are primary participants in cellular antioxidant systems. Glutathione ([Fig. 46.8](#)) is abundant (3 to 10 mM) in cytoplasm, nuclei, and mitochondria and is the major soluble antioxidant in these cell compartments ([28](#)). Reactive protein sulfhydryls are abundant in both soluble and membrane-bound proteins ([29](#)).

glutathione (GSH)

Figure 46.8. Structure of glutathione.

The sulfur atom in sulfhydryl groups easily accommodates the loss of a single electron ([reaction 1](#) below). The resultant radical species of sulfur (e.g., a thiyl radical) may have significantly longer lifetimes than many other radicals generated during stress. Sulfhydryl groups also partially ionize at cellular pH values, producing the more reactive nucleophile, thiolate anion ([reaction 2](#)). The pK_a of the sulfhydryl group of glutathione is 9.3, and many other sulfhydryl groups, especially those on proteins, may have considerably lower pK_a s because of local electronic effects. The thiolate anion is responsible for the reactivity of thiols with a variety of foreign materials in conjugation reactions during xenobiotic metabolism. Thus, the reactions of sulfhydryl groups during oxidative stress include examples in which both sulfur radicals and thiolate anions are important.

The enzymes of the glutathione redox cycle and the protein S-thiolation cycle are shown in [Figure 46.9A](#). The glutathione redox cycle is primarily mediated by enzyme-catalyzed reactions. Glutathione is oxidized by hydrogen peroxide to glutathione disulfide by the selenium-containing enzyme glutathione peroxidase and other enzymes that may use lipid peroxides rather than hydrogen peroxide as the oxidant. Thus, glutathione can detoxify both soluble and lipid peroxides. Glutathione disulfide is subsequently reduced by glutathione reductase, using NADPH as the reductant. Cellular NADPH, produced by the pentose-P pathway and other cytoplasmic sources, provides the major source of reducing power for detoxifying many peroxides.

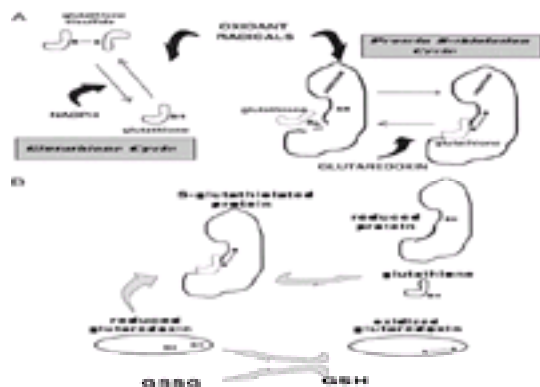

Figure 46.9. Redox cycles of cellular thiols. *A.* The figure on the *top* shows the glutathione and protein S-thiolation redox cycles. Glutathione is oxidized to glutathione disulfide primarily by hydrogen peroxide. It is reduced again by an enzyme, glutathione reductase, that requires NADPH. Proteins are oxidized to S-thiolated forms by several oxidants and reduced again by the protein glutaredoxin. Glutaredoxin is kept reduced by glutathione. *B.* Molecular details of the reaction of glutaredoxin, a dithiol protein, with S-thiolated proteins.

The concentration of cellular glutathione has a major effect on its antioxidant function, and it varies considerably as a result of nutrient limitation, exercise, and oxidative stress. Under oxidative conditions, the glutathione concentration can be considerably diminished through conjugation to xenobiotics and by secretion of both the glutathione conjugates and glutathione disulfide from the affected cells. Considerable glutathione may also become protein bound during severe oxidative stress. Recently, compounds have been developed that can both increase and decrease the glutathione concentration when administered to animals (30). Some of these compounds may provide the means to modify glutathione concentration in humans in the future. Experiments have already shown benefits in autoimmune disease in which glutathione concentrations are reduced.

The protein S-thiolation cycle (Fig. 46.9A) shows the effects of reactive oxidizing molecules on proteins that contain at least one reactive sulfhydryl. During oxidative stress, a large family of proteins that contain reactive sulfhydryls are modified by oxidation to mixed disulfides with attached glutathione (S-thiolation) (20). Other oxidized forms of protein sulfhydryls may occur in special circumstances. One such case may be when the glutathione concentration is too low for reaction with the protein sulfhydryl and reaction with molecular oxygen irreversibly oxidizes it to the sulfonic acid. Another case might be found in proteins in which adjacent protein sulfhydryls can react together to form a protein disulfide. The potential to form protein disulfides is not great for intracellular proteins, although these modifications are abundant in extracellular proteins. Figure 46.9A illustrates the protein oxidation cycle that involves formation of S-thiolated proteins. Figure 46.9B illustrates the mechanism for reduction of S-thiolated proteins by the low-molecular-weight protein glutaredoxin (31, 32). Glutaredoxin is kept reduced by the glutathione pool. It binds to, and reduces, proteins that have glutathione

attached by S-thiolation, by virtue of the specific binding site for glutathione at the active site of the protein. This protein is uniquely designed to reduce S-thiolated proteins.

Vitamin E and Membrane Peroxidation

The term *vitamin E* refers to a family of related compounds (tocopherols) that have hydroxylated aromatic rings (chromanol rings) and isoprenoid side chains. These molecules are highly lipophilic and reside almost exclusively in cell membranes, where the chromanol ring may be at the surface of the membrane, with the isoprenoid chain inserted into the bilayer (33). Since lipid peroxidation occurs on unsaturated fatty acid chains that reside within the lipid bilayer and the chromanol ring is the active radical-quenching part of the vitamin, the function of vitamin E as an antioxidant must involve considerable movement of lipids and vitamin E to promote molecular interaction (34). The reactions in which a chromanol ring can participate in these processes are shown in Figure 46.10. This figure shows that vitamin E is a chain-reaction-breaking antioxidant since it quenches the intermediate in the chain reaction. The ascorbate radical formed in this process reacts rapidly with the reduced glutathione pool or with a specific vitamin C reductase enzyme.

Figure 46.10. Oxidation of vitamin E by lipid radicals and reduction by vitamin C.

Enzymes As Antioxidants in Cells

Superoxide dismutase (SOD) is one of the most important enzymes that function as cellular antioxidants (35). It is present in cell cytoplasm (copper-zinc enzyme) and in mitochondria (manganese enzyme) to maintain a low concentration of superoxide anion. It catalyzes the dismutation of superoxide anion in the following manner.

Absence of this enzyme is lethal. However, too much may also be detrimental, since an

excess of this enzyme may produce hydrogen peroxide at a rate that is toxic to cells during oxidative stress. The amount of superoxide dismutase is controlled by specific redox-sensitive genes in cells (36). An extracellular form of superoxide dismutase exists in plasma, lymph, and synovial fluid that differs from the intracellular forms of the enzyme (37). This enzyme may function at cell surfaces.

Catalase is a heme protein that catalyzes the reaction shown below in which hydrogen peroxide is detoxified. It is usually found in peroxisomes, but in cells like erythrocytes that do not contain these organelles (38), it is a cytoplasmic enzyme. Catalase provides a protective role that is similar to that of glutathione peroxidase in that both remove hydrogen peroxide. The relative contributions of catalase and glutathione peroxidase to hydrogen peroxide detoxification may be quite variable (39).

PLASMA ANTIOXIDANTS

Human plasma contains little catalase, superoxide dismutase, glutathione, or glutathione peroxidase, but a number of small molecules and protein constituents contribute to the antioxidant properties of this important fluid. Plasma has been studied by use of artificially generated oxidants and with such natural oxidants a cigarette smoke. Plasma ascorbate is among the first compounds that become oxidized in stress (40, 41). Other materials may become oxidized only when ascorbate is depleted. Oxidation affects thiol groups (mostly on proteins), bilirubin, urate, and vitamin E. Bilirubin (bound to albumin) and uric acid, both considered to be waste products in plasma, are potentially good scavengers of oxyradicals. Transport in and out of erythrocytes may provide additional antioxidant potential, since the reductive processes of these cells are quite vigorous.

The most important antioxidant proteins of plasma include ceruloplasmin, albumin, transferrin, haptoglobin, and hemopexin. The first three proteins may sequester iron and copper ions in forms that prevent their participation in reactions that generate the aggressive hydroxyl radical. Haptoglobin and hemopexin bind free heme, a source of iron that can participate in lipid oxidation reactions.

A second aspect of oxidative stress in plasma fractions is the oxidation of lipid particles such as low-density lipoproteins (LDLs) (42). These materials contain proteins and lipids that are good targets for oxidation, and the oxidized forms of LDLs are strongly implicated in fatty lesions (atheromas) in artery walls. Oxidation of LDLs causes a fragmentation of the apoprotein B component of these particles and also producing a variety of lipid peroxidation products, including adducts between lipid and apoprotein B. LDL particles contain a significant amount of vitamin E, which serves as a primary antioxidant.

HUMAN DISEASE AND OXIDATIVE STRESS

The role of oxidative stress in human disease is a subject of intense interest in recent

years. The human immune response makes extensive use of many of the oxidative molecules discussed here, generating both superoxide anion and nitric oxide as an integral part of the response to foreign materials. Clearly, this defense system is a two-edged sword that also increases the oxidative risk to its human host. Other foreign materials, including some medicines, also generate oxidative stress during metabolic events associated with their detoxification or excretion. The following paragraphs summarize research that points to the potential importance of oxidative stress in specific human diseases.

Cancer

Radicals of different kinds are potentially involved in both initiation and promotion in multistage cancer development (43, 44). In this process, DNA is damaged and cellular antioxidant systems are modified as a result of expression of different genetic components in precancerous and tumor cells. Since specific genes are apparently controlled by oxidation/reduction switching of important gene regulatory proteins, the effect of oxidative stress may be manifested directly by alterations in these specific proteins (36, 44). On the other hand, base modifications (Fig. 46.5) may also alter the response of certain genes during oxidative stress. Free-radical scavengers function as inhibitors at both the initiation and promotion stage of carcinogenesis, thus protecting cells from the oxidative damage that occurs (45). In tumors the enzymes involved in antioxidant systems are altered, i.e., tumors are low in manganese superoxide dismutase and possibly the copper-zinc enzyme, while glutathione peroxidase, reductase, and S-transferase are increased. In keeping with increased glutathione metabolism, one also finds increased glucose 6-P dehydrogenase, a source of NADPH for the glutathione and protein S-thiolation cycles (Fig. 46.9).

Some of the effective quinone-type anticancer drugs are promoters of oxyradical production (46). These drugs may be effective in part because of their ability to generate oxidative species that cause DNA, membrane, or enzyme damage in tumor cells.

Cataracts and Eye Injury

The crystallins, major proteins of the eye lens, are long-lived proteins that are abundant in methionine and cysteine. As discussed above, these amino acids are sensitive to oxidation, and much work has suggested that oxidation of these proteins is involved in development of lens opacities (47, 48). The lens is a highly susceptible target, since it is continually exposed to the effects of light and a number of oxidizing metabolic products. It has a high concentration of glutathione and glutathione reductase, and there is evidence that glutathione decreases substantially in lens lesions. The vitreous humor of the eye also contains hyaluronic acid that is depolymerized when exposed to oxyradicals. Dietary vitamin E helps to prevent eye damage in infants exposed to high oxygen concentrations.

Reperfusion Injury

There is growing evidence that oxyradicals can mediate tissue injury during ischemia and reperfusion (49). Accumulation of neutrophils in the damaged tissue produces a

significant oxidant stress to the surviving tissue cells, leading to irreversible injury to those cells as a result of massive generation of superoxide anion and other neutrophil products (50). Much of this damage is preventable by inhibitors of oxyradical generation and by materials that destroy the radicals after generation (e.g., superoxide dismutase or mannitol).

Arthritis and Rheumatic Disorders

Arthritis and rheumatic disorders are characterized by inflammatory responses in which extensive tissue damage can occur through oxidative stress (51). In rheumatoid arthritis, the effects of oxyradicals on the function of synovial fluid have been well documented (see Fig. 46.4). In addition, extensive cellular damage results in release of clastogenic factors, and typical cellular damage products are detected in urine. Thus, materials such as peroxidized lipid or modified bases from cellular DNA have been found in patients suffering from these diseases. It has been postulated that antigens may be created by oxyradical attack on biomolecules, thereby instigating development of autoimmune antibodies and a continuing inflammatory response in affected tissue.

Amyotrophic Lateral Sclerosis

The motor neuron degeneration characteristic of amyotrophic lateral sclerosis has been related to genetic defects in the superoxide dismutase gene (52). Many of the patients with the familial form of this disease have defective superoxide dismutase enzymes. The mutations in the protein occur in many different locations, and apparently all can be related to a loss of enzymatic activity. Since nonhereditary forms of this disease do not contain these lesions, the exact role of oxidative stress in motor neuron degeneration is unclear.

Viral Autoimmune Disease

The autoimmune disease caused by retroviruses is characterized by a loss of specific circulatory immune cells and depression of the glutathione content of virus-infected cells (53). It has been suggested that glutathione deficiency is permissive for replication of the AIDS virus and that supplementation with agents that can increase glutathione is preventive for virus replication (54, 55). It has also been suggested that part of this effect may result from oxidation/reduction control of certain transcription factors, including NF κ B.

[Selected Readings](#)

Interest in the relationship between diet and activity, whether athletic, combative, or occupational, is not new, although the current explosion of literature in the field would suggest the opposite. An adequate intake of foodstuffs is fundamental to the maintenance of health and the survival of the individual. Reportedly, both the Greeks and Romans were interested in the best foodstuffs for maximal performance, but it

would be surprising if even earlier, man did not have a similar interest. Understanding the significance of different foodstuffs and rationalization of this information to the energy requirements of different levels of activity, however, only really began in the last century with the work of the German physiologist von Liebig (1). He considered that muscle proteins were the main provider of energy in working skeletal muscle, although by the end of the 19th century, it was clear that this was incorrect and the main sources were in fact carbohydrate and possibly also fat (2, 3).

The first positive evidence of the importance of fat as a substrate for energy production during contraction of muscle was presented by Himwich and Rose (4). They measured respiratory quotients (RQs) of muscle in dogs, which in the well-fed state were 0.92 at rest and 0.94 during exercise. After 5 to 15 days of starvation, these values decreased to 0.80 both at rest and during exercise. Since oxidation of carbohydrates results in an RQ of 1.00 and fat one of 0.70, the results clearly indicated increased use of fat by the muscle after starvation. A decade later, Christensen and Hansen in their classic study of the influence of diet on work performance in man similarly observed lower RQs both at rest and during exercise after a high-fat diet and a 30% reduction in endurance time compared with that when a mixed diet was given (5). In contrast, a high-carbohydrate diet resulted in an increase in exercise RQ, and although this value decreased during exercise (showing an increase in fat use), it never went below the resting value measured after the mixed diet. Endurance time after the carbohydrate diet was about twice that after the mixed diet.

Today, we know that some energy expenditure during exercise can also be derived from protein use, especially when the work time is prolonged. The amount of energy covered, however, is only a few percent of the total, and in the isocaloric state, carbohydrate and fatty acids constitute the major energy sources. Final proof was eventually provided by direct measurement of the different substrates in the working muscles, using the needle biopsy technique introduced by Bergström and Hultman in the mid-1960s. Initially devised to study water and electrolytes in kidney patients (6), the biopsy technique was subsequently used to study muscle glycogen in diabetic patients (7) and local energy stores in normal muscle at rest and during exercise (8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20 and 21). Introduction of the needle biopsy technique had a major, almost catalytic effect on the growth of exercise biochemistry and physiology as scientific disciplines. In 1970, the closely similar liver biopsy technique was used to measure the second major carbohydrate store in the body (22, 23, 24, 25 and 26). In combination with muscle, blood, and respiratory measurements, an almost complete picture of substrate use in exercising man could be obtained.

An understanding of substrate use by the body during exercise and work is basic to a rational assessment of the nutritive needs of an individual. Today, with the immense popularity of recreational exercise, awareness of the effects of adequate nutrition on work performance is perhaps greater than ever before. However, even among the most fastidious—the elite athletes and their trainers—a plethora of nutritive practices exist that seem to owe more to the early work of von Liebig than to subsequent studies.

ENERGY SUBSTRATES AVAILABLE FOR WORK

When a muscle such as the quadriceps femoris is stimulated from rest to near maximal activity, the rate of energy expenditure increases approximately 300-fold. The energy used by the body to perform work is chemical, and the immediate energy source for muscle contraction is adenosine triphosphate (ATP). ATP, however, is stored in only small amounts in the muscle cells (approximately 5.5 mmol/kg) and must be continually resynthesized from adenosine diphosphate (ADP). The energy for rephosphorylation can be derived from several reactions that can be divided into those requiring oxygen (aerobic metabolism) and those that can proceed in its absence (anaerobic metabolism).

Aerobic resynthesis of ATP occurs only within the mitochondria, the rate of synthesis depending largely on the size and number of mitochondria per muscle cell and the rate of oxygen uptake. Basic fuels that can supply substrates for oxidation are glucose transported from the liver by the blood, locally stored glycogen, and free fatty acids (FFAs) taken up from the blood or to a limited extent derived from triglyceride depots within the muscle. Each of these fuels may be metabolized within the cytoplasm to smaller subunits that then enter the tricarboxylic cycle within the mitochondria.

When oxidative energy production is insufficient to cover the expenditure, as in the early stages of exercise before full readjustment of the blood supply or during high-intensity exercise, ATP is also resynthesized anaerobically, which involves two metabolic pathways. The first is from phosphocreatine (PCr), which in the presence of creatine kinase can directly rephosphorylate ADP to ATP. The second route is from glycogen or glucose with formation of lactate. This process is energetically far less efficient than metabolizing either substrate completely to CO_2 and H_2O ; anaerobic metabolism generates only 2 to 3 ATPs compared with 38 to 39 ATPs per glucose unit when oxidized.

The contribution of the different fuel supplies to the total energy output by the muscle varies with both the intensity and duration of exercise and is influenced further by the fitness of the individual, the nutritional status both before and during exercise, the level of anxiety, and even the environment (altitude, temperature, and humidity). Morphologic differences in muscle fiber makeup between individuals may also affect their use of the different fuels available during a standard exercise.

The maximum theoretical rate of use of a particular fuel for muscle contraction is determined by the activity of the enzymes involved in its metabolism. Estimates of the maximum power available from PCr, carbohydrate, and fat use by muscle are presented here both as the maximum amount of high-energy phosphate ($\sim\text{P}$) that may be generated per kilogram of fresh muscle per second and as the maximum rate calculated for the whole muscle mass, assumed to be 28 kg in a 70-kg person. Values in this latter case are given as moles of $\sim\text{P}$ per minute.

- a. Max. rate of degradation: 2.6 mmol $\sim\text{P}$ /kg muscle/sec, corresponding totally to 4.4

mol ~P/min

- b. Amount available (quadriceps muscle): 24 mmol ~P/kg muscle, or totally, 0.67 mol/28 kg of muscle

The estimate of 2.6 mmol ~P/kg muscle/sec was calculated from direct measurements in needle biopsy samples obtained from human quadriceps muscle during near-maximum voluntary isometric contraction (27, 28) or during tetanic electrical stimulation (29). Other workers have suggested a figure nearer to 6 mmol ~P/kg muscle/sec on the basis of less-direct measurements (30, 31 and 32). This is close to the maximum velocity of creatine kinase measured in human muscle (33).

- a. Max. rate of ~P generation: 1.4 mmol ~P/kg muscle/sec, corresponding totally to 2.35 mol ~P/min
b. Amount available (quadriceps muscle): 240 mmol ~P/kg, or totally, 6.7 mol/28 kg of muscle

The estimate of 1.4 mmol ~P/kg muscle/sec was calculated from direct measurements of metabolite changes during near-maximum isometric contraction of the quadriceps muscle (27, 28). The total amount of ~P available from glycogen was calculated assuming that 90% of the normal store (i.e., 80 mmol glucose units/kg) is used (13) and that 3 mmol ~P is formed per mole of glucose in glycolysis. Total use of the muscle glycogen stores, however, never occurs, because of increased acidosis within the muscle. According to Margaria et al., accumulation of 1 mol of lactate is the maximum the body can tolerate (34). This amount would limit the total amount of ~P from anaerobic use of glycogen to 1.5 mol during heavy continuous work.

- a. Max. rate of ~P generation: 0.51 to 0.68 mmol ~P/kg muscle/sec, corresponding totally to 0.85 to 1.14 mol ~P/min.
b. Amount available (quadriceps femoris): 3000 mmol ~P/kg, or totally 84 mol/28 kg of muscle.

The limiting factor for the rate of glycogen oxidation is most probably mitochondrial electron transport determined by the activity of the oxygen transfer mechanisms. The rates of 0.51 to 0.68 were calculated assuming maximum rates of oxygen use available for glycogen oxidation of 3 L O₂/min in an untrained individual and 4 L/min in a marathon runner. Aerobic glycogen degradation gives 38 mol ~P/mol glucose.

- a. Max. rate of ~P generation: 0.22 mmol ~P/kg muscle/sec, corresponding totally to 0.16 mol ~P/min.

- b. Total amount available: 18 mol ~P.

The maximum rate of use is approximate and assumes maximum output from the liver of 5 mmol glucose/min, of which 4 mmol/min is available to the working muscles (calculated in this study as 11 kg) (20, 35). During a short period of exercise, most of this glucose is derived from liver glycogen, which corresponds to 500 mmol glucose totally in the resting state after a mixed diet (36). This quantity will amount to 18 mol ~P.

- a. Max. rate of ~P generation: 0.24 mmol ~P/kg muscle/sec, corresponding totally to 0.4 mol ~P/min
b. Amount available: in adipose tissues, about 4000 mol ~P.

The maximum rate of ~P generation, which was calculated by McGilvery (37), is based on experimental results published by Pernow and Saltin (38). As noted by McGilvery, the low rate of ~P generation from FFA oxidation must be the result of a limiting step located before formation of acetyl coenzyme A (acetyl-CoA), because the later steps are also used when carbohydrates are oxidized.

SUBSTRATE USE IN RELATION TO WORKLOAD

The mechanisms by which the muscle cells regulate the use of the different fuels are complex. In essence, FFAs constitute the main energy substrate at rest and are used in preference to carbohydrate; at supramaximal workloads, muscle glycogen and PCr are the major fuels. At no one workload, however, does muscle use just one fuel.

Some examples of energy demands during different types of exercise are given in [Table 47.1](#). The rate of energy expenditure and the amount of energy needed for the activity determine the choice of substrate. Estimates of the energy requirement used in different activities are derived from Fox (39). Estimates of maximum rates available from the different fuel sources together with the total amount available are drawn from our own work based on direct measurements from biopsy studies, with the exception of the estimates for fat oxidation. Values for fat oxidation were recalculated by McGilvery from studies by Pernow and Saltin. The maximum rate during a 100-m sprint has been estimated to be 2.6 mol ~P/min. This value is below the maximum rate obtainable from PCr breakdown but above that from anaerobic glycolysis. On energetic grounds, therefore, ATP and PCr are obligatory fuels for this level of activity, although supply is augmented by anaerobic glycolysis. It was held previously that during intense exercise, an alactic acid period of up to 10 seconds occurred, but lactic acid accumulation begins within 1.3 sec (29). Other athletic activities that depend mainly on PCr breakdown are the shot-put, high jump, javelin, tossing the caber, and the hammer throw.

Activity	Energy Requirement		Energy Available from Substrate		Source
	Rate	Amount	Max. Rate	Amount	
100-m sprint	2.5	0.40	44	0.50	ATP + PCr
400-m sprint	2.3	1.72	—	—	—
800-m run	2.0	3.40	2.25	1.50	Glucose ^a lactate ^b
1000-m run	1.7	6.80	0.85-1.14	85	Glucose oxidation
Marathon	1.0	150.00	0.4-0.5	400	All of the above plus fat oxidation
Rest	0.07	0.36	—	—	—

^aCalculated from the amount of lactate identified by the body in 1 ml total.

Table 47.1 Energy Requirements for Different Activities and the Maximum Rate of Energy Provision and Amounts Available from Different Substrates ($\sim P$ mol \cdot min⁻¹ and $\sim P$, respectively)

During a 400-m sprint, PCr breakdown is again used to meet the rate of $\sim P$ expenditure (2.3 mol/min) but alone cannot cover the total energy requirement of 1.72 mol $\sim P$. To meet this demand, further energy is required from anaerobic glycolysis with, in practice, an increasing contribution from aerobic glycolysis as the race continues. The same is true both for 800- and 1500-m distances, but in these races, total expenditure exceeds even the combined total possible from PCr breakdown and tolerance from the accumulation of lactate. At these distances, energy demand necessitates oxidative use of muscle glycogen. At ultralong distances, such as the marathon, the ATP turnover rate in an elite athlete lies just below the rate sustainable by aerobic use of carbohydrate; however, the total demand requires considerable use of fat as well. When all available carbohydrate has been used, running speed is dictated by the maximum rate of fat use. Some marathon runners can reach this point (synonymous with “hitting the wall”) at about 15 to 20 miles, depending on how the race is run. From then on, the race is run on oxidation of fat, the only fuel available, with little or no possibility for acceleration of pace.

The preceding calculations are drawn from athletic performances, but undoubtedly, the same spectrum of fuel use also exists in occupational work ranging from light office work to hard intermittent manual labor.

During exercise, PCr functions both as an energy buffer to ATP use, particularly when the ATP demand is momentarily increased and/or sustained above the level available from glycolysis and oxidation, and as a buffer to the release of free ADP (ADP_f) at the muscle contractile site. A fall in the PCr content below the critical threshold required to maintain ADP_f homeostasis will result in the onset of adenine nucleotide degradation to inosine monophosphate (IMP) as the adenosine monophosphate (AMP) concentration increases. In normal subjects undertaking strenuous exercise, the onset of adenine nucleotide degradation is linked to the decline in intracellular pH, possibly because of displacement of the equilibrium of the creatine kinase reaction. In other situations,

adenine nucleotide degradation may be precipitated by an insufficient rate of glycolysis caused by a lack of available glycogen. In either case, a decline in the availability of PCr near the site of ATP use is seen as the primary cause of the increase in ADP_i . Accumulation of AMP and IMP within fibers may contribute to the activation of glycogenolysis during intense exercise (40).

Accumulation of lactate is, however, self-limiting, because the decrease in muscle pH in turn inhibits further glycolysis and/or muscle contraction at the end of work with maximum power output (41). Under these conditions, the glycogen store is never totally used. At work rates close to the subject's maximum oxygen uptake (VO_{2max}), total glycogen use in the working muscles can occur (Fig. 47.1), and the amount of glycogen initially present is a determinant of work capacity. If work continues beyond this point, the work rate will decline as the muscles become progressively more dependent on FFAs and blood-borne glucose for their supply of energy. As discussed above, the maximum rate of $\sim P$ production from these two sources is appreciably lower than that from local muscle glycogen degradation.

Figure 47.1. Glycogen content in the quadriceps femoris muscle during continuous bicycle exercise maintained at a load corresponding to 75% VO_{2max} (14). Each point is the mean value determined on 10 subjects. In each case the exercise was continued until exhaustion, at which time depletion of the muscle glycogen stores was virtually complete. (From Bergström J, Hultman E. Scand J Clin Lab Invest 1967;19:218–28, with permission.)

During any form of prolonged exercise in excess of 1 hour, the use of fat progressively increases with time because of the increased availability of FFAs. For instance, in a study by Ahlborg et al., a 4-hour exercise at a work load corresponding to 30% of VO_{2max} resulted in an energy contribution by FFAs of 37% during the first 40 minutes and 62% during the final hour (Fig. 47.2) (42).

Figure 47.2. Use of carbohydrate and fat during prolonged bicycle exercise at a workload of 40% VO_2max . (From Ahlborg G, Felig G, Hagenfeldt L, et al. *J Clin Invest* 1974;53:1080–90, with permission.)

The above estimates of maximal fuel use assume a mean muscle fiber composition of 50% type I and 50% type II fibers. Subjects with a higher type I fiber composition, are likely to have a lower maximum rate of glycolysis and increased oxidative capacity. The opposite will be observed when the fraction of type II fibers is higher than 50%. Superimposed on this is the effect of any physical training, which favors an increase in the oxidative capacity of both fiber types, resulting in a still higher maximum use of FFAs (43, 44, 45 and 46). The maximum power output sustainable by FFA use in trained subjects will increase from about 55 to 65% of the person's VO_2max . Above this level, however, work performance is still limited by the availability of muscle glycogen (47). The relationship between the glycogen degradation rate and work intensity is shown in Figure 47.3. The almost exponential rise in the rate of glycogen degradation with increased workload is consistent with (a) high use of other energy sources (predominantly fat) at low workloads; (b) principally oxidative use of glycogen at middle loads; and (c) rapid but energetically inefficient anaerobic use of glycogen at the highest workloads.

Figure 47.3. Rate of muscle glycogen degradation during bicycle exercise sustained at different workloads. (From Hultman E. Muscle glycogen store and prolonged exercise. In: Shephard EJ, ed. *Frontiers of fitness*. Springfield, IL: Charles C Thomas, 1971;30–9, with permission.)

Use of Protein

The quantitative role of protein as an energy substrate in the isocaloric state is small, contributing at most about 5 to 10% of the total energy turnover (48, 49). Nonetheless, during prolonged exercise or training, degradation of protein can be important with respect to whole body homeostasis.

Studies have shown that the extracellular level of urea nitrogen increases during prolonged exercise (48, 50, 51 and 52), and urinary output of urea increases during the rest period immediately after exercise (51, 52, 53 and 54). In addition, measurements of the uptake and release of amino acids over the working muscles and over the splanchnic area and of the metabolism of isotopically labeled amino acids also indicate a significant contribution by protein to total energy turnover during exercise. Transport of amino acids from the working muscles as alanine and glutamine was first shown by Felig and coworkers (55, 56 and 57). The carbon skeletons of alanine and glutamine apparently were derived from pyruvate and glutamate, and the amino groups from deamination of amino acids in the muscle. The alanine and glutamine are converted to glucose in the liver (55).

Branched-chain amino acids are released from the liver and taken up by working muscle (42). Studies have also suggested that branched-chain amino acids are oxidized during prolonged exercise to exhaustion at 75% VO_2max and that a significant amount of the ammonia released from muscle is derived from amino acid degradation (58, 59). When a low-carbohydrate diet was ingested before exercise at 75% VO_2max , resting plasma branched-chain amino acid concentrations were elevated, and the exercise-induced decrease in levels of these amino acids was greater, suggesting that amino acid oxidation was higher (60). Plasma ammonia levels were also elevated during exercise, suggesting that a significant amount of the released ammonia was derived from amino acid metabolism.

The carbon skeleton of the branched-chain amino acid leucine is used for production of CO_2 during exercise (61, 62 and 63) at a rate that is related to the work output (64, 65). Use of leucine, however, is modified by the amount of glycogen available in the muscles; a high glycogen content depresses the rate of leucine use (48). Glucose infusion during exercise also decreases the use of leucine (64), whereas increased availability of FFAs can have the opposite effect (66). Increased oxidation of fat as a result of increased availability of FFAs or decreased use of carbohydrate during prolonged exercise apparently increases oxidation of the carbon skeleton of

branched-chain amino acids, possibly by direct stimulation of oxidative decarboxylation of the ketoacids formed (66).

Possible sources of amino acids for energy production are the free amino acid pools in muscle or plasma or those released from protein catabolism. A decreased level of amino acids in plasma is observed during prolonged exercise (53, 67, 68). Similarly, Rennie et al. found a lower free amino acid content in muscle at the end of prolonged exercise and calculated that the decrease in the amino acid pool in plasma and muscle corresponded to 20% of the total nitrogen loss (52). Thus, 80% of the nitrogen in this study must have been derived from degradation of body protein. The origin of this protein, however, is not known. Studies of 3-methyl-histidine excretion as a marker of muscle protein turnover have produced conflicting results (53, 64, 69), but they generally indicate that the contractile proteins are not broken down in exercise bouts if no apparent damage occurs to the muscle cells. Millward et al. indicated that the liver may be an important source of protein for use by the working muscles (64). Most probably, the use of protein as a fuel represents a general effect in which the normal protein synthesis rate (about 300 g/day) (70) is decreased, and part of the amino acids released by normal protein degradation supplies energy in working muscle cells. During recovery after prolonged exercise, the rate of protein synthesis increases (52).

ENERGY STORES AND EXERCISE CAPACITY

Phosphocreatine

At supramaximal power outputs with endurance times of just a few seconds, energy supply is mainly derived from the use of PCr, supplemented by anaerobic glycolysis. At maximum or near-maximum exercise intensities, performance may be limited by the ability of PCr to regulate the accumulation of ADP_i at the contraction site. Until recently it was commonly held that the PCr stores were essentially impervious to dietary manipulation and were unaffected by physical training (71, 72), despite earlier indirect data suggesting that creatine supplied in the diet was retained in the body. Confirmation that the muscle content was increased by oral administration of creatine (Cr) was obtained by Harris et al. (73). In addition, this study showed an increase in PCr content, demonstrating that the additional Cr taken up was fully assimilated into the general metabolic pool. Subsequent studies demonstrated that elevation of the muscle Cr content significantly increases work output during single or repeated bouts of maximal exercise (74, 75, 76, 77, 78 and 79). The increased work output is found only in short-duration exercise performed at maximum or near-maximum intensity; no effect on performance or metabolism has been recorded during prolonged submaximal exercise (80).

Carbohydrate

At work intensities close to or above the subject's VO_{2max} , lactate accumulation with an attendant decrease in muscle pH inhibits work output and energy production before depletion of the local glycogen stores. However, at work intensities corresponding to 65 to 85% VO_{2max} , the entire muscle store of glycogen may be used if the exercise is

sufficiently prolonged, and power output from the muscle then declines. The onset of hypoglycemia can limit prolonged performance if the liver glycogen store at the start of exercise is low and no carbohydrate is taken during the work. In this range, any increase in the muscle glycogen store helps improve performance. Increased glycogen storage can, as discussed below, be achieved by one or more regimens of exercise and diet.

Fat

Because of the almost limitless stores of FFAs in the well-fed individual, no grounds exist for supposing that an increase in the lipid stores will increase endurance performance, even during excessively prolonged exercise periods. The limitation to work at low workloads appears to be related to factors other than the lack of substrate.

Protein

In contrast to fat and carbohydrates, no evidence exists of any specific body protein store available for exercise that can be increased by diet. A dietary effect related to protein, however, is the protein-sparing effect of carbohydrates shown by lower use of protein when blood glucose levels and muscle glycogen content are high ([48](#), [64](#)). Lemon and Mullin showed that the protein share of the energy substrates used during a 60-minute exercise was 4% if the glycogen store in the muscle was increased but 10% if it was depleted before the start of exercise ([48](#)). Therefore, athletes engaged in frequent training sessions should increase their total energy intake to meet the needs of training. Most of the increased energy intake should be carbohydrate.

NUTRITION FOR INCREASED WORK PERFORMANCE

Phosphocreatine Store and Diet

Only the Cr store in muscle can be increased directly through the diet; no dietary means to increase the ATP store is known. Dietary intake of creatine is highly variable, ranging from none in a vegetarian to 2 g/day with consumption of meat and fish. Cr in meat is relatively stable to storage but may be partially destroyed by cooking and processing ([81](#)). Even in the absence of a dietary source, biosynthesis of Cr from arginine, glycine, and methionine suffices to maintain a body store in the human of 120 to 160 g. A 20% increase in skeletal muscle Cr content can, however, be achieved through additional ingestion of 100 g Cr monohydrate taken as four 5-g doses/day for 5 days ("rapid"-loading regimen) ([73](#)). The resulting increase in Cr can then be maintained by continued supplementation of 2 g/day ([82](#)). A slower method of achieving a 20% increase in muscle Cr content uses consumption of 3 g Cr/day for 30 days ("slow"-loading regimen) ([82](#)). Elevation of the total Cr store is accompanied by an increase in PCr at rest ([73](#)), which is manifested also during recovery from intense exercise ([83](#)). Elevation of the muscle Cr store appears to increase work output significantly during single or repeated bouts of maximal exercise ([74](#), [75](#), [76](#), [77](#), [78](#) and [79](#)).

Muscle Glycogen Store and Diet

Initial studies on the influence of diet on muscle glycogen stores showed that feeding a carbohydrate-rich or carbohydrate-poor diet or even total starvation over a period of days had little effect on the stores at rest (Fig. 47.4) (16). However, a remarkable difference was noted between diets when feeding was preceded by depletion of the stores by exercise. Total starvation or a carbohydrate-free diet resulted in low rates of glycogen resynthesis, and normal values were not achieved for several days, whereas a carbohydrate-rich diet resulted in rapid resynthesis to values above the normal range (Fig. 47.5). Studies in which only one leg was exercised showed that rapid resynthesis of glycogen to supernormal values was a local phenomenon restricted to the exercised muscles (Fig. 47.6 and Fig. 47.7) (9).

Figure 47.4. Glycogen content in the quadriceps femoris muscle after mixed diet (*solid triangles*), during 5 days of total starvation (*open squares*), and during 8 days of carbohydrate-free diet (*open circles*) followed by a carbohydrate-rich diet (*solid circle*). (From Hultman E, Bergström J. *Acta Med Scand* 1967;182:109–17, with permission.)

Figure 47.5. Muscle glycogen content before and after exercise. Before exercise the

diet was normal mixed (*solid triangles*), and on the following days either total starvation (*open squares*) or a carbohydrate-free diet (*open circles*) was followed by 1 or 2 days of carbohydrate-rich diet (*solid circles*) (16). Note the slow rate of glycogen resynthesis when the diet is carbohydrate free compared with the rate when the diet is rich in carbohydrate (see also Fig. 47.7).

Figure 47.6. One-leg exercise study showing the glycogen content of the exercised (*solid lines*) and rested (*broken lines*) legs of two subjects (9). Biopsies were obtained immediately after the exercise and during 3 days when subjects were fed a carbohydrate-rich diet.

Figure 47.7. The same “one-leg exercise” procedure as in Figure 47.6 showing the glycogen content in the exercised (*solid lines*) and the rested leg (*broken lines*). The diet was either total starvation (*open squares*) or carbohydrate free (*open circles*) during 2 and 3 days, respectively (16). This was followed by a second one-leg exercise, after which a carbohydrate-rich diet (*solid circles*) was given. The *solid triangles* represent a normal diet.

How “supercompensation” in glycogen is brought about is not known. Enzyme studies revealed that glycogen synthetase, the enzyme responsible for glycogen formation, is transformed from the inactive D form to active I form when the glycogen store is depleted. After 1 day of carbohydrate refeeding, the I form falls to normal (84). Other forms of the enzyme, intermediate between active and inactive, however, have been described (85), and these forms could account for the continuation of glycogen synthesis to supernormal values.

The dramatic effect of increased muscle glycogen content on work capacity is illustrated in Figure 47.8. In this study, exhaustive exercise was repeated three times with an interval of 3 days between bouts. The diet given before the first exercise was a normal mixed diet, which was followed by a carbohydrate-free diet and finally (before the last exercise) by a carbohydrate-rich diet (18). The effect of the different diets was to increase work time from 1 hour after the carbohydrate-free diet to 3 hours or more after the carbohydrate-rich diet. The study was done originally to demonstrate the relationship between work capacity and the size of the muscle glycogen stores, but the method used to increase the muscle glycogen content has since been adopted by athletes as a procedure to increase these stores.

Figure 47.8. Relationship between the initial glycogen content in the quadriceps femoris muscle and work time. Bicycle work was performed to exhaustion at a workload corresponding to 75% of VO_2max . Each subject worked three times, and the experiments were preceded by 3 days of a dietary regimen: initially a mixed normal diet (*solid triangles*), followed by a carbohydrate-free diet (*open circles*) and thereafter a carbohydrate-rich diet (*solid circles*). The energy content of the diets was the same. (From Bergström J, Hermansen L, Hultman E, et al. *Acta Physiol Scand* 1967;71:140–50, with permission.)

A drawback to this regimen is that it leaves athletes with extremely low muscle glycogen

stores for a period of 2 to 3 days, and this state could interfere with training. Sherman et al. proposed a modified regimen of diet and exercise that avoids any period of carbohydrate-free diet yet still results in equally high glycogen levels (86). For subjects in regular training, it is probably sufficient if they perform a depleting exercise twice during a period of mixed diet and thereafter change to a carbohydrate-rich diet during the final 3 days before competition. During the first two of these days, light exercise is possible, leaving only the last day for total rest.

Glycogen is stored in muscle together with water and potassium ions, 1 g (6 mmol) being associated with 2.7 g of water and 0.45 mmol of potassium (21, 87, 88). Consequently, glycogen supercompensation considerably increases muscle water content, which increases body weight and may induce feelings of heaviness and stiffness in the muscle. Supercompensation cannot, therefore, be recommended for athletes needing only limited supplies of glycogen, e.g., sprinters.

Liver Glycogen Store—Effect of Diet

In contrast to muscle, the liver glycogen store is extremely labile, even in the resting state. The glycogen content after an overnight fast varies from 90 to 500 mmol glucose units/kg liver tissue (about 14–80 g glycogen) (36). This value corresponds to a total glycogen store of 160 to 900 mmol glucose units in a 1.8-kg liver, which is the normal weight. Measurements of glycogen in repeated liver biopsy samples taken in the postprandial state showed a continuous decrease, amounting to 0.3 mmol glucose units/min/kg liver, from which it can be calculated that just 1 day of starvation would empty the liver glycogen stores (23). This situation was found in two subjects from whom biopsies were taken after 1 day without food: liver glycogen stores decreased from 155 to 24 and 345 to 48 mmol glucose units/kg. In one of the subjects, starvation was continued for a further 2 days, with biopsies performed each morning. Liver glycogen contents in these biopsy samples were 15 and 21 mmol glucose units/kg (Fig. 47.9) (23).

Figure 47.9. Glycogen content in the liver determined in needle biopsy specimens from normal subjects after different diets (23). A normal mixed diet (*solid triangles*) was followed by 1 or 3 days of starvation (*open squares*) or 1 to 10 days of a carbohydrate-free diet (*open circles*). The period was ended by 1 or 3 days of a

carbohydrate-rich diet (*closed circles*).

However, during even short periods of starvation, both fat and protein degradation increase, which results in an increase in gluconeogenic substrate brought to the liver. Evidently, this increase does not suffice for *de novo* synthesis of glycogen in the liver. To increase the supply of gluconeogenic substrates, a diet consisting of protein and fat with a caloric content of 8400 kilojoules (kJ)/day was administered to subjects, but liver glycogen content showed no increase during a 10-day period ([Fig. 47.9](#)) ([23](#)). When the diet was changed to one rich in carbohydrates with the same caloric content, the liver glycogen content increased immediately (up to 500–600 mmol glucose units/kg). Dietary carbohydrate intake is obviously necessary to preserve the liver glycogen store. In these studies, the fat and protein diet consisted of bacon, eggs, meat, vegetable oils, butter, and small amounts of tomatoes and lettuce, and the carbohydrate-rich diet contained bread, spaghetti, potatoes, sugar, fruit, and juice such that 90% of the consumed energy was derived from carbohydrates. Spices and meat extract were added for taste.

The blood glucose concentration during fasting or during the period of carbohydrate-free diet decreased only marginally from 5.2 to 4.3 mmol/L after 10 days, with the lowest value being recorded on day 5 (3.8 mmol/L). Only light office work was done during the experimental period. Glucose output by the liver decreased, however, by 60%, which corresponds to the share normally derived from glycogen degradation ([24](#)). The fact that the blood glucose concentration shows only a small change is the result of various adaptations in body metabolism, including increased output of ketone bodies from the liver ([24](#)) and a shift from glucose use to ketone body oxidation by the brain ([89](#), [90](#)). Seemingly, the adaptation by the brain is a rapid process.

Liver Glycogen Store—Glucose Release and Effect of Exercise

During exercise, glucose output from the liver increases. In one study of intense bicycle exercise, a continuous increase in output was seen from 1 mmol/min before exercise to 5 mmol/min during the last minute of work ([20](#)). The average output over the entire exercise period was 2.4 mmol/min. In a further study in which liver biopsies were taken, 1 hour of intense bicycle exercise resulted in a mean glycogen degradation rate of 2.1 mmol glucose units/min/kg liver ([25](#)). This result means that up to one-half of the normal liver glycogen store is lost during 1 hour of heavy exercise, and most of the glucose output is derived from liver glycogen, with only a small fraction from gluconeogenesis.

If exercise is performed after a carbohydrate-free diet, glucose output from liver glycogen is decreased and is compensated only in part by increased gluconeogenesis from the precursors lactate, amino acids, and glycerol. The effect, therefore, is a decrease in the blood glucose concentration during exercise. This process is illustrated in the study of Bergström et al. mentioned above in which a pronounced decrease in blood glucose concentration occurred shortly after the start of exercise performed following a period of carbohydrate-free diet ([18](#)). The mean total glucose content decreased during the first hour of exercise from 5.0 to 2.8 mmol/L, and several subjects

suffered from headache and dizziness during the later part of the exercise. One subject had to stop working because of hypoglycemic effects on the central nervous system. With a blood glucose concentration of 1.7 mmol/L, the subject could not continue the exercise because of severe dizziness and headache. The corresponding mean blood glucose level after the carbohydrate-rich diet was 4.4 mmol/L after 1 hour of exercise and 3.5 mmol/L at the end of the work (after 3 hours).

Glucose production through gluconeogenesis normally is not increased during short-term exercise, but it can increase during prolonged work to values nearly twice the resting level (42). An increased rate of gluconeogenesis, however, does occur during short intervals of hard exercise preceded by a period of carbohydrate-free diet (35, 91), although total glucose output, as mentioned above, is still lower than after a normal mixed diet. After a carbohydrate-free diet, about 50% of the glucose released from the liver can be accounted for by use of gluconeogenic substrates, whereas after a carbohydrate-rich diet, the corresponding share is only 5 to 10%. After the carbohydrate-free diet, increased oxygen uptake by the liver was observed (91), which is consistent with the increased rate of gluconeogenesis, an energy-consuming process.

In summary, dietary increase in liver glycogen stores would be beneficial in most types of continuous or prolonged intermittent exercise/work. During work of several hours duration, a high liver glycogen level buffers against development of hypoglycemia that may lead to deleterious effects on central nervous function and exhaustion. One day of a carbohydrate-rich diet before competition suffices to produce high levels of glycogen in the liver.

ENERGY REQUIREMENTS

During Occupational Work

The caloric need at rest has been calculated by Passmore and Durnin to be 105 kJ/kg body weight (BW)/day for men and 100 kJ/kg BW/day for women (92). The FAO/WHO recommendations on the energy needs for men and women in occupational work are indicated in [Table 47.2](#) (93). These estimates are for subjects with body weights of 65 and 55 kg, respectively, and aged 20 to 39 years. Energy requirement decreases with increasing age; subjects aged 40 to 49 years require 95% of the preceding estimates; 50 to 59 years, 90%; 60 to 69 years, 80%; and above 70 years old, 70%. Energy needs increase with activity ([Fig. 47.2](#)). The numbers in [Table 47.2](#) are similar to those presented by other authors such as Norgan and Ferro-Luzzi for Italian shipyard workers engaged in occupational work requiring light activity (94). The same authors also studied horticulturists in Papua New Guinea and found a similar requirement in dietary energy of 160 to 190 kJ/kg BW/day. Total energy requirements are obtained by multiplying the preceding estimates by body weight (in kg). Thus, for occupational work with light activity, total daily requirements for a 65-kg man and 55-kg woman would be 10.9 megajoules (MJ; 1 MJ = 1000 kJ) and 8.4 MJ, respectively (93). More-recent estimates of the energy costs of work are given in Appendix [Table III-A-11-d](#) and [Table III-A-11-e](#).

Activity	Men	Women
Light	167	157
Moderate	192	167
High	225	194
Exceptionally high	257	225

^a1 kJ = 4.18 kcal.

Table 47.2 Energy Needs ($\text{kJ} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$)^a for Occupational Work Activity

During Exercise

The energy requirement during athletic performance or training is determined by the type of activity and its duration. Several studies of the relative caloric costs of different sports have been published (92, 95). No details are given here, however, except to note that requirements vary from 12.5 to 25 MJ, the higher values associated with high-intensity endurance sports such as cross-country running or skiing and marathon running. High-energy intakes of the same order are also required in the course of sports requiring intense repetitive effort such as team sports (football, ice hockey, basketball), tennis, and fencing. In sports requiring sustained intense effort for shorter periods, such as swimming events over 100 m, wrestling, downhill skiing, and running for 1 to 2 miles, the average daily expenditure is on the order of 12.5 to 21 MJ. The lowest energy requirement, up to 16.7 MJ per day, is observed in low-intensity sports of long duration, such as baseball or golf, and when strenuous or maximal efforts are produced only during short periods, i.e., hurdles, long jump, 50- to 100-m swimming events, discus, hammer throw, high jump, and javelin.

The total caloric need is influenced also by body weight, the frequency of repetition of the event, and the length of practice during training. Training itself increases the daily caloric need by 5 to 40%, depending on the nature of the exercise and the length of practice (see 95). The preceding estimates of energy expenditure were adapted from Buskirk and are calculated to cover the caloric needs of 75% of all male subjects (95). Women athletes require 10% fewer calories to cover the energy need for each type of sport or during training.

RECOMMENDED USE OF MACRONUTRIENTS DURING WORK

Estimates of energy expenditure during normal occupational work were given above. This energy can be derived from a variety of combinations of fat and carbohydrate. Protein is used as a significant energy source only when the carbohydrate stores have

been exhausted and then only during prolonged work periods. Available free amino acids may be used, although as indicated above, their contribution to the total amount of energy used is probably small.

As seen in [Table 47.3](#), much more energy is stored in the body as fat than is stored as carbohydrate. Theoretically, fat can sustain light work for long periods without supplementation. In contrast, the body's glycogen store would be exhausted within half a day if used exclusively. In practice, light occupational work relies mainly on fat use, delaying considerably exhaustion of the carbohydrate stores. At exceptionally high workloads, the capacity to oxidize fats is insufficient to meet energy needs, and at these work rates, carbohydrate plays the central role in energy provision. Only carbohydrate use can match the high rates of energy expenditure necessary to fulfill the work. In practice, intense labor is interspersed with periods of lighter activity with lower energy demand that can be sustained through fat oxidation. The limited availability of the carbohydrate store in the body ([Table 47.3](#)), however, ultimately determines the duration of the work. This fact emphasizes the importance of a regular intake of sufficient carbohydrate to keep the body's stores high.

Fuel	Fuel Reserves		Days Reserves Last if Used As Exclusive Source	
	(g)	(kJ)	Light Exercise	Exceptionally High Activity
Adipose tissue	9000	337,570	29	18.8
Liver glycogen	100	1,600	0.14	0.09
Muscle glycogen	350	5,800	0.5	0.3
Blood glucose	3	48	—	—

Table 47.3 Fuel Stores in the Average Man

Carbohydrate

Dietary carbohydrate is essential for both maintenance of the liver glycogen store and rapid resynthesis of muscle glycogen. A loss of liver glycogen results in decreased blood glucose content, and a lack of muscle glycogen decreases the work capacity. Omitting carbohydrate from the diet for more than 1 day results in increased production of ketone bodies, degradation of body protein, and loss of cations and water. These effects are counteracted by a minimum intake of about 100 g of carbohydrate (600 mmol glucose units) per day.

Generally, however, it is recommended that 60 to 65% of the energy content of the diet be carbohydrate. In a 70-kg person given a normal mixed diet, 70 to 150 g carbohydrate

is stored as glycogen in the liver and 300 to 500 g in muscles. The energy equivalents of these stores are 1.25 to 2.5 MJ and 5.0 to 8.3 MJ, respectively. As discussed above, these stores may be greatly increased by a combination of diet and exercise. If the carbohydrate intake exceeds the capacity for storage and its immediate requirement as an energy source, transformation to fat and subsequent storage will occur.

For optimal use, carbohydrates should be included in the diet as complex saccharides, such as starch in bread, pasta, potatoes, rice, and cereals, and not as simple sugars, such as glucose and sucrose. Starch and other complex carbohydrates are digested more slowly in the intestine and are absorbed over a longer time so that a larger fraction is deposited in the glycogen stores and less as fat.

Fat

Fat in the form of FFAs can be used directly as an energy substrate by most of the tissues in the body. Exceptions are the cells in the central nervous system and the red blood cells. Central nervous system cells can use both carbohydrate and ketone bodies if available, but the red blood cells and some other small cell compartments rely totally on carbohydrate. FFAs constitute the largest energy reserve in the body and are stored as triglycerides in adipose tissue. The store in an average 70-kg person is about 9 kg, which corresponds to approximately 338 MJ. It is generally recommended that the diet contain 8 to 10% of the total energy in the form of polyunsaturated fatty acids and the total fat intake not exceed 30% of the dietary energy.

Protein

Dietary proteins provide amino acids for de novo synthesis of proteins and other tissue constituents in the body. Replacement of protein is an ongoing process in the body. The result is a daily loss of nitrogen in the form of urea and amino acids, which must be covered by the intake of nitrogen-containing nutrients.

Dietary amino acids are used primarily for protein synthesis, but in excess, they are degraded rapidly because the body has no protein or amino acid store. An intake in excess of the need for synthesis of proteins results in increased formation of urea, which is excreted in urine and sweat. The carbon skeleton of the amino acids, however, is retained and used as an energy substrate. The carbon skeleton in some cases can also be converted to glucose in the liver. If protein and energy intake is greater than required, the extra amino acids may be converted to fat and carbohydrate and stored.

Energy production by the body is fundamental to life, and amino acids are used preferentially as an energy source if the total energy intake is lower than the amount needed. Calculation of the minimum protein requirement in the diet thus requires that the caloric need is adequately met by other dietary sources. The mean daily use of body protein in a normal individual fed a protein-free diet is of the order of 0.45 g/kg BW (96). When a high-quality protein is given, such as egg protein, the efficiency of use is about 70%, which increases the estimate of protein required to 0.59 g/kg BW. For the North American diet, the average efficiency of use for the mixture of protein ingested is still lower, so that the recommended protein intake is increased to 0.8 g/kg BW (96). A

70-kg man would thus require 56 g protein per day, and a 55-kg woman would require 44 g. Further data on dietary protein are given in Appendix [Table A-2-a-1](#), [Table A-2-a-2](#), [Table A-2-a-3](#), [Table A-2-b-1](#), [Table A-2-b-2](#), [Table A-2-b-3](#), [Table A-2-b-4](#), [Table A-2-b-5](#), [Table A-2-b-6](#), [Table A-2-c-1](#), [Table A-2-c-2](#), [Table A-2-c-3](#), [Table A-2-c-4](#), [Table A-2-c-5](#), [Table II-A-3-a](#), [Table II-A-3-b](#), [Table II-A-4-b](#), [Table II-A-4-c](#), [Table II-A-4-d](#), [Table II-A-4-e-1](#), [Table II-A-4-e-2](#), [Table II-A-4-f](#), [Table II-A-5-a](#), [Table II-A-5-b](#), [Table II-A-5-c](#), [Table II-A-5-d](#), [Table II-A-6](#), [Table II-A-7-a](#), [Table II-A-7-c](#), [Table II-A-7-a](#), [Table II-A-7-d-1](#), [Table II-A-7-d-2](#), [Table II-A-7-d-3](#), [Table II-A-7-d-4](#), [Table II-A-7-d-5](#), [Table II-A-7-d-6](#), [Table II-A-8-a-1](#), [Table II-A-8-a-2-a](#), [Table II-A-8-a-2-b](#), [Table II-A-8-a-2-c](#), [Table II-A-8-a-3](#), [Table II-A-8-b-2](#), [Table II-A-8-b-2-a](#), [Table II-A-8-b-3](#) and [Table II-A-8-b-4](#).

Dietary Protein Intake in Different Diets

The actual protein intake in the average Swedish diet with an energy content of 11.7 MJ is 84 g, corresponding to 1.2 g/kg BW for a 70-kg man. This amount is 50% higher than the recommendations by the Committee on Dietary Allowances, Food and Nutrition Board (RDA) (96). The energy value of the protein intake corresponds to 12% of the total content in the Swedish diet. The corresponding value for protein intake for Italian shipyard workers is 12.5 to 12.8% (97), the mean Japanese diet is reported to contain 14.4% of the energy in the form of protein (98), the West German diet contains 11.1% (99), and the American diet about 12% (96).

PROTEIN REQUIREMENT IN TRAINING

As discussed above, the increase in the use of protein during exercise is only marginal. According to RDA, no increase in protein intake is needed when energy output is increased during training and competition or even during heavy exercise (96). The increased loss of protein during prolonged heavy exercise/work was estimated by Lemon and Mullin to be only 4% of the total energy expenditure when there were adequate levels of glycogen in both muscle and liver, but about 10% when these were depleted (48). Similar figures were presented by Rennie et al., who calculated the contribution of amino acid oxidation as 4 to 8% of the total energy expenditure during prolonged exercise (3 3/4 hours) (52). In studies examining the protein requirements of untrained subjects initiating a training program at 40 to 50% VO_2max , investigators found an initial decline in nitrogen balance that reached equilibrium within 2 weeks while ingesting 0.57 g egg white protein/kg BW/day (100, 101). The protein requirement for trained endurance runners maintained on an adequate energy intake and either 1.1 or 2.4 g mixed food protein/kg/day during alternate 10-day periods was measured and compared with that of a sedentary control group (102). The predicted nitrogen intake required for equilibrium was 1.37 and 0.73 g/kg/day in the athlete and sedentary group, respectively.

These results suggest that athletes engaged in endurance training require more protein than sedentary individuals. However, the requirement is still well within the amount that the average North American consumes, so extra protein supplements are not required. Also, the protein requirements derived from high protein intakes may result in inflated values; however, the relative relationship of protein requirements between sedentary

and trained individuals appears valid (103). Thus, if protein is to be increased during heavy endurance training, it seems reasonable to limit the increase to 10% of the extra requirement of energy intake. Because the protein content of a normal diet constitutes 11 to 14% of the total energy, simply increasing the amounts consumed to comply with the increased energy requirement will suffice. No adjustment in the actual makeup of the diet is required. This recommendation is probably still valid when the daily energy requirement is far above that of normal athletes, as in ultraendurance events. For example, a study that simulated the 22-day Tour de France demonstrated that these cyclists require more than 1.5 g of protein/kg/day (104). This amount could be achieved by increasing the energy intake without altering the proportion of protein consumed.

In calculating the required increase in protein, however, it was assumed that no preferential loss of any one essential amino acid (possible exception, leucine) occurred. If such a loss did occur, it would result in a negative nitrogen balance during longer periods of training, because a lack of essential amino acids would decrease the normal protein synthesis rate. Although findings of a few studies support this hypothesis (50, 54), most results indicate that nitrogen balance is maintained during training (105, 106, 107, 108 and 109) and may even be positive during heavy weight training (110), when subjects are given a moderate protein intake of 0.8 to 1.4 g/kg/day. Marable et al. observed an increase in lean body mass of 2 kg after 28 days of heavy weight training with a protein intake of 0.8 g/kg/day (110). A protein intake of 2.4 g/kg resulted in a large increase in urinary nitrogen loss but the same rate of body protein synthesis. Similarly, Toråun et al. found that total body potassium, an indicator of muscle mass, was unchanged or increased after 4 to 6 weeks of isometric exercise training when the subjects were given an egg protein intake of 1 g/kg/day (105).

Much higher intakes of protein, however, are often seen in athletes. A dietary survey of Italian athletes showed an intake of protein corresponding to 17 to 18% of the energy content of the food, or 2.2 to 2.8 g/kg BW (97). Laritcheva et al. reported a protein intake of 2.12 to 2.76 g/kg in weight lifters during training, although this amount decreased to 1.36 to 1.80 g/kg between training sessions (111). Russian athletes studied by Rogozkin had a recommended intake of 13% of the dietary nutrients as protein for a total intake of 18.8 to 21 MJ, 12% for 23 to 27 MJ, and 11% at about 33 MJ (112).

The excess of dietary protein of an athlete is often on the order of 100 g/day. If the protein were used for muscle protein synthesis, muscle mass would increase by 500 g/day. This of course is not the case. The extra dietary protein only increases production and release of urea and thus increases the metabolic and excretory work by the liver and kidney. The calculation shows that extra intake of protein concentrates and protein pills, which is common today among athletes and muscle builders, is of no value when the normal diet already contains protein in excess of that needed for both energy production and muscle protein synthesis.

Diet Composition

Depending on work rate, the recommended daily energy intake is 160 to 250 kJ/kg BW for men and 130 to 220 kJ/kg BW for women. Between 60 and 65% of the energy intake should be in the form of complex carbohydrates, 25% as fat (about half of which should

be supplied as vegetable fat), and the remaining 10 to 15% in the form of high-quality protein. Athletes in training can use essentially the same diet but with increased energy intake to meet the increase in energy expenditure. Exceptions to this statement are long-distance runners, cyclists, and cross-country skiers, who need to especially increase their carbohydrate intake during prolonged bouts of training. For such individuals, 70 to 75% of the extra energy should be in the form of carbohydrate and a maximum of 10% as protein.

DIET IN PREPARATION FOR COMPETITION

Based on current published data, Creatine (Cr) may be given as a supplement when preparing for competition involving short-term intense exercise or repeated bouts of maximal or near-maximal exercise. Supplementation should be instituted at least 1 week before the start of competition when 20 g of Cr monohydrate may be given daily for 5 days (rapid-loading regimen). The 20 g of Cr should be taken as 5-g doses four times during the waking hours of the day. An additional increase in muscle Cr content will be obtained if supplementation is taken in conjunction with exercise training (73). It is also possible to increase muscle Cr content before competition in a slower manner by consuming 3 g of Cr/day for 30 days (slow-loading regimen) (82).

When the athlete is preparing for a competition involving prolonged heavy exercise for more than 60 minutes, the muscle glycogen stores may be increased to maximum by the following program of diet and exercise. On day 1 (i.e., 6 days before the competition), an exhausting exercise is performed, followed by 2 days of a low-carbohydrate diet with further bouts of exhausting exercise. Thereafter, a carbohydrate-rich diet (75–80% carbohydrate) is given for 3 days, during which no hard exercise is performed. To avoid excessive depletion of the muscle glycogen stores, Sherman et al. recommend a normal mixed diet for the first 3 days (50% carbohydrate) after which the carbohydrate-rich diet is given (86). At the same time, shorter periods of exercise are performed also on days 4 and 5, and rest is taken only on the day preceding the competition. This procedure is probably sufficient for athletes in regular training.

For competitions lasting less than 1 hour, a normal mixed diet is adequate during the final day of preparation. The protein intake recommended in the normal diet is sufficient for resistance sports, even during intensive training periods, provided the total caloric intake is adequate to meet energy needs.

On the day of competition, a carbohydrate-rich meal should be given, preferably at least 2 hours before the start of the event. Intake of rapidly absorbed sugars, notably glucose, within 1 hour before competition may result in increased release of insulin leading to decreased blood glucose levels, inhibition of FFA release (113), and eventually, greater use of muscle glycogen stores. In longer events of 2 hours or more, in which replacement of water and electrolytes also is necessary, repeated intake of a glucose polymer solution can delay the onset of fatigue (114, 115). These findings demonstrate that glucose ingestion is important to maintain the blood glucose concentration, a fall in which may inhibit sustained prolonged exercise because of the effect of hypoglycemia on the central nervous system and/or decreased carbohydrate availability in the working

muscle. Hypoglycemia results from increased glucose use by exercising muscle when the local glycogen store is depleted and the liver glycogen store is emptied during prolonged exercise. The carbohydrate solution, taken in small amounts at frequent intervals, counteracts hypoglycemia and depletion of the liver glycogen store.

WATER AND ELECTROLYTE BALANCE IN PHYSICAL ACTIVITY

Water is of great importance to those performing physical activity. Indeed, it is the only nutrient whose lack presents an immediate and serious health risk or even the possibility of death to the participants ([116](#), [117](#)). Without question, dehydration can decrease performance ([118](#), [119](#) and [120](#)). Water balance, therefore, should be of concern to all involved with physical activity.

Role of Water

The central role of water in the performance of exercise is a direct consequence of its involvement in the cardiovascular, metabolic, and thermoregulatory systems of the human body. During exercise, oxygen and fuel substrates must be delivered to the working cell, and metabolites must be removed. Consequently, a redistribution of cardiac output to the working muscles must occur. A consequence of the elevated rate of work is additional heat production. Heat production in contracting muscles during intense physical exercise can be 15 to 20 times that of basal metabolism. This rate of heat production is sufficient to raise core body temperature in an average person by 1°C every 5 to 8 minutes if no temperature-regulating mechanisms are activated ([117](#), [121](#)). The metabolic heat must be dissipated to prevent hyperthermia from occurring in 15 to 25 minutes. Fortunately, the body activates heat loss mechanisms. One of these mechanisms is to dilate the skin blood vessels and thus redistribute the cardiac output to the periphery ([122](#)). Skin temperature increases because of the increased skin blood flow that permits heat to be lost from the skin to the environment by radiation and convection. A second heat loss mechanism is the activation of sweating. Sweat glands secrete water onto the surface of the skin where it can evaporate. Because sweat rates can be as high as 2 to 2.8 L/h, nearly all of the heat produced during exercise can be dissipated through this mechanism under ideal conditions.

When the weather is cool, most of the required heat loss during exercise occurs through radiation and convection from the exposed skin. Extensive sweating is not needed and does not occur, making the risk of dehydration relatively low. As the environmental temperature increases and approaches the skin temperature, heat transfer by radiation and convection cannot occur to any great extent. This condition leaves evaporation of sweat as the only effective means of dissipating heat. Consequently, the sweat rate is high during exercise in hot environments, and the lost body fluids must be replenished to maintain exercise performance and to prevent fatigue and hyperthermia ([123](#), [124](#) and [125](#)). The extent to which body fluid loss affects performance is governed by many factors, including the type and mode of exercise, the intensity and duration of the work, the environmental conditions under which the work is performed, and the physical characteristics of the athlete (age, sex, weight, height, state of nutrition, hydration, and training).

Water metabolism during activity cannot be separated from the body's mineral balance. Water shifts between intracellular and extracellular spaces are accompanied by shifts in sodium, potassium, magnesium, and chloride ions (Na^+ , K^+ , Mg^{2+} , Cl^- , respectively). Sweat losses also provide a means for electrolyte loss ([119](#), [126](#), [127](#)). Disturbance of water and electrolyte balance occurs not only during single exercise bouts but also over prolonged periods of training.

Types of Stress

Two different situations stress water balance. In “make weight” sports such as wrestling, the competitor deliberately restricts intake of food and fluid and strives to lose water by exercise, heat exposure, laxatives, and diuretics, ostensibly to meet a smaller and weaker opponent ([128](#), [129](#)). This practice has been rejected for health reasons by professional associations ([118](#)). Even so, the abuse continues and is prevalent in intense activities of brief duration that emphasize strength and coordination.

In contrast to such activities are endurance events such as road racing. These events may last for several hours, and the exertional and environmental heat load imposed on the body may produce rectal temperatures in excess of 40.6°C ([117](#)). Under such conditions, athletes may lose fluid at rates of 2.0 to 2.8 L/h, resulting in a water deficit of 6 to 8% of body weight ([130](#), [131](#)).

Effects of Dehydration

Numerous studies have been performed to assess the effects of dehydration on performance; the data reported include physiologic and biochemical variables and measures of muscular strength and endurance, anaerobic capacity, and aerobic power. Dehydration states have been produced thermally or in combination with exercise. The results depend on the extent of the dehydration, which is expressed as the percentage of body weight lost (%BWL).

As little as 2% BWL imposes an increased strain on the cardiovascular ([132](#)) and thermoregulatory systems ([127](#)). A 2.5% decrease in plasma volume and a 1% decline in muscle water typically occur for each 1% BWL. Plasma water accounts for 10 to 11% of the total water deficit ([119](#)). Rectal temperature increases 0.4 to 0.5°C for each 1% BWL ([133](#)). A 4% BWL results in an approximately 30% decline in isometric and isotonic strength, although peak isokinetic torque declined only 13% when an 8% BWL was induced by food and fluid restriction ([129](#)). However, 5% BWL was without effect in an anaerobic cycling test, and no impairment was noted at 8% BWL in an anaerobic running test ([129](#)). A 4 to 5% BWL produced no change in VO_2max , although a decrease in the maximal work time was seen ([132](#)). Similarly, during activities of long duration, dehydration has invariably been reported to result in a decreased ability to work ([118](#), [124](#), [132](#), [134](#), [135](#)). In other studies, a decreased capacity is strongly suggested ([126](#), [133](#)). No positive benefits of weight reduction by hypohydration have been shown.

Electrolyte losses occur together with water loss, but because sweat is hypotonic, the loss in water exceeds the loss of Na^+ , K^+ , Mg^{2+} , or Cl^- . The net result is that the plasma becomes hypertonic. The principal ions lost in sweat are Na^+ and Cl^- (119). A sweat loss causing a 5.8% BWL was found to produce a deficit of 5.7% in body Na^+ and Cl^- , but a 1% loss of K^+ and Mg^{2+} (124).

Replacement Strategies

Rehydration strategies to prevent, compensate for, or replace water loss are important in avoiding hypohydration. The aim of rehydration is either to replace water and reestablish water and electrolyte balance quickly, as in the case of dehydrated performer about to enter an event, or to prevent or retard water loss that occurs during an endurance event. Studies reveal that several factors are involved in fluid replacement, such as fluid composition, drinking frequency, volume intake, and fluid temperature (136, 137). The rate of gastric emptying provides a measure of rehydration efficiency, because almost all absorption of sugar, electrolytes, and water proceeds from the intestine (138).

Effect of Fluid Composition. It is often necessary during endurance exercise to supplement not only fluid stores but also carbohydrate stores through oral ingestion of glucose, fructose, sucrose, or carbohydrate polymers. These carbohydrate solutions can provide a slow release of energy substrate to the body over a prolonged period (124). However, results of initial studies revealed that carbohydrate concentrations above 140 mM (25 g/L) significantly retarded gastric emptying, which is detrimental for rapid rehydration (136). More-recent studies demonstrated that both carbohydrate and water were delivered to the duodenum at near-maximal rates when the carbohydrate concentration of the drink was 440 to 560 mM (80–100 g/L) (138, 139 and 140). During these studies, subjects exercised for 2 hours and drank 120 mL every 15 minutes. Therefore, if water replacement is the major concern during exercise, solutions with lower carbohydrate content should be ingested, and if water replacement is not a priority, more-concentrated carbohydrate solutions can be ingested. Most sports beverages routinely contain carbohydrate concentrations of 280 to 560 mM (50–100 g/L).

Many fluid replacement drinks also contain small amounts of salt. The addition of 10 to 30 mM NaCl may help replace body stores of Na^+ and Cl^- , the major ions lost in sweat (119). Low levels of Na^+ are also reported to improve gastric emptying and to assist in maintaining the osmotic drive for drinking (141). Drinking water only rapidly dilutes the blood, removes the drive for drinking, and stimulates urine output. However, large amounts of NaCl increase the osmolality of the drink and may actually cause fluid shifts into the gastrointestinal tract, thereby hindering gastric emptying (134). Potassium supplements are not needed in replacement drinks because little K^+ is lost in sweat, and these supplements are considered dangerous (142).

Fluid Volume. Although large volumes of ingested fluid (up to 600 mL) increase the emptying rate, gastric discomfort may result. Drinking 100 to 200 mL every 10 to 15

minutes seems appropriate ([137](#), [139](#), [140](#)).

Fluid Temperature. Chilled fluids (6–12°C) leave the stomach more quickly than warm ones and can reduce body temperatures ([133](#), [136](#)).

Drinking Schedule. It is recommended that 400 to 500 mL of fluid be taken 10 to 15 minutes before competition, although this does not replace the need for drinking during the event ([133](#)). Hyperhydration 40 to 80 minutes before an event can precipitate diuresis, and rapid rehydration after exercise-induced dehydration can produce the same result ([143](#)).

The consensus of reviews on this topic is to drink 100 to 200 mL of solution containing 280 to 560 mM (50–100 g/L) carbohydrate and 10 to 30 mM NaCl every 15 to 20 minutes when engaging in exercise lasting longer than 1 hour ([119](#), [137](#), [138](#), [144](#), [145](#)). It is also beneficial if the solution is chilled to 6 to 12°C. Tremendous individual variation exists in the ability to tolerate carbohydrate-electrolyte drinks during prolonged strenuous exercise. This variation necessitates that individuals experiment with these drinks before competition to develop their own optimal strategy.

Efficacy of Rehydration

Rehydration before or during an event is of significant benefit. Consuming 150 mL of fluid every 10 minutes during a 2-hour cycling task in the heat dramatically limits the reduction in plasma volume, elevation of heart rate, and increase in body temperature ([124](#)). Rectal temperature was about 0.7°C lower at the end of 2 hours of exercise when 200 mL of fluid was consumed every 20 minutes ([133](#)).

The problems of dehydration may be alleviated in part during activity by the availability of water produced by metabolism and liberated during the breakdown of glycogen. Similarly, K⁺ is released as glycogen is used ([11](#), [21](#), [87](#)). These effects should help maintain fluid and electrolyte balance during exercise. Glycogen degradation and oxidation provide more water than does fat metabolism because of the release of stored water as well as metabolic water. As the fuel source shifts in favor of muscle glycogen at higher workloads, plasma volume and thermoregulatory control are maintained. In practice, however, production of metabolic water plays only a minor role ([146](#)).

Unfortunately, rehydration often is only partially complete during exercise ([131](#), [136](#)). Inevitably, a delay in drinking sufficient fluid occurs because of increased exercise/thermal stress, termed *involuntary dehydration* ([147](#)). Rules of a given event may also impede drinking ([114](#)). Between 800 and 1500 mL/h of fluid can be replaced ([134](#), [136](#)), but fluid deficits of 400 to 800 mL during even light exercise (with free drinking) have been reported ([147](#)). Forced drinking before the onset of thirst may be used to minimize dehydration ([124](#)).

After thermal dehydration, even a 4-hour rehydration period is insufficient to restore fluid and electrolyte balances ([143](#)). During repeated, heavy exercise, normal fluid balance is regained within 12 hours, but sodium conservation by the kidneys continues for 24

hours.

Training Adaptation

In response to endurance training, heat-exposed athletes adapt and improve their work-heat tolerance (148). Hypervolemia develops over several days of prolonged training or with three or more bouts of intense, inter-mittent work. This expansion of plasma volume may contribute to the cardiovascular and thermoregulatory adaptations resulting from training (149, 150 and 151). These adaptations reduce the extent of body fluid shifts during exercise in the trained person (123). Sweat rates increase as an adaptive response (147, 148, 151), but water and electrolyte balances appear to be maintained. Together with an increase in voluntary fluid ingestion, the effect is a reduced fluid deficit during work (147). Hormonal control mechanisms operate to cause renal conservation and minimize the disturbance of water and electrolyte balance (150, 152). Given free access to food and fluid, trained runners can maintain body weight and normal fluid balance during 20 days of severe prolonged exercise in warm temperatures (152).

IRON BALANCE IN PHYSICAL ACTIVITY

Iron balance and metabolism in humans at rest and during exercise has been the topic of several reviews (153, 154 and 156). The subject is complex and still not fully understood. Its importance to persons engaged in physical activity derives from the central role of iron in cell metabolism. Iron is essential in the transport and delivery of O₂ to the mitochondria of the working cell through the proteins hemoglobin and myoglobin. It is also a component of many other protein systems, including the cytochromes and α -glycerophosphate oxidase (157) (see Chapter 10). Iron deficiency, with or without anemia, is frequent, especially in women in childbearing years, and is generally associated with decreased work performance and other discomforting symptoms (158).

Incidence of Iron Deficiency in Athletes

Surveys of athletic groups have shown that both males and females, particularly those involved in intense endurance sports, have hemoglobin concentrations in the low and midrange of the population norms (158, 159, 160, 161, 162, 163 and 164). This state is often referred to as "sports anemia," but this term is imprecise and a misnomer (165). In most athletes, the lower hemoglobin concentration is caused by a training-induced increase in plasma volume that dilutes the red blood cells (149, 150). The increase in blood plasma is a beneficial adaptation to aerobic exercise and should be called dilutional pseudoanemia. Some athletes, however, develop true anemia (iron deficiency anemia), which is a deficiency in the total amount of circulating hemoglobin or red blood cells. The number of athletes with true anemia is low, although significant. In one study, 11% of the females in a small group were anemic (162), and in a second study, 10% of the males and none of the women had anemia (160).

Serum ferritin, transferrin saturation, and bone marrow iron levels are sensitive indicators of prelatent and latent iron deficiency and are used in assessing tissue iron

stores (153). From these measurements it has been determined that many male and female endurance runners, although not anemic, are at risk for depletion of the iron stores. In studies including a range of sample sizes, investigators report 8 to 58% of male athletes and 40 to 80% of female athletes are iron deficient (160, 162, 166, 167, 168 and 169). The extent of iron deficiency in athletes appears to be far higher than in the general population (162). Without question, elite runners have lower plasma ferritin levels (protein-bound iron) than the general population. This difference may be related to hemodilution, transfer of stored iron into larger muscles and red blood cells, or altered iron metabolism, but regardless of the cause, this is the norm for these people. Comprehensive examinations of iron metabolism and dilutional pseudoanemia in male endurance athletes have concluded that no sports anemia or iron deficiency existed when all markers of iron status were considered (166, 170, 171).

Factors Influencing Iron Status

Several mechanisms have been proposed to account for iron deficiency anemia in athletes. This situation is most commonly caused by iron deficiency secondary to inadequate ingestion of iron to meet the body needs (155, 156). It typically occurs in rapidly growing adolescents involved in athletics, females involved in athletics, and those athletes engaged in activities that encourage low-energy intakes and low body weights (160, 162). A second and far less important cause is "footstrike" hemolysis (172, 173). Several other factors may also contribute to iron status and ultimately iron deficiency anemia, but most are considered minor. Exercise increases the elimination of iron and interferes with the normal increase in iron absorption when iron stores are depleted (164). Iron loss from gastrointestinal bleeding has been noted in some athletes associated with racing, but this condition is not a major cause of iron loss in most athletes (156). The focus of some studies has been on iron loss in sweat (164, 167), but findings of one detailed study suggest these losses are trivial (174).

Effects on Performance

Investigators have studied the ability to work aerobically over a wide range of hemoglobin concentrations, ranging from severe anemia to blood doping or induced erythrocythemia (175, 176 and 177). It is clear that VO_2 max and the capacity for intense endurance exercise are correlated with hemoglobin concentration when the hemoglobin levels are below the mean of the population, including when anemia is present. Blood doping and recombinant human erythropoietin injection studies have also shown that increasing the hemoglobin concentration by about 10%, without altering blood volume, increases VO_2 max and aerobic performance (177, 178, 179, 180 and 181). Reinfusion of red blood cells into trained athletes was first shown by Buick et al. to increase VO_2 max by 5% and work performance by 35% (179). Also, some evidence shows that iron deficiency anemia has detrimental effects on the endurance and productivity of workers (175, 182).

Controversy exists regarding whether iron depletion without anemia adversely affects athletic performance. Results of some studies suggest that performance is adversely affected only when anemia is present. Iron deficiency induced without anemia in healthy

males had no effect on VO_2max or endurance performance (183). In addition, iron therapy in female marathoners with low ferritin levels did not improve performance (184).

Treatment of Iron Deficiency

When iron deficiency anemia has been diagnosed in athletes, oral iron therapy has corrected the condition, and athletic performance has improved (161, 162). Oral iron treatment for iron deficiency without anemia has more inconsistent results. Hematologic variables of elite long-distance runners failed to show uniform improvement with iron therapy over 2 years during which a rich dietary source and supplemental iron were given. Iron stores remained depleted, although iron balance was maintained (164), suggesting again that iron metabolism in endurance athletes is unlike that of the normal population. Iron supplementation restored measures of mild iron deficiency to normal and lowered blood lactate levels during maximal exercise, but it had no effect on performance (185). When iron deficiency has not been diagnosed, iron supplementation has had little or no effect on hematologic measures or performance (158, 163).

Endurance athletes of both sexes, particularly runners who undergo prolonged, intense training, are susceptible to iron deficiency, with or without anemia. Impairment of performance may result. Iron status should be monitored regularly by serum ferritin and hemoglobin analyses. If latent or manifest iron deficiency is seen, supplemental oral iron treatments appear justified. When several measures of iron status reveal no true iron deficiency, routine iron supplementation is not indicated (171). Iron deficiency can be prevented in most athletes by manipulating the diet to increase iron intake, such as eating more lean red meat and dark meat of chicken; drinking a source of vitamin C instead of coffee or tea when eating bread and cereal to improve iron absorption; cooking in cast iron pans; and eating dried beans or peas with poultry or seafood to increase iron absorption from the vegetables.

VITAMINS, TRACE MINERALS, AND EXERCISE

The use of vitamins and minerals remains controversial. The conservative recommendations of most recognized scientific authorities contrast sharply with the practice of athletes and coaches who experiment with a wide range of diets and supplements in the hope of maximizing performance. Clearly, physical work capacity is reduced by deficient nutrition, and an adequate diet is an important base for optimal work performance.

Results of studies suggest that exercise increases the need for some vitamins and minerals and that certain groups of athletes have specific vitamin and mineral deficiencies (186, 187). However, findings also show that the increased need can be met and the deficiencies can be corrected by a well-balanced diet. The most common method of assessing vitamin and mineral status in athletes is to monitor dietary intake. Unfortunately, this method relies on the accuracy of the recollection of the subject and records from only a few days may not be representative for some minerals and vitamins. Clinical signs are also used in evaluating a vitamin and mineral status. However, the

most accurate methods are direct biochemical assays of blood and, in many individuals, tissue vitamin and mineral levels.

Although controversy exists, few authors have documented any beneficial effect of vitamin and mineral supplementation in subjects who are not deficient. In addition, large doses of certain vitamins and minerals can be toxic. Reviews on this topic consistently agree with the above conclusions and note that most studies in this area have weak experimental designs and are poorly controlled ([186](#), [187](#), [188](#) and [189](#)). Some of the problems are lack of control and placebo groups, lack of double-blind and crossover designs, inappropriate measurements of performance for the vitamin or mineral studied, and lack of an initial assessment of subject fitness ([186](#)). Properly designed, well-controlled studies are difficult to perform in this area.

This chapter does not include an examination of all the vitamins and trace minerals that may relate to exercise for several reasons: the numerous reviews that exist in this area ([186](#), [187](#), [188](#) and [189](#)), the large number of poorly designed and controlled studies, and the lack of investigations examining the relationship between exercise and some vitamins and minerals.

Fat-Soluble Vitamins

The fat-soluble vitamins include vitamins A, D, and E. Vitamins A and E may be related to exercise as antioxidants and vitamin D is instrumental in bone mineral metabolism. No evidence exists that these compounds enhance performance in nutritionally adequate individuals. Overdoses of vitamin A may lead to anorexia, hypercalcemia, and liver and kidney damage, and overdoses of vitamin D can produce hypercalcemia and hypercalciuria ([186](#), [190](#)).

Water-Soluble Vitamins

Evidence suggests that exercise may affect the need for vitamin C, riboflavin, and thiamin ([187](#), [191](#), [192](#)). Vitamin C supplementation did improve the ability to train in subjects who were vitamin C depleted ([193](#)). However, in nutritionally balanced sedentary individuals and athletes, supplementation with thiamin, riboflavin, vitamin B₆ (pyridoxine), pantothenic acid, vitamin B₁₂ (cobalamin), so-called vitamin B₁₅ ("pangamic" acid), and vitamin C had no effect on performance ([186](#), [194](#), [195](#), [196](#), [197](#), [198](#) and [199](#)). No study has been made of the effects of folate and biotin supplementation on exercise performance. The intake of a niacin supplement is known to inhibit the release of FFAs from adipose tissue ([200](#)). The result is increased muscle glycogen degradation during prolonged exercise, which leads to an earlier onset of fatigue ([201](#)). Therefore, niacin supplements should be avoided.

TRACE MINERALS

Many trace elements are involved directly in energy metabolism or in other functions related to exercise or recovery from exercise. Zinc is involved in carbohydrate (e.g., lactate dehydrogenase), fat, and protein metabolism, and in tissue repair. Copper is

involved in oxidative phosphorylation (e.g., cytochrome aa_3), erythropoiesis, and catecholamine regulation. Chromium potentiates the effect of insulin and is involved in carbohydrate and fat metabolism. Selenium is an antioxidant, and iron has a well-known role in oxygen delivery to tissues.

Iron status is examined above, and no studies have assessed the effects of chromium and selenium supplementation on athletic performance. Small amounts of zinc are known to be lost in sweat, and reports indicate that some athletes ingest inadequate amounts of zinc ([202](#), [203](#)). Some endurance athletes have low resting blood levels of zinc ([202](#), [204](#)), whereas others have adequate levels ([205](#), [206](#)). One investigation measured plasma and red blood cell concentrations of zinc and copper and reported no relationship with VO_2 max in athletes ([207](#)). Surprisingly, few studies have examined the effect of zinc supplementation on exercise performance. However, this may be due to the negative effects of excessive zinc consumption: impaired copper absorption from the diet and hypocupremia, a reduction in levels of circulating high-density lipoproteins, and impaired immune responses ([186](#), [208](#)).

Several studies have also attempted to assess the potential benefits of supplementation with multivitamin/mineral combinations because several vitamins and minerals act synergistically. Two studies demonstrate no effects of 1 to 3 months of multivitamin/mineral ingestion on VO_2 max and metabolic profiles during submaximal endurance tests to exhaustion in well-trained athletes ([209](#), [210](#)).

All athletes should eat a varied and well-balanced, nutrient-dense diet to ensure adequate vitamin and mineral intake. No evidence supports the idea that consuming large doses of vitamin and mineral supplements improves athletic performance and that some vitamins/minerals decrease performance or produce negative side effects. The most recent United States ([96](#)) and Canadian dietary recommendations ([211](#)) review data concerning needs for thiamin, riboflavin, and niacin in relation to energy expenditure (see also Appendix [Table A-2b](#) and [Table A-3a](#)). If the demands of training increase the need for energy, the intake of vitamins and minerals also increases. Therefore, the most logical way to ensure that both of these conditions are met is simply to increase the daily energy intake. However, many groups of athletes limit their energy intake, including those concerned with the cosmetic and performance aspects of extra weight (gymnasts, dancers, figure skaters, and divers) and those who must “make weight” to compete (wrestlers, boxers, jockeys, and lightweight-class sports participants). For these people and any athletes who for a number of reasons do not consume an adequate diet, a basic daily multivitamin/mineral tablet is appropriate, but megadose supplements are not.

SUMMARY

The recent interest concerning nutrition and diet in work and exercise stems not so much from our interest in occupational work but from those of high-caliber training and competition in sports. It seems we have come full circle from the times of the Greeks and Romans. Elite athletes now experiment with a wide range of so-called ergogenic acids, including nutrients and foodstuffs, in what is often an irrational attempt to succeed

(212). It is at this level of exercise, which in the modern world places the greatest degree of physical stress on the human body, that the relationship between nutrition and performance is best seen.

Scientific investigations have provided a sound understanding of the physiologic and biochemical events that occur in a variety of exercise situations; these studies form the basis for the recommendations on energy and fluid intake for optimization of performance and avoidance of exertional injury. Research has shown that dietary supplementation with vitamins and minerals above physiologic needs is both ineffective and unnecessary and, with abuse, may actually impair performance and health.

Results of studies have shown, however, that physical activity can make an individual susceptible to micronutrient deficiency states that may ultimately impair performance. Accompanying any increase in energy requirement is an increased need for thiamin, riboflavin, and niacin. Thus, the diet of an athlete must maintain a proper nutrient density as well as energy content. Exercise, by affecting absorption and/or elimination of nutrients, can upset the nutritional balance. Examples include riboflavin and minerals such as iron. At present, the risk of iron deficiency is best documented in young athletes. Continued research is needed in this area to better define the proper analytic measures as they relate to exercise performance, the effect of exercise on nutrient balance, and the means of preventing occurrence of a suboptimal nutritional state.

A factor complicating general recommendations on nutrition and diet for athletes is the variety of activities constituting what is known as sport. This variety is highlighted in a detailed 4-year study of the dietary intake of university athletes (213). At one extreme are strength sports (American football) in which one 118-kg player consumed 61.2 MJ in 1 day. At the other end of the continuum are lightweight wrestlers, gymnasts, and dancers with small bodies and dietary patterns that fluctuate widely in energy content but average 8.5 MJ daily. This extensive analysis of athletic diets across the range of sports revealed two points: that proper diet can provide the nutrition required for performance across the sports spectrum and that many athletes were at risk because of poor intake of one or more nutrients. Trends in these athletic diets reflect certain modern concerns, such as a high intake of saturated fat, cholesterol, and sodium and appreciable vitamin and mineral supplementation (214). Studies reveal the need for more education programs about nutrition for athletes, trainers, and coaches and show that these groups are eager for factual information (213, 215).

Nutritional advice must be tailored to the demands of the specific work and exercise (213). The statement by the American Dietetic Association provides a good model (216). Recommendations for the general public and for athletes involved in training or competition are separated, yet span the categories of athletic, combative, or occupational activity. The recommendations and overall viewpoint within the present review are in basic agreement with the succinct recommendations contained in the statement. The significance of diet, nutrition, work, and exercise are best summarized as follows:

1. An adequate, balanced diet is necessary for effective performance but does not guarantee it, because nutrition is but one aspect of performance.

2. A poor diet, on the other hand, guarantees substandard performance.
3. Being a fit, trained athlete does not alter the dietary requirements for most nutrients. Energy (carbohydrates), water, iron, and certain B vitamins are possible exceptions. These increased needs may, however, still be met through a balanced diet.
4. Ingestion of one or more nutrients in amounts much greater than body needs will not enhance performance and may actually impair it.

Conversion of SI to traditional units: phosphate (as inorganic phosphorus), mmol/L \times 3.097 = mg/dL; glucose, mmol/L \times 18 = mg/dL; 1 kilojoule (kJ) = 4.18 kcal; 1 megajoule (MJ) = 1000 kJ.

- [Selected Readings](#)

Humans have been flying in space for more than 35 years ([Table 48.1](#)). In the early days of the space program concerns centered around crewmembers' ability even to swallow food in weightlessness. Now it is apparent that nutrition plays a critical role in the ability of humans to explore the solar system.

Year	Flight Program	Flight Duration
1961-1963	Mercury	15 minutes-34 hours
1965-1966	Gemini	5 hours-14 days
1968-1972	Apollo	5-13 days
1973-1974	Skylab	28, 59, and 64 days
1981-present	Space Shuttle	4-16 days
1995-present	Joint U.S.-Russian (Mir)	90-180 days
2000	International Space Station Program	120-180 days

Table 48.1 Chronology of Crewed U.S. Space Flights

Although most medical research has been conducted before and after flight, short-term in-flight studies have been conducted, especially on missions in which a laboratory module is carried in the Shuttle's cargo bay. In the United States space program, the key opportunities for studying physiology and nutrition during long-term flights have been the Skylab missions and the joint U.S.-Russian missions on board the Russian space station, Mir. Studies of energy requirements, body composition, fluid homeostasis, protein metabolism, calcium/bone metabolism, and hematology have

been conducted.

Ground-based models have been used to simulate the effects of microgravity (weightlessness) on humans. Bed rest, either horizontal or head-down (-6°) tilt, simulates the headward shift of fluids, disuse atrophy of muscle, and bone loss. Unfortunately, as more results from space flight become available, the limitations of bed rest as a model for nutritional studies have become apparent.

In this chapter, we review current knowledge regarding human nutrition during space flight, with emphasis on results from flight research. Spacecraft food systems and crew dietary intake patterns are reviewed, and suggestions for research are offered.

BODY MASS

Body composition changes with a 1 to 5% loss of total body mass during space flight (1, 2, 3 and 4). Decreases in total body water usually represent 0.5 to 1.0 kg, with the remainder from loss of muscle, bone, and adipose tissues. Results from Skylab, Space Shuttle, and Russian flights have shown that crewmembers lose body mass despite being provided adequate energy from food sources (1, 2, 3 and 4). In-flight energy intake, particularly during short flights, is often considerably less than preflight intake. During Shuttle flights, body weight loss in 13 crewmembers varied from none to 3.9 kg (5). Their mean energy consumption was 11.38 ± 2.06 MJ/day before flight, but only 8.76 ± 2.26 MJ/day during flight. This intake was less than the WHO standard (6) for people with moderate activity levels. The crew on the 84-day Skylab flight proved that people can consume enough food to maintain body weight during flight (7). Nevertheless, inadequate food consumption contributes to in-flight weight loss.

ENERGY UTILIZATION

Another potential reason for loss of body mass in space relates to energy utilization: is it different in space than on Earth? The work expended in aerobic exercise during flight generally is less than that on Earth, not only because of the absence of gravity but because of limitations on crew time and the habitable volume in spacecraft (8). Studies using a doubly labeled water technique showed energy expenditures of 13 Shuttle crewmembers to be 12.40 ± 2.83 MJ/day before flight and 11.70 ± 1.89 MJ/day during flight (5). Resting energy expenditure may increase during space flight as indicated by elevated plasma and urine cortisol concentrations (9). The combination of lesser energy expenditure from exercise and greater energy expenditure at rest may explain the finding that total energy expenditure is similar in space and on Earth. NASA uses the WHO calculation with moderate activity for estimating space flight energy requirements (Table 48.2).

Substrate	Recommendation*
Energy	METD (moderate activity level)
Protein	1.0-1.5% of total energy consumed
Carbohydrate	50% of total energy consumed
Fat	20-25% of total energy consumed
Fluid	2000-2500 mL per day consumed
Fiber	10-20 g
Vitamin A	10000 and 20000 IUs/day
Vitamin C	10 mg
Vitamin E	300 mg as antioxidant agent
Vitamin K	800 mg for inert, 600 mg for inert and for inert
Vitamin B1	1000 mg
Vitamin B2	0.0 mg
Vitamin B3	0.0 mg
Vitamin B6	0.0 mg
Vitamin B12	0.0 mg
Niacin	0.0 mg
Choline	0.0 mg
Phosphorus	8000 mg
Potassium	8000 mg
Sulfur	8000 mg
Selenium	5.0 mg
Zinc	0.0 mg
Copper	0.0 mg
Manganese	0.0 mg
Fluorine	0.0 mg
Magnesium	0.0 mg
Iron	1000 mg
Calcium	10000-15000 mg
Phosphorus	10000-15000 mg
Sulfur	10000-15000 mg
Selenium	5.0000 mg
Zinc	10000 mg
Copper	1.0 mg
Manganese	0.0 mg
Fluorine	0.0 mg
Magnesium	0.0 mg
Iron	1000 mg
Calcium	10000 mg

*Data recommendations were generated by two astronaut dietary recommendations panel.

Table 48.2 Daily Nutritional Recommendations for 90- to 360-Day Space Flights

Energy expenditure during extravehicular activities (“space walks”), which might be expected to be physically stressful, was found to be relatively low, i.e., 9–12 kJ · kg⁻¹ · h⁻¹ during Shuttle flights (10). This finding, calculated from the CO₂ production and heart rate of spacesuited crewmembers, reflects the relative comfort and heat-dissipation capability of the current spacesuits (11), as well as the tendency for movements made during spacewalks to be slow and deliberate, requiring minimal exertion. No additional energy is required for extravehicular activities.

FLUID AND ELECTROLYTE REGULATION

The characteristic facial puffiness of space crewmembers (12) is related to the headward shift of fluids without significant loss of total body water (9). Plasma volume declines during the first 24 hours of space flight and levels off at about 15% less than preflight values. Glomerular filtration rate increases by about 15% during the first few hours of space flight and remains elevated. Also reductions in plasma aldosterone and atrial natriuretic peptide and sometimes increases in plasma antidiuretic hormone occurred with Shuttle crewmembers (9). Concurrent decreases in total plasma protein levels resulted in isotonic plasma with normal electrolyte composition. The mechanisms underlying these effects are unknown. After the initial decline in plasma volume, the body seems to adjust to a new homeostatic setpoint. Decreased plasma volume at landing probably contributes to orthostatic intolerance (13). Shuttle crewmembers are required to consume salt tablets with water (to equal 1 L of isotonic saline) immediately before landing, which replaces about half of the plasma volume decrement and seems to improve postflight orthostatic intolerance (14 and 15).

Fluid intake, in the form of food moisture and beverages, varies from 2000 to less than 1000 mL/day during flight, apparently because of reductions in thirst. Urine production is correspondingly low and ranges from 2800 mL to less than 500 mL/day. Crewmembers are encouraged to consume at least 2000 mL of fluids daily during flight (Table 48.2).

BONE AND CALCIUM HOMEOSTASIS

Bone metabolism is affected by weight-bearing ambulation, ultraviolet (UV) light, and stress, all of which are altered during space flight. All crewmembers lose bone mineral during flight, most notably in weight-bearing bones such as the calcaneus. Biochemical evidence of changes in bone homeostasis is present within the first hours to days of weightlessness ([16](#), [17](#), [18](#), [19](#) and [20](#)).

Bone loss during space flight and accretion following return to a gravitational environment vary among crewmembers and among bones. Those Skylab crewmen who experienced significant loss in calcaneal density had not regained their preflight densities by 95 days after landing. Similar results have been demonstrated in Russian studies. Bed rest also produces bone loss, biochemical and endocrine changes, and bone resorption. Recovery of bone mass after bed rest is also slow and variable.

Serum concentrations of calcium do not seem to change during space flight. Small increases (<10%) were noted in the ionized calcium fraction during a 115-day Mir mission, but not on Shuttle missions. Both short and long space flights, however, are associated with increases in urinary calcium and in the risk of renal stone formation. All nine of the Skylab crewmen had higher urine calcium concentrations during flight than before, with the greatest difference occurring in those who also had significant loss in calcaneal density.

Insight into the mechanisms underlying bone loss comes from the study of factors known to regulate bone and calcium homeostasis, such as parathyroid hormone (PTH), calcitonin, alkaline phosphatase, and vitamin D. Plasma PTH concentrations decline during flight, which probably explains the corresponding decreases in serum calcitriol. Serum calcidiol concentrations after a 115-day mission aboard Mir were less than preflight values, probably because of low ambient UV light. After the 84-day Skylab-4 mission (but not after the two shorter missions), plasma calcidiol was slightly less than preflight concentrations, despite daily supplementation of vitamin D (12.5 mg) on all three missions. NASA's current recommendation for vitamin D is 10 µg/day ([Table 48.2](#)), which is provided as a supplement to ensure the adequacy of intake in the absence of adequate food sources and UV light.

Markers of bone metabolism have been studied to determine whether bone loss is associated with changes in bone resorption or formation ([21](#) and [22](#)). During a 115-day Mir mission, serum concentrations of bone-specific alkaline phosphatase dropped from preflight levels by 39% on flight day 14 and by 11% on flight day 110. Urine concentrations of collagen metabolites provide additional clues of bone turnover. In six of the Skylab crewmen, urinary hydroxyproline was 33% higher after flight than before. Urine concentrations of pyridinium cross-links and *n*-telopeptide (markers of bone resorption) were almost 40% higher during and after space flight (Shuttle) or bed rest, relative to their respective control periods. These results suggest that microgravity-related bone loss is associated with both increases in resorption and decreases in formation. Reductions in PTH and calcidiol shift the calcium balance toward the negative, because of a combination of reduced absorption and increased

excretion of calcium. NASA recommendations for calcium and phosphorus are 1000 to 1200 mg/day for crewmembers on long-duration space flights ([Table 48.2](#)).

MUSCLE AND PROTEIN

Exposure to microgravity reduces muscle mass and performance, especially in the legs. Magnetic resonance imaging and manual measurements with tape measures have revealed decreases of 4 to 10% in calf-muscle volume, with the amount lost corresponding to flight duration ([23](#)). Leg strength, measured with a dynamometer, declines in similar fashion. Another study, in which five Space Shuttle crewmembers (3 men and 2 women) underwent biopsy of the vastus lateralis before and after an 11-day flight, showed decreased cross-sectional area only in type II (fast-twitch) myofibers, the fiber type that responds to resistive exercise ([24](#)).

Other assessments of muscle loss in space include nitrogen and potassium balances, urinary 4-pyridoxic acid excretion, creatinine clearance, and whole-body protein turnover, as well as records of protein and energy consumption ([7](#), [25](#), [26](#), [27](#) and [28](#)). Potassium and nitrogen balances became significantly negative throughout the Skylab flights, but urinary creatinine did not change, despite losses of muscle volume. Disuse atrophy of muscle in space may be related to changes in whole-body protein turnover. A comparison of whole-body protein turnover (^{15}N -alanine) to phenylalanine kinetics in leg tissue before, during, and after a 2-week -6° bed-rest period showed that whole-body protein synthesis decreased by about 13% during bed rest and that half of that decrease could be accounted for by the leg muscles ([26](#)). Excretion of 4-pyridoxic acid increases during bed rest, possibly indicating a decrease in metabolically active muscle tissue ([27](#)). Whole-body protein turnover was measured in four crewmembers before and during a 9-day space flight ([28](#)). Unlike the bed-rest subjects, whose diet was controlled, crewmembers' ad lib consumption of protein and energy decreased during flight, and they lost an average of 0.5 kg of body mass. Urinary nitrogen in this group declined sharply, but whole-body protein turnover increased from $2.0\text{--}2.3 \text{ g} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ before flight to $3.0\text{--}3.1 \text{ g} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ during flight. Stein et al. ([28](#)) suggested that flight-induced muscle atrophy is caused by an increase in protein-turnover rate that may be related to stress.

Nutritional means of preventing disuse atrophy have been evaluated ([29](#), [30](#)). Oral doses of branched-chain amino acids had little effect on leg-muscle protein kinetics; however, feeding a bed-rest group adequate energy with excess protein reversed nitrogen losses. On the other hand, Skylab crewmen fed energy and protein equivalent to those in the bed-rest group still had negative nitrogen balance and lost muscle strength in their legs ([21](#), [31](#)). It remains unclear whether nutritional means beyond the consumption of adequate energy and protein would be beneficial in reducing muscle atrophy. NASA's current protein recommendation resembles the RDA ([Table 48.2](#)).

HEMATOLOGY

Anemia, manifested as a reduction in circulating red blood cell (RBC) mass, has been found after space flights ([32](#), [33](#), [34](#) and [35](#)). After a 115-day Mir mission, RBC mass

was 93% of preflight values. On shorter Shuttle flights, RBC mass decreased at a rate of approximately 1%/day. Plasma erythropoietin levels decrease early in flight. The high partial pressure of oxygen in early spacecraft led some to propose that hyperoxia was inducing RBC membrane peroxidation; however, changes in erythropoiesis are still evident in Space Shuttle crews, even though the ambient air is normoxic (35). Radiochromate studies have shown that the rate at which RBCs are removed from circulation is unchanged during flight but that release of new red cells halts upon exposure to microgravity. Iron turnover does not change during flight, suggesting that synthesis of hemoglobin and RBCs is unchanged from preflight levels. These findings suggest that new RBCs are destroyed before they are released into circulation.

One consequence of a reduced RBC mass is increased iron storage (34). Serum ferritin concentrations are elevated during and after flight, and serum iron concentrations are normal to elevated as well. The implications of excess iron storage during long space flights are unknown. Current space food systems provide excessive amounts of dietary iron (approximately 20 mg/day), which may compound the potential for deleterious effects. Dietary iron absorption in space has not been studied; results from such studies may alleviate concerns about iron overload during long flights. The recommendation for future 90- to 360-day missions is for men and women to limit their iron intake to no more than 10 mg/day (Table 48.2).

Indices of iron metabolism and erythropoiesis quickly return to normal after landing. This efficient recovery suggests that in-flight anemia represents an adaptation to weightlessness, perhaps in response to easier delivery of oxygen to tissues in the absence of gravity or to the relatively high concentrations of RBCs during the first few days of flight, because of decreased plasma volume.

OTHER CONSIDERATIONS

Other flight-related circumstances that influence nutritional requirements and status are changes in gastrointestinal (GI) function and exposure to space radiation. Fluid shifts, in combination with reduced fluid intake and possibly space motion sickness, could be expected to slow GI motility. Although GI transit time has not been systematically studied in flight, 10 days of -6° head-down bed rest significantly extended the mouth-to-cecum transit time relative to ambulatory control periods (1). Russian scientists have reported that the bacterial count in the GI tract increases during flight, and the composition of the flora differs as well (36, 37). However, absorption of protein and total available dietary energy were no different during than before Skylab flights.

Radiation can be a major risk factor because of unavoidable encounters with various types and elevated levels of radiation that are not present on Earth (38, 39 and 40). Radiation exposures up to 30 rem are possible during long-term space flight. Radiation can kill, mutate, or transform cells, either through direct interactions with nuclear DNA or through production of free radicals. Accumulated doses can significantly increase cancer incidence. Any means of mitigating the radiation health risk to crewmembers is desirable, including the use of antioxidants that have low toxicity. Protease inhibitors, retinoids, and selenium can suppress the promotion or progression of radiocarcinogenesis. Although the protective value of antioxidants has not been tested,

their potential for mitigating radiation risk has been considered in establishing the dietary recommendations for vitamin C, selenium, vitamin E, and vitamin A (as carotene) (Table 48.2).

DIETARY INTAKE

Crewmembers in all U.S. space programs typically are provided with about 125% of the nutrient recommendations shown in Table 48.2, although actual intake can vary widely (1, 41, 42, 43). Figure 48.1 illustrates the relative intakes of crewmembers during Skylab ($n = 9$), Space Shuttle ($n = 21$), and Mir ($n = 3$) flights as percentages of the recommendations for energy, protein, carbohydrate, fat, and fluid. The Skylab group met all of their nutritional recommendations through consumption of adequate amounts of energy and fluid. Their diet was high in protein (114 ± 25 g/day), with 58% of their energy derived from carbohydrates and 15% from fat. In contrast, for Mir and Shuttle crewmembers, the dietary intakes were 49 to 76% of their recommended energy levels and their protein intakes were 55 ± 10 and 79 ± 20 g/day, respectively. Calcium and potassium intakes were adequate at 800 mg and over 2 g/day, respectively, but sodium intakes were generally high at about 4 g/day. Iron intakes tended to be above the 10 mg/day requirement, with the exception of the Mir crewmembers, who consumed only about 8 to 9 mg/day because of their low energy intakes.

Figure 48.1. Macronutrient consumption by Skylab (*solid bar*), Space Shuttle (*hatched bar*), and Mir (*open bar*) crewmembers as a percentage of NASA nutrient recommendations. Energy requirements were derived from the WHO calculation for people engaged in moderate activity; macronutrient recommendations were calculated as percentage of calories as follows: protein, 12–15%; carbohydrates, 50%; and fat, 30–35%. 100% indicates that energy requirements or nutritional recommendations were met.

Except for iron, consumption of micronutrients has not been adequately studied. However, given the menu available, if crewmembers had consumed adequate energy, they could have met most of the micronutrient recommendations, except for those for

vitamin D and perhaps the antioxidants. For flights longer than 180 days, vitamin D supplements along with antioxidants are provided. Adequate levels of fiber have been available in the foods supplied. However, fluid intake (food moisture plus beverages) was sometimes below nutritional recommendations with 2829 ± 700 , 2379 ± 750 , and 1128 ± 315 mL/day, for Skylab, Shuttle, and Mir crewmembers, respectively.

The food intake by the Skylab crews was much greater than that of Shuttle or Mir crews ([Fig. 48.1](#)). The Skylab and Mir crewmembers participated in metabolic studies during flight, whereas most Shuttle crews did not. The importance of food intake was stressed to Skylab crews, and they received daily advice on their food and fluid intake for the metabolic studies. This is the only program in which such intense concern about diet occurred. The Skylab crews also ate fresh and frozen foods, whereas Shuttle and Mir crews ingested mostly dehydrated or canned foods. For Shuttle flights, no emphasis was placed on food intake nor was a specified time allowed for eating. Skylab crews probably ingested more food than other crews because (a) nutrition was emphasized, (b) fresh and frozen foods similar to those found on Earth were provided, and (c) adequate time was scheduled for meals.

Another potential explanation for inadequate food consumption in space is that food may taste different, perhaps because of nasal congestion from fluid shifts or the effects of a closed air system on odor perception. In the single controlled in-flight test completed to date, with one subject, taste perception during space flight and on Earth did not differ ([44](#)). A -6° head-down bed-rest study with six subjects, designed to test whether headward fluid shifts would change perceptions of taste and odor, demonstrated no change in sensitivity to taste (sucrose, sodium chloride, citric acid, quinine, monosodium glutamate, and capsaicin), odor (isoamylbutyrate and menthone), or other trigeminal stimuli. Space foods are generally soft, and this lack of textural variety, in combination with a lack of food odors because of packaging and the presence of odors in recycled air, may confer taste-sensory monotony, which also would discourage adequate food consumption.

SPACE FOOD SYSTEMS

NASA has always strived to provide a palatable, nutritious diet in space; however, every space food system is subject to constraints on weight, volume, storage, preparation time and techniques, odors, and waste materials ([41](#), [43](#)). On the Mercury, Gemini, and early Apollo missions, many foods were provided in tubes that were squeezed directly into the mouth. Other foods were packaged in bite-size units to minimize formation of crumbs. The Gemini and early Apollo programs had no means of heating foods, while later Apollo missions had heated water (65°C) available.

Skylab is the only space program to date that included on-board freezers and refrigerators for food storage. Although refrigerators and freezers are costly in terms of stowage and power, they allow a greater variety of food during flight and reduce the need for salt or other preservatives.

Current space food systems attempt to emulate foods on Earth. Despite the lack of refrigeration for food on Space Shuttle flights, many items in the Shuttle food system are

similar to standard American foods. The Shuttle galley includes a small convection oven for reheating entrees. Rehydratable foods are common; their packaging adds little weight, and forms a ready-to-use bowl when water is added. The inclusion of “off-menu” items has improved crew interest in meals. The advent of joint U.S.-Russian missions brought more variety to the food system, which tends to include about equal proportions of U.S. and Russian items. Menus for Shuttle-Mir missions consisted of 6-day menu cycles, with some additional food items provided for variety.

The International Space Station will include freezers and refrigerators for food storage and a combination microwave/convection oven. Many unique items are being developed for extended missions aboard this station, such as tortillas that have a 6-month shelf life. Current plans call for a 28-day menu cycle for 90- to 120-day missions. Facilities aboard the International Space Station are expected to provide a nutritious, appealing diet ([Fig. 48.2](#)) that can maintain crew nutritional status and confer the psychosocial sense of well-being associated with group mealtimes.

Figure 48.2. Space station food items.

Future missions, such as those involved in establishing a permanent lunar base or traveling to Mars, undoubtedly will require some form of regenerative life-support system. The advantages of such a system would include the production of fresh food for crewmembers, as well as the opportunity for plants to be used in producing oxygen and recycling water.

SUMMARY

Food serves multiple roles during space flight, with perhaps the most obvious being the ingestion of recommended amounts of essential nutrients. Nutrition is an essential aspect of maintaining skeletal and muscle integrity, hydration status, and hematologic and endocrine function. All of these physiologic systems play essential roles in maintaining the health and safety of space crews, particularly during long missions. Group mealtimes can also build team morale and foster productivity. In summary, the

realization of the full role of nutrition will be critical for the success of space exploration.

Der sehr fettarme Muskel eines verhungerten Tiers kann nicht ohne weiteres dem fettreichen bei normaler Ernährung gegenübergestellt werden. Zülässig ist nur der Vergleich fettfrei berechneter Organe.¹

Adolph Magnus-Levy (1906)

The promulgation of the concept of fat-free tissue at the turn of the century paved the way for development of techniques for estimating body composition in vivo; and

physiologists of that era spoke of the existence of an “active protoplasmic mass,” to which various metabolic phenomena could be related. The 19th century continental chemists had established with some precision the composition of blood and tissue; now the 20th century investigators were to supply the concept of volume, first with blood and later with other body fluid compartments, and to conceive the idea of metabolic balance. Soon after the discovery of deuterium, Georg von Hevesy used this isotope to estimate total body water, and later Francis Moore introduced the concept of total exchangeable potassium and sodium. By applying Archimedes' principle, Albert Behnke showed us how to estimate the relative proportions of lean and fat in the human body. Rudolph Sievert found that the human body contained enough ^{40}K (a natural isotope) to be easily detectable and thus opened the way for the use of this technique to estimate lean and fat noninvasively. More recent years have seen the use of neutron activation, of special roentgenographic procedures (such as the CAT scan), of electrical conductivity and bioimpedance, and of nuclear magnetic resonance. Conceptualization and technical development both have played a role in this historical development, the one powerless without the other, to the point where we now possess a great deal of information on certain aspects of body composition throughout the age span of man.

The literature on body composition is vast. I have listed a number of books and review articles that contain a great deal of basic information ([1](#), [2](#), [3](#), [4](#), [5](#), [6](#), [7](#), [8](#), [9](#), [10](#), [11](#), [12](#), [13](#), [14](#), [15](#), [16](#), [17](#) and [18](#)). Individual references are limited for the most part to articles published in recent years.

BODY WEIGHT AND HEIGHT

Body weight and height measurements are easily done and are of great use in assessing growth and nutritional status. For the infant and child, growth velocity is truly a bioassay for energy balance and certain hormonal functions; in the adult, a change in weight suggests an abnormal process, nutritional or otherwise. See the Appendix for height-weight standards.

Normative values, despite what the adjective implies, cannot necessarily be construed as optimum. In an attempt to define optimum, tables of “desirable weight” for height have been developed from actuarial data gathered by the Metropolitan Life Insurance Company. Tables in the Appendices list such “desirable weights” for adults 25 years of age and older. While no provision is made for age, adults are categorized by body frame size, which is determined by inspection or by elbow width; the lack of precision in defining “desirable” is evident in the range of values given for each frame and height category. These ranges vary progressively from 2.7 kg for the shortest “small frame” category to 11.8 kg for the tallest “large frame” category of persons.

Body Mass Index

BMI is body weight divided by a power of height, usually $(\text{height})^2$, which is said to be independent of stature. Calculations based on values for ideal body weight suggest that BMIs for normal men and women should be in the range of 20 to 27 kg/m^2 . Indeed, this range roughly corresponds to the 10th to 75th percentile values recorded from adult

individuals who participated in the 1971–74 National Health and Nutrition Survey. For infants and children, average BMI values change with age, from 13 kg/m² at birth, to a peak of 18 at about 1 year, a nadir of 15 at about age 6 years, and then a rise to adult values during adolescence. Individuals with high indices are classified as overweight, even obese, and those with subnormal indices as undernourished. However, such classifications cannot be applied, for example, to short muscular men or to tall asthenic women, and despite the sex difference in body fat, the average index is about the same for both sexes during the adolescent and young adult years.

The numerator of the index is total body weight, and the BMI provides a good approximation of body fat for population groups because most of the weight differential among adults is due to body fat. This is demonstrated in [Figure 49.1](#), which is derived from body composition assays of adult females. Once a body weight of about 60 kg is reached, further increases in weight are principally due to increases in body fat.

Figure 49.1. Plots of body fat, fat-free mass, and percentage fat in relation to weight for women. Author's observations on 164 women 156–170 cm in height, assayed by ⁴⁰K counting.

Andres has analyzed the relationship between BMI and mortality in adults ([19](#)). The curve is U-shaped: the lowest mortality rate is at a BMI of about 20 kg/m² for individuals 20 to 29 years old, and the nadir progressively increases with age to reach about 27 kg/m² for those 60 to 69 years old. Based on morbidity, the lowest rate for Japanese men and women aged 30 to 59 years is at a BMI of 22 kg/m² ([20](#)). Of interest is the lack of a sex difference for this ideal body mass index. Since males generally have more lean weight (fat-free mass, [FFM]) and less fat than females at any given BMI, FFM must be a factor in health risk as well as body fat.

Constancy of Body Weight

Support for the hypothesis that body weight is homeostatically controlled comes from

the observation that many adults maintain their weight within narrow limits over long periods of time, and many children maintain their relative weight status as they grow. Indeed, following a period of weight loss, overweight individuals tend to return to their previous weight. Parizkova's (5) study of Olympic gymnasts showed that the gain in FFM and loss of body fat during training were completely reversed in time once the contests were finished. Individuals who gain FFM and lose body fat in response to anabolic steroids tend to revert in time to their previous body composition status and weight when the drugs are stopped (21, 22). Short-term fluctuations in weight can result from changes in water balance or changes in liver and muscle glycogen induced by diet and/or physical activity. Episodes of infection, serious trauma, enforced bed rest, malignancy, and nutritional inadequacy and surfeit lead to weight change; and many women state that they gain weight toward the end of the menstrual cycle.

The fluctuations noted above indicate that homeostatic control is not perfect; nevertheless, the absence of long-term change in healthy individuals suggests that energy balance oscillates around a mean value and that appetite (which controls intake) is geared in some mysterious manner to metabolic rate (which determines expenditure). When these homeostatic mechanisms fail, body weight changes significantly, and the result is obesity or anorexia nervosa.

Influence of Heredity

A significant influence on children's height is the height of their parents. Family resemblances in relative weight and in body build are readily appreciated, as is the tendency toward obesity. Monozygotic twins are more concordant for body size, even if reared apart, than are dizygotic twins (23). Genetic influence on metacarpal cortex thickness (24), bone density (25), skinfold thickness (26), body fat, FFM, BMI, and body fat distribution has been demonstrated (26, 27 and 28). While family lifestyle and feeding practices may modulate the amount of body fat, studies of adopted children as well as animal models provide additional evidence for the role of heredity.

Racial differences in stature are well known; generally speaking, Oriental adults are shorter than Caucasians and have a smaller FFM, and southern Europeans are shorter than northern Europeans. North American blacks exhibit higher values for total body K and Ca than whites (29). The average Pygmy male is 144 cm tall, the female 137 cm, and the average birth weight is 2600 g.

Secular Changes

Today's children are taller and heavier and have an earlier puberty than those of previous generations, a phenomenon that has occurred in all countries in which it has been studied. While the reason(s) for this change is not known, the recorded increases in weight/height ratios suggest that improved nutrition is a prime factor.

Aging

Once middle age is reached, there is a progressive decline in stature, the result of

thoracic kyphosis, compression of intervertebral discs, and change in angulation of the femoral neck. Borkan et al. (30) report a loss of 7.3 cm in males between age 22 and 82 years, and they estimate that 3.0 cm (41%) of the total change is secular in origin and 4.3 cm is due to aging. The longitudinal data of Flynn et al. (31) show a decline of 0.3 cm per decade in young adult males and 0.8 cm in females, with a gradual increase to 1.4 cm and 3.3 cm per decade, respectively, in those over 60 years of age.

BODY COMPOSITION

Body weight is the sum total of its parts. Modern techniques have made it possible to partition the body into several components, to carry out a “bloodless dissection.”

In reports of animal experiments, the word *carcass* seems to have more than one definition: the entire animal body; body minus viscera, head, and hooves; body minus contents of the gastrointestinal tract. The first of these is comparable to the human situation, while the third is often used because of the comparatively large capacity of the gastrointestinal tract in many animals. The second is designed for the meat processor and is in no way comparable to the body composition situation for the living human.

The techniques used are listed in [Table 49.1](#) and discussed in detail below. Most are considered *direct*, based on anatomic or chemical analysis. The last three in the list are considered *derivative* by comparison with other in vivo techniques; another example is intracellular fluid (ICF) volume.

	Advantages	Disadvantages
Density	Estimates TBW and fat simultaneously Noninvasive	Subject cooperation necessary Unsuitable for young children and elderly people May have regional gain
Dilution methods	Estimates body fluid volumes Single volume determines Na, K, Cl, etc. High cost	Requires extensive donor material Blood sample needed during collection Inconvenient/irradiation of Na, K Overestimation by metabolism; subject gain by excretion; fluid retention in medical illness; Na water volume estimate requirement
¹⁵ N counting	No hazard Minimal subject cooperation required	Subject cooperation necessary Protein retention necessary Protein in excretion or excretion limits K diffusion
Viscosity balance	No hazard Suitable for many situations Can detect small changes in body content (e.g., TBW)	Difficult to do change in body composition Intravenous catheter necessary Intravenous weight requirement
Anthropometry	Noninvasive	Poor precision in obese subjects and in those with fluid retention
Isotopic techniques (radioisotopes)	Direct estimates of body fat and regional fluids; fat distribution	Requires retention of a.c. for days; excretion data not available for all isotopes
CMF scan	Determines organ size, fat and muscle Distribution; better scan	Requires anesthesia Requires catheterization Collection area difficult
Muscle activation	Body content of Ca, K, Fe, Na, Cl	Requires regional electrical Resistance measurement
Nuclear magnetic resonance	Determines organ size, fluidity, fat, fat distribution; better scan	Expensive Requires anesthesia; regional Resistance measurement
Ultrasound	Estimates trunk visceral contents, liver and kidney; better scan; soft tissue loss	Expensive Requires anesthesia; regional Resistance measurement
Electrocardiography	Estimates of TBW	Many prediction formulas
Electrolyte balance	Estimates of total body NaCl	Difficult to do Collection area difficult Excretion variable (e.g., Na, K, Cl, etc.)
Computer simulation	No hazard Estimates of muscle mass	Difficult to do Collection area difficult Excretion variable (e.g., Na, K, Cl, etc.)

Table 49.1 Body Composition Techniques: Advantages and Disadvantages

Body Fluid Volumes

Body fluid volumes are based on the dilution principle: a known amount of material is injected intravenously (or in certain instances given by mouth) and after an interval for equilibration, a sample of blood, urine, or saliva is obtained for analysis (in the case of

metabolizable substances, several such samples are required, with subsequent extrapolation to time zero). When urinary losses are appreciable, a correction is made for these; however, losses into the lumen of the gastrointestinal tract are usually neglected.

The general equation is

$$V_2 = C_1 V_1 / C_2$$

where V is volume, C is concentration, $C_1 V_1$ is the quantity of material administered, C_2 is the concentration in body fluid at equilibrium, and V_2 is body fluid volume.

Since the body is not a static system, true equilibrium may never be achieved, particularly in the central nervous system and in bone, and there is always some question as to whether the apparent volume of distribution of the administered material coincides with that of the compartment in question. ICF volume cannot be determined directly, only by the difference between total body water and extracellular fluid (ECF) volume, and the value for the latter varies with the material used for its determination.

Plasma volume can be estimated with indocyanine green or Evans blue dye (T-1824) or ^{131}I -labeled albumin, and total red cell mass estimated with red blood cells (RBCs) tagged with ^{32}P , ^{51}Cr , ^{55}Fe , or ^{59}Fe or by carbon monoxide uptake. Materials for ECF volume are inulin, $^{35}\text{S}_2\text{O}_3^-$, $^{35}\text{SO}_4^{2-}$, SCN^- , Br^- , and $^{82}\text{Br}^-$. Cohn et al. (32) have used the ratio of total body Cl (by neutron activation) to serum Cl for this purpose. The first two materials in this list yield smaller values for ECF volume than the others. Appropriate corrections must be made for serum water, and in the case of ionized injectates, for the Donnan equilibrium.

Total body water is estimated by deuterium or tritium dilution or by dilution of urea, alcohol, or *N*-acetyl-4-aminopyrine. Water labeled with oxygen-18 is also used to estimate total body water (33). Administered deuterium and tritium undergo some exchange with nonaqueous hydrogen and thus overestimate total body water by 4 to 5%; this is not the case for oxygen-18. Bromide and SCN^- both overestimate ECF volume by about 10% because of penetration of erythrocytes.

Some of these materials can be given by mouth, others must be given intravenously; some readily penetrate the cerebrospinal fluid, and others do so very slowly. However, all appear in gastrointestinal secretions, which poses a problem in animals with a large gastrointestinal tract.

Repeat determinations in normal subjects show that the total error (i.e., biologic variation plus technical error) ranges from 2 to 9% for the various assay methods. It should be remembered that body weight, which can be measured quite accurately, varies by at least 1% during a 24-hour day, and individuals tend to be 1 to 2 cm (up to 1%) shorter in the evening than in the morning.

Total Body Content of Elements

The body content of a number of elements can now be assayed, by several methods. The isotope dilution technique can be applied to Na, K, and Cl as well as water by using the following equation:

$$Q = \frac{[Q^* \text{ admin} - Q^* \text{ excreted}]}{[Q^*/Q \text{ (serum, urine, saliva)}]}$$

where Q is body content (g, mmol) and Q* is the isotope (²⁴Na, ²²Na, ⁴²K, ⁸²Br, stable Br). Bromide is used because there is no convenient isotope of Cl. The result is expressed as total exchangeable content (Na_e, K_e, Cl_e), since this procedure underestimates total body content of both K and Na. Total exchangeable K (K_e) is 90 to 95% of total body K because of incomplete exchange with erythrocytes and brain. Total exchangeable Na is only 70 to 80% of total body Na, because of incomplete exchange with bone. However, Br dilution appears to be a good reflection of total body Cl.

Shizgal et al. (34) have devised a method for estimating total exchangeable K without the need to use the short-lived and inconvenient ⁴²K (t_{1/2} = 12 h). Total body water and total exchangeable Na (Na_e) are measured together with Na, K, and H₂O in a sample of whole blood, and

$$K_e = [(Na + K)/H_2O \text{ (blood)} \times \text{body } H_2O] - Na_e$$

The correlation between measured K_e and K_e estimated by this method is high. Since Na_e is measured with long-lived ²²Na, some of which goes to bone, this method may not be suitable for children.

Francis Moore et al. (2) developed the concept of body cell mass (BCM), which they defined as “the working, energy-metabolizing portion of the human body in relation to its supporting structures.” BCM consists of the cellular components of muscle, viscera, blood, and brain; and its size is estimated from total body K content, either as K_e from isotopic dilution or from ⁴⁰K counting. The BCM concept is useful because it encompasses those lean tissues most likely to be affected by nutrition, disease, or physical activity over relatively short intervals of time.

Neutron Activation

Neutron activation has been used to estimate total body Na, Cl, N, Ca, and P (8, 14). The subject is irradiated with neutrons, and the induced radioactivity determined by suitable gamma-ray detectors. The dose of radiation to the subject is about 30 millirads. However, the facilities required are very expensive and highly sophisticated, so only a

very few are in existence. Total body N is proportional to FFM.

The possibility exists of determining total body Mg, H, C, O and individual organ content of I and Cd and possibly Pb. Details can be found in reviews by Cohn ([6](#), [7](#)).

⁴⁰K Counting

The body contains enough of the naturally occurring isotope ⁴⁰K ($t_{1/2} = 1.3 \times 10^9$ years; body content, 0.1 μ Ci) to permit its detection and quantitation by low-background scintillation counters. From the known abundance of ⁴⁰K (0.012%) one can then calculate total body K content, which provides an estimate of FFM. This technique is noninvasive and requires very little cooperation by the subject. Each instrument must be properly calibrated to account for absorption of ⁴⁰K gamma rays by subcutaneous fat and for subject geometry.

Body Density

Archimedes is credited with discovering that one can estimate the relative proportions of a two-component mixture, each of known density, by measuring the density of the whole system. Hence from a measurement of body density, the relative proportions of lean ($D = 1.100 \text{ g/cm}^3$) and fat ($D = 0.900 \text{ g/cm}^3$) can be calculated. Body density can be measured by underwater weighing, i.e., weight in air divided by loss of weight submerged, with corrections for the density of water and air and for the volume of air in the lungs. Body volume can also be estimated by water displacement, helium dilution, and special photographic and acoustic techniques. A new procedure in which the subject is seated in a closed chamber on land is now undergoing trials ([35](#), [36](#)); the pressure change induced by a known change in the volume of the chamber is used (Boyle's law) to calculate the volume of the subject. This technique has the great advantage of being quick and of requiring relatively little cooperation by the subject.

Metabolic Balance

The metabolic balance technique can detect small changes in body content and body composition. For example, a change in body N content of 16 g (1.1 mol), equivalent to 0.5 kg FFM, is easily detected, whereas such a change is well within the error of body composition techniques. However, the metabolic balance technique cannot provide data on actual body content, and it is actually rather expensive when one adds up the cost of running a metabolic ward and supporting laboratory facilities.

The usual procedure is to subtract urine and fecal excretions from intake, neglecting cutaneous losses since they are very difficult to measure. If the balance is strongly positive or negative, the introduced error is small, but it becomes appreciable as balance approaches zero. Cutaneous losses of N and K increase as their respective intakes rise, and many authors automatically subtract 5 or 8 mg N/kg/day. Another problem is the nonrandom nature of the intake and excretion variables; this results in positive balances being overestimated and negative balances underestimated, never the reverse. Corrections must be made for element content of blood samples and for

menstrual losses. For elements such as Ca, Fe, and Pb whose main route of excretion is fecal, the balance periods must be long enough to account for day-to-day variation and to include intestinal transit time.

Anthropometry

Anthropometry includes measurement of skinfold thickness—really a double layer of skin and subcutaneous tissue measured with special calipers—and various body circumferences. The usual sites for skinfold measurements are the midtriceps region, the midbiceps region, at the inferior tip of the scapula, and just above the iliac crest. Since human skin is only 0.5 to 2 mm thick, subcutaneous fat contributes the bulk of the measured value. One grasps the tissue between thumb and forefinger, shaking it gently in hopes of excluding underlying muscle and stretching it just far enough to permit the jaws of the spring-activated caliper to impinge on the tissue. Since the jaws compress the tissue, the caliper reading diminishes for a few seconds and then the dial is read. (Satisfactory calipers include Harpenden Caliper, H. E. Morse Co., Holland, Michigan; Holtain-Harpenden Caliper, Holtain Ltd, Brynberian, Crymmych, Pembrokeshire, Wales; Lange Caliper, Cambridge Scientific Industries, Inc., Cambridge, Maryland.) In subjects with moderately firm, rather thin subcutaneous tissue, the measurement is easy to make, but those with flabby, easily compressible tissue and those with very firm tissue not easily deformable present a real problem. A recent comparison between caliper measurements and CAT scans of the midarm region showed that the former progressively underestimated subcutaneous tissue thickness as thickness increased (37).

Cross-sectional area of the muscle and bone (M + B) and fat components of the arm can be calculated from the arm circumference (circ, in cm) and skinfold thickness (SF, in cm) at the midpoint as follows (T is triceps skinfold, B is biceps):

$$M + B \text{ area} = 1/4p [\text{cir} - (p/2)(T + B)SF]^2$$

Subtraction of M+B area from total arm area ($\text{circ}^2/4p$) yields a value for arm fat area. Data on arm M+B area and arm fat area for 6- to 17-year-old children have been published by the National Center for Health Statistics (see Appendices [Table III A 16a](#), [Table III A 16b](#), [Table III A 16c](#) and [Table III A 16d](#)). The values were calculated using only arm circumference and TSF

$$M + B \text{ area} = 1/4p [\text{circ} - p\text{TSF}]^2$$

The problem here is that TSF often differs from BSF and hence is not representative of the entire subcutaneous mantle of the arm.

Extensive studies by many investigators have established relationships between various anthropometric measurements and FFM or body fat, and although the correlations are often not very high, the simplicity of the techniques allows them to be applied to large numbers of individuals in the field. Obviously such measurements as skinfold thickness and abdominal and buttocks circumference bear some relationship to body fat, and

bisacromial, wrist, elbow, and knee diameters vary with FFM. The quantitative relationships between anthropometric measurements and body composition vary somewhat by age and sex.

Durnin and Womersley (38) measured skinfold thickness and body density in a large number of men and women and developed relationships between body density and the logarithm of the sum of four skinfolds (biceps, triceps, subscapular, and suprailiac). They present a table from which percentage body fat for various age and sex groups can be read from the sum of skinfold values (Appendix [Table III-A-17-a](#)). Pollock et al. (39) constructed a similar table from which percentage fat can be read from a sum of skinfold measurements (triceps, iliac, thigh for women; chest, abdomen, thigh for men) (Appendices [Table III-A-17-b](#) and [Table III-A-17-c](#). See also [III-A-17-d](#) for other measurements).

While these tables have been widely used, there are some problems. Durnin and Womersley's (38) gives rather high estimates of percentage fat for subjects with low values for skinfold thickness. Their estimates, as well as those of others using different anthropometric formulations, do not provide satisfactory values for subjects who are ill or who have lost considerable weight. The subcutaneous tissues in the elderly are easily compressed by the caliper jaws, which leads to falsely low readings.

Since FFM comprises 70 to 90% of body weight in normal children and adults, it is obvious that FFM and weight are related; and body fat and weight should also be related in subjects of widely varying fat content. As noted below, FFM is a function of stature at all ages. It was the failure of weight-height functions for individuals whose excess weight consisted of muscle that led Albert Behnke to develop the specific gravity technique.

There is now considerable interest in body fat distribution as a possible factor in adult health. Long-term studies have shown that men and women with high ratios of abdomen circumference to hip circumference (the "apple" configuration) have a higher mortality from cardiovascular disease and stroke than those with low ratios (the "pear" configuration) (references in [8, 49]).

[Figure 49.2](#) shows a plot of abdomen:hip ratio against age for normal individuals studied in the author's laboratory (40). This ratio varies with age, and a definite sex difference develops by about age 12 years.

Figure 49.2. Normative data for abdomen:hip ratio derived from 661 normal males and 646 normal females (40). Abdominal circumference measured at the level of the umbilicus, hip circumference at maximum protuberance of the buttocks. *Vertical bars* are \pm SEM. (From Forbes GB. *Int J Obes* 1990;14:149, with permission.)

Imaging Techniques

Computerized Axial Tomography (CAT Scan)

A CAT scan can differentiate lean soft tissue from fat and bone from soft tissue as well as determine organ size. However, assessment of visceral fat is hampered by intestinal peristalsis, and the use of the CAT scan to estimate total body FFM, fat, and bone is limited because of the radiation dose. This instrument is very expensive.

Tokunaga et al. (41), Kvist et al. (42) and Chowdhury et al. (42a) have made serial CAT scans of the body, from which they determined body fat volumes in both subcutaneous and internal sites. Of the total body fat volume in women, a large proportion is located in the pelvis, thigh, and hip regions. A variable relationship between visceral and subcutaneous fat has been noted in individuals with the same abdominal circumference. It is apparent that regional variations in adipose tissue sites exist, and there is now some interest in determining whether such variations influence health.

Magnetic Resonance Imaging (MRI)

MRI is a powerful tool that permits assessment of body fat, fat-free lean, bone, total body water, and the size of individual organs, large blood vessels, and muscles, all without radiation exposure. Estimates of adipose tissue at various sites in the pig correspond to chemical analysis, except in the abdominal region, where intestinal movement interferes (43). MRI facilities are expensive and very sophisticated.

Dual-Energy X-ray Absorptiometry (DEXA)

The body is scanned by two x-ray beams of different intensities, after which a complicated and as yet undisclosed computer program can be used to estimate bone mineral, soft tissue lean, and fat in the body. Pietrobelli et al. have reviewed the basic principles underlying this technique (43a). It is widely used to assess the bone mineral content and density of the pelvic region and hence the likelihood of hip fracture. There is some difficulty in estimating visceral fat and the soft tissue content of the head, and because a sizable portion of the soft tissue of the body lies in the shadow of bone, special compensatory maneuvers are needed to provide an estimate of total nonbone mass. Comparisons of DEXA-derived estimates of body fat and skeletal size with chemical analysis in pigs have shown some discrepancies (44, 45), and Jebb et al. (46) have found that DEXA readings are influenced by tissue thickness. The radiation dose is small, less than that acquired during a transcontinental airplane flight, but the instrument is expensive.

Creatinine Excretion

The assumption that urinary creatinine excretion is an index of muscle mass is supported by the work of Schutte et al. who found a good correlation between urinary creatinine excretion and dissectable muscle mass in dogs and a good correlation between creatinine (Cr) excretion and total plasma creatinine (plasma Cr concentration times plasma volume) (47). Urine collections must be timed accurately, and the excretion rate can be affected by diet. Studies of subjects of widely varying body size and both sexes have also shown a good relationship between creatinine excretion and lean weight (8). For subjects on *ad libitum* intake, this relationship is

$$\text{FFM (kg)} = 29.1 \text{ Cr (g/day)} + 7.38, \text{ with } r^2 = 0.97$$

and for those on meat-free diets it is

$$\text{FFM (kg)} = 24.1 \text{ Cr (g/day)} + 20.7, \text{ with } r^2 = 0.91$$

Welle et al. (48) found a similar relationship for older adults

$$\text{FFM (kg)} = 23.3 \text{ Cr (g/day)} + 21.1, \text{ with } r^2 = 0.87$$

They also found that creatinine excretion bore a good relationship ($r^2 = 0.76$ – 0.87) to arm and thigh cross-sectional muscle areas. Heymsfield et al. (49) concluded that the ratio of muscle mass to daily Cr excretion is in the range of 17 to 22 kg/g, which includes Schutte's earlier value (47) of 17.9 kg/g.

In a small group of adult males ($n = 12$) on a meat-free diet, Wang et al. (50) found that total muscle mass estimated by MRI was related to creatinine excretion

$$\text{Muscle mass (kg)} = 18.9 \text{ Cr (g/day)} + 4.1, \text{ with } r^2 = 0.85$$

It will be interesting to see whether this relationship holds for children and women. However, it seems that urinary Cr excretion can be used to estimate total fat-free weight and total muscle mass.

Electrical Conductivity Methods

Total Body Electrical Conductivity (TOBEC)

The subject is placed in a hollow cylinder containing a solenoid coil driven by a 2.5- to 5-MHz oscillating-radiofrequency current. The perturbation of the electromagnetic field by the subject is an index of electrical conductivity, which is a property of lean tissue. The instrument has been validated against carcass analysis of rabbits and pigs (8, 51), and DeBruin et al. (52, 52a) report an excellent correlation between TOBEC readings and total body water in infants. Studies of both static subjects (53) and those losing weight (54) give evidence of the usefulness of this instrument. The energy delivered to the subject is small enough (7 mW/cm²) to pose no hazard. Unfortunately, the manufacturers have ceased production of this instrument.

Bioelectrical Impedance (BIA)

Electrodes are attached to the subject's wrist and ankle, a weak alternating current (800 μ A, 50 kHz) is applied, and the voltage drop is detected by electrodes placed proximal to those carrying the current. The hypothesis is that the resistance (impedance) to the electrical current is directly proportional to the length (L) of the conductor (lean tissue) and inversely proportional to its cross-sectional area (A), so that $R = \rho L/A$, where ρ is volume resistivity. Multiplying the right side of the equation by L/L, $R = \rho L^2/V$, or in terms of height (H), volume = $\rho H^2/R$ (for some unexplained reason, height is used instead of total length between the electrodes). Some investigators have used more than one frequency in an attempt to improve precision. Certain precautions (subject position, avoidance of recent food, etc.) are necessary to achieve reliable readings (14, 55), but the fact that the measurement is quick and without discomfort has made BIA very popular.

The problems are that the body is far from a perfect cylinder, that resistivity undoubtedly varies from tissue to tissue, and that the arms and legs contribute almost all of the resistance of the body (56). Reactance, a measure of cell membrane capacitance, can also be recorded by the instrument; however, it is small in comparison to resistance and is usually neglected. A discussion of the principles of the technique can be found in reference 55a. A disturbing feature is that "the theoretical basis of the technique is ... unclear" (55a, p. 388S).

There are conflicting reports about the validity of this technique. Some report excellent correlations between BIA estimates of lean weight and density, total body water, and/or ⁴⁰K counting (53, 57, 58), while others (59, 60) claim it is no better than anthropometry. The failure (in some hands) of the BIA technique to predict body composition change

accurately during diet-induced weight loss or gain ([61](#), [62](#)) is disturbing.

Precision of BIA estimates of lean weight is improved by adding weight, sex, and age to the basic H^2/R parameter. Several prediction equations have been devised. Unfortunately, the computerized analytic program provided by the manufacturer is a closely guarded secret. The inclusion of height and weight in the final calculation is bound to improve predictability because lean weight is related to both of these parameters.

[Table 49.1](#) lists the advantages and disadvantages of the various techniques. Some are inexpensive, easy to use, and suitable for individuals in the field; others require a laboratory and rather expensive equipment; yet others are so sophisticated that few are actually in operation. Before proceeding, the investigator should determine the reliability and precision of the technique to be used. This is especially important in evaluating changes in body composition resulting from nutrition or disease.

Multicompartment Techniques

In the realization that the ratios of body water, body protein, and bone mineral are probably not constant throughout the life span, and that there are gender differences, some investigators have suggested that precision could be improved by making simultaneous measurements of total body water and body density; or body water, body nitrogen, and body calcium; or body water, density and DEXA ([13](#), [14](#)). The claim that such techniques yield more precise estimates of body composition than the simpler two-component models must be tempered by the realization that they place much more strenuous demands on the investigator.

Other Techniques

Other techniques are listed below. Some are not in common use because of expense, the need for special diet precautions, or lack of advantage over other techniques.

1. Uptake of fat-soluble gases (cyclopropane, xenon, radiokrypton) provides a direct estimate of total body fat ([8](#))
2. Subcutaneous fat thickness by ultrasound ([14](#)), infrared interactance ([63](#))
3. Urinary excretion of 3-methylhistidine as an index of muscle mass; a prerequisite is 3 days on a meat-free diet
4. Energy balance together with change in body weight yields a satisfactory estimate of body fat loss during weight reduction, according to Garrow ([64](#)); the formula is $D_{fat} (kg) = [DE (Mcal) - DW (kg)]/8$, which assumes energy equivalents of fat and lean as 9 and 1 kcal/g, respectively
5. Estimates of body volume by special photographic techniques and by acoustic plethysmography ([8](#)); density then is W/V
6. Estimation of body fat from total body carbon ([65](#))

Variables in Estimating Body Composition

Estimates of lean weight and total body fat from measurements of body density; total body K, N, and H₂O; electrical conductivity; and bioimpedance all assume that the composition of the lean body mass does not vary among normal adult individuals. The water, K, and N contents of the FFM do vary somewhat, as determined by carcass analysis (51, others in [8]). Of these, K exhibits the greatest variability, water the least. Bone has a low water content and a low K content but a high density in comparison to soft tissue; hence one must assume that bone:soft tissue ratios do not vary greatly among individuals. In neutron activation studies, Ellis and Cohn (66, 66a) found that the whole body Ca:K ratio is related to stature and so is a little lower in men than in women; nonetheless, the limited variability of this ratio indicates that the bone:soft tissue ratio does not vary a great deal among normal individuals.

In an extensive DEXA study of children and adolescents Ogle et al. (67) found a good correlation ($r = 0.98$) between soft tissue lean (i.e., total lean tissue minus bone) and total bone mineral content, as did Faulkner et al. (68) earlier. Indeed, the adolescent spurt in total bone mineral content is rather similar to that described for total FFM: bone mineral content reaches an apparent peak earlier in females and attains a value about three-quarters that of males. The ratio of bone mineral content to soft tissue lean weight was somewhat higher in girls, reminiscent of the earlier observation by Ellis and Cohn (66) that the total body Ca:K ratio is a little higher in women. From one point of view, males have more soft tissue lean per unit skeleton; alternatively, females have more skeleton per unit of soft tissue lean mass. These data pertain to young and middle-aged adults.

Assessment of individuals with massive obesity presents a problem. They cannot cooperate with the underwater weighing procedure, proper calibration of ⁴⁰K counters is difficult, skinfold measurements are imprecise, and the thickness may exceed the maximum jaw width of the usual calipers. Some patients have mild to moderate edema.

Another consideration stems from the fact that the ECF:total water ratio varies somewhat with age, being higher in neonates than in young adults and rising again in the elderly (8). Hence neither the K, N, or H₂O contents of the FFM nor its density can be considered constant throughout the human age span. The K:N ratio varies among body tissues, from a high of 24 mmol K/g N in erythrocytes, to 5.0 in brain, 2.8 in skeletal muscle, about 2.5 in viscera, to a low of 0.45 in plasma and skin (3). Hence the ratio of change in body K to change in body N resulting from a change in weight will depend on the particular tissue components involved. In states of under- or overhydration the density of the FFM will be altered, and in states of K deficiency the K content of the FFM will be subnormal. This is particularly important when dealing with diseased subjects.

The values for K, H₂O, and N content of the FFM listed in Table 49.2 are based on cadaver analyses (8), with the K:FFM ratio altered for females on the basis of the reported sex difference in the K_e:H₂O ratio. Some investigators prefer to derive values for FFM composition from a comparison of in vivo assays. Cohn et al. (69) have chosen values of 64.5 and 58 mmol K/kg FFM for males and females, respectively, while

Womersley et al. (70) suggest 66.4 and 59.7. Lukaski et al. (71, 71a) derived a value of 62.6 mmol K/kg FFM for males. They also offer one of 746 mL H₂O/kg FFM; however, their values of 32.1 g N and 32.7 g N/kg FFM are close to the one derived from cadaver analysis. A number of values for total body K:N ratios (mmol/g) in living subjects have been reported: 1.88 to 1.95 for males; 1.67 to 1.78 for females. The average value from cadaver analysis is 2 mmol K/g N.

Age	H ₂ O (%)	ECF/ICF Ratio	K (mmol/kg)	N (%)	Density (g/mL)
Fetus, 24 weeks	89	1.9	40	1.4	
Birth ^a	81	1.5	49	2.4	1.063
Adult	73	0.70	68 (64) ^b	3.3	1.10
Elderly		0.85			

^aFomon et al. (60a) provide estimates for ages birth to 10 years.

^bFemales in parentheses.

Table 49.2 Composition of Fat-Free Mass

The variations noted above reflect the criteria used to assess FFM, differences in analytic techniques, or even biologic variability. Investigators tend to use the densitometric techniques as the “standard” with which results of other techniques should be compared. While densitometry is subject to less technical error than the other techniques, it is obviously impossible to determine its accuracy for living subjects, and it is likely that the density of the FFM (upon which the test implicitly depends) varies with age (it does change with growth) and perhaps with sex. There would seem to be no a priori reason to choose any one technique as a standard for comparison.

Effects of Age on Composition of FFM

Some effects of age on composition of FFM are shown in [Table 49.2](#). Composition of the fetus and newborn is quite different, and changes occur with aging. Water content falls progressively during early life, as does the ratio of ECF volume to total body water, which rises again in old age. K and N contents rise, as does calculated density. Cross-sectional data on aging adults show that the ratio of N and K to total body water tends to decline with age; total body Ca declines faster in females, but the ratio of N decline to K decline is variable (14). Problems with the cross-sectional data include the relatively small number of subjects, the possibility of selection bias, and the failure to account for variations in height and weight, both of which influence total body K, N, and Ca.

Precision of Various Techniques

Two factors must be considered: technical error and biologic variability. These include such phenomena as the random nature of radioactive isotope emissions and the day-to-day fluctuations in urinary creatinine excretion. Body weight exhibits diurnal and day-to-day variations, and it is safe to assume that certain features of body composition also exhibit some variability. It is instructive to calculate the effect of adding or subtracting 500 mL H₂O from an adult subject, which will change the density and the K, N, and H₂O contents of the FFM slightly, as well as the ratio of element metabolic balance to weight change. A change in the ECF:ICF ratio will change the K:FFM ratio of the body as well as the density and H₂O content of the FFM. The *total* error—technical plus biologic—must be taken into account, and this can only be evaluated by replicate assays on individuals, which is not always feasible with assays involving radiation exposure.

The magnitude of the observed error will depend on the method used to express the results. When FFM is measured, fat is determined by subtraction, so in subjects in whom FFM exceeds 50% of body weight, the relative error for fat will be greater than that for FFM; the same is true for densitometry. The existence on rare occasions of individuals with an estimated body fat content of 1% or even a negative value proves that error can occur.

Published data show coefficients of variation (c.v.) of 2 to 4% for ⁴⁰K counting, 2.5 to 6.1% for total exchangeable K, 5.5% for body Ca, 3.5% for total body N, and 5 to 10% for urinary Cr excretion. Densitometry appears to be the most reproducible technique (c.v. 1.2%); skinfold thickness is the worst, with recorded c.v.'s of 6 to 24% (references in [8]). The c.v. for bioimpedance ranges from 1.3 to 7% (55a), for TOBEC is about 1% (54), and for DEXA about 1% (67). Error can be reduced somewhat by making two or more assays at the start of an experimental procedure (e.g., induced weight loss) and again at the end.

Not even the newer techniques are problem free. As noted above, DEXA readings are influenced by tissue thickness, and DEXA estimates of soft tissue and bone do not always correspond to chemically determined values in pigs. Inaccurate MRI readings of intraabdominal fat were mentioned above. Adipose tissue is not pure fat; it contains a variable amount of connective tissue, blood vessels, and adipocyte nuclei, and hence some water, nitrogen, and electrolytes (pork fat contains 18% water). While the total body K and H₂O methods do detect the fat-free portion of adipose tissue, DEXA, MRI, and CAT do not; hence their estimates of body fat may be a bit too high. However, both CAT and MRI can detect intramuscular adipose tissue.

CHANGES IN BODY COMPOSITION WITH GROWTH AND AGING

Reference Data by Gender and Age

[Table 49.3](#) lists many of the elements found in the body of a male adult, the so-called reference man, as determined by the International Committee on Radiation Protection (72). Since the FFM of the average woman is about two-thirds that of the average man, her body content will be two-thirds to three-fourths of the amounts listed, with exception of O₂, C, and H₂, which are present in fat. Hence I have added some values for the average woman estimated from body composition assays of living subjects; the male values for Ca and P were also derived in this manner. The values listed are averages; for some, such as F, Se, and Fe, the quantities depend on diet.

Substance*	Amount (g)	
	Male	Female
Water	45,000 (2500 mol)	31,000 (1700 mol)
Hydrogen, nonaqueous	2,000 (1000 mol)	
Oxygen, nonaqueous	2,500 (63 mol)	
Carbon	15,000 (1333 mol)	
Nitrogen	1,800 (64 mol)	1,300 (46 mol)
Calcium	1,100 (27 mol)	830 (21 mol)
Phosphorus	500 (16 mol)	400 (13 mol)
Potassium	140 (3500 mmol)	100 (2500 mmol)
Sodium	100 (4350 mmol)	77 (3350 mmol)
Chlorine	95 (2680 mmol)	70 (2000 mol)
Sulfur	140 (4400 mmol)	
Magnesium	19 (790 mmol)	
Silicon	18 (680 mmol)	
Iron	4.2 (75 mmol)	
Fluorine	2.6 (140 mmol)	
Zinc	2.3 (35 mmol)	
Copper	0.07 (1.1 mmol)	
Manganese	0.01 (180 μmol)	
Iodine	0.01 (79 μmol)	

*Seventeen additional elements (all less than 200 mg) are listed in reference 72. For many the body content is a function of diet. The body also contains a number of radioactive elements: uranium (10⁻³ g), radium (10⁻¹¹), strontium (80), and cesium (137).

Table 49.3 Reference Man and Woman: Total Body Content

Average organ weights for an adult man are listed in [Table 49.4](#) and compared with those for the newborn infant (8). The adult, who weighs 20 times as much as the newborn, has 33 times as much muscle, 23 times as much skeleton, 19 times as much heart, and 10 times as much skin, liver, and kidney; however, brain is only about 3 times as large. One-third of the newborn skeleton consists of cartilage, and relative organ size is different in the neonate: at this age muscle accounts for 22% of body weight, brain for 10%, and liver for 4%, compared with 40, 2, and 2.6%, respectively, in the adult.

	Adult	Newborn
Weight	70,000	3,400
Skeletal muscle	28,000	850
Adipose tissue (fat 12,000)	15,000	500
Skeleton	10,000	440
(cortical bone 4,000, trabecular bone 1,000, marrow 3,000, cartilage 1,100, periarticular tissue 900)		(cartilage 140)
Skin	4,900	510
Liver	1,800	170
Brain	1,400	440
Heart	330	17
Kidneys	310	34

Table 49.4 Reference Man and Neonate: Gross Organ Size (g)

FFM and Weight Variability Compared

Among individuals of the same age and sex, body fat exhibits much more variability than FFM; hence body fat accounts for most of the variability in body weight. However, FFM and fat are *not* completely independent entities. As shown below, a change in body weight that results from changes in energy balance usually involves both body components.

In women, the maximum FFM appears to be about 70 kg, in men, about 100 kg; although a few Japanese sumo wrestlers (73) and professional football players (74) have achieved values as high as 118 kg. Perhaps there is a limit to FFM as there is for stature, while body fat can increase enormously.

Age and Sex

Figure 49.3 and Figure 49.4 show average values for FFM and fat from midgestation through the eighth decade, compiled from several sources. Note that the abscissa scale for Figure 49.3 is in postconception years. The fetus does not acquire appreciable amounts of body fat until the last trimester of gestation, and the human neonate has a larger percentage of body fat (14%) than other mammals at birth. Relative body fat continues to increase during the first 6 months of postnatal life to a maximum of 25% and to a nadir of about 13% in boys and 19% in girls in late childhood (Table 49.5).

Figure 49.3. Average value for FFM and fat in fetus and infant. Age in postconception years. Boys (*solid line*), girls (*dotted line*). (From Forbes GB. Human body composition. New York: Springer-Verlag, 1987, with permission.)

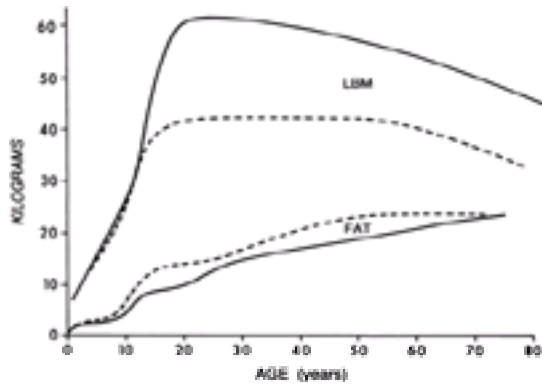

Figure 49.4. Average values for FFM and fat in child and adult. Males (*solid line*), females (*dotted line*). (Sources of data in reference [8].)

	Newborn	10-Year-Old Boy	10-Year-Old Girl	Adult Man	Adult Woman
Weight (kg)	3.4	31	32	72	58
FFM (kg)	2.9	27	26	61	42
Fat (%)	14	13	19	15	28

Table 49.5 The Reference Person

Sexual dimorphism in body composition is present in early life, well in advance of mature gonadal function. Once adolescence is under way, the sex difference becomes pronounced, the male spurt in FFM being much more rapid while females acquire more fat. Between the ages of 10 and 20 years the average increment in FFM is 33 kg in boys but only 16 kg in girls, and by age 20 years, the male:female FFM ratio is 1.45. This can be compared with a weight ratio of 1.25 and a height ratio of 1.08 at age 20. During the male adolescent spurt, the peak velocity for FFM coincides with peak height velocity (5). The sex difference in the magnitude of the adolescent spurt in FFM is likely due to the fact that the testosterone production rate in males is about 6 times that of females. Earlier mention was made of the good correlation between bone and soft tissue at this

time of life; hence the sex difference in the former is similar to that of the FFM.

The adult years are characterized by a slow fall in FFM, which is somewhat more rapid in males. The data appear to indicate that female FFM is preserved until menopause. By age 75 years, FFM in males is roughly equivalent to that of the average 14-year-old boy, and in females to that of the average 13-year-old girl. So it appears that much of the FFM increment acquired during the adolescent growth spurt is dissipated by the aging process.

The cross-sectional studies of Cohn et al. (32, others in [14]) show a progressive decline in total body K, N, and Ca during the adult years. Between ages 25 and 75 years, body K declines by about 4.5% per decade and body N by about 3.5% per decade in both sexes. However, body Ca declines by 5.4% per decade in women and 2% per decade in men, which is consistent with observed decreases in the density of the spine and appendicular skeleton, especially in women, with advancing years. The decline in total body water is somewhat less than that for K and N, (14) which agrees with the age-associated increase in the ECF:ICF ratio. However, all of these values are derived from cross-sectional observations.

A few investigators have followed adults over extended periods of time, and such longitudinal observations tend to show a somewhat smaller age decline than do the cross-sectional data. Steen et al. (75) did repeat assays of total body water and body K in men and women from age 70 to age 81. An analysis of the individual data (kindly provided by Dr. Bertil Steen) showed that those who lost significant amounts of weight lost more total body water and K than those who had minimal weight loss or some weight gain. On average, the former group lost about 5 kg FFM/decade, the latter only 2 kg FFM/decade. Flynn et al. (76) did repeated ⁴⁰K assays on a large group of adults over an 18-year period. Those individuals under 51 years of age at the initial assay who gained weight tended to gain FFM, and those who lost weight tended to lose FFM. On the other hand, older individuals tended to lose FFM regardless of body weight change; the average loss was about 4 kg/decade for both sexes. I have made repeated ⁴⁰K assays on two adult males—one for 27 years, the other for 37 years, by which time both were in their early 80s. The first subject lost an average of 0.5 kg FFM/decade, the second 1.0 kg/decade; the first tended to put on weight, the second did not. This observation taken in conjunction with those noted above makes it necessary to consider body weight change in evaluating longitudinal changes in FFM. Incidentally, in keeping with cross-sectional data, the decline in FFM as calculated from total body water was somewhat less, namely 0.6 kg/decade, for the second subject (77).

As shown in [Figure 49.3](#) and [Figure 49.4](#), girls have slightly more body fat than boys from an early age; once adolescence is under way girls acquire much more body fat than boys, and this sex difference persists throughout the adult years. [Figure 49.5](#) shows that these changes are reflected in triceps skinfold thickness; the great variability in this measurement is clearly evident.

Figure 49.5. 50th and 90th percentiles for triceps skinfold thickness. Data for infants and children less than 6 years old from Tanner and Whitehouse (78), others from Cronk and Roche (79).

Stature

At all ages studied, FFM is a function of height. On average, the regression slope is 0.69 kg/cm in adult males and 0.29 kg/cm in adult females (8). Skeletal size is also a function of height (80); and Ellis and Cohn's data (66, 66a) show that the same is true for total body Ca, whose regression slope is 20 g Ca/cm. Based on their findings a 186-cm male would be expected to have about 1370 g Ca in his body, a 154-cm woman only 730 g Ca.

Data such as these mean that comparisons of FFM and total body Ca among individuals are valid only if height, as well as age and sex, is controlled. Many athletes are taller than average, which is one reason why they tend to have a larger FFM.

Pregnancy

Of the total weight gain during pregnancy, 12 to 13 kg on average, the fetus, placenta, and amniotic fluid together account for about 4.2 kg; the remaining 8 kg is maternal tissue. All components of body water increase—plasma, ECF, and ICF volumes—as well as total red cell mass, and since the ratio of body water:body K increases, the increase in ECF volume is proportionately greater than that of ICF volume, which is consistent with the observation that many pregnant women have mild edema. A portion of the weight gain, variously estimated at 2 to 4 kg, consists of fat (references in [8]).

Correlates of Body Composition

Since the adult female has on average only about 70% the amount of FFM of the average male, the requirements for energy and protein are correspondingly less. The recommended dietary allowances of the National Research Council reflect this sex

difference (see Appendices [Table II A-2-a-1](#) and [Table II A-2-a-2](#)). Both basal metabolic rate (BMR) and blood volume are more closely related to FFM than to body weight. Prentice et al. (81) found a fairly constant relationship between BMR and FFM during pregnancy. It would seem prudent to adjust the dose of various drugs on the basis of FFM rather than body weight. Some of the adult decline in such metabolic parameters as glucose tolerance and maximal oxygen consumption may possibly reflect the age-associated decline in FFM.

Studies of individuals consuming “essentially” protein-free diets (references in [8]) show a linear relationship between endogenous urinary N excretion and body cell mass. The dietary protein requirement is thus a function of body cell mass, and hence of FFM rather than body weight with its variable component of fat. On this basis, the need for protein—and perhaps other dietary nutrients as well—should be lower in the elderly than in the young adult and lower in women than in men.

INFLUENCE OF NUTRITION

Energy Deficit and Excess

Maintenance of body weight in the adult and satisfactory growth rate in the child depends on an adequate supply of energy. Subnormal intakes lead to a decline in the child's growth rate and the adult's body weight, and generally speaking, the rate of weight loss is a function of the magnitude of the energy deficit. After the first few days, fasting results in a loss of about 0.5 kg/day in the obese (82) and about 0.35 kg/day in the nonobese (83). Mathematical analysis shows that the weight loss during fasting is exponential (8), which suggests that the loss rate is proportional to weight itself (body tissues being the only source of energy) and so tends to diminish with time. The same phenomena has been described in fasting geese (84), although toward the end of the fast weight loss tends to increase, as fat reserves are exhausted. In thin rats this premortem phase is associated with increased urinary N loss in about 2 weeks of fasting; the obese rat can tolerate fasts for 2 months or more without such an occurrence (85). The fractional loss rate is lower in the obese human than in the nonobese (0.34 vs. 0.56%/day). Smaller energy deficits produce slower rates of weight loss.

Consumption of energy in excess of maintenance needs produces an increase in body weight; and close observation reveals that the increase is roughly proportional to the total excess energy consumed during the overfeeding period (86). The energy cost of weight gain has been computed for several types of human subjects. On average this turns out to be 5.0 kcal/g gain for infants recovering from malnutrition (87), 4.0 kcal/g gain for growing prematurely born infants (88), 4.7 kcal/g for adolescent girls recovering from anorexia nervosa (89), and 8.0 kcal/g for normal adults who are deliberately overfed (86, 90); the energy cost is about the same for women as for men.

Body Composition Changes

Nutrition can affect lean weight as well as body fat. Compared with normal individuals of

the same stature, age, and sex, undernourished subjects have a lower FFM and less fat, and the obese have an increase in both (8, 91). Indeed, Keys and Brozek (1) spoke many years ago of “obesity tissue” consisting of protein and body fluid as well as fat.

When rats are systematically underfed from an early age they are smaller and thinner than ad libitum-fed controls, but they are longer-lived and have fewer neoplasms and degenerative lesions. Studies have shown that fat-free tissue accounts for one-half to two-thirds of the weight difference (92).

Young adult monkeys whose body weight is held fairly constant for many years by careful feeding (including some with frank diabetes) totally escape the glucose intolerance that affects about half of their ad libitum-fed controls. By age 18 years the former animals weigh about two-thirds as much as the latter, and about half of this 5-kg difference consists of lean tissue (93). The question is whether the enhanced life span and better health of the underfed animals is due to the smaller fat burden or the smaller FFM.

Careful studies of underfed subjects, using either nitrogen balance or body composition techniques or urinary creatinine excretion, have shown that significant weight reduction involves loss of both FFM and fat. Underfed animals, including hibernators, lose lean as well as fat. CAT scans of fasting seals clearly show a decrease in muscle tissue as well as fat (94). The relative contribution of lean and fat components to the total weight loss depends on two principal factors: the *initial body fat* content and the *magnitude of the energy deficit*.

During a fast, thin individuals lose twice as much body N per unit weight loss as do obese individuals (95); about two-thirds of their weight loss consists of lean tissues, while for the obese about two-thirds of the loss consists of fat. The same general trend holds for fasting animals, including hibernators. Figure 49.6 is a plot of the fraction of weight loss due to FFM as a function of initial body fat percentage for several species. It shows that the obese preferentially burn fat and so tend to conserve lean.

Figure 49.6. Relative contribution of FFM to weight loss during fasting plotted against initial percentage body fat. Symbols: humans (*circle with dot*); bears (*solid circles*); other mammals (rat, brown bat, marmot, arctic ground squirrel, seal) (*open circles*); birds

(antarctic penguin, great-winged petrel) (*open squares*); hibernation (*). Duration of fast 3 weeks or more, except for rat (13–15 days) and petrel (17 days). Unduly long fasts include hibernating arctic ground squirrel (6 months) and marmot (5 months); and female polar bears (207 days). (Data from references [84](#), [85](#), [95](#), [96](#), [97](#), [98](#), [99](#), [100](#), [101](#), [102](#), [103](#), [104](#), [105](#), [106](#), [107](#), [108](#), [109](#), [110](#) and [111](#).)

Even though hibernators lose weight very slowly, the composition of their weight loss for a given initial body fat percentage does not differ greatly from that of the nonhibernators. However, the hibernating black bear seems to be unusually efficient in this respect; the three animals studied by Lundberg et al. ([101](#)) (average body fat, 46%) did not on average lose any lean tissue during 60 days of winter sleep, despite a 13% weight loss. According to Nelson et al. ([112](#)), the animal achieves this by reabsorbing nitrogen and electrolytes through the wall of the bladder.

The other exception to the general trend is the obese fasting human, who appears to be less efficient at conserving lean weight at a given level of fatness than other species. A possible explanation could be the relatively large size of the human brain compared with that of animals. According to Brody ([113](#)), the human brain weighing 1300 g makes up 2 to 2.5% of body weight; the value for small animals is about 0.5% of body weight, and the ratio drops progressively to about 0.15% in animals as large as the bear. The high demand of the brain for glucose means that the fasting human has a greater need for gluconeogenesis than most animals. Of additional interest is the situation for winged species such as the goose and the bat, in whom the pectoral muscles suffer a smaller weight loss during fasting than do other muscles ([105](#), [114](#)).

Henry ([13](#)) has described an interesting relationship between the BMR and the loss of body N during fasting. While this ratio is fairly constant for a given individual throughout a fast, it is 3 to 4 times higher in the obese than in the nonobese; hence the obese waste less nitrogen per basal calorie expended, which is consistent with the observation that the obese excrete less nitrogen per unit weight loss.

The second factor is equally important: for all categories of initial body fat content studied to date, the DFFM:DW loss ratio is inversely related to energy intake and thus directly related to the energy deficit. As Benedict et al. ([115](#)) showed many years ago, even modest energy deficits lead to some loss of body N, and densitometric techniques have confirmed the loss of FFM, as has the CAT scan ([94](#)). One searches in vain for well-controlled studies showing that body N and FFM can be preserved on low-energy diets. Nitrogen losses do tend to diminish with time, however, both on low-energy diets and during fasting, as do weight losses. Indeed, during fasting, N loss is exponential, and the fractional N loss is greater in the nonobese than in the obese ([95](#)), which may partly account for the greater tolerance of the obese for fasting.

The combined influence of initial body fat content and energy deficit on the composition of the weight lost during weight reduction is shown in [Figure 49.7](#). Included are data on 704 men and women who had body composition assays both before and after at least

several weeks or complete nitrogen balance on a weight-reduction diet. Except for those given 300 kcal or less daily, all had adequate protein intakes. Average values for the proportion of weight loss represented by FFM (the DFFM:DW loss ratio) are grouped in categories according to initial body fat content and reported energy intake. DFFM:DW is very high for thin subjects and falls progressively for all energy intake categories as initial body fat increases; and for any given value for body fat, the ratio progressively rises with decreasing energy intakes (and hence increasing energy deficits).

Figure 49.7. Plot of the ratio of FFM loss to total weight loss as a function of body fat content in individuals fed various energy-deficient diets. (Modified from Forbes GB. Human body composition. New York: Springer-Verlag, 1987 with additional data from references [86](#), [116](#), [118](#), [119](#), [120](#), [121](#), [122](#), [123](#), [124](#), [125](#), [126](#), [127](#), [128](#), [129](#), [130](#), [131](#) and [132](#).)

Obese patients subjected to intestinal bypass or gastric stapling operations also lose FFM as they lose weight. In various studies, 15 to 40% of the weight lost by these patients consisted of FFM (references in [\[8\]](#)).

When undernourished individuals are induced to gain weight, FFM and fat both increase ([91](#)), and the same is true for growing infants and children. Both components also increase when normal adults are deliberately overfed. For such subjects the energy cost of the weight gain averages 8 kcal/g, and about one-third of the gain consists of FFM ([86](#), [90](#), [133](#)). From their study of overfed twins, Bouchard et al. ([134](#)) concluded that genetic factors influenced the magnitude of the response. These data were collected from experiments lasting only a few weeks, the longest being 100 days. Since no controlled studies of longer duration in man exist, the situation over the long term is unknown.

The importance of adequate protein intake cannot be overemphasized. While undernourished men can gain weight on low-protein diets, some FFM is lost while body fat is gained. When adequate protein was given to these subjects without a change in energy intake, they gained FFM as well as fat ([135](#)). When Miller and Mumford ([136](#))

gave excess food low in protein to normal individuals, they lost FFM (as judged by body K content) as they gained weight, whereas excess food high in protein produced a gain in FFM and a greater total gain per excess calorie consumed. Hence low-protein diets are inefficient and even hazardous.

Reasons for FFM Change in Response to Nutritional Intervention

It is easy to understand why FFM declines during fasting: blood glucose must be maintained, and since the glycerol moiety of the mobilized lipids is not equal to this task, gluconeogenesis from protein becomes necessary. Low-energy diets containing carbohydrate do reduce nitrogen losses ([137](#), [138](#)). The detailed studies of Moore et al. ([116](#)) show that energy deficits are accompanied by reductions in plasma levels of testosterone, insulin-like growth factor, and insulin, all of which are anabolic. Moreover, the plasma levels of these three hormones rise when adult females are overfed ([139](#)).

Body Composition in Obesity

Human obesity can occur only in the face of a positive energy balance, so in this sense, it is a nutritional disease. It is fruitless to argue whether decreased physical activity or increased food intake is the prime factor; obesity results from a failure of the homeostatic mechanisms that balance energy intake and outgo in normal people. Studies of obese children, adolescents, and young adults show that 10 to 30% of their excess weight consists of FFM; however, a few have normal FFM values ([91](#)). Data on polar bears show a similar trend; very obese animals have a larger FFM than those with lesser fat burdens, and about one-third of the weight difference is lean tissue ([99](#)). Overfed rats acquire some additional lean weight as well as fat ([140](#)).

The situation is very different in animals rendered obese by experimentally produced hypothalamic lesions, for they tend to have a smaller FFM than controls. Children and adolescents with the Prader-Willi syndrome (obesity, hypogonadism, muscle hypotonia, and mild mental retardation) also have a subnormal FFM and smaller skeleton in the face of a supranormal body fat content ([141](#), [141a](#)).

Obese children tend to be taller than average and to have some advance in skeletal maturation, and obese girls have an earlier menarche. Such data indicate that most obese individuals are overnourished and that the foods eaten are nutritious. Autopsy observations show that the obese have larger hearts, kidneys, and livers ([142](#)). BMR is increased ([143](#)), as are blood hemoglobin levels ([144](#)), metacarpal cortex thickness ([145](#)), and total bone mineral content ([141a](#)). These observations speak against the hypothesis that the increased lean weight in obesity is due to muscle hypertrophy from greater weight-bearing; indeed they support the concept that the obese are simply overnourished.

One of the goals of obesity research should be to distinguish cosmetic fatness from fatness that is hazardous to health ([13](#)).

Body Composition in Undernutrition

Individuals with chronic energy deficits uncomplicated by significant infection or disease usually have normal, or only slightly reduced, serum protein levels and are not incapacitated. Patients with anorexia nervosa have very thin subcutaneous tissue, small heart and liver volumes, reduced blood volume, and even some reduction in renal function (146). There is a reduction in both FFM and body fat (89). The same is true of undernourished male laborers; however, ECF volume is not reduced, so the ratio of ECF/ICF volume is supranormal (135).

INFLUENCE OF PHYSICAL ACTIVITY

Exercise

The well-known phenomenon of work hypertrophy is nicely illustrated by the fact that the dominant arm of professional tennis players has larger muscles and thicker bones. Generally, athletes of both sexes have a larger FFM than their nonathletic peers and many have less body fat. The enlarged FFM is particularly true of weight lifters, "body builders," discus throwers, shot putters, and football players.

The question is whether the larger FFM is the result of training and/or exercise or is merely an inherent feature of the athletic individual. A number of studies have been done on individuals engaged in training and/or exercise programs of various types who have presumably not taken androgenic/anabolic steroids. These studies show a tendency for FFM to rise and for body fat to fall, but the documented changes are not great. Wilmore's (147) review of 55 such studies shows that FFM increased in 22 (maximum, 3.1 kg), decreased in 7, and was unchanged in 26. Parizkova (5) studied gymnasts in training for the Olympics and found that FFM increased by an average of 1.8 kg in the males and 1.2 kg in the females, with an equivalent loss of body fat. After the contests, body composition reverted in time to its pretraining status.

The experiments described by Oscai et al. (148, 149) are of interest in this regard. When rats are forced to swim daily for many weeks (about 20% of their life span), they acquire more lean tissue (+5%) and less fat (-16%) than their *paired-weight sedentary* controls; skeletal muscle accounts for one-third of the FFM increase. However, when the exercised animals were compared with sedentary controls *fed ad libitum*, the results were very different. Now the exercised animals weighed less than the controls and had a *smaller* FFM (by 14%) as well as less fat. The explanation is that the exercised animals ate less food and expended more energy and so incurred an energy deficit. A review of experiments conducted on exercising rats showed that they gained some FFM and lost some body fat if their body weight did not change much. However, if they lost more than about 30 g weight, there was some loss of FFM as well as fat (150a). On average, FFM contributed about one-third of the total weight loss.

The finding in experimental animals that exercise-induced increases in FFM depend on adequate intake of food has been confirmed in humans. An analysis of Wilmore's (147)

compilation of body composition changes induced by exercise shows that subject groups that maintained their weight or gained little had a modest increase in FFM, while those who lost weight lost FFM as well as body fat (150). This phenomenon has recently been confirmed by an analysis of individual subjects, including athletes and sedentary individuals, who engaged in exercise programs (150a). Body fat content influenced the body composition response to exercise and/or training; individuals (of both sexes) with body fat burdens of 25 kg or more could sustain a greater weight loss without incurring a loss of FFM than those who were thin (150). Bouchard et al. (151) studied a group of males kept on a constant diet for 100 days while exercising vigorously. Their estimated energy deficit was 353 MJ (84,370 kcal); average weight loss was 8 kg, of which 1.3 kg represented FFM.

Figure 49.8 shows the observed change in FFM as a function of change in body weight resulting from exercise programs. Adults of both sexes are included as well as a variety of exercise programs. Only subjects who had body composition assays at the beginning and at the end of the exercise period were included. There were 12 groups of males, 15 groups of females (1 group lactating), and 3 groups of mixed sexes. Exercise programs consisted of either aerobics, resistance training, or weight lifting, singly or in combination, and one group of Army Rangers (116). The two solid dots in the upper right quadrant of the illustration, at about +10 and +20 kg DW, represent the difference between body builders and Japanese sumo wrestlers, respectively, and control males of comparable stature. Individuals who maintain their body weight during exercise tend to gain FFM and lose body fat; those who gain weight also gain FFM; those who lose weight tend to lose FFM also, but those with larger body fat burdens tend to lose less FFM for a given weight loss than those who are thin. Exercise and/or training cannot sustain lean weight, much less increase it, in the face of an appreciable energy deficit. Athletes who have high energy expenditures must eat well if they want to augment, or even sustain, their lean weight.

Figure 49.8. Plot of change in FFM against change in weight resulting from exercise programs. The regression lines are based on earlier data (150a) for 166 subjects with less than 20 kg body fat (solid line) and 248 subjects with larger burdens of body fat (dotted line). More-recent data are indicated for 171 thin subjects (solid circles) and for 301 subjects with more body fat (open circles). (From 73, 116, 117, 118, 119, 123, 125, 126, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164 and 165.)

Immobilization and Space Travel

Decreased muscle mass and bone density in immobilized or paralyzed limbs is a well-known phenomenon. Healthy young men placed in plaster spicas from the waist down for several weeks lost some body nitrogen, calcium, and phosphorus and had a reduction in blood volume, although body weight did not change (166). Ordinary bed rest also results in negative balance of Ca, K, and P.

Studies of astronauts have included estimates of FFM. The loss of FFM during the 84-day flight varied according to the method used: 3.4 kg by ^{42}K dilution, 1.2 kg by densitometry, 2.6 kg by nitrogen balance, and 1.1 kg by total body water. The average is 2.1 kg FFM loss in the face of 2.8 kg weight loss (167). Blood volume declined by 10% (168). Mild hyponatremia, suggesting a change in body fluid osmolality, the strong positive N balance prior to the flight, and the fact that body weight was rapidly regained on returning to Earth make interpretation of these results difficult. Pitts et al. (169) found an 8% drop in fat-free weight, a drop in total body Ca, and an increase in body fat in rats who had spent 18 days in space. (See also Chapter 48.) Thus, maintenance of normal body composition depends on gravity and normal physical activity as well as muscle innervation.

IMPORTANCE OF BODY FAT

Data now suffice to show that relative changes in body composition are influenced by the amount of body fat. Obese animals tolerate starvation better than thin ones, and the same is true of humans. Obese subjects can survive fasts of more than 100 days, while the Irish hunger strikers of some years ago (who did not appear obese) died in about 2 months. During fasting, obese humans and animals both lose proportionally less lean tissue than those with lower burdens of body fat (Fig. 49.6). Observations on individuals fed low-energy diets also show that the relative contribution of FFM to the total weight loss is an inverse function of body fat content. Animals are known to increase their body fat stores prior to hibernation. When weight is gained in response to nutritional surfeit, thin individuals tend to put on relatively more FFM than the obese, at least in the initial phase (170).

Studies of twins show that the intrapair difference in FFM is quantitatively related to the difference in body weight for both monozygous and dizygous like-sexed twins (28). Furthermore, the slope of the intrapair DFFM/DW regression is about twice as steep for thin twins than for those with large body-fat burdens; hence for the latter, body fat accounts for more of the intrapair weight difference.

The body composition response to exercise is also influenced by body fat: those with generous fat burdens tend to lose less FFM and more fat when weight is lost during exercise than those who are thin (Fig. 49.8). The limited data on migrating birds suggest that fatter species conserve FFM better than thinner ones, in the face of what surely

must be vigorous exercise (8).

INFLUENCE OF HORMONES

Large doses of adrenal corticosteroids act to decrease muscle and bone mass; hence individuals with Cushing's syndrome have subnormal total body K and Ca and an increased body Na:K ratio, and total body K increases with treatment. Excessive amounts of parathyroid and thyroid hormones result in negative Ca balance, and the latter in loss of body N as well. Treatment of children with hypopituitarism is associated with an increase in FFM and a decrease in body fat. Individuals with acromegaly have increased body K, N, Na, and Ca and an increase in ECF volume (references in [8]).

In normal individuals (including the elderly), growth hormone causes an increase in FFM and a loss of body fat (171). In cattle, the effect on nitrogen balance is dose related (172).

Striking effects are produced by the androgenic/anabolic steroids. Nitrogen balance becomes positive, and animal studies have shown an increase in amino acid uptake in muscle and an increase in muscle size. Large doses enhance muscle protein synthesis (173) and produce a significant increase in FFM and a fall in body fat in man (8, 22), and this effect is dose related. These effects are apparently perceived by athletes, among whom the use of such steroids is said to be widespread. Indeed, androgenic/anabolic steroids can enhance FFM in the absence of exercise, and large doses produce a greater effect than does exercise alone.

Insulin has both anabolic and lipotropic activity, so deficiency of this hormone leads to negative nitrogen balance and fat dissolution. Normal pregnancy is associated with an increase in maternal FFM and fat, changes facilitated by the increased levels of testosterone, prolactin, progesterone, estrogen, and insulin that occur, as well as the increase in food intake.

Although vitamin D is now considered a hormone, its action on body tissues is presented in [Chapter 18](#) on this vitamin.

INFLUENCE OF DISEASE

Cuthbertson showed many years ago that severe trauma to the limbs was accompanied by a significant loss of body nitrogen; the negative balance in his patients was as high as 137 g, equivalent to a loss of 4 kg FFM. Earlier, Shaffer and Coleman had found that N losses occurred during the course of typhoid fever and that addition of energy in the form of carbohydrate could minimize the N loss in such patients. Beisel et al. recorded significant N losses in other types of infections and showed that these losses exceeded those due to the decreased food intake that often accompanies infection. They also recorded losses of K, Na, P, and Mg in their subjects. It is now common practice to provide extra nutrients—often by the parenteral route—to patients with severe trauma or infection or who have had major surgery. The metabolic response to surgery also

includes an increase in the $\text{Na}_e:\text{K}_e$ ratio (references in [8]).

Neuromuscular disease has a profound effect. Serial studies of boys with the Duchenne type of muscular dystrophy show a progressive departure from the normal total body K with age (8). Individuals with cirrhosis as well as those with cardiac failure have an increase in the ratio of Na space to total body water. As expected, individuals with osteoporosis have reduced total body Ca. The loss of weight in patients with cancer involves FFM as well as fat (references in [8]).

Severe malnutrition is associated with increases in the ECF:ICF ratio, the $\text{Na}_e:\text{K}_e$ ratio, and intracellular Na in muscle and a decrease in K. In such states, ECF volume appears to be better preserved than cell mass, the shrunken cells retaining their fluid covering. Picou et al. (174) evaluated the relative amounts of collagen and noncollagen protein in the bodies of malnourished infants. While the latter was reduced to about one-half the expected value, the former had not changed significantly. Skin and bone accounts for about 70% of the total body collagen.

The observations of Picou et al. (174) help to explain the difference in calculated changes in body composition produced by different techniques. Tendon has a higher density and a lower K concentration than muscle, so an increase in the ratio of collagen to noncollagen protein during weight loss would be expected to increase the density and decrease the K content of the FFM. Hence the use of standard values for each will result in a slight underestimation of the FFM contribution to the weight loss by densitometry and an overestimation by ^{40}K counting. The smaller contribution of FFM to total weight loss by density than by ^{40}K counting found by Garrow (15) during weight reduction and by Leonard et al. (167) during space flight is consistent with this hypothesis. Such inconsistencies serve as a reminder that body composition measurement techniques may not always yield precise results.

COMPANIONSHIP OF LEAN AND FAT

Modern body composition techniques have helped define the composition of the weight change induced by nutritional maneuvers. As discussed above, nutritional surfeit produces an increase in FFM as well as fat both in animals and humans, and a portion of the excess weight in obese individuals consists of lean tissue; energy deficits lead to a decline in both lean and fat, even in hibernating animals (Fig. 49.6 and Fig. 49.7). Prehibernation fattening of arctic ground squirrels includes an increase in lean weight (106) as does premigratory fattening of birds (175, 176). Very obese polar bears have a larger FFM than those with lesser burdens of body fat (99). Hence, these two body components—lean and fat—are not independent of each other, but are linked together in some fashion, whose elucidation would seem most worthwhile.

However, there are situations in which this linkage is violated. The best example of discordant changes in FFM and fat is provided by the effect of androgen administration. Large doses of anabolic/androgenic steroids act to increase FFM (a proportion of which is muscle) and decrease body fat, changes that are welcomed by athletes, especially by body builders. Similar changes occur with administration of growth hormone in both

normal and hypopituitary subjects. Another discordant situation involves obese patients with the Prader-Willi syndrome, who have a subnormal FFM despite their large burden of body fat, as do animals with experimental lesions of the hypothalamus. Hence these are not appropriate models for the usual type of human obesity.

Exercise and/or physical training can lead to a modest gain in FFM and a fall in body fat if body weight does not change much; however, if more than a few kilograms of weight are lost, FFM usually declines. As shown in [Figure 49.8](#) exercisers who eat enough to produce a positive energy balance and hence gain weight show the largest increase in FFM. Bed rest and zero gravity cause a modest reduction in FFM.

Modern techniques have helped define a constellation of body composition changes that result from various stimuli. Inferences derived from work on animals can now be tested in man, and the investigator, now freed from the constraints of the metabolic balance method, can assess body content at any point in time as well as changes that occur over long periods.

ACKNOWLEDGMENT

Supported in part by NIH grants HD18454 and RR00044.

¹The fat-poor muscle of a starved animal cannot be compared directly to one normally nourished and rich in fat. It is permitted only to compare organs on a fat-free basis.

[Selected Readings](#)

Significant changes in the female life cycle have occurred over the past 150 years. The decline in the average age of the onset of menarche has apparently stabilized at about 12.5 years. The average age of menopause is now more than 50 years. Consequently, female reproductive potential has expanded to nearly 40 years of a female's 75-year life span (1).

During the last two decades, the number of live births to women younger than 20 years of age has decreased slightly, and the number of women delaying their first pregnancy until they are over 30 years of age has increased significantly. In the United States, of the more than 5 million pregnancies annually, only 75% result in live births. The remainder end in induced abortions or spontaneous miscarriages before the 20th week of pregnancy.

The ever-improving availability and quality of obstetric and neonatal care has produced a downward trend in perinatal and infant mortality in the United States; however, the rates among the black population remain twice those of the white or Hispanic populations. Little change has occurred in the incidence of low birth weight (LBW, <2500 g), which remains at 7%, also twice as high among the black population. The incidence of very LBW infants (weighing <1500 g) is three times higher in the black population. Unfortunately, between 25 and 30% of all pregnant patients do not enter into prenatal care before the second trimester of pregnancy. Few public-sector patients achieve the recommended standard of 14 prenatal visits. They average fewer than eight visits, most of which occur in the late second and third trimester of pregnancy (2).

Nationally, approximately 40% of all pregnant women receive their prenatal care and delivery services in the public sector. Health care insurance coverage, available through the expanded federal and state Medicaid program, covers most pregnant women with incomes below 185% of the poverty level. In many areas of the United States, medical manpower (particularly for public-sector patients) for prenatal and delivery services is being replaced by physician extenders—certified nurse midwives, clinical nurse practitioners, and physician assistants.

What are these mothers' expectations in the 1990s? The number of pregnancies per reproductive career has decreased by 25% in the past 30 years (from 3.2 to 2.3 children per reproductive career). The present-day American mother expects a perfect outcome to each pregnancy. If any question arises about the condition of her fetus, she is likely to exercise her option to interrupt the pregnancy. When the maternal and/or fetal outcome is not perfect, she is predisposed to blame her health care team for the failures that result and frequently seeks legal recourse.

Several reviews of the current state of prenatal nutrition emphasize that the goals for the mother and her offspring remain constant (3, 4 and 5): (a) for the mother, freedom from complications and intercurrent diseases throughout pregnancy and postpartum and a return to her normal, healthy nonpregnant state free of sequelae; and (b) for the infant, a mature baby of normal gestational age and birth weight, free of any anomalies or disabilities, and able to thrive in the external environment.

OPTIMAL NEEDS FOR REPRODUCTIVE PERFORMANCE

Pregnancy should not be treated as a haphazard event. If the common goals of the mother and her health care team are to be achieved, one must identify and eliminate as many maternal risk factors as possible by careful evaluation and appropriate treatment, and prevent or ameliorate as many of the actual risks as possible before the pregnancy begins. Usual prenatal care in the United States consists of an initial visit for pregnancy confirmation and health examination after the individual's second missed menstrual period, followed by 12 periodic examinations at 4-, 2-, and 1-week intervals during the remaining course of the pregnancy, plus a minimum of one postpartum visit 4 to 6 weeks after delivery. A well-planned pregnancy in the late 1990s should include an initial health examination 8 to 12 weeks before conception. Those 60 to 90 days of preconceptional care are essential to controlling all maternal risk factors. Pregnancy preparation should start a year before the desired month of delivery, and care should extend at least 6 weeks after delivery. This regimen covers 54 weeks or more from the time that the prospective mother should have discontinued her nonbarrier forms of contraception. Two or more normal, spontaneous menstrual cycles are desirable before the barrier contraception is removed for the purpose of conceiving. Similarly, after delivery, time is required for reproductive involution and maternal nutritional repletion to occur.

Prerequisites for Optimal Performance

At least nine prerequisites for optimal maternal reproductive performance are recognized ([Table 50.1](#)).

- Biologic maturity of the prospective mother
- Preparation begun at conception minus 60 days
- Protection from all preventable diseases
- Tight control of all chronic and metabolic disorders
- Eradication of all habits harmful to the fetus
- Early and frequent prenatal care
- Body weight within an acceptable range
- Adequate nutrient intake and transport system
- Working placental transfer and lactation delivery system

Table 50.1 Needs for Optimal Reproductive Performances

Pregnancy Is Optimal When the Mother Is Biologically Mature

A biologically mature female is a young woman who is at least 5 years postmenarchal. This has greater impact on pregnancy performance than her chronologic age. Thus, if a 14-year-old girl began menstruating when she was 9 years old, she is 5 years postmenarchal and as biologically mature as she will ever become. Certainly, she may not be emotionally, economically, educationally, or psychosocially mature, but she is as biologically mature as her 20-year-old counterpart. If another 14-year-old girl were to become pregnant during the first year after menarche, however, she would be biologically immature. The growth demands of the pregnancy and fetus superimposed on the growth demands of an adolescent during the first year after menarche may result in undesirable reproductive outcomes.

Prevent Everything That You Possibly Can

The risk of German measles in the first trimester of pregnancy has been all but eliminated by an effective immunization program whereby all young girls are vaccinated against the disease before menarche. As discussed below, an intake of 400 µg folic acid/day (0.9 µmol/day; conversion factors to SI units for various nutrients are given in Appendix [Table I-A-1-a](#)), from diet and/or as a supplement before conception and throughout the first trimester of pregnancy, significantly reduces both the initial and recurrent risks of neural tube defects (NTDs) in the fetus.

Control of Maternal Chronic and Metabolic Disorders

Pregnancy in the diabetic mother requires enough dietary and insulin control so that throughout the pregnancy, blood levels of glucose fluctuate only within the normal range of the nondiabetic patient. If so, the expected perinatal mortality associated with diabetic mothers is now 4%, a fourfold reduction in the last 20 years. The associated risk of fetal congenital malformations in the diabetic mother can be reduced by 50% only if her glycosylated hemoglobin (A₁C) is brought into the normal range prior to conception.

The young patient with a classical phenylalanine metabolism disorder (phenylketonuria, PKU) typically has been on a special diet from infancy until the age of 8 or 9 years, after which she may have been able to manage on a more regular diet. However, she needs to be back on strict dietary control before and throughout her pregnancy. Otherwise, the probability of offspring developing some form of congenital malformation and/or another developmental abnormality is greater than 80%. All female reproductive-aged patients must be asked specifically whether they have ever been on a special diet. If the maternal serum phenylalanine level prior to conception and throughout the first trimester is maintained below 6 to 10 ng/dL (<605 nmol/L), major congenital malformations can be essentially eliminated.

All pregnancies should be started with a maternal height/weight relationship between 90 and 120% of standard weight, equivalent to a body mass index (BMI) of 20 to 26, because maternal and fetal consequences occur at both extremes. BMI is more fully discussed in [Chapter 87](#); a nomograph is given in Appendix [Table II-A-13-b](#). A patient's percentage of standard weight (PSW) is calculated by first measuring her nude height

and weight, then using the American Diabetes Association's formulas to calculate PSW. Based on 1983 height/weight standards (see Appendix [Table III-A-12-a-2](#)), 105 lb (48 kg) are allotted for the first 5 ft (175 cm) of height, and then 5 lb (2.3 kg) is added for every additional inch (2.5 cm) of height. This calculated weight defines the 100% value of PSW. The patient's actual weight is then divided by this calculated ideal weight to give her own PSW. When a woman is underweight (<90% standard weight) when her child is conceived, her infant is more likely to be of low birth weight, particularly if weight gain is also inadequate during her pregnancy. On the other hand, a prepregnant weight that is more than 135% of standard weight (BMI > 29) predisposes the patient to maternal hypertension, pregnancy-induced toxemia, diabetes, cesarean section, and other maternal complications. Also, the fetus of a significantly obese mother is twice as prone to central nervous system congenital malformations ([6](#)). Maternal weight gain targets for the patient during her pregnancy should be based on her prepregnancy PSW or BMI category, as discussed below.

Reduce and/or Eliminate All Substance Abuse, Be It Tobacco, Alcohol, or Drugs

Tobacco, alcohol, and drugs all have an impact on the maternal and/or fetal outcome of the pregnancy. The impact may be direct or indirect, through the pocketbook, through physiologic alterations, or by metabolic competition with nutrient intake.

PROVISION OF ADEQUATE NUTRITION

A pregnant woman can provide the nutrients for herself and her fetus to meet the demands during her pregnancy in three ways. The most common and desirable way is ingestion of an adequate, safe food intake by mouth, with normal digestion, absorption, and transport into maternal circulation, normal metabolism, and normal transfer of simple nutrient building blocks from mother to fetus across the placenta. Individual nutrients cross with the assistance of maternal transport carriers and are released within placental cell(s) to be picked up by their fetal counterparts ([7](#)). This transfer system requires a functioning maternal cardiovascular system and adequate uterine blood flow, with an ample concentration of nutrients on the maternal side to transfer the building blocks to the fetal side. Without these essential components, there will be some intrauterine fetal growth retardation. The same is true with respect to the normal lactation system in the nursing mother. Second, where necessary, provision of nutrients may be replaced or augmented by use of enteral ([8](#)) and/or parenteral ([8](#), [9](#)) feeding, even for prolonged periods of time. A third and less desirable pathway is mobilization of the mother's body reserves for the required calories, proteins, minerals, and vitamins needed for growth and development of mother and fetus.

To ensure the expectant mother an adequate diet, there must be an available, safe food supply and functioning food distribution system, as well as the necessary economic capacity to produce and/or procure the food. Without a safe, dependable, and abundant supply of all food needs, the woman has no way to provide the nutrients for her pregnancy. Two important supplemental food programs exist for public-sector patients: the Food Stamp Program, which serves millions of patients per month, and the Supplemental Feeding Program for Women, Infants, and Children (WIC), which serves

over 7 million persons per month, of whom 22 to 25% are pregnant or lactating women.

Additional Risk Factors

Low Hemoglobin

A woman living at sea level should maintain her hemoglobin above 110 g/L (11 g/dL) or her hematocrit above 33% (33%). For an adequate oxygen transport system, this hemoglobin level should be above 110 g/L (11 g/dL), whether she is pregnant, not pregnant, or lactating. The odds of detecting any type of nutrient-deficiency anemia when hemoglobin is above 11 g/dL are less than 1%. This standard needs to be increased about 1 g/dL for every 5000 feet of elevation above sea level to provide for the needed expansion of the hemoglobin oxygen-carrying capacity of the red cells during pregnancy. This hemoglobin standard is 20 g/L (2 g/dL) higher than those used in many developing countries where mothers may have complicating diseases, such as malaria and other parasites in addition to an inadequate dietary intake of available hemopoietic nutrients—iron, folate, and vitamin B₁₂. These mothers may have some unique capacity to compensate for the lower levels of hemoglobin; however, their maternal risks are enhanced, and their margin of safety is compromised. One of the few illustrations of nutritional fetal parasitism is that the hematologic condition of the fetus may be protected during pregnancy and the early weeks of lactation ([10](#), [11](#) and [12](#)).

Pregnancy is the occasion for the mother to gain weight. Maternal weight gain should be based on the prepregnant weight status and should occur in an orderly manner during the second and third trimesters of pregnancy. Of all the biologic factors that influence the birth weight of the fetus, maternal weight gain has the strongest influence.

Maternal weight gains above 1 kg/week are cause for concern. A weight gain above 1 kg/week solely from the ingestion of food would require an intake of 7000 kcal (1000 kcal/day) in excess of her need. This amount is unlikely because it represents almost 50% more than the usual total daily caloric intake during pregnancy. Hence, this level of weight gain suggests an abnormal accumulation of tissue fluid. Beware of any weight losses and/or weight gains of less than 1 kg/month. The impact of weight loss on the mother or the fetus is discussed below.

The decision and plans for breast-feeding should be made when the mother first feels her baby move, or at approximately 20 weeks of gestation, rather than at or after the actual delivery. Making the decision to nurse at this time allows time for weight gain to be targeted to accumulate body stores during the third trimester for use during lactation. If the expectant mother is not going to nurse, then her maternal weight gain goals need to be decreased modestly to facilitate her return to her prepregnant weight status. Under ideal circumstances, breast-feeding is the method of choice in both developed societies and the less-developed societies of the world. However, such is not the case in the United States. Most-recent data indicate a downward trend in breast-feeding among all segments of American society, being more pronounced in the black population ([2](#)). Only 50% of mothers are breast-feeding their babies at the time of hospital discharge, and only one-third of those continue breast-feeding for 6 months; but remember, the first 4

to 6 weeks of infant breast-feeding is a very important start of the newborn's nutrition.

PRENATAL HISTORY, PHYSICAL EXAMINATION, AND NUTRITIONAL ASSESSMENT OF THE EXPECTANT MOTHER

General obstetric care requires, at the initial visit, a thorough evaluation of the pregnant woman and a careful and complete history of her obstetric and medical characteristics followed by a comprehensive physical examination. Prior to this, the patient has been weighed, her pulse taken, respiration and blood pressure recorded, and a urine sample tested by dipstick for several items of diagnostic value. A series of blood samples are drawn for determination of any abnormalities that may exist in her hematologic, serologic, immunologic, and metabolic status. A few simple nutritional assessments can readily be added that are not time consuming and can be carried out by members of the health care team. Simply prescribing a mineral/vitamin prenatal supplement does not substitute for basic nutritional assessment.

Both height and weight measurements are an essential part of the initial clinical anthropometry. Together, these measurements permit calculation of PSW and BMI and proper targeting of weight gain throughout pregnancy. A detailed nutritional assessment requires

1. A physical examination of the appropriate exposed portions of the body including the arms, legs, face, and neck for clinical evidence of nutritional deficiencies
2. A dietary food intake assessment based on either a food frequency questionnaire or a dietary history of 3-, 5-, or 7-day food intake
3. Basic anthropometric measurements of height, weight, and, on occasion, skinfold thickness
4. A biochemical assessment of selected nutrients or their metabolites as measured in blood and urine

All of these measurements are usually not possible on an individual obstetric patient. However, a rapid nutritional assessment is needed for every pregnant patient to identify any significant nutritional problems that may exist. If evidence of depletion is found, further assessments by the dietitian and/or nutritionist are needed to develop recommendations for nutritional therapies.

The physician in solo, group, or clinic practice must be able to identify available personnel in the community who can provide a detailed nutritional assessment. Such individuals may be within the hospital setting as a part of its dietary department, they may be associated with the local health clinic and/or WIC program, or they may be in private practice.

Most expectant mothers are normal, healthy women without conditions that interfere with ingestion, digestion, absorption, metabolism, or use of a normal well-balanced diet. If all of the hematologic data and multiple biochemical items on the health screening profile are normal—among which are measurements of direct nutritional significance, namely, electrolytes, glucose, magnesium, calcium, cholesterol, serum lipids, liver

enzymes, albumin, urea nitrogen, and ferritin—they are unlikely to have evidence of either biochemical or clinical manifestations of any nutritional disorder. Hence, a more detailed assessment by trained nutrition personnel is not necessary. However, if a person's intake is regularly below 70% of the recommended dietary intake levels (see Appendices Tables I-A-2-a and b), one anticipates detecting abnormally low biochemical levels such as hemoglobin, serum ferritin, or serum albumin. When the patient's dietary intake is consistently below 50% of the recommended dietary allowance (RDA), one should anticipate finding clinical manifestations of early nutritional disorders. These will not be the classical pictures of nutritional deficiency, but early manifestations of abnormalities such as

1. Lesions of the gums associated with low vitamin C
2. Fissures around the angles of the mouth associated with ariboflavinosis
3. Lesions of the eyes and the skin over the arms associated with inadequate vitamin A
4. Symmetric enlargement of the thyroid gland associated with the lack of iodine

National dietary goals suggest that 15% of total caloric intake come from protein, 30% from fat, and the remainder from carbohydrates, primarily starches. The United States Department of Agriculture (USDA) recently issued a food guide pyramid to guide choices of various food groups and to achieve the proper mix of foods (13). This system provides adequate calories and healthier sources of proteins, fats, and carbohydrates coupled with the necessary amounts of minerals, vitamins, and fiber. The prescription is fairly simple: an average daily intake of 6 to 11 servings of breads, cereals, rice, and pasta; 2 to 4 servings of various fruits; 3 to 5 servings of various vegetables; 2 to 3 servings of dairy products, and a similar number of servings of meats, fish, poultry, legumes, eggs, or nuts; fats, oils, and sweets are to be used sparingly.

It has been convenient to assume that the average prepregnant and pregnant woman in America has a more-than-adequate nutrient intake of calories, proteins, minerals, and vitamins, but the results of 1980 and 1986 market-basket surveys by the USDA give reason to question that assumption. This survey showed that 50 to 60% of the female population failed to ingest 70% or more of the recommended intake of several nutrients (14). Watch for the patient who seldom eats any vegetables, fruits, or dairy products. Such a patient is probably consuming less than half of her RDA of vitamins A and C, calcium, and riboflavin. She needs more than a supplemental mineral/vitamin pill; she needs nutritional counseling. Physicians and other members of the health care team should ensure that their obstetric patients have an adequate nutrient intake. The nutritional/biochemical assessment is designed to help in that determination. Needed help can be given in group education classes or, in specific circumstances, may require individual therapeutic dietary instruction.

PHYSIOLOGIC AND METABOLIC CHANGES IN PREGNANCY

Pregnancy is a normal physiologic process associated with major alterations affecting every maternal organ system and metabolic pathway. Every single blood and urine measurement—nutrients included—is significantly altered from nonpregnant values as a result of these changes. Values change as the pregnancy advances from first to third

trimester and to delivery and then return toward normal during the postpartum period. The two major physiologic forces driving these changes are (a) the 50% expansion of plasma volume with a 20% increase in hemoglobin mass and (b) the ever-increasing levels of estrogen and progesterone as well as other placenta-related hormones. These have a particular impact on the maternal lipids, cholesterol, carotene, and vitamin E, as well as on blood-clotting factors. These two physiologic modifications result in two dominant patterns of change. The first leads to decreased biochemical levels of substances in the blood such as albumin and hemoglobin during pregnancy, with a return to normal 8 to 10 weeks postpartum. Second, the estrogen-progesterone placental hormone changes cause lipid levels to rise during pregnancy and return to baseline levels postpartum.

Nutritional Biochemical and Laboratory Measurements

The 50% expansion of plasma volume during the last trimester reaches a peak by weeks 28 to 32 of gestation. The red blood cell (RBC) and hemoglobin mass also increases about 20% and peaks at about the time of delivery (15). This physiologic dilution results in a mandatory decrease of over 20% in blood hemoglobin concentration and of about 15% in hematocrit. Despite these changes, the mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) remain relatively unchanged in the nonanemic patient throughout pregnancy.

Other adaptations include progressive increases in cardiac output to a peak at 28 weeks, accumulation of body water, and changes in renal, respiratory, gastrointestinal, and genitourinary functions (Table 50.2). These physiologic adaptations during pregnancy alter the blood levels of many nutritional components.

↑↑ Plasma volume
↑ Red blood cell volume
↑ Cardiac output
↑ Body water
↑↑ Renal glomerular filtration rate
↑ Respiratory tidal volume
↓ Gastrointestinal and genitourinary motility

Table 50.2 Major Prenatal Physiologic Alterations

Generally, nutrients that are water-soluble follow the progressive decline of serum albumin level and ferritin, for example, the serum levels of vitamin C, folic acid, vitamin B₆, and vitamin B₁₂ (Table 50.3). In addition, urinary excretion of the end products of

folate, niacin, and pyridoxine metabolism, and of intact riboflavin increases. In contrast, the serum levels of several fat-soluble nutrients such as carotene and vitamin E increase as much as 50% during pregnancy; vitamin A levels, however, are relatively unchanged.

Table 50.3 Calculated Percentage Ratios of Nutrients in Maternal and Fetal Serum by Gestational Age

Proper interpretation of laboratory results of the pregnant patient with these normal physiologic changes requires conducting biochemical assessments at suitable intervals throughout gestation and interpreting the results against gestational norms, not the nonpregnant female standards. By converting blood nutrient values to levels per unit hematocrit, one can partially adjust for expansion of maternal blood volume for a better measure of absolute nutrient change in gestation (16). [Table 50.4](#) identifies major prenatal nutritional alterations.

↓ Hematologic status
↑ White blood cells
↓↓ Serum albumin

↑ Serum carotene
→ Vitamin A
↑ Serum tocopherol
↑ Urinary N-methylnicotinamide
↑ Urinary riboflavin
↑ Urinary xanthuric-acid excretion

Table 50.4 Major Prenatal Nutritional Alterations

The preferred initial assessment of maternal hematologic status is an automated complete blood count (CBC) profile that provides more information than a hemoglobin or hematocrit level. Such data allow detection of iron-deficiency anemia or macrocytic anemia. One of the first clues to macrocytic anemia, when associated with a low hemoglobin, is a decrease in the total number of RBCs. An erythrocyte count at or near the 3 million/mL level is due to only one of three possible problems: (a) macrocytic anemia, (b) hemolysis that is destroying red cells, or (c) a recent, significant acute blood loss. All of these abnormalities result in an MCV in excess of 100.

As noted above, a health screening biochemical profile will provide several different biochemical measurements for monitoring organ and hormonal functions. [Table 50.5](#) identifies key metabolic alterations during pregnancy, including increased plasma levels of the thyroid hormones T_3 and T_4 , resulting in a physiologic state of mild hyperthyroidism. Changes in plasma insulin result in variations in the metabolism of glucose and the occurrence of gestational diabetes. No other “stress test” can match the pronounced challenge of pregnancy for identification of subsequent onset of adult diabetes. Calcium, iron, and zinc are probably required in proportionally greater quantities because of the requirements of the fetal skeletal and blood-forming tissues and factors related to the efficiency of their placental transport systems early in pregnancy. As noted below, folate catabolism increases, with a resultant increase in the requirement for folate.

↑ Plasma T_3 and T_4
↑ Plasma insulin
↑ Abnormal glucose tolerance test
↑ Calcium and iron absorption
↑ Nitrogen retention (anabolic)
↑ Triglyceride, cholesterol, fibrinogen

Table 50.5 Major Prenatal Metabolic Alterations

The pregnant woman becomes anabolic for protein with significant nitrogen retention, particularly during the first 24 weeks of gestation. Enhanced alterations in the lipid metabolic pathways occur, and the serum levels of triglycerides and cholesterol double. Almost all blood-clotting factors increase. Intestinal absorption of all nutrients is enhanced to a degree that depends on the amount presented from the diet, the

maternal body stores, and the progressively increasing maternal and fetal nutrient use.

PLACENTAL TRANSFER OF NUTRIENTS

All nourishment to the fetus is provided by the mother across the placental barrier during intrauterine life and, if the infant is fully breast-fed, by the mother and her mammary transfer system during extrauterine life. Both supply systems depend on an adequate maternal nutrient intake. These nutrient delivery systems are impeded and a fetal deficiency is created, if the mother cannot ingest, absorb, metabolize, use, and transport these nutrients to the placenta or breast. Maternal pregnancy complications, such as (a) chronic cardiovascular and renal disease, (b) diabetes, and (c) pregnancy-induced preeclampsia, compromise the maternal capacity to deliver essential nutrients, as well as oxygen, across the placenta to her fetus. Normal fetal growth increases rapidly and reaches a rate of 30 g/day during the last 16 weeks of gestation, which is 50% more than can be achieved at any time during the infant's neonatal period.

Placental transfer of nutrients depends on their concentration in the maternal plasma as well as the adequacy of the uterine blood flow perfusing the placenta. The transfer of nutrients increases up to sixfold as pregnancy advances and is fueled by maternal glucose. As shown in [Table 50.6](#), most of the electrolytes, gases, and fat-soluble vitamins cross the placental syncytiotrophoblast by simple diffusion; carbohydrates cross by facilitated diffusion; and active transport is required for amino acids, water-soluble vitamins, and essential metal ions such as calcium and iron.

Diffusion		
Simple	Facilitated	Active Transport
Gases	Carbohydrates	Amino acids
Free fatty acids		Water-soluble vitamins
Electrolytes		Sodium/calcium/iron
Fat-soluble vitamins		
Plus: Pinocytosis, solute drag, breaks in villi		

Table 50.6 Methods of Placental Transfer of Nutrients

As a result of three pathways, gradients in nutrient concentration on the maternal and fetal side of the placenta establish a maternal/fetal nutrient ratio. Certain entities are lower in the fetus and higher in the mother; others are equal in concentration on both sides of the placenta barrier; and some are lower in concentration in the mother and higher in the fetus. Levels of the water-soluble vitamins and some of the essential metals tend to be lower in the mother than in the fetus in the unsupplemented pregnant

woman. Plasma levels of the fat-soluble vitamins, in contrast, are higher in the mother than in the fetus, maintaining the diffusion gradient. Maternal supplementation of some of the water-soluble vitamins, such as folic acid, pyridoxine, and vitamin B₁₂ may significantly alter their plasma levels but not eliminate these maternal/fetal ratios (17).

Years ago, we reported seasonal variations in the placental concentration of nine cations that coincided with the concentrations in the water supply in Galveston, Texas. As of the onset of our tourist season (May to October), our well water supply had to use more brackish water from the deeper wells on the mainland. About 6 weeks later, we found significant changes in deposition of several metals in the placentae of our obstetric patients—high concentrations of sodium, potassium, copper, zinc, and lead. These levels remained elevated until mid-November, about 6 weeks after the secondary sources of our community's well water were shut off. This summer period also correlated with our peak incidence and frequency of pregnancy-induced toxemia of pregnancy (18, 19).

NUTRITION PROBLEMS AMONG THE YOUNG AND OLD

Pregnant Teenagers

As noted above, the onset of menses ranges between 9 and 16 years of age in the United States, with a mean of less than 13 years. Improved nutritional status, particularly increased calorie consumption, has contributed to the decrease of about 2.5 years that has occurred over many years. A difference in intake of 200 kcal/day between two groups of young girls resulted in a 1.5-year earlier onset of menarche in the group with the higher intake (20). Frisch's (21) study of 38 young female runners and swimmers in training for the 1980 Olympics also emphasizes the importance of adequate intake at this period.

The United States has the highest frequency of teenage pregnancy of all industrialized countries in the world, and Texas ranks second among the states. About 16% of all live births occur to young women who are younger than 20 years of age, with a little over one-third (6%) of those births occurring in women younger than 18 years of age, many of whom are less than 5 years postmenarchal. The results of the Texas section of the Ten State Nutrition Survey Report (1968 to 1970) provided convincing evidence that significant numbers of adolescent females failed to ingest 50% of the RDA of all nutrients excluding calories.

Evidence indicates no real improvement in the intervening years. In general, teenagers currently appear to be in poorer overall health and nutritional condition than their parents (22). They continue to have significant excesses and deficits in calories, fat, calcium, and iron; calcium intake remains below half the RDA, with 40% of the females not regularly ingesting dairy products. Their diets are high in fat, both as total fat and as saturated components. In 1968, 10% of the Texas teenage population were obese (over 120% of standard weight). In comparison, 1990 data indicate an obesity problem in the range of 15 to 25% (23).

All obstetric and fetal performance studies of teenage pregnancies, particularly among those younger than 18 years of age (less than 5 years postmenarchal), have reported three common trends: (a) a decrease in mean infant birth weight that results in an increased percentage of LBW newborns, (b) an increase in the perinatal mortality rate, and (c) an increase in pregnancy-induced toxemia. These pregnant teenagers are part of a population group that receives its health care primarily in the public sector. This issue was examined recently in a series of reports in a volume on adolescent nutritional disorders ([23a](#)).

Older Primigravidas

Over the past 25 years, we have seen a significant twofold increase in the number of women 30 years old or older who are delivering their first child. The older primigravida patient usually receives her health care in the private sector.

How nutritionally well prepared is the older patient for pregnancy? Upward of 40% of women in this age group are on, or have been on, some type of weight-reduction diet for the previous 5 to 6 months ([24](#)). Of the 10 most popular types of diets evaluated in 1987, 90% had fewer than 1500 calories, 70% had more than 20% of their calories coming from protein, and 60% had more than 30% coming from fat ([25](#)). Seven out of 10 of these diets were inadequate in essential minerals and vitamins. For many women, their nutritional status before their first pregnancy is not better than that of many teenagers. Pregnant women over 35 years of age have more chronic hypertension, a threefold increase in diabetes, and twice the incidence of third-trimester bleeding—placenta previa and abruptio placentae. They also have a higher rate of cesarean section that is not necessarily associated with obstructive labor problems and a higher incidence of LBW infants than women under 18 years old.

RECOMMENDED DIETARY ALLOWANCES FOR PREGNANCY AND LACTATION

During the half-century that successive editions of the United States RDAs have been published, changes have occurred in recommendations for nutrients, minerals, and vitamins based on the then-current status of nutritional knowledge. For example, energy recommendations for nonpregnant adult women have varied from a low of 2000 kcal/day in 1948 and 1968 to a high of 2300 kcal in 1953 and 1958. Data based on the 1983 revision of the Metropolitan Life Height, Age, and Weight Tables and on data derived from the National Health and Nutrition Examination Survey (NHANES) II indicate that women of reproductive age are about 2 cm taller and 2 kg heavier than the RDA reference woman of the 1960s ([26](#)). Since 1974, the recommendations for increased energy need during the second and third trimesters of pregnancy and the first 6 months of lactation have remained constant at 300 and 500 kcal/day, respectively.

The 1989 revision of the RDAs had several significant changes in the recommendation for the nonpregnant, pregnant, and lactating woman ([Table 50.7](#)); see also Appendix [Table II-A-2-a-1](#) and [Table II-A-2-a-2](#). Compared with the 1980 RDAs ([27](#)), the 1989

RDA's for nonpregnant women recommended a small increase in protein and a decreased need for iron, zinc, folate, and vitamin B₆, in the face of a 5% increase of energy—100 kcal/day (4.2×10^5 joules), an increase from 2100 to 2200 kcal/day. The 1989 RDA for the pregnant woman included a 15 to 25% increase above the recommendations for the nonpregnant woman for calories, protein, magnesium, iodine, zinc, selenium, vitamin E, vitamin C, thiamin, and niacin. The recommendations also included a 50% increase in calcium and phosphorus to the same amount recommended for a growing teenager. Only the RDA's for iron and folic acid are more than 100% over those for nonpregnant women. The 1997 Food and Nutrition Board dietary reference intakes increase the RDA's for calcium, phosphorus, and magnesium, especially for female adolescents (see Appendix [Table II-A-2-b-1](#), [Table II-A-2-b-2](#) and [Table II-A-2-b-3](#)).

Table 50.7 1989 Recommended Dietary Allowances for Pregnant and Lactating Women 15 to 25+ Years Old

Essentials of Human Lactation

The nutritional requirements for successful human lactation have been reviewed ([27a](#)). During pregnancy, the breasts readied for the demands of the infant postdelivery. Stimulation of the ductal system by the ever-increasing production of estrogen, and the concurrent enhancement of alveolar growth by maternally produced progesterone, result in enlargement of the breasts and nipples, their increased blood supply, and development of skin striae. Colostrum can be expressed from the nipples throughout the latter half of pregnancy.

The alveoli produce the milk that flows along the ducts to the nipple; milk is then withdrawn by the infant's sucking and ejected secondary to the release of maternal oxytocin. Initiation of breast milk flow begins with the release of prolactin by the mother's pituitary gland; this is the byproduct of the sharp fall in maternal estrogen and

progesterone levels that occurs following delivery of the infant and placenta.

Some 90% of infant breast milk feeding occurs in the first 3 to 5 minutes of suckling, as the milk letdown reflex comes into operation. A full-term infant will receive 90 to 270 mL/day from the first to third postdelivery day. By the end of the first week, milk production reaches 420 mL; and by days 28 to 30 it exceeds 600 mL/day.

Human breast milk is unique and quite different from cow's milk and soy-based formulas. In addition to the nutritional advantages, its immunologic characteristics provide essential protection during those critical 100 to 120 days postdelivery. In no way have our most sophisticated infant formulas been able to match human milk as the preferred food for all newborn infants, be they in developed or developing regions of the world.

Human breast milk, for the first 100 days, is a complete meal in itself (Table 50.8). Protein (1.5%) is in the form lactalbumin and a fine, digestible casein. Fat (3.5%) occurs as fine droplets. Carbohydrate (7.0%) is in the form of lactose. All the essential minerals and vitamins are included in adequate amounts except iron, which requires supplementation. Each 30 mL of breast milk provides 20 kcal, or about 600 to 750 kcal daily.

Adapted from Institute of Medicine. Nutrition during lactation—role composition. Washington, DC: National Academy Press, 1991:116.

Table 50.8 Estimate of Mean Concentration of Nutrients per Liter of Mature Human Milk

Maternal macronutrient dietary intake has little effect on the nutrient composition of human milk, except for its fatty acid content. Major minerals in the milk, such as calcium, phosphorus, magnesium, sodium, potassium, and iron, are not affected by maternal dietary intake. In contrast, content is positively correlated with intake of selenium and iodine. All essential water- and fat-soluble vitamins in milk depend on current maternal intake and stores. Chronically low maternal intake leads to low content in the milk. Infant parasitism is evidenced by iron, calcium, folate, and vitamin C—the milk content is maintained irrespective of the maternal concentration. If the maternal dietary intake consistently exceeds the RDA, only vitamin D, vitamin B₆, iodine, and selenium appear

in higher than usual concentrations in breast milk.

Recent studies have added to our knowledge about the interaction between the mother's and infant's nutritional status as a result of full lactation during the 6 months following delivery. Among lactating Mexican Indian women with low BMI (21.4) at delivery, maternal weight and body fat declined during the first 6 months of nursing. However, their low-energy balance was not associated with significant changes in production and composition of breast milk or infant growth rate (27b). Investigators from Iowa reported a careful 10-week weight-reduction study of a small group of postpartum nursing mothers. They averaged a calorie deficit of 538 kcal/day. While maternal weight was reduced 4.8 kg, there was no significant decrease in breast milk production or infant growth rate (27c).

Michigan investigators examined prolonged lactation effects on maternal bone density among two groups of biologically mature postpartum women (mean age, 27 and 29 years) with a calcium intake of almost 1700 mg and 1600 mg/day, respectively, during pregnancy and lactation. They found no significant changes in bone density during the first 5 months of nursing, compared with nonnursing controls. Beyond 6 months of nursing, there was a significant decrease in maternal bone density, even with a maternal daily calcium intake in excess of 1200 mg (27d). We wonder what these effects would be among 17-year-old nursing mothers with a calcium intake below 800 mg/day.

Nutritional Requirements

During the first 6 months of lactation, the maternal requirements for protein, zinc, niacin, and vitamins A, E, and C increase above those in pregnancy. However, compared with the requirements of the pregnant woman, the requirements for iron and folic acid decrease.

Concern has been expressed that excessive calories during and after pregnancy and lactation may be a major contributor to obesity. Pregnant and lactating women *do* need additional energy, but whether the additional 300 and 500 kcal/day that are recommended for pregnancy and lactation are truly needed, on top of the nonpregnant recommendation of 1800 or 2200 kcal/day, remains unresolved.

In developing countries, pregnant and lactating women with caloric intakes of 60 to 80% and 50 to 72%, respectively, of the 1989 RDAs are supporting pregnancies and lactation (26, 28). Depressed basal metabolic rate during the first 18 weeks of gestation was noted in chronically and marginally undernourished Gambian women (29). In western and northern European and in Australian studies, actual caloric intakes for pregnant women averaged 78 to 100% (mean, 2140 kcal/day) per day of the RDAs and 85 to 109% (mean, 2480 kcal/day) of the RDAs for women during lactation, with superior maternal and fetal performance (28). However, this summary also included data from a study in the United States on lactating women (30), which had the lowest average of any of the studies listed. Appendix Table II-A-3-a shows that the 1990 Canadian recommendations for pregnant and lactating women averaged 200 and 250 kcal/day lower than those of the U.S. RDAs. United Kingdom standards are also

appreciably lower than U.S. RDAs (see Appendix Table II-A-4-a).

Since the 1970s, the usual reference standard for the pregnant woman has been based on Hytten and Leitch's calculation that pregnancy requires an additional 80,000 kcal (31), believed to accumulate in the course of pregnancy, as illustrated in Fig. 50.1. This figure of 80,000 is based on a pregnancy in which the mother gained 12.5 kg (27.5 lb) and gave birth to an infant weighing 3.3 kg (7.3 lb). This estimate was used by the World Health Organization (WHO) in 1973 for the energy allowances for pregnancy, with an increase from an extra 150 kcal/day for the first trimester to 350 kcal/day for the second and third trimesters. In the 1985 WHO revision, an additional 250 kcal/day was recommended throughout pregnancy, with a reduction to 200 kcal/day throughout pregnancy when the expectant mother can reduce physical activity proportionately (32). One of the major components of the energy cost is the accumulation of approximately 3.5 kg of fat, most of which is laid down by the 30th week. This accumulation occurs while the fetus and maternal reproductive organs are increasing slowly in weight and was considered protective against the high energy costs of the last trimester of pregnancy and lactation. The other major energy cost concerns the increased requirements for maintenance metabolism that occur in the latter half of pregnancy.

Figure 50.1. The cumulative energy cost of pregnancy and its components. (From Hytten F, Chamberlain G. Clinical physiology in obstetrics. Oxford: Blackwell Scientific Publications, 1980, with permission.)

Alternative assumptions have been made on the basis of further analyses of composition of the new tissues and more detailed observations of both energy intakes and expenditures of pregnant women and of their resting metabolism. Such calculations have led to estimates of the cost of pregnancy in healthy, well-nourished women as low as 45,000 kcal (33) or 68,000 kcal (34), and as high as 110,000 kcal (35). The lower figures are based on the assumption of decreased activity of the pregnant woman during the third trimester of pregnancy.

For the healthy pregnant woman, an adequate intake (with supplementation of iron,

folate, and perhaps zinc) is achieved by choosing among a variety of foods in the proportions recommended in the USDA pyramid. Weight gain management should follow appropriate weight targets, as described below. Individuals who prefer an ethnic diet (e.g., Far Eastern, Near Eastern, Hispanic, and vegetarian) can meet their nutrient needs with proper food selection. Food exchange lists for a variety of food patterns are given in Appendix [Table V-A-25-a](#). A strict vegan has dietary deficits in nutrients important for hematologic well-being, particularly vitamin B₁₂. To maintain adequate nutritional status during pregnancy, strict vegans must regularly ingest a mineral/vitamin supplement that contains, at least, iron, zinc, folate, and vitamin B₁₂.

Not all family providers in our society have the economic means to support their family's needs for food, clothing, and shelter. Some 10% of the U.S. population receives food stamps, and their children participate in the school lunch and breakfast programs. Another 1.5 million women and over 5.5 million children are enrolled in the WIC program. The WIC Food Package V for pregnant and breast-feeding women provides more than 840 kcal/day, which is more than 30% of the total recommended caloric intake, 65% of protein needs, and 100% of almost all the mineral and vitamin requirements except for iron and zinc during pregnancy and lactation. Apparently, not all this supplemental food is ingested by the mother but is assimilated into the total food availability of the family unit. Evidence indicates an increase in mean infant birth weight of only 30 to 100 g for infants whose mothers receive the WIC supplement during pregnancy ([2](#)).

MATERNAL WEIGHT GAIN

In the last two decades, the prevalence of obesity among American women has increased greatly. Overall, 33 to 50% of potential American mothers are obese (>27 BMI or >120% PSW). Studies from the United States, United Kingdom, and France have all found excess perinatal mortality, hypertension, pregnancy-induced toxemia, gestational diabetes, cesarean section, and congenital malformations in the fetus. These obstetric complications all convert to a major increase in medical and hospital costs ([36](#), [37](#), [38](#) and [39](#)).

Maternal weight gain during pregnancy is an essential component of the normal growth and development of the mother and her fetus. Over the past 100 years, the medical profession has adopted acceptable/optimal weight gain guidelines. In the late 1890s, under the fear of maternal mortality associated with overly large infants and the risks of cesarean section delivery, our German predecessors initiated the pattern of trying to restrict maternal weight gain deliberately in an attempt to reduce infant size and weight, therefore expediting the vaginal birth process. This pattern existed in one form or another through the 1960s. In 1970, the National Research Council's report *Maternal Nutrition and the Course of Pregnancy* increased weight gain targets by a modest 5 to 8 lb/pregnancy ([40](#)).

Today, the pendulum has swung toward "ad libitum feeding" and further maternal weight gain, to the extent that it may be a major contributor to the ever-increasing incidence of obesity in the female population of the United States. Over 25% of young women below 20 years of age are obese, and one-third of all females in the United States weigh more

than 120% of standard weight (24). On any given day, 40% of adult U.S. women are on diets and have been for 6 months or longer. The birth weight of the offspring depends on two major maternal weight-related factors: (a) how much weight did the mother gain during her pregnancy? and (b) what was her height/weight relationship (PSW or BMI) when she began her pregnancy?

In its 1990 report on maternal weight gain, the National Research Council (3) recommended that all pregnant women have a BMI calculation on entry into prenatal care. If a woman has a BMI below 20, her weight gain target should be 1.1 lb/week during the second and third trimester, leading to 31 lb (14 kg) of overall weight gain; the woman whose BMI is above 26, has a weight gain target of only 0.7 lb/week, requiring up to 20 lb (9 kg) of overall weight gain (2). As noted above, another method of weight/height expression of PSW, from the American Diabetes Association, equates a PSW below 90% of standard weight with a BMI below 20, and a PSW of 135 with a BMI above 29.

Components of Weight Gain

During normal pregnancy, the components of weight gain consist of the fetus, placenta, amniotic fluid, enlarged uterine and breast tissue, and expanded maternal blood components (Fig. 50.2). Together, they constitute the “obligatory” weight gain associated with pregnancy. In addition, there are highly variable accumulations of tissue fluid, adipose tissue, and protein stores. Studies from industrialized countries show obligatory weight gains of about 7.5 kg (16.5 lb). Among developing countries, obligatory maternal weight gain is about 20% less (6 kg, or 13.2 lb), with lesser accumulations of tissue fluid, adipose tissue, and protein stores (41).

Figure 50.2. Components of weight gain in normal pregnancy. (From Hytten FE, Leith I. Physiology of human pregnancy. Oxford: Blackwell Scientific Publications, 1964, with permission.)

If a woman 65 in (1.67 m) tall begins her pregnancy at 128 lb (58.2 kg), over the 40

weeks of pregnancy her PSW will increase 13% (16.5 lb = 7.5 kg) from the obligatory weight gain of pregnancy alone. If, instead, she gains 32 lb (15 kg), her PSW will increase almost 26%, of which 1 to 2 kg will be tissue fluid and 7 kg will be in the form of fat deposits. Returning to her prepregnant weight after delivery or nursing will require at least 12 weeks of reduced calories and increased exercise. It may well take a year for a primiparous, singleton mother who gains over 40 lb (18.2 kg) to return to her initial weight.

Individual Weight Gain Targets

No single maternal weight gain target meets the needs of all types of pregnant women. Individualized pattern(s) of maternal weight gain should be adjusted for (a) height and/or PSW, (b) biologic age, (c) plans to breast-feed, and (d) whether more than one fetus is being carried.

Does a biologically immature female need more weight gain during pregnancy to produce an equivalent-weight offspring? Garn et al. (42) examined the data from the National Perinatal Study and found that white and black women 14 years of age required almost 4 g of maternal weight to yield 1 g of baby. Their fully mature counterparts produced 200-g heavier infants on only 3 g of maternal weight for every 1 g of baby. These findings translate into a need for an additional 150 kcal/day (3 kg in overall weight gain) for the biologically immature pregnant woman.

General Targets of Appropriate Weight Gain

We have developed five maternal weight-gain targets (Fig. 50.3):

Figure 50.3. Maternal weight gain targets.

1. The woman who enters her pregnancy at more than 120% of standard weight, has an obligatory weight gain of 7 to 8 kg (15–18 lb) at a rate of no more than 300 g

- (0.7 lb) per week (target I)
2. The woman of normal PSW who is not going to nurse, has the target of 10 kg overall at a rate of 350 g (0.8 lb) per week (target II)
 3. The woman who enters her pregnancy between 90 and 110% of standard weight and is planning to nurse her baby, has the target of 12 kg (26 lb) overall at a rate of 400 g (0.9 lb) per week during the second and third trimesters (target III)
 4. The biologically immature adolescent and the woman less than 90% of standard weight have the target of 14 to 15 kg (32 lb) at a rate of 500 g (1.1 lb) per week (target IV)
 5. The woman who is going to have twins has the target of 18 kg (40 lb) of weight gain, with a weekly rate of 650 g (1.4 lb) during the last 20 weeks of her pregnancy (target V)

Risks of Excessive Weight Gain

As noted above, the 1990 maternal nutrition report of the National Research Council ([3, 126](#)) recommended an additional 5- to 10-lb increase above the 1980 targets for maternal weight gain to produce heavier, but not necessarily more biologically mature, newborns ([31](#)). This recommendation implies that the benefits of a heavier baby outweigh the costs associated with increased problems with delivery, as well as the maternal health costs associated with ever-increasing residual obesity. The wisdom of this recommendation merits discussion.

No convincing evidence indicates that an infant who is biologically mature at birth and who weighs over 3200 g would be better off or healthier if he or she were to weigh 3500 g. In contrast, there is tremendous difference with respect to neonatal morbidity and mortality if an infant, at birth, weighs 1000, 1250, 1500, or 2000 g. Here fetal weight status is far more important. A 300-g weight differential with its 10 days of additional biologic maturation may be crucial to the survival and well-being of the fetus. Furthermore, excessive maternal weight gain has been associated with increased rates of labor problems, cesarean section, fetal macrosomia, late delivery dates, and meconium staining of the fetus.

Obesity, Age, and Parity

Cross-sectional data from the Texas Nutritional Survey of 1968 showed a progressive increase in the incidence of female obesity associated with advancing maternal age, from 10% obesity in the 15- to 19-year-old age group to as much as 60% in 40- to 44-year-old women ([43](#)). Although obesity is directly related to advancing age, a much higher correlation exists between obesity and the number of times a woman has been pregnant (gravidity). Our data showed a 16% obesity rate among those who were never pregnant; this rate rose to 50 to 68% among grand multiparous women ([Table 50.9](#)). An average of 2.5 kg (5.5 lb) was added permanently to the woman's body for each of her pregnancies.

Percentage of Standard Weight		<80	≥120
No. Pregnancy	N		
0	286	7.5	15.7
1	57	5.4	33.3
2	65	7.7	36.9
3	72	4.2	47.2
4	73	1.4	47.9
5	67	3.0	55.2
6	57	—	45.6
7	38	—	50.0
8	33	3.1	66.6
9	22	—	68.2
10	70	—	52.9

Table 50.9 Percentage Under and Overweight by Gravidity

Longitudinal data from separate national collaborative studies of over 1200 and 600 women also found residual weight gain correlated with the number of prior pregnancies. Weiss and Jackson (44) reported a 3-lb increase in black mothers and 3.8-lb increase in white mothers from one pregnancy to the next. Garn et al. (42) found an increase greater than 5 kg from the first to the third pregnancy, with lesser gains in smokers. More-recent reports confirm this trend and add that the weight increases are greater in multiparous women over 35 years of age and that black women have twice the relative risk of white women of adding to their obesity with successive pregnancies (45).

As described above, the pregnant woman has been encouraged to increase her dietary intake by 300 kcal/day for the last 200 days of prenatal care and by 500 kcal or more per day during her months of full lactation. However, once these needs end, she must be prepared to reduce her caloric intake and increase her activity. Otherwise, she will continue with a 2200- to 2700-kcal appetite and an energy expenditure of only 1800 to 2000 kcal/day. Remember, 250 excess calories per day will add over 2 lb (1 kg) of weight *per month* to her frame. In reality, a 500 kcal/day *deficit* is desired, so she will lose 1 lb/week until she returns to a normal BMI or PSW.

Lactation itself may or may not help the mother return to her prepregnant weight status. Some evidence suggests that the nonlactating female loses more weight and at a faster rate than the lactating mother (46). These data also suggest that greater prenatal weight gain is associated with greater weight loss. In a well-controlled study, Dewey et al. (45) demonstrated that the long-term, breast-feeding mother lost considerably more weight postpartum than the mother who fed less than 3 months.

IODINE

Iodine deficiency remains a major international public health problem (see [Chapter 13](#)). It is estimated that 800 million people may be at risk for the effects of iodine deficiency, known as iodine deficiency disorders (47). In humans, these effects occur at all stages of development: the fetus, the neonate, the child, and the adult. Low levels of dietary

iodine, observed in endemic areas, decrease the synthesis of the thyroid hormones and result in maternal hypothyroidism, lowered maternal metabolism, and lowered fetal nutrition (48, 49). Overt or marginal hypothyroidism occurs in about 50% of pregnant women residing in areas of endemic iodine deficiency (50) when the iodine need is dramatically increased during the first 20 weeks of pregnancy (49, 51). The effects include miscarriages, stillbirths, and congenital anomalies, as well as goiter, cretinism, impaired brain function, and hypothyroidism in children and adults (47). Endemic areas of iodine deficiency are located in mountainous regions of Europe, the eastern Mediterranean, Asia, South and Central America, and Africa (52, 53). Indeed, iodine deficiency is considered the single most important and widespread nutrient deficiency (54) (also see Chapter 13).

Although North America is no longer a region of endemic iodine deficiency (50), the Ten State Nutrition Survey of 1971–1972 revealed a goiter rate of 3.1%, with a slightly higher rate among females than males (53). Apparently, the low incidence of iodine deficiency in the United States may be attributed to iodination of several commercial foodstuffs: salt, bread, cereal, etc. (50). However, marginal prenatal iodine deficiency remains a clinical problem in North America. It has been hypothesized that women relying heavily or solely on vegetable diets prior to pregnancy and in early pregnancy are at risk for prenatal iodine deficiency (55). No adverse effects on mother or fetus have been reported from prenatal iodine supplementation (56).

ANEMIA PREVENTION

“Low” hemoglobin is the most common nutritional biochemical problem encountered in everyday prenatal care. If not accounted for by the normal 12 to 20% decline due to hemodilution, 9 in 10 true hemopoietic nutrient deficit problems are related to iron, and 1 in 10 is related to folic acid. Except in those few individuals who are strict vegans (see Chapter 106) and the rare patients who have had a vitamin B₁₂ problem diagnosed and treated before their pregnancy, it is essentially unknown for macrocytic anemia to develop during pregnancy because of inadequate vitamin B₁₂.

In the United States, the most common cause of a hemoglobin concentration below 110 g/L (11 g/dL) is an exaggerated hemodilution caused by the expansion of blood volume. A true nutritional anemia will develop when one or more of the following occur: (a) an inadequate dietary intake of hematopoietic nutrients, (b) an excess loss of blood, or (c) inadequate nutrient stores to maintain hemoglobin production and RBC maturation.

Iron

Iron is an essential trace metal that functions as a cofactor for transporting oxygen in the hemoglobin in RBCs, the myoglobin in muscle, and the cytochrome systems within mitochondria. Within each of these systems, the iron atom transfers the oxygen molecule for respiration of all maternal and fetal cells. However, the primary function of RBC hemoglobin is to transport oxygen from the lungs to the other respiratory systems, and it is critical for cellular metabolism. The oxygen requirement for cellular metabolism increases during pregnancy (with increased demands for maternal and fetal growth and

development); the highest risk of nutritional inadequacy occurs during the last weeks of pregnancy. Consequently, maintaining the oxygen-carrying capacity of the pregnant woman is essential for her and for the developing fetus. The oxygen-carrying capacity is most conveniently estimated by the level of maternal hemoglobin, which in turn depends on the pregnant woman's plasma iron level.

The iron status (hemoglobin status, O₂ carrying capacity) depends on (a) the level of maternal hemopoietic stores, (b) intestinal absorption of iron, folate, vitamin B₁₂, etc., (c) acute or chronic loss of blood due to internal or external bleeding, (d) the absence of any hemolyzing agents, (e) an adequate supply of other essential hemopoietic nutrients to permit the synthesis of RBCs and to fill them with iron-containing hemoglobin, and (f) a working placental transfer system for iron, folate, vitamin B₁₂, etc., from mother to fetus.

The change from full iron stores with an adequate dietary intake to a classic, chronic iron-deficiency anemia (small, hemoglobin-poor RBCs) has many steps. An RBC distribution width of 15% or more, determined by the automated Coulter Counter CBC, is one of the earliest indicators of a developing iron-deficiency anemia. Another key is the level of plasma ferritin, which reflects the adequacy of the body's iron stores. Levels of 12 µg/L (ng/mL) or less have been considered deficient, and even levels below 35 µg/dL in the first trimester provide little margin of safety in meeting the later iron requirements of mother and fetus for optimal growth and development.

The typical American diet contains between 6 and 7 mg (0.5 and 0.6 nmol) of iron per 1000 kcal. An average of only 10% of the ingested iron is transported into the portal circulation. [Table 50.10](#) lists the mean number of milligrams of iron per day that must be transported into the maternal circulation during the various stages of the reproductive cycle from nonpregnant, through the three trimesters of pregnancy, and during lactation. Cessation of menses decreases the amount of iron required in the first trimester. In response to maternal and fetal demands, however, the requirement increases throughout both the second and third trimesters. As long as total lactation continues, the mother will remain amenorrheic and her own postpartum iron requirement will remain low. In the third trimester of pregnancy, an average 4 mg/day of iron must cross into the maternal circulation. However, because of fetal demands this requirement may peak as high as 7 mg/day of iron for a short time during the middle (30–34 weeks) of the third trimester.

Age	Daily Requirements (mg)	Iron Available in Daily Diet (mg)		
		10%	20%	30%
11–50 years, nonpregnant, nonlactating	1.8	18.0	9.0	6.0
Pregnant 1st trimester	1.0	10.0	5.0	3.0
2nd trimester	3.0	30.0	15.0	10.0
3rd trimester	4.0	40.0	20.0	13.0
Lactating	1.5	15.0	7.5	5.0

Table 50.10 Provisional Requirements of Dietary Iron in Women

How much dietary iron is required to transport 4 to 7 mg iron across the intestinal barrier and into the maternal circulation? Based on the current RDA for pregnant women and usual dietary intakes, this might require an efficiency of iron absorption of 50%, if iron was available only from dietary sources. Various investigators have found that pregnant women have an enhanced ability to absorb iron across the intestinal mucosa (57). Maternal intestinal iron absorption increases from 10% to more than 50% during the last trimester of pregnancy. This ability to increase the efficiency of iron absorption may suffice to meet the increased maternal and fetal requirements of pregnancy, provided there are sufficient maternal stores of iron and an acceptable level of available iron is ingested and presented to the intestinal cells for mucosal transfer (58). If the pregnant woman ingests 15 mg of iron from dietary sources and another 30 mg is available as an iron supplement, she should have no difficulty meeting the iron requirements for pregnancy and her fetus during pregnancy, lactation, and the first 100 days postpartum. If the maternal hemoglobin level exceeds 110 g/L (11 g/dL) at sea level and the serum ferritin is 35 ng/dL or more, a 30-mg iron supplement is adequate. If a typical prenatal mineral/vitamin supplement containing 30 mg of iron and an additional three tablets of 325-mg ferrous sulfate (60 mg of Fe²⁺) are prescribed, the patient will ingest over 200 mg of elemental iron to get 7 mg across the gut. This is iron excess, which leads to gastric irritation and patient noncompliance. If the pregnant woman's hemoglobin level is below 100 g/L (10 g/dL) and her serum ferritin is 12 ng/dL or less, with low MCV and MCHC—characteristic of classic iron-deficiency anemia—she will need a total of 120 to 150 mg/day of elemental iron to meet these demands until her hemoglobin exceeds 120 g/L (12 g/dL) and her serum ferritin level is again over 35 µg/L.

Maintaining optimal oxygen-carrying capacity requires almost 1 g/dL more hemoglobin for each 5000 feet of elevation for all persons, including prospective mothers, compared with those residing at sea level (1). For example, an acceptable hemoglobin level may be more than 11.0 g/dL in Galveston (sea level), while the standard needs to be more than 12.0 g/dL in Denver (1 mile high) and more than 13.0 g/dL in Leadville, Colorado (elevation above 10,000 feet).

The NHANES II and other studies found that hemoglobin and serum transferrin levels of black women are about 10% lower than those of either white or Hispanic women. Similarly, hemoglobin levels are 12% higher in the first trimester of pregnancy than in the third; they are also higher in obese pregnant women than in those who are underweight (59). In a therapeutic trial using a mineral/vitamin supplement containing three dosage levels of iron (0, 18, and 65 mg/day) and two levels of folate (400 and 1000 µg/day) (Table 50.11), young women were studied from the 16th week of pregnancy through the remainder of their pregnancy, at delivery, and for the first 12 weeks postpartum. Fig. 50.4 illustrates that the mean serum ferritin in each group dropped significantly from the initial values at entry into the study to the time of delivery, and all values recovered somewhat in the postpartum period. Only in group C, women who were receiving the 65-mg iron supplement, did values return to their initial entry levels by the 12th week postpartum. None of these three levels of maternal iron supplementation sufficed to overcome the dilutional effect of blood volume expansion and/or the demands for iron by the mother and fetus during the second and third trimester of pregnancy. In contrast, the mothers' ability to lay down new iron stores occurred when the iron supplement was given before the pregnancy began and during the first weeks after delivery.

Iron Supplementation Group	N	Gestational (N = 61)		Therapeutic Failure (N = 14)	
		Ferritin >35	Ferritin <35	Ferritin >35	Ferritin <35
A (0 mg) ^a	21	4	17	0	9
B (18 mg) ^b	19	11	8	1	4
C (65 mg) ^c	21	10	11	0	0
Total	61	25	36	1	13

^a1 mg iron = 18 µmol.

^b400 µg (0.31 µmol) folate.

^c800 µg (1.02 µmol) folate.

Table 50.11 Hematologic Outcome versus Serum Ferritin at 20 Weeks Gestational Age

Figure 50.4. Mean relative percentage of change from prestudy baseline of serum ferritin levels (adjusted for serum volume) for groups A, B, and C, who were given an iron supplement of 0, 18, and 65 mg/day.

Women may be in a state of low or deficient iron at the beginning of pregnancy because of an inadequate diet, excessive menstrual losses, or other factors. Iron status should be determined very early in pregnancy or, even better, before conception. Unfortunately, many women don't enter prenatal care until after the first trimester of pregnancy, by which time nutrient inadequacy has already developed. Normal expansion of maternal blood volume has begun, which renders several maternal laboratory indices less diagnostic. The leading cause of low maternal hemoglobin (<11.0 g/dL) during the second and third trimesters of pregnancy is expansion of blood volume, particularly of the plasma component. The vital importance of an adequate expansion of maternal blood volume is emphasized by its positive correlations with low hemoglobin in the third trimester of pregnancy and with mean birth weight. When the lowest third-trimester hemoglobin levels in an iron-unsupplemented group of over 150,000 Englishwomen remained above 10.5 g/dL, there were increased risks of LBW and preterm delivery (60). Similar results have been reported for plasma ferritin, with high values in the late second trimester of pregnancy being associated with low birth weight and preterm delivery (61).

[Table 50.11](#) also compares the adolescent pregnant groups by level of iron supplementation, initial serum ferritin level, and the number who failed to maintain their hemoglobin above 110 g/L (11 g/dL) throughout their pregnancy. Some 40% of group A, who were not receiving additional iron, dropped below the 11 g/dL lower limit; 20% of group B, receiving 18 mg of iron, were also in this category; but none of group C, receiving 65 mg/day, fell below 11 g/dL. Only 1 of 15 (7%) subjects receiving either 0 or 18 mg of iron fell below 11 g/dL when her serum ferritin level prior to 20 weeks of gestation was above 35 µg/L (ng/mL), whereas 13 of 25 (52%) of the subjects did so if their initial serum was below 35 µg/L (ng/mL).

Deficient serum ferritin levels (below 12 ng/mL) have been associated with a two- to threefold increase in the incidence of LBW and preterm deliveries. Our data (1, 63) suggest that pregnant women with serum ferritin levels below 35 ng/mL during the first trimester are also at risk unless they receive adequate iron supplementation during the last half of their pregnancy. Routine assessment of maternal serum ferritin before 20 weeks of gestation should indicate the need for an appropriate level of elemental iron supplementation throughout the remainder of the pregnancy and for 100 days postpartum.

In contrast to reports from Norway (62) and the United States (above), our counterparts in the United Kingdom do not believe that all pregnant women should routinely receive supplemental iron. A recent paper (58) concluded that a normal pregnant woman can maintain her hemoglobin level at 11.0 g/dL or above by using her natural ability to

increase iron absorption as pregnancy advances and maternal and fetal demands expand. A comparison of our Galveston data of 1987 (1, 63) with their Newcastle data of 1994 (58) is summarized in Table 50.12. Our group of women who received no additional iron in their supplement is very similar to their group of women. If anything, our women's serum ferritin concentrations dropped more severely than those of the women from Newcastle. In the third trimester of pregnancy, 40% of our patients and 16% of theirs had Hb values below 11.0 g/dL. Only the Galveston group that received 65 mg/day of iron in their supplement had their mean serum ferritin values return to first-trimester levels by 12 weeks postpartum (63). We remain skeptical of iron sufficiency when published data from Newcastle reveal that their subjects' late third-trimester serum ferritin levels ranged from 5 to 6 ng/dL—almost 90% lower than their initial mean levels at the end of the first trimester. Even at 12 weeks postpartum, the women in Newcastle had mean levels of iron stores 60% below the first trimester. What they consider as normal physiologic adaptation, we consider to be serious iron deficiency.

Wkrs Gestion	Mean Hb (g/dL)				Mean HCT				Mean Serum Ferritin (ng/dL)				Mean RDW (%)

Table 50.12 Comparisons of Mean iron Status among Pregnant Women Galveston 1987* versus Newcastle 1994†

The Preventive Services Task Force of the U.S. Public Health Services issued, in late 1993, a policy statement on iron supplementation (64). It stated that iron supplementation can improve maternal hematologic indices; however, controlled clinical trials have not resulted in improvement in maternal or newborn outcomes. The task force acknowledged that 20 to 40% of all American pregnant women have hemoglobin levels of 10.0 g/dL or less and that many studies confirm an association between “anemia” during pregnancy and outcomes such as LBW and preterm delivery. These reports were dismissed by the task force for lack of control of other variables that might have directly affected the pregnancy. They carefully excluded from their conclusions pregnant women in developing countries. We wonder if our obstetric patients from the barrios of south Texas and the inner city of Camden, New Jersey, belong in the American or Third World groups. Somehow the fact that hemoglobin is the O₂ transport and transfer carrier to all maternal and fetal tissues seems to have been lost in the task

force's statistical fury (64).

It is true that pregnant women and their infants, over the centuries and in the developing world today, have survived the consequences of even severe maternal chronic anemia (Hb < 7.0 g/dL). However, as we enter the 21st century, we contend that the standard of care should not be what a pregnant woman can tolerate, but what provides optimal nutritional health for her and her newborn offspring.

Folic Acid

Deficiency of folic acid (folate) is associated with an increased incidence of LBW babies and megaloblastic anemia in mothers (65). Because the calculated total fetal and placental folate content is about 800 µg at term, the increased demand for this vitamin is not likely to be due merely to fetal transfer, which represents a drain of less than 5 µg/day (66). In normal pregnant women, the urinary concentration of a breakdown product of folate (*p*-acetamidobenzoylglutamate) rose significantly in the second trimester and returned to baseline postpartum (67). The increased rate of folate metabolism during the second and third trimesters was estimated to produce an extra demand for dietary folate of about 200 to 300 µg/day in pregnant women.

Folate supplementation given to the same three groups of women noted in [Table 50.11](#) increased levels of tissue storage in all three groups during gestation, measured as folate in the maternal RBC. The higher 800 µg/day folate supplement resulted in higher tissue levels throughout the pregnancy and beyond.

The role of folic acid and vitamin B₁₂ in the prevention of NTDs is reviewed below.

Homeostasis of Iron Status in the Fetus and Newborn Infant

Over the last 60 years, various investigators have demonstrated the ability of the maternal hemopoietic system to protect the fetus in the face of a range of severe hematologic deficits (10, 11 and 12). Hemoglobin, serum iron, and serum ferritin all can be low during pregnancy and lactation, yet the newborn infant's iron status and mother's breast-milk content remain unaffected.

As noted in [Chapter 10](#), "Iron," [Table 10.5](#), the total iron cost of an uncomplicated pregnancy, plus that lost in milk during lactation for 6 months, is in the broad range of 420 to 1030 mg or 1.2 to 2.5 mg/day over this 15-month period—with the major need in the third trimester, as noted above. Adequate maternal iron stores must be created before pregnancy, not by trying to do catch-up during gestation. Adequate dietary intake and/or iron supplementation should begin in the months before conception. The typical well-balanced American diet alone does not provide adequate iron to meet maternal and fetal needs during the last half of pregnancy, nor does it provide iron to replenish the 600 to 1000 mL of maternal blood lost at delivery. Even the nonlactating, postpartum woman needs iron supplementation for 100 days (12 weeks) after delivery to replenish her own body stores. And, even though the pregnant woman has an increased ability to absorb iron from her diet, a supplement of 30 mg/day is protective and preventative

during the period from the 12th week of gestation through 12 weeks postdelivery and/or postweaning.

From these observations, we have concluded that for optimal maternal, fetal, and neonatal health, a woman should maintain 11.0 g/dL or more of hemoglobin throughout her reproductive years and 35 ng/dL or more of serum ferritin at the 20th week of pregnancy.

PERINATAL MORBIDITY AND MORTALITY

Over the past 100 years, the rate of infant mortality in the United States has dropped from 15% to less than 1%, as sanitation, immunizations, antibiotics, blood replacements, and the development of start-of-the-art neonatal care have become generally available.

Infant Mortality

Before the mid-1980s, the leading cause of infant mortality in the United States was associated with LBW and prematurity. Over the past 10 years, birth defects (at 25%) have replaced them. Both the infant and perinatal mortality rates in the United States and the percentage of LBW infants have decreased by over 20% since 1980 (2). This decrease has occurred to a greater extent in the white population than among African Americans. Among all developed countries, the United States ranks below 20th in overall infant and perinatal mortality.

Perinatal Mortality

Perinatal mortality (fetal deaths plus neonatal deaths), on the other hand, remains strongly associated with the fetus's birth weight and gestational age at the time of delivery. Birth defects contribute 25 to 30% of overall perinatal mortality. As noted in [Chapter 51](#), approximately 7% of all infants born in the United States weigh less than 2500 g at birth. Newborn infants who weigh less than 700 g and have a biologic age below 24 weeks of gestation have the risk of perinatal mortality of 80% or more; whereas those weighing 2000 g and over 34 weeks gestational age have a perinatal mortality risk below 1.5%. How much of this improvement may be due to maternal nutritional status before and during pregnancy? Certainly the amount of maternal weight gain is inversely proportional to the rate of perinatal mortality. Poor maternal weight gain during pregnancy increases the risks to the fetus in utero. Increased perinatal mortality rates have also been associated with consistently low levels of serum vitamin C (68).

Pregnancy-Induced Hypertension

Pregnancy-induced hypertension (PIH) remains a significant cause of worldwide maternal and fetal morbidity and mortality. Approximately 6% of gravidas develop PIH (69). PIH is further subdivided into preeclampsia (PE), eclampsia, and late transient hypertension (70). Patients with preexisting hypertension are at increased risk for development of superimposed PE. PE is multisystem—including hypertension and

concomitant proteinuria with or without edema. Patients with PE who exhibit seizure activity are classified as having eclampsia. Pregnant patients with severe PE may also exhibit hepatic failure, thrombocytopenia, coagulation disorder, renal failure, and pulmonary edema. The multisystem nature of PE suggests a complex etiology. It also suggests that hypertension is a symptom and manifestation rather than a causative factor in the underlying disease process ([70](#), [71](#)).

The precise etiology of PIH/PE remains unknown, but most data suggest that poor tissue perfusion is essential in development of PIH/PE. Placental “hypoplasia” in patients with PE implies at least a relationship between PE and placental homeostasis ([72](#), [73](#)). Hemodynamically, patients destined to develop PE display altered vascular responsiveness to angiotensin and catecholamines long before clinical development of PE ([74](#)). Theories abound concerning the pathogenesis of PE/PIH, but most involve alterations in placental or vascular vasoactive mediators producing endothelial tissue injury. Given the placenta's large arachidonic acid content, prostaglandins (see [Chapter 4](#)) have been at least partially implicated in the pathogenesis of PIH. Alterations in thromboxane and/or prostacyclin are also involved in the pathogenesis of the disease. Endothelium-derived relaxation factor has been more recently implicated in PIH/PE. Quite possibly, a complex set of mediator-driven events is central to development of PIH/PE ([75](#), [76](#)).

Over the past century, the influence of nutrition on PIH/PE has been investigated from several perspectives. Maternal weight and body mass are related to development of PIH/PE. After controlling for several confounding factors, excessive maternal weight appears to cause a graded, up to 12-fold risk on development of PIH/PE ([74](#), [76](#)) and to cause a 9-fold increase in the likelihood of becoming hypertensive ([39](#)).

Nutritional intake has been evaluated in patients at risk for development of PIH/PE. Patients with PIH/PE often have diminished protein stores, and while this was generally attributed to renal losses (proteinuria), Brewer ([77](#), [78](#)) postulated that consumption of adequate protein would prevent PIH/PE. Other investigators do not support this view ([79](#), [80](#)). A very compelling, but unproven, effect of renal hyperperfusion (as caused by excessive protein intake) also deserves investigation. Lipid supplementation has a theoretical influence on hypertension. Magness et al. ([81](#)) reported that daily supplementation with the n-6 polyunsaturated fatty acid linoleic acid reduced blood pressure and prolonged pregnancy in patients with PE. The lack of PIH/PE in pregnant patients receiving n-6 and/or n-3 polyunsaturated fatty acids through parenteral hyperalimentation has also been observed ([81](#), [82](#), [83](#)). Their effect on thromboxane or prostacyclin production has been postulated ([75](#), [81](#), [82](#), [83](#)). Further work in this area is necessary to elucidate a possible relationship between lipid supplementation and PIH/PE.

Because pregnancy is normally associated with an increased renin-angiotensin-aldosterone axis and since resistance to the pressor effects of angiotensin II is lost in pregnant patients destined to develop PIH/PE, salt restriction at one time was thought to play a role in prevention of the disease ([84](#)). Since most pregnant patients with PIH/PE are volume contracted, excessive salt restriction to less

than 2 to 4 g/day is not recommended (75, 76, 85).

More compelling is the possible relationship between calcium and hypertension. Villar et al. (86) showed a hypotensive effect in a pregnant population supplemented with calcium. Other studies have reported this effect as well (87, 88 and 89). Populations low in calcium intake have a higher incidence of PIH/PE than do those with calcium supplementation (90, 91). In contrast, based on a metaanalysis of 33 trials involving over 2400 nonpregnant subjects, a group from McMaster University found that calcium supplementation only modestly reduced systolic blood pressure and had an insignificant effect on the diastolic component (92). Based on a metaanalysis of 14 randomized trials involving almost 2500 pregnant women who received calcium supplementation of 1500 to 2000 mg/day, the same group from McMaster found significant reductions of 5.4 and 3.4 mm Hg in systolic and diastolic blood pressure, respectively. Of the various maternal and fetal outcomes of pregnancy, only mild PE was significantly reduced (93). A more recent randomized double-blind study in the United States of 4589 healthy women, 13 to 21 weeks pregnant, given either 2 g of elemental calcium or a placebo found that the calcium supplement did not prevent preeclampsia, pregnancy-associated hypertension, or adverse perinatal outcomes (93a).

Magnesium may also play a role in PIH/PE, although the interaction between magnesium and calcium may be the actual mechanism (75). For years, magnesium sulfate has been used in the United States as the first-line medication for the nutritionally unrelated pharmacologic indication of seizure prophylaxis in patients with PIH/PE (69) (see also Chapter 9).
