1-Allyl-3,4-methylenedioxybenzene, safrole, is a major constituent of the oil of the sassafras tree and has been used as a fragrance in soft drinks and soaps. Estragole is present in tarragon and sweet basil and is used as an essence. Miller et al. showed that these two alkenylbenzenes induce hepatomas and angiosarcomas in mice, both apparently being metabolically activated to 1 ϕ -hydroxy derivatives (42). In addition, isosafrole (3,4-methylenedioxy-1-propenylbenzene) and methyleugenol (1-allyl-3,4-dimethoxybenzene) were reported to induce hepatocarcinomas in rats and mice, respectively (42, 43). The related β -asarone (*cis*-1-propenyl-2,4,5-trimethoxybenzene) causes highly malignant mesenchymal tumors of the small intestine in rats (44).

NITROSAMINES

N-Nitrosamines are both mutagenic and carcinogenic compounds. One example of their toxicity was provided by the severe liver disease observed in sheep fed a diet containing fishmeal preserved with nitrite (45). The toxic principle was subsequently identified as *N*-nitrosodimethylamine (46), which led to estimation of nitrosamine contamination of human foodstuffs. *N*-Nitrosamines are formed by the reaction of secondary amines with nitrite under acidic conditions, both in vitro and in vivo (47). Nitrite exists in various foods and is also produced endogenously from nitrate contained mainly in vegetables. In addition, highly reactive nitric oxide formed from L-arginine by nitric oxide synthase in inflammatory processes is involved in generation of *N*-nitroso compounds (48). Nitrosation of *N*-nitrosamines can occur not only with nitrous acid but also with the oxides of nitrogen formed by combustion in open fires. *N*-Nitrosodimethylamine was found in cooked bacon, cheese, and some nitrite-preserved foods in microgram amounts per kilogram, and *N*-nitrosopyrrolidine was also identified in cooked bacon

(49). Beer has been known to contain *N*-nitrosodimethylamine. This nitroso compound is produced during direct-fire drying of barley malt by the reaction of oxides of nitrogen with the barley malt alkaloids, gramine and hordenine, which possess a dimethylamine moiety as a common structure (49). Discovery of this problem led to adoption of an improved method for drying malt to reduce the level of *N*-nitrosodimethylamine.

CARCINOGENS IN HEATED MATERIALS

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons produced by heating crude materials are widely distributed in our environment, being present in cigarette smoke, exhaust gas, and cooked food. Charred parts of biscuits have been found to contain benzo[*a*]pyrene (50), and broiled steak is reported to be contaminated by various polycyclic aromatic hydrocarbons (51). Among these, benzo[*a*]pyrene is present at an average of 8 ng per gram of steak. Benzo[*a*]pyrene requires metabolic activation to the ultimate diol epoxide form, which binds to DNA and predominantly forms adducts at the N2 position of guanine (52). A high frequency of G to T transversions in the *p53* gene has been observed in benzo[*a*]pyrene-induced mouse skin tumors (53).

Heterocyclic Amines

As was the case with cigarette smoke condensate, the smoke particles collected on a glass-fiber filter by broiling fish over a naked gas flame were found to be mutagenic in Ames's *Salmonella* assay in the presence of the metabolic activation system, S9 mix (54, 55). The charred parts of broiled fish and meat also proved to be mutagenic. *S. typhimurium* TA98, a detector of frameshift mutations, was more sensitive to the mutagenicity of these agents than TA100, a detector of base-pair change mutations. Although the polycyclic aromatic hydrocarbons were reported earlier in samples of smoke condensate and charred material, their levels could not account for most of the mutagenicity. Actually, the mutagenic activity was mainly associated with the basic fraction of charred materials obtained from broiled fish and meat. In addition to broiled fish and meat, formation of mutagens in cooked ground beef and beef extract was also the subject of an early report (56).

By monitoring the mutagenicity at each purification step with *S. typhimurium* TA98 or TA1538 with S9 mix, a series of new mutagenic substances were purified, and their structures determined. One approach was to isolate mutagenic substances from pyrolysates of amino acids and proteins that are constituents of foods. For example, Trp-P-1 and Trp-P-2 were isolated from a pyrolysate of D,L-tryptophan, Glu-P-1 and Glu-P-2 from that of L-glutamic acid. AaC and MeAaC were isolated from a pyrolysate of a protein, soybean globulin. Some of these mutagenic heterocyclic amines (HCAs) were also found in cooked foods.

The second approach was to isolate mutagens directly from cooked fish and meat. IQ and MeIQx were isolated from broiled sardines and MeIQx from fried beef. PhIP was also isolated from fried ground beef. This class of HCAs have a 2-aminoimidazole

moiety as a common structure and are formed by heating mixtures of creatine, sugars, and amino acids, which are present in raw meat and fish. So far, 19 HCAs have been isolated as mutagens and their structures determined (2, 57, 58, 59 and 60). Their chemical structures, chemical names, and abbreviations are shown in Figure 80.3.

Figure 80.3. Structures of heterocyclic amines. Trp-P-1, 2-Amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole; Trp-P-2, 3-Amino-1-methyl-5*H*-pyrido[4,3-*b*]indole; Glu-P-1, 2-Amino-6-methyldipyrido[1,2-*a*:3*ϕ*,2*ϕ*-*d*]imidazole; Glu-P-2, 2-Aminodipyrido[1,2-*a*:3*ϕ*,2*ϕ*-*d*]imidazole; Phe-P-1, 2-Amino-5-phenylpyridine; Orn-P-1, 4-Amino-6-methyl-1*H*-2,5,10,10*b*-tetraazafluoranthene; AaC, 2-Amino-9*H*-pyrido[2,3-*b*]indole; MeAaC, 2-Amino-3-methyl-9*H*-pyrido[2,3-*b*]indole; IQ, 2-Amino-3-methylimidazo[4,5-*f*]quinoline; MeIQ, 2-Amino-3,4-dimethylimidazo[4,5-*f*]quinoline; IQX, 2-Amino-3-methylimidazo[4,5-*f*]quinoxaline; MeIQx, 2-Amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline; 4,8-DiMeIQx, 2-Amino-3,4,8-trimethylimidazo[4,5-*f*]quinoxaline; 7,8-DiMeIQx, 2-Amino-3,7,8-trimethylimidazo[4,5-*f*]quinoxaline; PhIP, 2-Amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine; 4*ϕ*-OH-PhIP, 2-Amino-1-methyl-6-(4-hydroxyphenyl)imidazo[4,5-*b*]pyridine; Cre-P-1, 4-Amino-1,6-dimethyl-2-methylamino-1*H*,6*H*-pyrrolo-[3,4-*f*]benzimidazole-5,7[dione]; 4-CH₂OH-8-MeIQx, 2-Amino-4-hydroxymethyl-3,8-dimethylimidazo[4,5-*f*]quinoxaline; 7,9-DiMeIQx, 2-Amino-1,7,9-trimethylimidazo[4,5-*g*]quinoxaline.

All HCAs show higher mutagenicity in *S. typhimurium* TA98 than in TA100 with S9 mix made with S9 that was prepared from livers of rats treated with polychlorinated biphenyls. The mutagenicity of 19 HCAs varies, depending on the chemical structure, ranging from 2 to 661,000 revertants/μg. Some HCAs show higher mutagenicity than typical mutagens/carcinogens such as aflatoxin B₁, 4-nitroquinoline 1-oxide, and benzo[*a*]pyrene.

These HCAs are also mutagenic to cultured mammalian cells including Chinese

hamster lung cells with diphtheria toxin resistance (61) and repair-deficient Chinese hamster ovary cells with 6-thioguanine resistance (62). Further, HCAs induce sister-chromatid exchanges and chromosomal aberrations in cultured mammalian cells (63, 64, 65 and 66).

Ten HCAs (Trp-P-1, Trp-P-2, Glu-P-1, Glu-P-2, AaC, MeAaC, IQ, MeIQ, MeIQx, and PhIP) were chemically synthesized in large scale to test long-term carcinogenicity in CDF₁ mice and F344 rats of both sexes. These HCAs were mixed with diet at concentrations of 100 to 800 ppm and given to animals continuously throughout the experiments. All HCAs tested were carcinogenic (2, 57, 58, 67, 68, 69 and 70). All these compounds, except PhIP, induced tumors in the liver. Other tumors were also found in the small and large intestines, Zymbal glands, clitoral gland, skin, oral cavity, urinary bladder, prostate, and mammary glands of rats, and in the forestomach, lung, hematopoietic system, lymphoid tissue, and blood vessels of mice. PhIP induced lymphoma in mice (68) and colon, mammary gland, and prostate cancers in rats (69, 70). IQ was also carcinogenic in monkeys (71).

Cultured mammalian cells infected with vaccinia virus bearing cloned cDNA of a single molecular species of cytochrome P-450 were used to identify the particular molecular species of P-450 responsible for metabolic activation of HCAs. All HCAs tested were most effectively oxidized to their *N*-hydroxyamino derivatives by CYP1A2 (72). These results are consistent with the observation that S9 obtained from the liver of rats treated with polychlorinated biphenyls and 3-methylcholanthrene is more active than that treated with phenobarbital (73). The *N*-hydroxyamino derivatives of HCAs are further activated to final forms by esterification with acetic acid and sulfuric acid, and these final metabolites react with guanine bases in DNA. HCAs such as Trp-P-2, Glu-P-1, IQ, MeIQx, and PhIP form DNA adducts, primarily at the C-8 position of guanine residues, *N*²-(deoxyguanosin-8-yl)-HCA in vitro and in vivo (58, 74, 75). In the case of IQ, 5-(deoxyguanosin-*N*²-yl)IQ (dG-*N*²-IQ) was also identified as a minor adduct in vitro and in vivo (76). Removal of dG-*N*²-IQ was much slower than that of dG-C8-IQ in the liver and kidney of rats.

Formation of adduct of the guanine base in DNA with HCAs is involved in induction of mutations in cancer-related genes. Mutations of *H-ras*, *K-ras*, and *p53* were observed in Zymbal gland, mammary, forestomach, and liver cancers induced by HCAs (77, 78 and 79). In the case of colon cancer induced by PhIP, IQ, and Glu-P-1, mutations of *K-ras* and *p53* were very rare (79). Instead, a specific mutation of the *Apc* gene, deletion of a guanine base at a 5'-GGGA-3' site, was frequently detected in rat colon cancers induced by PhIP (80). Moreover, microsatellite mutation is more frequent in colon and mammary cancers induced by PhIP than in those induced by IQ and 7,12-dimethylbenz[*a*]anthracene, respectively (81, 82).

Quantification of HCA levels in cooked foods and human urine samples indicates that humans are continuously exposed to low levels of HCAs derived from their daily diet (83). For example, daily exposure to MeIQx of 10 healthy volunteers living in Tokyo was estimated to be 0.3 to 3.9 µg per person (84). A linear relationship was observed between the dose of MeIQx and the MeIQx-DNA adduct level in the livers of rats and mice by ³²P-postlabeling and accelerator mass spectrometry analyses (85, 86). This

suggests that MeIQx could form DNA adducts in human organs, even at doses as low as human exposure levels. Actually, MeIQx-DNA adducts were found in human tissues, colon, rectum, and kidney at levels of 14, 18, and $1.8/10^{10}$ nucleotides, respectively (87).

There are now several epidemiologic studies indicating a positive association between cooked meat consumption and development of colorectal, pancreatic, and urothelial cancers (88, 89, 90 and 91). Moreover, rapid metabolic phenotypes for acetyltransferase and CYP1A2 significantly increase the risk of colorectal neoplasia associated with cooked meat intake in man (92, 93). Thus, these findings suggest that HCAs are involved in human cancer development.

MAJOR COMPONENTS IN FOOD FOR PROMOTING CARCINOGENESIS

Sodium Chloride

Epidemiologic studies have linked sodium chloride intake and development of human gastric cancer (94). Administration of a high concentration of dietary sodium chloride after treatment with a gastric carcinogen, *N*-methyl-*N*-nitro-*N*-nitrosoguanidine (MNNG) also significantly enhanced development of adenomas and adenocarcinomas in the glandular stomach of rats (95). Excess sodium chloride results in formation of malondialdehyde in the mucosa of the glandular stomach and increases its excretion into the urine (96). Thus, lipid peroxidation occurs in the glandular stomach damaged by sodium chloride.

Fat

Epidemiologic studies have generally associated high-fat diets with a high risk of colon and breast cancer (97). Consistent with these epidemiologic data, experiments with rodents demonstrated that elevated levels of dietary fat can enhance mammary and colon carcinogenesis in rats (98, 99). In these experiments, vegetable oils containing large amounts of w6 polyunsaturated fatty acids were found to enhance the carcinogenicity more effectively than saturated fat. Although the mechanism of the effect of fat is not yet fully elucidated, it probably acts at the tumor-promotion stage. High fat intake could yield a tumor-promoting condition for colon cancer development through increased bile acid formation (100) and for breast cancer development through increased estrogen production by aromatase in adipose tissues (101).

PUBLIC HEALTH SIGNIFICANCE

Cancer development in man can be viewed as a multistage process involving multiple genetic alterations. The multiple genetic alterations are caused by various kinds of environmental xenobiotics including the food-derived carcinogens detailed above as well as autoxobiotics, such as endogenously generated oxygen radicals, which can also induce DNA damage. Chronic inflammation may be involved in cancer development by causing continuous cell turnover and creating a favorable environment for carcinogenesis. For example, infection with *Helicobacter pylori* resulting in gastritis is a risk factor for gastric

cancer in man. On the other hand, a number of foods appear protective because they contain a variety of cancer preventive substances such as fiber, fish oil, polyphenols and vitamins. Although single carcinogenic factors are not in themselves sufficient to induce cancers, their genotoxic effects accumulate. Moreover, carcinogenic factors interact with each other and thus could play some role in carcinogenesis. Thus, it is desirable to avoid exposure to carcinogens in food as much as possible and adapt all feasible measures to reduce their adverse effects.

This chapter reviews recent information on cancer prevention by diet. The role of macronutrients such as dietary fat and properties of macronutrients, such as calorie contribution, are covered to emphasize their importance. Since macronutrient effects on cancer epidemiology are covered in [Chapter 80](#), this chapter is limited to a consideration of the animal and mechanistic studies. Micronutrient effects on cancer prevention emphasize nutrient interactions and specific micronutrients that have been extensively studied or for which recent provocative observations have been reported. The discussion of the role of nonnutrient components of diet in cancer prevention emphasizes agents and classes of agents that have received considerable recent attention. These compounds are grouped according to the major potential mechanism for cancer prevention.

MACRONUTRIENTS AND PROPERTIES OF MACRONUTRIENTS

Dietary Energy

Laboratory Studies

Dietary energy restriction is one of the most potent and reproducible inhibitors of carcinogenesis in rodent tumor models (1). Restriction of energy from carbohydrate or carbohydrate and fat inhibited mammary (2), colon (3), liver (4), and skin (5) carcinogenesis in recent studies. The rodent energy restriction paradigm is not a starvation protocol. The dietary energy-restricted rodents do eat their diet over a shortened time frame (meal eaters), and they do gain less weight than the fully fed rodent, but they live considerably longer than their fully fed controls (1). The fully fed rodents can reasonably be considered overfed. Epidemiologic studies that suggest obesity as a risk factor for cancers of the colon, endometrium, prostate, and breast and indicate the role of physical activity in prevention of cancers of the colon and breast provide strong support for a role of dietary energy and energy balance in cancer.

Energy restriction appeared somewhat more effective in prevention of late events in carcinogenesis studies with breast (6) and skin (7), but this may simply be due to the carcinogenesis protocols, which attempt to divide cancer into initiation and promotional events. Research in breast (6) and skin (7) cancer suggested that energy restriction must be of long duration for effective cancer prevention. However, peripubertal dietary restriction inhibited virus-induced mammary carcinogenesis later in life in mice (8).

Mechanism of Action

Oxidative Processes. Numerous mechanisms have been explored for prevention of cancer by dietary energy restriction. Energy and/or diet restriction of rodents and humans reduces oxidative damage (9, 10). Restriction changes numerous metabolic processes, including reduced oxidative metabolism, improved elimination of carcinogens, and slowing of the age-related decline in various repair processes (11).

Hormonal Modulation. Hormonal adaptation to dietary energy restriction may be an important mediator of energy-restriction prevention of cancer. Glucocorticoid hormones increase in response to dietary energy restriction in mice (12) and in anorexia nervosa patients (cortisol) (13). Glucocorticoid hormones and glucocorticoid drugs have long been known to inhibit skin tumor promotion in mouse skin, and more recent studies demonstrated the importance of an intact adrenal gland in prevention of cancer by energy restriction. When mice were adrenalectomized and fed restricted diets, skin tumor promotion was not inhibited. However, parallel groups with intact adrenal glands demonstrated striking inhibition of skin tumor promotion in the energy-restricted mouse (12) (Fig. 81.1). Recent studies demonstrated the importance of an intact adrenal gland in prevention of lung carcinogenesis by dietary restriction (14). These studies do not indicate which adrenal hormones were necessary for energy-restriction prevention of skin and lung carcinogenesis because of the number of hormones produced by the adrenal gland. However, the fact that energy restriction increased glucocorticoid hormone secretion and that glucocorticoid hormones are potent inhibitors of skin carcinogenesis (15) supports the hypothesis that energy-restriction inhibition of lung and skin carcinogenesis may require glucocorticoid hormone.

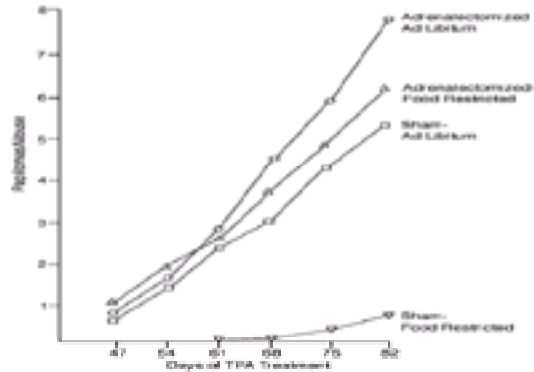

Figure 81.1. Inhibition of papilloma development by food restriction and its reversal by adrenalectomy. (From Pashko LL, Schwartz AG. *Carcinogenesis* 1992;13:1925–8, with permission.)

Studies are currently testing the hypothesis that the elevated glucocorticoid hormone secretion may mediate downstream events that are necessary for energy–restriction inhibition of carcinogenesis. Birt et al. previously demonstrated inhibition of epidermal protein kinase C (PKC) α and ζ (two of the four isoforms of the enzyme) in the skin of the energy–restricted mouse (16). This reduction may be relevant to energy–restriction inhibition of cancer, since the phorbol ester tumor promoter 12-O-tetradecanoylphorbol-13-acetate (TPA) binds to specific PKC isoenzymes with phorbol ester binding domains. This interaction is believed to be important for skin tumor promotion by TPA (17). Indeed, epidermal cells from energy–restricted mice had reduced phorbol ester–binding sites (16). It is possible that the reduction in PKC isoforms is mediated, at least in part, by the elevated glucocorticoid hormone. A number of studies have suggested that PKC may play a role in downstream signaling from the glucocorticoid receptor (18) (see also Chapter 37). Furthermore, our preliminary studies suggest that glucocorticoid treatment of adrenalectomized mice reduces PKC ζ expression (Birt et al., unpublished).

Cellular Proliferation and Apoptosis. Observations from other laboratories demonstrate the importance of inhibition of cellular proliferation and enhanced programmed cell death (apoptosis) in tissues from energy–restricted rodents. In particular, James and Muskhelishvili (19) demonstrated inhibition of hepatic cell proliferation and accelerated hepatic apoptosis in the liver of energy–restricted mice (Fig. 81.2). In parallel studies, energy restriction inhibited spontaneous hepatoma development (19). Earlier studies focusing on regression of nafenopin, a peroxisome proliferator that induces hepatocellular carcinomas and adenomas in diet-restricted rats, suggested that enhanced apoptosis of preneoplastic cells, in addition to reduced cell replication, was responsible for the protective effect of diet restriction (20). The evolving role for PKC in the process of apoptosis suggests the possibility that changes induced in PKC by dietary-energy restriction may play a role in induction of apoptosis in the restricted

animal (21).

Figure 81.2. Rates of apoptosis (apoptosis bodies/100 nuclei) and proliferation (proliferating cell nuclear antigen⁺/100 hepatocytes) within livers of 12-month-old ad libitum and 40% diet-restricted B6C3F¹ mice. Comparison of indices between the two dietary groups demonstrates the relative increase in incidence of apoptotic bodies and decrease in incidence of proliferating cell nuclear antigen⁺ cells in livers of diet-restricted mice compared with ad libitum mice. (From James SJ, Muskhelishvili L. *Cancer Res* 1994;54:5508–10, with permission.)

Immunologic Modulation. Dietary restriction is certainly important in modulation of immunologic responses (22, 23). How alterations in immune function in underfed animals relate to reduced rates of cancer development is unclear, but this is a fertile area for further research.

Gene Expression. Dietary food restriction causes significant alterations in gene expression that may be important in cancer development. For example, heat-shock proteins, which are important for normal cell growth and homeostasis as well as in protecting cells from the toxic effects of extreme temperatures, were induced to a greater extent in aged diet-restricted rats than in aged control-fed rats (24).

Dietary Fat

Laboratory Studies

The level and type of dietary fat have been extensively studied in animal models for cancer modulation. In general, diets rich in polyunsaturated fatty acids have enhanced development of mammary (25), colon (26), pancreas, (27), and prostate (28) cancer. Investigations on dietary fat and skin cancer promotion provide different results, depending upon experimental design (5). It has been suggested that the influence of diets rich in polyunsaturated fatty acids (PUFAs) on carcinogenesis in the mammary

gland and colon may be caused by the content of linoleic acid in such diets. A threshold of linoleic acid was demonstrated to be necessary for cancer enhancement in mammary gland (29) (Fig. 81.3).

Figure 81.3. Autopsy data of tumor incidence and tumor yield of rats fed diets containing different levels of EFA. There were 30 rats/group. (From Ip C, Carter CA, Ip MM. *Cancer Res* 1985;45:1997–2001, with permission.)

In a number of studies, oils rich in oleic acid, such as olive oil, were found to result in lower cancer rates than diets rich in PUFAs such as corn oil (30). This observation may relate more to the removal of high levels of dietary linoleic acid in corn oil than to addition of olive oil (30).

Diets rich in ω -3 fatty acids have also been investigated for their influence on cancer at a number of sites. Studies in the breast and colon have provided some evidence for cancer prevention, but in general, fish oil does not appear to prevent cancer induction; it simply lacks cancer-enhancing properties (30).

Mechanism of Action

There are probably more mechanisms for dietary fat modulation of cancer than there are convincing data that dietary fat is an important risk factor for human cancer. The major problem may be the complexity of lipids in the human diet and the possibility that only specific fatty acids are really important in cancer cause and prevention.

Eicosanoid Metabolism. A favorite hypothesis for involvement of dietary fat in carcinogenesis is that different lipids provide alternative substrates for eicosanoid synthesis. Furthermore, experimental studies provide the most compelling evidence for a promotional role for linoleic acid, and linoleic acid is the dietary precursor to arachidonic acid. Arachidonic acid clearly plays a central role in cellular regulation as the precursor of eicosanoid synthesis. Our poor understanding of the role of eicosanoids

in human cancer cause and development makes it difficult to assess the importance of dietary modulation of eicosanoid synthesis in cancer. Another problem with trying to relate diet to prostaglandin production is that radical changes in dietary fat intake are required, such as an essential fatty acid deficiency or a linoleate:saturated fatty acid ratio greater than 5 (31). Some of the influence of ω -3 fatty acids on cancer prevention may possibly be related to reduced basal prostaglandin levels.

However, compelling data on the importance of prostaglandin synthesis in cancer has been obtained from studies using inhibitors of prostaglandin synthesis as inhibitors of cancer. A number of inhibitors have been very effective, especially in inhibition of colon carcinogenesis (32). However, these drugs inhibit many other enzymes as well as prostaglandin synthesis, and it is impossible to know which effects are the most important.

Cellular Proliferation. Dietary fat may also influence cellular proliferation. Studies in colon (33) and breast (34) suggest that high-fat diets result in greater cellular proliferation than low-fat diets. Since this is also influenced by dietary energy, it is important to know if the animals fed high-fat diets had an equivalent intake of dietary energy. In general, dietary fat influences a number of processes, which may account for the observed enhancement of cell proliferation. High-fat diets were shown to increase colonic ornithine decarboxylase (ODC) activity (35). ODC is the rate-limiting enzyme in polyamine synthesis, and polyamines are needed for DNA replication. Thus, a number of agents that increase cell proliferation induce ODC activity. Induction of ODC appears necessary, but not sufficient, for tumor promotion in the skin (36), and overexpression of ODC in transgenic mice increased the incidence of spontaneous skin tumors (37). Tyrosine kinase activity was also increased in association with accelerated cellular proliferation, and studies determined increased tyrosine kinase activity in the colon of rats fed a high-fat diet (35). Since oxidative products of fatty acids appear to induce ODC and tyrosine kinase activity, lipid oxidation may possibly be necessary for these observations (38).

Protein Kinase C (PKC). Recent studies have assessed the role of dietary fat in modulation of PKC. PKC, as mentioned above, is important in cellular proliferation and differentiation. Our understanding of the specific tissue and isoenzyme selectivity in modulating cellular proliferation and differentiation is in its infancy (39). A series of studies focused on mouse epidermis suggested that high dietary fat (24.6%) increased the activity of PKC in comparison with diets low in fat (5%) (40). This increased PKC activity was associated with a 36% increase in 1,2-*sn*-diacylglycerol (DAG), an activator of PKC (40). Further investigations to assess if this increase was due to changes in the expression of specific isoforms indicated that dietary fat did not influence the expression of PKC α , ϵ , δ , and ζ (16). These results suggest that dietary fat effects on PKC in the epidermis must have been due to changes in the activation of the epidermal enzyme. This is certainly possible, since PKC is known to respond to cellular lipid composition and metabolism (41).

Recent studies in *in vitro* systems and in rodents fed diets containing different levels and types of fat have explored the relationship of dietary fat to colonic PKC activity and isoenzyme expression. Weinstein and collaborators (42) explored the hypothesis that

dietary fat in the colonic mucosa results in generation of DAG, which is then available to activate colonic PKC (Fig. 81.4). This activation is hypothesized to result in a proliferative environment in the colonic epithelium. Assessment of colonic DAG in rats fed diets differing in fat (corn oil and fish oil) and fiber (cellulose and pectin) indicated approximately 2.5-fold more DAG excretion in animals fed cellulose than in those fed pectin and somewhat higher DAG excretion in rats fed corn oil than in those fed fish oil (43). These results demonstrate that diet can alter fecal DAG concentration and excretion. Lafave et al. (44) compared a diet containing 15% beef tallow and 5% corn oil with a diet containing 5% corn oil and reported that the high-fat diet caused a translocation of PKC activity from soluble to particulate fractions, which is consistent with increased PKC in the plasma membrane, believed to be the more active state. Davidson et al. (45) compared colonic PKC isoform expression in rats fed diets differing in fiber and fat. Their results provided little evidence that the type of dietary fat affected colonic PKC isoform expression.

Figure 81.4. Hypothesis relating production of diacylglycerol (DAG) by the intestinal microflora to colon cancer. Conversion by intestinal bacteria of dietary phospholipids to DAG would be enhanced by a high-fat diet and by secondary bile acids. Intestinal bacteria also play a role in conversion of bile acids to secondary bile acids. It was proposed that the DAG thus produced enters colonic epithelial cells and stimulates protein kinase C directly. This mechanism would bypass the usual pathway in mammalian cells in which hormones and other agonists occupy membrane-associated receptors leading to activation of cellular phospholipase C. (From Weinstein IB. *Cancer Res* 1991;51(Suppl):5080s–5s, with permission.)

Modulation of Gene Expression. Another potential role of dietary fat in cancer is alteration of gene expression. Studies of transcription of mouse mammary tumor virus (MMTV) proviral DNA at the MTV-1 locus in mammary glands from C3H Heston mice fed 23.5% or 5% corn oil diets demonstrated accelerated transcription in the mice fed the high-fat diet (46). Mice fed the high-fat diet had accelerated mammary tumor development with shorter tumor latency and development of tumors after fewer litters (46). High dietary fat may also preferentially promote mammary tumor development in

methylnitrosourea-induced tumors that contain the wild-type *ras* gene, suggesting differential patterns of signal transduction and gene expression (47).

Conjugated Linoleic Acid

Occurrence

In contrast to linoleic acid, with double bonds at carbons 9 and 12, which has been studied as a potential factor in cancer promotion in animal and human studies, conjugated linoleic acid (CLA), which has conjugated double bonds at carbons 10 and 12 or at carbons 9 and 11, has antimutagenic and anticarcinogenic activity (48). CLA was first isolated from a fraction of cooked meat that had antimutagenic activity (49). It is now apparent that CLA is present in human diets, and the primary sources appear to be dairy and meat products. For example, cooked beef was reported to contain 6.6 to 8.2 mg/g fat (50). The most prevalent form of CLA in foods is the *cis* 9,11 isomer of CLA.

Laboratory Studies

CLA was effective in inhibiting carcinogenesis of skin (49) and forestomach (51). Studies in the laboratory of Dr. Clement Ip demonstrated inhibition of mammary and breast carcinogenesis (52). Triglyceride-CLA is as effective as free fatty acid-CLA in preventing mammary carcinogenesis (53). This is important, because dietary CLA is in the form of triglyceride-CLA, and previous carcinogenesis studies were done with fatty acid-CLA.

MICRONUTRIENT INTERACTIONS

Vitamin D, Calcium, and Phosphorus

Epidemiologic and Clinical Studies

The hypothesis that dietary calcium and vitamin D protect against colon cancer, and that dietary phosphorus may block this protection, has received considerable attention in recent years. The biochemical basis for this hypothesis comes from the ability of calcium to chemically interact with bile acids and fatty acids and potentially reduce their toxicity. The proposed antagonism by phosphorus is based on the ability of phosphorus to interfere with calcium absorption and use. Data supporting the hypothesis that dietary vitamin D and/or calcium could prevent cancer came from the observation of a gradient of increasing colon cancer mortality rates with increasing latitude north (55). Such an association could be due to the impact of ultraviolet light on synthesis of vitamin D in the skin and, subsequently, on absorption of dietary calcium. A 19-year prospective study in Chicago demonstrated a 50% reduction in colon cancer risk in men with a daily intake of 3.75 µg vitamin D and a 75% reduction in men with a daily intake above 1200 mg calcium (55). Levels of circulating 25-hydroxy-vitamin D were higher in controls than in patients (55). A prospective study on women in Iowa further supported the hypothesis

that vitamin D and/or calcium protect against colon cancer (56).

Further investigation into the relationship of calcium intake and colon cancer has not generally supported this hypothesis. Studies in the Netherlands focused on the relationship between consumption of fermented dairy products or dietary intake of calcium and the risk of colon cancer in a case-control study (57). Consumption of fermented dairy products, hard cheese, and unfermented dairy products was not associated with the risk of colon cancer. Furthermore, consumption of total dietary calcium was positively (significant in men but not in women) associated with colon cancer risk. In a prospective study on the relationship between serum levels of vitamin D metabolites and colon cancer in Washington County, Maryland, no relationship was observed between 25-hydroxy-vitamin D or 1,25-hydroxy-vitamin D levels and the subsequent risk of colon cancer in 20,305 subjects (58).

Recently, prostate cancer risk was similarly reported to be inversely associated with exposure to ultraviolet light and hypothesized to be another cancer related to vitamin D intake (59). This hypothesis is supported by the presence of vitamin D receptors in the normal prostate (60) and by evidence of vitamin D involvement in regulation of differentiation and gene expression (61).

Studies on the influence of calcium supplementation on colon cancer prevention have also been inconclusive (62, 63). Early investigations in subjects at high risk for colon cancer suggested that calcium supplements were effective in reducing cell proliferation, a potential biomarker for colon cancer risk (64). However, these studies were neither blinded nor placebo controlled, and they generally had short follow-ups. More-comprehensive placebo-controlled studies with longer follow-up have not shown appreciable reduction in colonic cell proliferation in calcium-supplemented subjects. In spite of these inconclusive results, the hypothesis continues to find support in human investigations. In a study of intestinal bypass patients, calcium supplementation (2.4 or 3.6 g/day) for 3 months reduced rectal hyperproliferation and decreased fecal DAG output. DAG is a second messenger for PKC, a key enzyme in cellular growth regulation. The authors hypothesized that the reduction in fecal DAG in calcium-supplemented patients was, at least in part, responsible for the reduced rectal cell proliferation (65).

Laboratory Studies and Mechanism of Action

The importance of dietary phosphorus in antagonizing protective effects of calcium was studied in rats supplemented with calcium from calcium carbonate, calcium phosphate, and milk mineral (66). This study was designed to determine whether the phosphorus in calcium phosphate or in milk mineral would block bile acid excretion and decrease cytolytic activity of fecal water, which was associated with calcium supplementation. The influence of these supplements on epithelial cell damage and proliferation and on serum gastrin was also measured. All three calcium sources decreased soluble bile acids and fatty acids and decreased the cytolytic activity of fecal water. Only minor differences between groups were observed, demonstrating that the hypothesized interference by phosphorus did not occur in this experimental paradigm.

Newmark and Lipkin (67) conducted an extensive series of experiments in rodents to assess a diet designed to mimic four of the suggested dietary risk factors for colon cancer: high fat and phosphate, and low calcium and vitamin D. They first demonstrated that feeding this “stress diet” for 12 weeks resulted in hyperproliferation in the sigmoid colon (67). Subsequent experiments demonstrated that increasing the level of dietary calcium in the “stress diet” could return colonic proliferation to normal values (68). Parallel studies assessed the influence of a “western-style stress diet” on mammary ductal epithelial cell hyperproliferation and hyperplasia (69). Following 20 weeks of consumption of the diet high in phosphorus and fat and low in calcium and vitamin D, the authors observed more mammary ducts and more proliferating cells in the small terminal ducts, a cancer-prone region of the mammary gland, in the experimental animals than in controls. Studies with cultured cells revealed induction of apoptosis in breast cancer cell lines treated with vitamin D or antiestrogens (70). The growth inhibitory properties of 1,25-dihydroxy-vitamin D₃ against cultured mouse keratinocytes were associated with induction of vitamin D receptor in an experiment comparing cells resistant to vitamin D growth inhibition with wild-type cells in which vitamin D receptor was induced (71).

Studies with rats treated with the colonic carcinogen 1,2-dimethylhydrazine (DMH) and fed graded levels of calcium and vitamin D showed that both of these nutrients reduced colonic carcinogenesis and altered colonic cell kinetics (72). Comparable studies on mammary carcinogenesis by 7,12-dimethylbenz[a]anthracene (DMBA) suggested that high dietary calcium and vitamin D protected against mammary carcinogenesis, while high dietary phosphate increased susceptibility (73).

Methyl Deficiency; Folic Acid, Vitamin B₁₂, Choline, and Methionine Interactions

Laboratory Studies

Observations on methyl group deficiency (folic acid, choline, and methionine) and increased cancer were originally made in animal models. In the early studies, combined deficiencies of choline and methionine were induced using diets contaminated with aflatoxin (74). The induced liver cancers were attributed to the aflatoxin. However, it was apparent that methyl deficiency was a potent facilitator of carcinogenesis. Further investigations demonstrated that methyl deficiency alone, using a deficiency of choline and methionine (75), or folic acid, vitamin B₁₂, choline, and/or methionine (76), induced preneoplastic or neoplastic lesions in animal livers. These observations led to the hypothesis that DNA methylation by methyl donors is important in cancer prevention.

Epidemiologic and Clinical Studies

Although it was not clear if imbalanced methyl-deficient conditions were present in human diets, the prevalence of inadequate folate intake had been documented (77). A role for folic acid in cancer prevention was suspected because folic acid is abundant in vegetables and fruits, and consumption of such foods has been associated with reduced cancer rates. Furthermore, the importance of adequate dietary folic acid for regulation of

normal gene expression suggests a potential role in cancer prevention. However, a case-control study of colon and rectal cancer did not show any association with dietary folate intake (78). Studies of women in the Nurses' Health Study and men in the Health Professionals Follow-up Study showed that dietary folate was inversely associated with risk of adenoma in women and men, alcohol intake above 30 g/day was positively associated with adenoma risk, and dietary methionine was inversely associated with risk of an adenoma 1 cm or larger (79). Combined intakes of high alcohol and low folate and methionine significantly increased the risk for adenomas 1 cm or larger (Table 81.1). These results support the importance of methyl group availability in preventing human colorectal cancer.

	High-Alcohol ^a Low-Folate vs. Low-Alcohol High-Folate	High-Alcohol Low-Methionine vs. Low-Alcohol High-Methionine	Low-Folate-Low-Methionine vs. High-Folate High-Methionine
Total	1.99 ^b (1.12–3.53)	2.21 ^c (1.32–3.69)	2.39 ^d (1.25–4.60)
Women	2.57 ^e (1.31–5.06)	2.17 ^f (1.18–3.98)	2.09 ^g (1.04–4.18)
Men	1.16 (0.59–2.43)	2.50 (0.93–6.71)	5.72 (0.85–38.3)

Data from Giovannucci E, Stampfer MJ, Colditz GA, et al. *J Natl Cancer Inst*. 1993;85:875–84.

^aHigh alcohol is defined as more than 20 g/day and low alcohol as less than 5 g/day; high and low folate are defined by high and low quintiles of intake. For women, median values are 0.9 g/day for low alcohol and 26.1 g/day for high alcohol; for men, 38.6 g/day for high alcohol and 1.8 g/day for low alcohol. Daily median energy-adjusted folate levels for women are 106 µg for the low category and 711 µg for the high category; for men, they are 241 µg and 847 µg. Daily median energy-adjusted methionine levels for women are 1.4 g for the low category and 2.5 g for the high category; for men, they are 1.9 g and 2.7 g.

Table 81.1 Relative Risk (95% CIS) of Adenoma [≥]1 cm of the Left Colon or Rectum by Combination of Alcohol, Methionine, and Folate Intake

Mechanism of Action

Recent studies in laboratory animals demonstrated that deficiencies of choline, methionine, or folic acid in rats fed semipurified diets could result in imbalances in deoxynucleotide pools, which are known to produce mutagenic events (80). In particular, folic acid–derived, one-carbon groups are required for synthesis of purines and the pyrimidine thymidylate. Deficiencies of folate and methionine in cultured rat splenic T-cells resulted in increased deoxythymidine pools and depleted deoxyguanosine triphosphate pools (81). These changes were associated with a decreased proportion of cells in the S phase of the cell cycle and an increase in cells in the G₂/M phase (81). Studies in Chinese hamster ovary cells demonstrated similar imbalances that, under conditions of long-term culture, resulted in massive cell death and apoptosis (82). However, minor subpopulations in these cells adapted to the folate-deficient conditions and exhibited phenotypic, biochemical, and genetic abnormalities that gave them a growth advantage (82).

Studies with severe methyl deficiency in animal models (diet lacking choline, methionine, folic acid, and vitamin B₁₂) demonstrated hypomethylation of CCGG sites in

genes involved in cell proliferation and cancer, such as *c-myc*, *c-fos*, and *c-Ha-ras* (83). Similarly, rats fed a diet deficient in methionine, choline, and folic acid for 9 weeks exhibited genomewide strand breaks, hypomethylation, and increased DNA methyltransferase activity (84). In exon 5 of the *p53* gene, strand breaks were associated with significant hypomethylation. Folate deficiency also potentiates the genetic damage by carcinogens, possibly by limiting DNA repair (85).

Choline deficiency appears to play a role beyond contributing methyl groups in the combined lipotrope deficiency (86). In particular, when a single nutrient deficiency is imposed, choline is the only lipotrope that induces cancer (76). Choline-deficiency cancer induction has been associated with induction of free radicals leading to necrosis and cancer (86). Furthermore, choline is required for a major membrane phospholipid, phosphatidylcholine (PC), and PC plays a role in cellular signaling as well as being a component of the membrane (87). Choline deficiency in rats was accompanied by a three- to five-fold increase in hepatic DAG in as short as 6 weeks of feeding (88). DAG is important in cellular signaling, as part of the activation of PKC (41). Rats fed choline-deficient diets had activated PKC, supporting the hypothesis that increases in hepatic DAG in choline deficiency activate PKC and contribute to increases in cell proliferation and hepatocellular carcinoma (89).

MICRONUTRIENTS

Dietary Iron and Neoplasia

Iron Overload As a Risk Factor for Cancer

Dietary iron is implicated in the pathogenesis of neoplasia in liver, lung, and colorectal tissues when cellular levels are excessively elevated. Iron overload, resulting from either excessive dietary intake or idiopathic hemochromatosis, is associated with increased risk for hepatocellular, gastric, and colorectal cancer (90). Site-specific associations between high iron stores and cancer risk have also been made for lung, esophageal, and bladder cancers (91, 92).

Southern Africa has the highest incidence of hepatocellular carcinoma in the world, with a reported incidence of 0.1% of the total population of Mozambique (93). By comparison, the incidence in the United States is approximately 0.004% (94). Although the high risk for hepatocellular cancer has been commonly linked to the high incidence of hepatitis B infection, Gangaidzo and Gordeuk (95) proposed that the similarity in pathology between dietary iron overload and idiopathic hemochromatosis suggests a strong correlation between excessive iron intake and hepatocellular cancer in the southern African population. They identified the source of dietary iron overload as consumption of a traditional home-brewed beer. However, beer consumption alone is not likely to result in toxic iron overload. Apparently, beer drinkers who also are genetically predisposed to iron overloading are at greatest risk (96).

Iron overload is also a factor in development of cirrhosis and may therefore be an indirect risk factor for hepatocellular cancer. Hepatocellular carcinoma is more likely to

develop when cirrhosis is present, independent of iron status (97).

Iron and Cellular Proliferation

The role of iron in cellular proliferation and differentiation has been studied in normal and transformed lymphomyeloid cells and hepatocytes (98). In normal cells, iron uptake is stimulated by growth factors specific to the cell type. Iron is presented to cells in transferrin, the plasma transport protein, binds to cell-surface receptors, and is incorporated through endocytosis (see Chapter 10). Iron-free transferrin acts to inhibit proliferation. However, as transferrin becomes saturated with iron, proliferation increases (98). Transferrin saturation levels over 60% have been associated with significantly elevated risk for cancer (99).

In cell-cycle studies, cancer cells have been shown to require iron to maintain a proliferative state (100). Although they have greater numbers of transferrin receptors than normal cells, cancer cells have a lower iron content and do not accumulate iron in the presence of iron overload (101).

In vivo, iron also has a mitostimulatory effect. However, the role of iron in initiation and/or promotion in vivo is not known (105). An important step in the progress of hepatocytes from normal to neoplastic is development of cirrhosis. Whether iron is a singular factor in that process or enhances other hepatocarcinogens is not clear (102).

Iron accumulation in cells has been proposed to be genotoxic because of free radical damage to DNA and to be mitogenic, stimulating proliferation of preneoplastic cells (102). Iron removed from ferritin by ascorbate and other reducing agents forms a small pool of non-protein-bound iron that can move freely between transferrin, cytoplasm, mitochondria, and ferritin (103). This small pool of free iron is subject to reaction with H_2O_2 to produce hydroxyl radicals in the Fenton reaction (104). Hydroxyl radicals attack DNA and yield single-strand breaks or 8-hydroxyguanine mutations that give rise to base substitutions (102).

Although iron is required for cellular proliferation, its role as a mitogenic agent remains unclear. Experiments in human hepatoma cell systems have demonstrated that iron deprivation results in cell cycle arrest at G_2 . However, whether these reactions also take place in vivo is not known.

Prevention and Therapy

Preventing iron overload in susceptible individuals is an important component of risk reduction for hepatic and other iron-associated cancers. Inclusion of dietary fiber that contains phytic acid suppresses iron absorption in rats and in humans (105). Phytic acid chelates polyvalent metals. Phytic acid included in the drinking water significantly reduced the incidence of intestinal tumors in rats treated with the chemical carcinogen azoxymethane (105).

Another method of depriving neoplastic cells of iron is to expose them to an antibody to the transferrin receptor. As the primary iron-transport protein, transferrin has a significant role in regulating iron availability to normal and neoplastic cells. In hematopoietic tumors, the combined effect of anti-transferrin receptor antibody and an iron chelating agent, such as deferoxamine, was even more efficacious in suppressing tumor growth in cultured lymphoid tumor cells (106).

Antioxidant Vitamins (A, E, and C) and Cancer

Vitamin Status Is Inversely Related to Risk for Cancer

An abundance of epidemiologic evidence exists to support or refute the antitumorigenic effects of retinol and related compounds. Most studies that support the antitumorigenicity of retinoids have found a correlation between low intake of vitamin A from fruits and vegetables or low levels of retinoids in serum or plasma and increased risk for certain cancers (107). On the other hand, studies that have tested the hypothesis that elevated levels of blood retinol decrease cancer risk have not been conclusive, in part because blood levels of retinol remain stable despite variations in intake, making it difficult to draw conclusions about possible protective effects of vitamin A based on such data. For example, studies of oral contraceptive (OCA) users, whose blood retinol levels were significantly higher than those of non-OCA users, failed to find convincing evidence for a reduced cancer risk due to the increased blood retinol levels (108). Studies of retinol intake may be further confounded by the fact that foods high in preformed vitamin A are also sources of animal fats, which may be a factor in tumor promotion (91). Additionally, food sources of carotenoids are also sources of other antioxidants, such as α -tocopherol and ascorbate, which have been shown to act cooperatively as inhibitors of tumorigenesis.

Epidemiologic evidence in support of an inhibitory role in tumorigenesis for α -tocopherol and ascorbate shows an inverse relationship between serum levels of ascorbate and α -tocopherol and risk for cancer (109). Byers et al. (110) examined a number of epidemiologic studies by cancer site and intake of vitamins E and C from dietary sources and found that the highest vitamin C intake from fruits and vegetables was correlated with the lowest risk for cancers of the gastrointestinal tract and lung. Studies of subjects taking vitamins E and C from oral supplements failed to show consistent correlations with decreased cancer risk from all sites. Furthermore, blood levels of these nutrients were not associated with cancer risk.

An inverse relationship between vitamin C intake and gastric cancer was found in the Seven Countries Study (111), in which 16 cohorts from seven different countries were compared for mortality from lung, stomach, and colorectal cancer and intake of antioxidant (pro)vitamins from dietary sources. However, this study failed to find a significant inverse relationship between vitamin C intake and lung or colorectal cancer.

Site specificity is an important consideration in determining whether a specific nutrient is an effective chemopreventive agent. In a review of epidemiologic studies on such chemopreventive agents, Bertram et al. (112) cited studies identifying associations

between cancer site and specific nutrient. This review reported inverse associations between vitamin A and risk for oral, esophageal, bladder, reproductive, lung, and stomach cancers; vitamin C and risk for colon, esophageal, stomach, lung, and oral cancers; and vitamin E with risk for lung and breast cancers. However, many of the epidemiologic studies reviewed by Bertram et al. (112) assessed intake of the antioxidant vitamins from food sources. This type of evaluation does not consider potential interactions between the many nutritive and nonnutritive components of foods and thus cannot determine specific chemopreventive effects of these vitamins.

Experimental and Clinical Trials

Evidence supporting a role for vitamin A or carotene deficiency in enhancing carcinogenesis is more convincing than evidence supporting prevention by supplementation. Peto et al. (108) reported that low intake of b-carotene from fruits and vegetables predicted increased risk for lung cancer. The same conclusion was reached in another study involving male smokers who also regularly consumed alcohol (113). Individuals in this study who had lower than average intakes of b-carotene, vitamin C, and fiber had higher incidences of oral cancers than those whose intakes were above the mean.

More recently, a study was carried out in the Chinese county of Linxian, where consumption of b-carotene, a-tocopherol, and ascorbic acid in foods was low and the incidence of esophageal and gastric cardia cancer was high (114). Although blood levels of retinol, b-carotene, and other nutrients were low in this population, signs of deficiency were not present. Subjects in this study who were given supplements of b-carotene, vitamin E, and selenium, up to twice the recommended dietary allowance (RDA), had significantly lower mortality rates due to cancer than subjects who did not receive supplements; subjects given ascorbic acid and molybdenum had the same incidence of cancer as the controls.

In contrast to the large body of evidence supporting a chemopreventive role for b-carotene, the Alpha-tocopherol, Beta Carotene Cancer Prevention Study (ATBC) (115) conducted on male subjects in Finland suggested that b-carotene was ineffective or might even enhance risk for lung cancer in male smokers. The study provided b-carotene (and vitamin E) as supplements for 5 to 8 years. The subjects in this study differed, however, in being male smokers at increased risk for lung cancer. The results of the study in part supported the finding of the Linxian study, in that subjects with the lowest baseline levels of serum b-carotene had a greater incidence of cancer than those with higher levels. However, this study found that subjects who took b-carotene supplements had an 18% greater incidence of lung cancer than those who did not. Subjects supplemented with a-tocopherol showed no difference in incidence of lung cancer from unsupplemented controls (Fig. 81.5). The level of b-carotene supplementation in the ATBC study was more than three times the level in the Linxian study. However, finding an association between increased incidence of cancer and increased intake of b-carotene does not necessarily suggest a role for this nutrient in development of lung cancer, because of the long latency period (10–30 years) from initiation to diagnosis of cancer.

Figure 81.5. Kaplan-Meier curves for the cumulative incidence of lung cancer among participants who received a-tocopherol supplements and those who did not (*upper panel*) and among participants who received b-carotene supplements and those who did not (*lower panel*). Data are shown only through 7½ years of follow-up because of the small numbers of participants beyond that time. Reprinted by permission of The New England Journal of Medicine. (From The Alpha-Tocopherol, Beta Carotene Cancer Prevention Study Group. *N Engl J Med* 1994;330(15):1029–1035, with permission.)

In a similar study, CARET, subjects received a daily supplement of 30 mg b-carotene and 25,000 IU retinyl palmitate. Initial results of the trial showed a 28% increased incidence of lung cancer in patients receiving supplements compared with controls. The increase in lung cancer and an increase in mortality among the supplemented subjects resulted in termination of the trial before the scheduled completion date in 1997. The similarity in results from the ATBC and the CARET trials exemplify the need for further evaluation of the role of carotenoids in lung cancer in populations at risk, i.e., smokers and individuals exposed to carcinogenic agents such as asbestos.

Other carotenoids, in particular a-carotene, may be more effective chemopreventive agents than b-carotene. Murakoshi et al. (117) studied the inhibitory effect of a- and b-carotene alone and mixed carotenoids in palm oil on both spontaneous and induced tumorigenesis. These experiments were carried out in mice that consumed the carotenoids through their drinking water. The fewest tumors in liver, lung, and skin occurred in the mice who received mixed carotenoids, followed by the a- and b-carotenoid groups, respectively. A similar study (118) also determined that mixed carotenoids were the most effective in inhibiting induced skin, lung, and liver tumorigenesis and that a-carotene was more effective than b-carotene in inhibiting tumorigenesis. Taken together, these studies suggest that dietary sources of carotenoids are more effective than supplementation with individual carotenoids and that there may be a cooperative or synergistic effect between carotenoids to achieve tumor inhibition.

The mechanism(s) through which vitamin A derivatives, particularly the carotenoids,

vitamin C, and vitamin E inhibit tumorigenesis has not been elucidated. Wattenberg (119) proposed three levels at which chemopreventive agents could act: (a) as inhibitors of carcinogenic precursors, (b) as blocking agents preventing carcinogens from acting at a target site, and (c) as suppressing agents that diminish the effect of a carcinogen already present (Fig. 81.6).

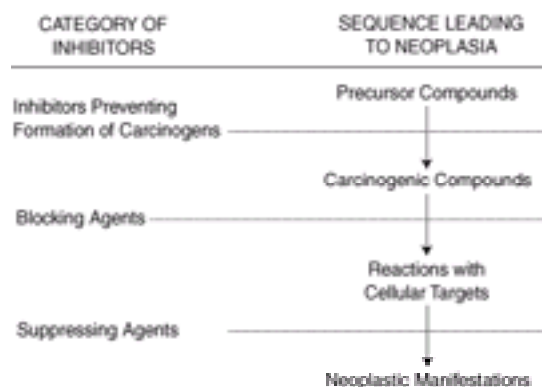

Figure 81.6. Classification of chemopreventive agents on the basis of the time at which they exert their protective effects. (From Wattenberg LW, Cancer Res 1985;45:1–8, with permission.)

A number of *in vitro* studies support the hypothesis that retinoids and carotenoids function as antioxidants in the promotional phase of carcinogenesis (120, 121). The antioxidant activity of carotenoids has been demonstrated *in vivo* by inhibition of lipid peroxidation (122).

The findings of a human study appear to support the inhibition of lipid peroxidation by carotenoids (123). In this study, volunteers were initially depleted of b-carotene, which significantly decreased their serum carotene levels. After 2 weeks, lipid peroxide measures were significantly decreased after supplementation, compared with peroxide levels in depleted subjects before supplementation. Serum b-carotene levels in the supplemented groups were twice the baseline levels. However, since the subjects were depleted of b-carotene prior to supplementation, it is difficult to determine if the response was due to the increased serum concentration of b-carotene or to repletion from a deficient state.

As with the carotenoids, vitamin C status has been found to be inversely related to risk for certain cancers, and experiments testing inhibition of tumorigenesis with supplementary vitamin C have shown mixed results (124). In clinical trials testing tumor recurrence in the presence and absence of supplemental vitamin C, no change in the incidence of tumor recurrence was found between the supplemented group and controls. However, when cellular proliferation assays were done with tissue samples, the vitamin C-supplemented subjects had significantly less proliferation in colonic crypts

(125). A similar study, in which subjects received a combination of retinol and vitamins E and C, also found significantly less proliferation in the supplemented group than in controls (126).

The role of ascorbic acid and α -tocopherol as inhibitors of tumorigenesis is similar to that of retinoids and carotenoids in that they share antioxidant properties (127). Additionally, in vitro, both ascorbic acid and α -tocopherol act as inhibitors at initiation by scavenging mutagens such as free radicals and by preventing formation of nitroso compounds (128). Nitrosamines are strongly implicated in the pathogenesis of gastric cancer, and thus ascorbic acid may be an important chemopreventive agent in this disease process (112). These and other studies further suggest that antioxidant vitamins are most effective in combination rather than as isolated supplements (115).

Prevention and Therapy

An important aspect of retinol as a chemopreventive agent is its toxicity in humans. Although a number of in vitro studies using retinol have shown inhibition of oncogene expression and decreased damage to DNA (97, 129), preformed vitamin A cannot be considered a supplemental chemopreventive vitamin at therapeutic doses. Supplementation may, however, be a factor in preventing esophageal-gastric carcinomas in a population that is deficient in vitamin A (130).

As an alternative to vitamin A supplementation, retinoid analogues have been studied as potential chemopreventive agents. Hong et al. (131) showed that the analogue 13-*cis*-retinoic acid effectively suppressed further development of premalignant lesions of the oral cavity and also reduced the incidence of second primary tumors in patients with squamous-cell carcinomas of the head and neck. However, primary tumor recurrence was not suppressed by the retinoid analogue (132).

Selenium and Cancer

Epidemiology of Selenium and Cancer Risk

Associations between selenium and cancer have been studied for more than 25 years. However, the findings of these studies remain controversial and contradictory. Correlations between selenium status and tumorigenesis are derived from studies demonstrating an increase in cancer risk with decreased blood, tissue, or intake levels of this micronutrient (133).

Early studies examined correlations between geographic regions with high forage plant-selenium levels and incidences of cancer. Clark (reviewed in [137]) reported from studies by Shamberger et al. and Kuboto that areas of high forage selenium were inversely related to incidences of lung, colon, rectal, bladder, esophageal, and pancreatic cancer and positively related to liver and stomach cancer, Hodgkin's lymphoma, and leukemia. In a subsequent study, Clark et al. (134) assessed the association of cancer mortality incidence and forage selenium in smaller geographic segments, by county rather than by state or nation. This study also found an inverse

correlation between forage selenium level and cancer mortality. More recently, however, the work of Nakadaira et al. (135) on soil selenium concentrations and cancer mortality failed to find any correlation. Vinceti et al. (136) also failed to find a correlation between levels of naturally occurring selenium in the drinking water and mortality from various cancers, except that a positive correlation was found in females between selenium and cancers of lymphatic and hematopoietic tissues, including non-Hodgkin's lymphoma.

Although forage selenium reflects exposure to this micronutrient within a geographic region, intake levels of selenium may vary because of consumption of foods transported from other geographic areas. Alternatively, tissue indicators of selenium status have been used, including urine, blood, or serum measures and selenium levels in hair and nails. However, blood selenium level may not be an accurate measure of selenium status as the plasma pool shifts with short-term changes in intake. Furthermore, selenium status changes in individuals with cancer, because of such factors as chemotherapy, radiotherapy, and stage of disease (133).

Clark et al. (137) examined plasma selenium levels in subjects with basal cell and squamous cell carcinomas. These skin cancers were chosen for study because of the low ratio of tumor mass to normal tissue and the decreased likelihood of influencing metabolic parameters, such as selenium level.

Another important consideration in determination of biologic/anticarcinogenic activity of selenium is its chemical form. Although the predominant form of selenium in the human diet is selenomethionine ([Se]Met), other forms, particularly selenite, have greater anticarcinogenic activity (142).

Selenite or [Se]Met enter the selenium metabolic pathway, where the initial compound is converted to methylated products or incorporated into selenoamino acids (see Chapter 14) (143). The methylated selenium products, particularly the monomethylated species, are proposed to have the greatest anticarcinogenic potential (149). Furthermore, the form of selenium, i.e., selenite, initially entering the metabolic pathway appears to determine the anticarcinogenic efficacy (145).

To be activated for anticarcinogenic potential, selenium compounds first go through the methylation pathway (146). Hydrogen selenide, an important intermediate in the pathway, can enter the assimilatory pathway and generate selenoproteins, such as glutathione peroxidase, or it can enter the detoxification pathway and undergo methylation.

In addition to the forms of selenium mentioned, other analogues, such as selenobetaine and se-methylselenocysteine, have been tested for anticarcinogenic potential (143). Both of these forms of selenium are metabolized to monomethylated selenide. However, the yield is much greater than from selenomethionine or selenite (143). Animal studies have shown that the partially methylated species have greater efficacy as antitumorigenic agents than the fully methylated species (143).

Aside from a role in inhibiting free radical formation, selenium compounds also induce programmed cell death, or apoptosis, in cultured cells (147). The ability of cells to program

their own death provides a mechanism to control mutations.

Clinical Trials of the Efficacy of Selenium in Cancer Inhibition

Clinical trials testing the anticarcinogenic effects of selenium obtained from foods or supplements have been carried out in areas of the world where nutrient deprivation is common, as in parts of China and India. Linxian, China, has been studied because it is part of a large region of high cancer mortality as well as micronutrient deficiency (130). Blot et al. (114) conducted supplementation trials that included combinations of micronutrients. Although neither of these studies evaluated the chemopreventive activity of selenium alone, both studies did find that selenium in combination with other nutrients, particularly vitamins A and E, had an inhibitory effect on esophageal and stomach cancers (reviewed in [118, 134]).

Prasad et al. (148) studied the inhibitory effects of a micronutrient cocktail of vitamin A, riboflavin, zinc, and selenium on tumorigenesis in tobacco chewers and smokers in India. The population chosen has a high incidence of both oral and upper airway cancers and of micronutrient deficiencies (149). Dietary assessment of study participants revealed that blood levels of micronutrients were similar, low-normal or deficient in all subjects (150). At the completion of the 1-year study, significantly fewer in the supplemented group developed oral lesions or ulcers than in the placebo group. Furthermore, of those subjects who had lesions initially, significantly fewer receiving the supplements regressed to more serious cancers. Biochemical assessment of study participants showed that formation of DNA adducts, an indicator of carcinogenicity, was significantly lower in the supplemented subjects than in those receiving placebo (150).

These trials among population groups at risk for micronutrient deficiencies suggest that supplementation with selenium (and other micronutrients) reduces the carcinogenic potential of other cancer-causing factors. Among a nutritionally healthy population, however, such a chemopreventive effect is not as clearly seen.

Inhibition of Carcinogenesis by Selenium in Animal Models

Inorganic selenium compounds, such as sodium selenite, inhibit tumorigenesis in laboratory animal models. These models have been used to demonstrate selenium inhibition of many types of cancer, including liver, skin, pancreas, mammary gland, and colon (151). Experiments in rats demonstrated that dietary selenium, in the form of sodium selenite in drinking water, inhibited formation of DMBA-DNA adducts and decreased the incidence of mammary tumors (152). In hamsters, sodium selenite inhibited *N*-nitrosobis(2-oxopropyl)amine (BOP)-induced pancreatic cancer, in a dose-dependent fashion (153). Decreased carcinogen-induced damage to DNA supports a role for selenium inhibition of cancer at the stage of initiation, and increased latency to tumor development suggests inhibition of tumor promotion. However, earlier studies by Birt et al. (152) found that dietary supplementation with sodium selenite and D,L-selenomethionine (153) had no inhibitory effect on pancreatic tumors in BOP-treated male hamsters or enhanced pancreatic carcinogenesis in BOP-treated male hamsters fed high-fat diets (153).

Recently developed compounds, such as 1,4-phenylene-bis(methylene)selenocyanate or xylene selenocyanate (p-XSC), have been found to be more efficacious inhibitors of mammary and colon carcinogenesis (154). This modified form of selenium has an LD₅₀ greater than 1 g/kg body weight, compared with an LD₅₀ of 35 mg/kg for sodium selenite and 125 mg/kg for benzyl selenocyanate (BSC) (155). Furthermore, when administered during initiation, p-XSC inhibited tumor formation by 80% (155). Although the inorganic selenocyanate compounds have been shown to be effective inhibitors of tumorigenesis in animal models, they are not yet applicable to humans.

Selenium in Chemoprevention and Therapy

Selenium enrichment of foods has shown promise as a means of increasing selenium intake and decreasing tumor incidence in animal models (156). The similarity between sulfur and selenium metabolism in plants has been exploited to increase the selenium content of foods rich in sulfur compounds (157). Garlic, an ideal candidate for selenium enrichment, demonstrated inhibition of mammary tumorigenesis in rat experiments. Ip et al. (158) fed freeze-dried powdered garlic, grown in normal soil or grown in selenium-enriched soil, to rats during DMBA initiation or through initiation and postinitiation until the end of the experiment. The total number of mammary tumors that developed were compared among rats fed regular garlic, selenium-enriched garlic, and supplemented with inorganic selenium compounds. Tumor inhibition was achieved in all three groups, but the rats fed selenium-enriched garlic had 69% inhibition compared with controls whereas the group fed regular garlic had 40% inhibition.

The advantage of dietary intake of selenium-enriched garlic, in addition to the increased tumor inhibition, was that tissue selenium levels were not elevated to the near-toxic levels seen with inorganic selenium compounds. Also, glutathione peroxidase activity was not perturbed by selenium-enriched foods (157). While selenium enrichment of garlic and other foods may be a practical means of providing this chemopreventive agent at nontoxic levels, further research is needed to determine efficacy and feasibility in humans.

NONNUTRIENT DIETARY COMPONENTS

Flavonoids

Occurrence and Intake

Flavonoids are widely distributed in fruits and vegetables. They are composed of a number of related compounds with the general structure shown in [Figure 81.7](#). It is estimated that we consume approximately 1 g of flavonoids daily, and the bulk of these compounds are in our diets as glycosides (159). Recent studies assessed the intake of particular flavonoids in the Netherlands, and an estimated daily consumption of 16 mg/day was made for quercetin (160, 161). However, the analysis of foods for these compounds is problematic, and estimates should be considered tentative. As indicated below, many of the biologic effects are associated more with the free aglycone that is

released in the intestine than with the compound bound in the glycoside.

Common Name	Substituents					
	3	4	5	7	3'	5'
Acacetin	H	H	OH	OH	H	OCH ₃
Apigenin	H	H	OH	OH	H	OH
Chrysin	H	H	OH	OH	H	H
Kaempferol	OH	H	OH	OH	H	OH
Quercetin	OH	H	OH	OH	OH	OH

Figure 81.7.

Mutagenicity Studies

Quercetin is the most extensively studied dietary flavonoid. Quercetin is a widely distributed flavonol that was initially studied for potential carcinogenicity because it functions as a frame-shift mutagen (162). Mutagenicity in a number of Ames strains was shown to require the 3' and 4' hydroxyls of quercetin and rhamnetin (163). Parallel studies with quercetin, rhamnetin, isohamnetin, apigenin, and luteolin isolated from medicinal herbs provided no evidence of mutagenicity for apigenin and luteolin (163). A number of studies reported inhibition of mutagenicity by a variety of flavonoids. In a study of 64 flavonoids for mutagenicity against the heterocyclic amines, Edenharder et al. (164) found that a carbonyl function at C-4 of the flavone nucleus was essential for antimutagenicity. Furthermore, increasing polarity by addition of hydroxyl groups reduced antimutagenicity, and 6-hydroxy- and 2'-hydroxy-substituted flavonoids were considerably less potent antimutagens. Apigenin treatment resulted in potent antimutagenesis compared with other phytochemicals when tested against nitropyrenes in *Salmonella* strains and in Chinese hamster ovary cells (165). In addition, apigenin inhibited mutagenicity induced by benzo[a]pyrene and 2-aminoanthracene induced in the Ames assay with TA98 bacteria (166).

Laboratory Studies

More-recent studies have focused on the ability of quercetin to prevent carcinogenesis (162). Quercetin was effective in prevention of skin carcinogenesis in the two-stage model of DMBA-initiated and TPA-promoted cancer (167). In addition, quercetin inhibited azoxymethanol (AOM)-induced aberrant crypt foci (ACF) (168, 169). Similar observations were reported for liquiritin, a glucosylated flavonoid (170). Quercetin and rutin, a common dietary source of quercetin, were not equally effective in prevention of colon carcinogenesis (168). Incorporation of 2% dietary quercetin decreased the

incidence of colon cancer in AOM-treated rats from 25 to 6% ($P < 0.003$), while 4% dietary rutin (roughly equivalent to the amount of quercetin in the 2% diet) decreased colon cancer incidence to 10% (not significant) in the same study. Later studies from the same laboratory demonstrated inhibition of AOM-induced ACF in mice fed high-fat diets with quercetin but not with rutin (169). Furthermore, rutin was not effective in another laboratory in inhibition of ACF (171).

Four citrus flavonoids (quercetin, taxifolin, nobiletin, and tangeretin) were studied in the in vitro growth of human squamous cell carcinoma cells, HTB43 (172). Nobiletin and tangeretin, hydroxymethylated flavonoids, markedly inhibited the growth of cells at doses from 2 to 8 $\mu\text{g/mL}$; quercetin and taxifolin were ineffective.

Studies have explored skin cancer prevention by flavonoids. Research in the Birt laboratory has focused on apigenin (4',5,7,-trihydroxyflavone), a widely distributed flavone. Apigenin inhibited both ultraviolet light-induced and DMBA- and TPA-induced skin carcinogenesis (166, 173, 174) (Fig. 81.8). In initial studies, apigenin inhibited ornithine decarboxylase activity induced by the tumor promoter TPA or by the complete carcinogen UV light in a dose-responsive manner (166, 174).

Figure 81.8. Skin papilloma multiplicity in apigenin-treated and control groups. (*circles*), 7,12-Dimethylbenz[*a*]anthracene (DMBA)/di-methylsulfoxide (DMSO)/12-*O*-tetradecanoylphorbol-13-acetate(TPA); (*squares*), DMBA/5 μmol apigenin/TPA; (*triangles*), DMBA/20 μmol apigenin/TPA. Average papilloma number of DMBA/DMSO/TPA is significantly higher than that of two apigenin-treated groups ($P < 0.001$), while there is no significant difference between two apigenin-treated groups by Student's *t* test. (From Wei H, Tye L, Bresnick E, et al. Cancer Res 1990;50:499–502, with permission.)

Flavonoids have recently been demonstrated to be effective in prevention of cellular proliferation and carcinogenesis in a number of other models. For example, bioflavonoids inhibited lymphocyte proliferation induced by con A or LPS in studies by

Lee et al. (175).

Mechanism of Action

Protein Phosphorylation. Numerous mechanisms have been suggested for flavonoid inhibition of carcinogenesis. Some of these may relate to the inhibition of cell cycle as discussed below, while others may be independent effects that interact with inhibition of cell cycle in the prevention of cancer. Several laboratories have associated changes in protein phosphorylation of cancer cell lines with growth inhibition by flavonoids. For example, apigenin, kampherol, and genistein (25 μM) reversed the transformed phenotype of v-H-*ras*-transformed NIH3T3 cells (176). Twelve other flavonoids were not effective. The observed reversion was associated with reduced phosphotyrosine content in the cells (176), and recent work from this group suggested that apigenin could inhibit mitogen-activated protein kinase (MAPK) (177). This inhibition was associated with reductions in *c-jun* and *c-fos* expression, but mRNA expression and protein level of *ras* were not influenced.

Topoisomerase Inhibition. A number of flavonoids are topoisomerase antagonists; myricetin, quercetin, fisetin, and morin inhibited both Topo I and Topo II, while phoretin, kaempherol, and 4',6,7-trihydroxyisoflavone inhibited only Topo I. Apigenin, prunetin, quercetin, and kaempferol stabilized the Topo II DNA complex (178). In addition, apigenin and tangeretin enhanced gap junctional intracellular communication in rat liver epithelial cells. Increased dye transfer was associated with increases in connexin 43 protein (179).

Antioxidant and Antiinflammation Activity. Flavonoids have also demonstrated antioxidant and antiinflammation properties. Thirty-five phenolic compounds, primarily flavonoids, were studied for their ability to prevent carbon tetrachloride lipid peroxidation of rat liver microsomes (180), and a number of flavones, flavonols, and related compounds were active. Furthermore, apigenin-7-glucoside was effective in prevention of skin inflammation induced by a number of generators of reactive oxygen species (181). In studies of 24 flavonoids, Tordera et al. (182) found a number of compounds to be effective in inhibiting b-glucuronidase activity, lysosome release, and arachidonic acid release from membranes.

Cell Cycle Arrest. Matsukawa et al. reported that a number of flavonoids, flavone, quercetin, and luteolin, arrested cells at G₂/M or G₁ (183). Flow-cytometric analysis showed that the flavonoids and daidzen induced cell cycle arrest at G₁, but genistein almost completely arrested the cell cycle progression at G₂/M. Cell cycle arrest by genistein was reversed in HGC-27 gastric cancer cells when genistein was removed from the culture medium. Quercetin inhibited the cell cycle at late G₁ in human leukemic T cells (184). Human colon cancer cells were also arrested in late G₁ (COLO320) (185), and the arrest was associated with inhibition of a cell cycle-related 17-kDa protein (1985). Another laboratory reported that apigenin induces G₂/M arrest in rat neuronal cells (186). Lepley et al. (187) demonstrated that apigenin arrests human promyelocytic leukemia cells and murine keratinocytes at G₂/M and that this effect is reversible. In the

apigenin-treated keratinocytes, inhibition of P34^{cdc2} kinase and reduction in the cyclin B protein, the cyclin associated with P34^{cdc2} kinase, was noted. In studies with immunoprecipitated P34^{cdc2} kinase, quercetin and genistein were reported to inhibit this kinase ([188](#)).

Wei et al. recently reported induction of apoptosis by quercetin in several tumor cell lines (K562, Molt-4, Raji, and MCAS), resulting in nuclear fragmentation, condensation of nuclear chromatin, and a subdiploid peak by DNA flow cytometry ([189](#)).

Absorption and Metabolism of Flavonoids

The literature has little information on the absorption and metabolism of flavonoids. Recent reports demonstrated good absorption of quercetin in female ileostomy patients ([190](#)). Absorption was estimated from oral intake minus ileostomy excretion, with correction for 14% degradation in the ileostomy bag. Estimated quercetin absorption from quercetin glycosides in onions was $52 \pm 15\%$, absorption from quercetin rutinoid (the common form in tea) was $17 \pm 15\%$, and absorption from quercetin aglycone was $24 \pm 9\%$ ([190](#)). Regarding the importance of flavonoid metabolism in cancer prevention, apigenin inhibition of skin carcinogenesis and cell cycle arrest do not appear to require apigenin metabolism ([191](#)). No evidence was found of apigenin metabolism in mouse skin, tissue culture systems, or cultured epidermal (C50) cells under conditions in which apigenin has been demonstrated to inhibit skin carcinogenesis in the intact animal or to cause cell cycle arrest in cultured cells ([187](#), [191](#)).

Isoflavonoids

Epidemiologic and Clinical Studies

Several epidemiologic studies indirectly suggest that consumption of dietary isoflavones may lend protection against certain cancers. Although these epidemiologic studies alone are not conclusive, they are supported by numerous laboratory studies indicating that isoflavones exhibit a large number of diverse biologic effects, both in vivo and in vitro, that may be associated with anticancer activities. Consequently, isoflavones receive much attention as possible cancer prevention agents.

Breast Cancer. Perhaps the strongest evidence suggesting that isoflavones possess anticancer activities in humans stems from studies demonstrating an inverse correlation between consumption of soy-derived products, known to contain substantial amounts of isoflavones, and risk of developing breast cancer (reviewed in [[192](#), [193](#)]). Nomura et al. ([194](#)) evaluated the association between the dietary practices of 6860 Hawaiian men of Japanese ancestry, who were participants in the Honolulu Heart Study, and breast cancer in their spouses, under the assumption that husbands and wives consume similar diets. The husbands of women with breast cancer consumed significantly less Japanese miso (fermented soybean paste) soup than husbands of women without breast cancer. Although the breast cancer group also consumed 22% less tofu (soy bean curd) than the control group, the difference was not statistically significant. Interpretation of these data was confounded by the observation that the husbands of

women with breast cancer consumed significantly more beef and wieners than the control group. In a prospective study of 142,857 Japanese women, Hirayama (195) demonstrated a significant inverse correlation between consumption of soybean paste soup and breast cancer risk. An inverse correlation between breast cancer risk and consumption of soy protein as well as total soy products was observed by Lee et al. (196) in a study of premenopausal Singapore Chinese women.

Prostate Cancer. The incidence of prostate cancers in North America and western Europe is much greater than in Asian populations. Because of this, it is often suggested that consumption of a diet high in soy provides protection against prostate cancer. However, two large prospective studies failed to reveal such an effect (197, 198).

Laboratory Studies

Several animal studies suggest that isoflavones possess anticarcinogenic properties. Some of these studies evaluated the effects of dietary soy on experimental carcinogenesis (192), whereas others evaluated specific isoflavones for their anticarcinogenic activities.

Experimental Mammary Cancer. Barnes et al. (199) demonstrated that consumption of diets containing either powdered soybean chips or isolated soy protein inhibited development of mammary tumors in female Sprague-Dawley rats treated with either *N*-methyl-*N'*-nitrosourea (MNU) or DMBA (Fig. 81.9). In this study, inhibition of mammary tumorigenesis was revealed by both a decreased tumor burden and an increased latency. Cooking the soybean chips did not eliminate their antitumorigenic activity, suggesting that isoflavones or other heat-stable components, not heat-labile proteinase inhibitors, may have been the active soy constituent. In a subsequent study, these investigators demonstrated that consumption of soy protein isolate, but not an alcohol-extracted soy protein isolate, inhibited DMBA-induced mammary carcinogenesis in the female Sprague-Dawley rat (200). These data again suggest that isoflavones, which are alcohol-soluble and therefore extracted from the protein isolate, contain the antitumorigenic activity in the soy diet.

Figure 81.9. Inhibition of mammary tumors induced by MNU in rats by addition of nonautoclaved (A) and autoclaved (B) powdered soybean chips (PSC) to AIN-76A diet.

(From Barnes S, Grubbs C, Setchell KDR, et al. Prog Clin Biol Res 1990;347:239–53, with permission.)

An antitumorigenic effect of soy protein isolate was also observed by Hawrylewicz et al. (201), who initiated mammary tumorigenesis with MNU and began feeding the soy diet 5 weeks thereafter. Their data indicate that soy protein isolate exerts its inhibitory effect during the promotion and/or progression phases of mammary tumorigenesis. Baggott et al. (202) demonstrated that miso consumption protected against DMBA-induced mammary adenocarcinomas in the Sprague-Dawley rat. Although cancer incidence was reduced and latency was increased by miso consumption, this protective effect was not attributed to consumption of soy-derived isoflavones. In contrast to the studies of Barnes and Hawrylewicz, Carroll (203) reported similar mammary tumor yields following DMBA treatment of female Sprague-Dawley rats fed diets in which the protein was derived from either casein or soy. The reason for these disparate observations is not clear. In summary, several studies suggest soy-containing diets may suppress chemically induced mammary cancers in the female rat. However, without additional evidence, the antitumorigenic activity in the different soy-containing diets cannot be attributed to isoflavones.

Genistein administered by subcutaneous injection to neonatal female Sprague-Dawley rats inhibited development of mammary tumors following subsequent treatment with DMBA at 50 days of age (204). Genistein treatment also altered the course of mammary gland development, leading to increased lobuloalveolar structures and decreased terminal end buds at the time of DMBA treatment. Because terminal end buds are highly susceptible to chemically induced tumorigenesis (205), it was suggested that induction of differentiation of end buds to lobules is the probable mechanism of genistein inhibition of mammary tumorigenesis in the DMBA-treated rat.

Formononetin was shown to stimulate mammary cell proliferation in ovariectomized mice (206). In this study, formononetin, administered for 5 days by subcutaneous injection at a dose of 40 mg/kg, stimulated mammary cell proliferation 3.3-fold, increased the level of estrogen receptor in the mammary tissues 2-fold, and increased the level of circulating prolactin 1.7-fold. Although these data strongly suggest that formononetin exerts weak estrogenic activity in the mouse mammary and anterior pituitary tissues, the relevance of this estrogenic activity to mammary cancer development and chemoprevention remains to be assessed.

Isoflavones inhibit proliferation of a number of human breast cancer cell lines. Peterson and Barnes (207) demonstrated that genistein, daidzein, and biochanin A each inhibit proliferation of the breast cancer cell lines MCF-7 and MDA-468, with IC₅₀ values of 39, 74, and 110 μM, respectively. Because similar IC₅₀ values for each of these isoflavones were observed in MCF-7 cells, which are estrogen-receptor positive, and MDA-468 cells, which do not express estrogen receptor, it was concluded that the inhibitory effects of these isoflavones on cell proliferation, at least in MDA-468 cells, are not mediated through the estrogen receptor. When treated with genistein at a concentration

of 10 μM , MCF-7 cells were reversibly arrested at the G₂/M cell cycle boundary; at concentrations of 50 μM , G₂/M arrest was not reversible, and cells underwent apoptosis (208). Kievitone, an isoflavonoid from red kidney beans, is a potent inhibitor of basal and growth factor–stimulated proliferation of the estrogen receptor–positive MCF-7 and T47D breast cancer cell lines, and the estrogen receptor–negative SKBR3 breast cancer cell line (209). At this time, the molecular mechanism of isoflavone inhibition of breast cancer cell proliferation in culture is not fully elucidated. Also not clear is whether isoflavones can exert selective inhibitory effects on breast cancer cell proliferation in vivo.

Other studies have revealed stimulatory effects of isoflavones on breast cancer cell proliferation. Welshons et al. (210) established and validated a highly sensitive assay for evaluating the phytoestrogen content of animal feeds. Using this assay, it was demonstrated that the isoflavones genistein, biochanin A, daidzein, and formononetin stimulate MCF-7 cell proliferation with potencies ranging from 3 to 5 orders of magnitude less than that of 17 β -estradiol. The ability of each of these isoflavones to stimulate MCF-7 cell proliferation was correlated with their binding affinities for the estrogen receptor. Moreover, the antiestrogens tamoxifen or LY156758 blocked induction of MCF-7 cell proliferation by each of these isoflavones, indicating that their effects on proliferation were mediated through the estrogen receptor. Stimulatory effects of genistein and biochanin A on MCF-7 cell proliferation have recently been reported by a second group (211), but no antiestrogenic activities of isoflavones were observed in this study. Sathyamoorthy et al. (212) observed that equol and daidzein added to estrogen-depleted culture media to a concentration of 1 μM stimulate MCF-7 cell proliferation. From these studies, it would appear that at physiologically relevant concentrations, isoflavones display estrogenic, not antiestrogenic, activities in cultured breast cancer cell lines.

Experimental Prostate Cancer. Genistein has been demonstrated to inhibit, in a concentration-dependent manner, proliferation of both human (PC-3) and rat (Dunning R-3327-MAT-LyLu) prostate cancer cell lines. However, when administered by either addition to the drinking water or intraperitoneal injection, genistein failed to inhibit growth of MAT-LyLu rat prostate cancer cells maintained as subcutaneous transplants in male Copenhagen rats (213). A probable explanation for the observed inability of genistein to inhibit prostate cancer cell proliferation in vivo is that the micromolar concentrations of the isoflavone required for inhibition of proliferation were not achieved within the transplanted tumor cells.

Mechanisms of Action

Estrogenic and Antiestrogenic Activities. *Interaction of Isoflavones with the Estrogen Receptor.* Probably the first indication that isoflavones interact with the estrogen receptor was the observation that genistein inhibited, in a dose-dependent manner, the uptake of 17 β -estradiol by the uterus and vagina of the immature mouse (214). Shutt and Cox (215) demonstrated that genistein, equol, daidzein, O-desmethyngolensin, biochanin A, and formononetin each inhibit binding of 17 β -estradiol to estrogen receptor in cytosol prepared from sheep uterus. Experiments in which a plasmid encoding the human estrogen receptor and a plasmid containing an estrogen-regulated

promoter/reporter gene construct (pERE/TK/CAT) are transfected into HeLa cells indicate that genistein, biochanin A, daidzein, and formononetin each act through the estrogen receptor to enhance expression of the reporter gene (216). Genistein and biochanin A behaved as full agonists in this experimental system, whereas daidzein and formononetin behaved as partial agonists. Together, these data strongly suggest that several isoflavones bind to the estrogen receptor and display agonistic activity.

Estrogen-Related Biologic Activities in Humans. It has recently been demonstrated that consumption of a diet containing soy protein and associated isoflavones modulates the menstrual cycle in young women (217). In a dietary intervention study, six young women were monitored over several consecutive menstrual cycles, initially while consuming a control diet and subsequently while consuming a diet that incorporated 60 g/day soy protein containing 45 mg of isoflavones. Consumption of the soy diet resulted in a 1000-fold increase in urinary excretion of isoflavones, primarily daidzein, genistein, and equol, and a significant lengthening of the menstrual cycles due to an extended follicular phase. The midcycle surges of luteinizing hormone and follicle-stimulating hormone were significantly diminished by the soy diet, but no effect on circulating sex hormone-binding globulin (SHBG) levels was observed. These data strongly suggest that dietary isoflavones exert physiologic effects in premenopausal women, possibly because of actions mediated through the estrogen receptor. Because the highest level of mammary epithelial cell proliferation occurs during the luteal phase of the menstrual cycle, it has often been suggested that prolongation of the follicular phase of the cycle would reduce the number of total cycles a woman would display in her lifetime and might thereby provide protection against development of breast cancer.

Incorporation of soy flour into the diets of 23 postmenopausal women markedly increased urinary excretion of the isoflavones daidzein and equol and significantly lessened menopause-associated symptoms, including hot flashes, when these symptoms were evaluated 6 and 12 weeks after initiation of the dietary intervention (218). No effects of soy flour consumption on vaginal cytology or circulating follicle-stimulating hormone (both regulated by estrogens) were observed in that study. Consequently, it is not clear that the reported relief of menopause symptoms was due to estrogenic activities of the soy-derived isoflavones. Another recently published dietary intervention study failed to demonstrate that consumption of a diet high in soy modulated any of four estrogen-regulated parameters in postmenopausal women (219). In this study, 91 postmenopausal women consumed for 4 weeks either a “normal” omnivorous diet (25 women) or a diet in which soy products accounted for approximately one-third of caloric intake (66 women). Although the women consuming the soy-based diet ingested substantially more isoflavones, as evidenced by a greater than 100-fold increase in urinary excretion of the isoflavones daidzein, genistein, and equol, no statistically significant changes in the levels of circulating luteinizing hormone, follicle-stimulating hormone, or SHBG or in vaginal cytology were observed.

Estrogen-Related Biologic Activities in Experimental Animals. A number of laboratory studies suggest that isoflavones may modulate estrogen-regulated functions. Six-week-old rats that had been treated as neonates with genistein administered by subcutaneous injection exhibited an altered pituitary gonadotroph response to administered gonadotropin-releasing hormone, suggesting neonatal exposure to this isoflavone may influence development of the hypothalamic-pituitary axis (220). In

contrast, pituitary gonadotroph responsiveness to gonadotropin-releasing hormone was not altered by prenatal exposure to genistein, although female rats exposed to this isoflavone in utero did display delayed onset of puberty ([221](#)).

Other Estrogen-Related Biologic Activities. Isoflavones modulate several biologic activities that could potentially affect production or action of endogenous estrogens. The physiologic relevance of these modulatory effects remains to be assessed, however. SHBG, present in the systemic circulation, binds estrogens and androgens with high affinity and thereby modulates the availability of these hormones for binding to their respective intracellular receptors. Genistein has been reported to increase production of SHBG by Hep-G₂ cells, a human hepatoma cell line, cultured under estrogen-depleted conditions ([222](#)). Induction of SHBG production occurred at genistein concentrations of 20 μ M or greater, which are greater than that observed in the circulation of humans consuming large amounts of dietary soy ([223](#), [224](#)). Although a positive correlation between isoflavone consumption, as indicated by urinary excretion, and the level of circulating SHBG has been reported ([225](#)), two dietary intervention studies failed to reveal significant effects of increased consumption of soy-derived isoflavones on circulating SHBG in women ([217](#), [219](#)). Thus, it is not clear that dietary isoflavones modulate SHBG levels in vivo.

Aromatase is a cytochrome P450 that catalyzes the conversion of androgens to estrogens. Numerous studies indicate the potential of certain isoflavones to competitively inhibit aromatase and thereby inhibit estrogen production ([226](#), [227](#) and [228](#)), but it has yet to be demonstrated that diet-derived isoflavones can modulate aromatase activity in vivo.

17 β -Hydroxysteroid oxidoreductase type I (17 β -HSOR) catalyzes the interconversion of estrone and 17 β -estradiol. It has recently been reported that genistein, but not biochanin A, inhibits 17 β -HSOR, both enzyme purified from human placenta and endogenous enzyme in T47D human breast cancer cells ([225](#)). In T47D₂₁ cells, which overexpress 17 β -HSOR activity because of a stably transfected cDNA, reduction of estrone to 17 β -estradiol was observed to predominate over oxidation of 17 β -estradiol to estrone. Interestingly, estrone reduction was inhibited by genistein, whereas oxidation of 17 β -estradiol was unaffected. At concentrations required to inhibit 17 β -HSOR activity in T47D cells, genistein displayed significant inherent estrogenic activity.

Inhibition of Protein Tyrosine Kinases. Tyrosine-specific protein kinases are a family of related enzymes that catalyze the addition of phosphate derived from ATP to the hydroxyl group of specific tyrosine residues in proteins. The membrane-associated receptors for a variety of cellular growth factors, such as insulin, insulin-like growth factor I (IGF-I), and epidermal growth factor (EGF), possess intrinsic tyrosine kinase activity. Mutations in the genes encoding these and other protein tyrosine kinases that result in unregulated kinase activity are often associated with the transformed phenotype displayed by cancer cells.

Akiyama et al. ([230](#)) were the first to demonstrate that the isoflavone genistein is a specific inhibitor of protein tyrosine kinases. Inhibition of kinase activity was competitive with respect to ATP binding. Although genistein was a potent inhibitor of the EGF

receptor and the protein products of the *v-src* and *v-fes* viral oncogenes, each of which possesses tyrosine kinase activity, no inhibition of kinases that phosphorylate serine and threonine residues, cyclic AMP-dependent protein kinase, and protein kinase C, was observed.

Genistein inhibits proliferation of a wide variety of cell lines (231). For example, genistein inhibits, in a concentration-dependent manner ($IC_{50} = 12 \mu M$), proliferation of NIH-3T3 fibroblasts that are growth stimulated by EGF (232). Interestingly, genistein, at concentrations ($40 \mu M$) that effectively inhibited cellular proliferation, did not inhibit the ability of EGF to induce expression of the *c-myc* gene, a cellular response that is well known to require the protein tyrosine kinase activity of the EGF receptor. From these data it would appear that inhibition of cellular proliferation by genistein is independent of inhibition of EGF receptor protein tyrosine kinase activity (232). Similar results were observed by Peterson and Barnes in studies of genistein action in DU-145 prostate cancer stimulated with EGF (233). Abler et al. (234) demonstrated that the ability of genistein to inhibit certain insulin-regulated responses in isolated rat adipocytes did not correlate with its ability to inhibit insulin receptor tyrosine kinase activity. Together, these data indicate that it should not be assumed that the protein tyrosine kinases are the cellular targets through which genistein exerts its cytostatic and cytotoxic properties.

Inhibition of Topoisomerases. Topoisomerases are enzymes that relieve torsional stress in DNA generated during replication and transcription. A number of widely used chemotherapeutic drugs, such as etoposide (VP-16), mitoxantrone, and adriamycin, act through inhibition of topoisomerase activity. Genistein inhibits the activities of purified preparations of both topoisomerase I and topoisomerase II (235) and appears to promote accumulation of topoisomerase-DNA intermediates, which may lead to single-strand and double-strand breaks in the DNA (235, 236 and 237). The isoflavone orobol (5,7,3',4'-tetrahydroxyisoflavone) displays a similar inhibitory effect on topoisomerase II activity (237), whereas biochanin A and daidzein do not (236, 237). Markovits et al. (236) demonstrated that different variants of the DC-3F Chinese hamster lung cell line display differing degrees of growth inhibition in response to genistein and that the variant cell line (DC-3F/9-OH-E) most resistant to genistein appears to express an altered form of topoisomerase II. These data were interpreted to suggest that the cytotoxic effects of genistein on cell proliferation may be mediated through inhibition of topoisomerase II activity. It has yet to be established whether topoisomerases are suitable *in vivo* targets for isoflavone-based chemoprevention or chemotherapeutic strategies.

Regulation of Cell Cycle Progression, Differentiation, and Apoptosis. The replicative cycle of cells can be divided into four major stages: G_1 (gap_1); S (synthesis), the stage of the cycle where cellular DNA is replicated; G_2 (gap_2); and M (mitosis), the stage during which the replicated chromosomes segregate. Terminally differentiated and other nonreplicating cells represent a quiescent stage often referred to as G_0 . Apoptosis is an active process in which cells undergo genetically programmed death. An understanding of the molecular events regulating cell cycle progression (238) and apoptosis (238, 239, 240 and 241) is rapidly emerging.

Genistein inhibits proliferation of HL-60 human promyelocytic leukemia cells and MOLT-4 human lymphocytic cells at IC_{50} concentrations of 31 and 48 μM , respectively (142). Genistein at higher concentrations (185 μM) promoted apoptosis within the treated HL-60 and MOLT-4 cell populations, whereas normal proliferating lymphocytes were unaffected by genistein at concentrations up to 739 μM . HL-60 and MOLT-4 cells treated with genistein were arrested at the S/G₂ boundary. In a subsequent study, genistein, at concentrations of 200 to 400 μM , was demonstrated to arrest progression of HL-60 cells in G₂ and to promote apoptosis independent of cell-cycle stage (243). Matsukawa et al. (183) demonstrated that genistein inhibited, in a concentration-dependent and reversible manner, progression of HGC-27 human gastric cancer cells in G₂/M. Interestingly, daidzein inhibited progression of this cell line in G₁. Therefore, it cannot be assumed that closely related isoflavones act through the same mechanisms to inhibit cell proliferation.

A number of reports indicate that isoflavones can induce differentiation of a variety of cell lines (reviewed in [244]). Genistein (37 μM) promotes differentiation of HL-60 human promyelocytic leukemia cells and K-562 human erythroid leukemia cells (245). Honma et al. (246) demonstrated that genistein and a second inhibitor of protein tyrosine kinase activity, herbimycin A, promote differentiation of K-562 cells and suggested this might occur either through inhibition of the tyrosine kinase encoded by the *c-abl* gene or the chimeric protein encoded by the *bcr/abl* oncogene, which results from a genetic translocation involving chromosomes 9 and 22. Genistein, at a concentration of 40 to 55 μM , effectively induced differentiation of mouse F9 embryonal carcinoma cells to cells displaying phenotypic features of parietal endoderm (247). Daidzein (37 μM) promotes differentiation of HL-60 cells while arresting cell cycle progression in G₁ (248). Although it has been suggested that induction of differentiation in these various cell systems results from inhibition of protein tyrosine kinases or topoisomerases, this has yet to be demonstrated conclusively.

Inhibition of Angiogenesis. Formation of new vasculature is required for a cancer to grow and metastasize. Consequently, much effort has been focused on identifying antiangiogenic agents that inhibit development and dissemination of tumors. Isoflavones, in particular genistein, have been identified as antiangiogenic factors contained in urine of healthy women consuming a diet high in fruits and vegetables (248). Genistein inhibits proliferation of bovine brain capillary endothelial cells in culture, whereas equol, daidzein, and O-desmethylangolensin are significantly less active in this regard. Genistein also displayed an inhibitory effect in an in vitro angiogenesis assay in which the ability of bovine microvascular endothelial cells to invade a collagen matrix serves as the surrogate indicator (249). Whether isoflavones, either consumed in the diet or administered by other means, are capable of modulating angiogenesis in vivo remains to be determined.

Modulation of Metabolism. Discussed above were data indicating that specific isoflavones can inhibit enzymes involved in estrogen metabolism. Effects of isoflavones on other metabolic processes are summarized in this section.

Isoflavones as Antioxidants. Much information suggests that reactive oxygen species play an important role in aging and cancer. Soy-derived isoflavones possess antioxidant activity (250). Genistein and, to a lesser extent, daidzein inhibit induction of H₂O₂ production by HL-60 cells treated with the tumor promoter TPA (251). In contrast, biochanin A had no effect on TPA-induced H₂O₂ production by HL-60 cells. Genistein, prunectin, and daidzein inhibit production of superoxide anion by xanthine oxidase, whereas biochanin A is ineffective in this regard (251). The investigators hypothesized that the antioxidant properties of genistein provide the mechanism for the antitumorigenic activity of this isoflavone in mouse skin during DMBA/TPA-mediated tumorigenesis.

Isoflavones as Inhibitors of Carcinogen Metabolism. In a search for natural products that inhibit metabolic activation of known carcinogens, Cassady et al. (252) identified biochanin A as the active component of an alcohol extract of red clover. Purified biochanin A was demonstrated to inhibit metabolic activation of benzo[a]pyrene (B[a]P) by approximately 50%. In a subsequent study, these investigators further defined the inhibitory effects of biochanin A on B[a]P metabolism and demonstrated that it significantly diminished the mutagenicity of B[a]P in a V79 cell-based assay (253). Biochanin A also inhibits the mutagenic effects of the direct-acting carcinogen *N*-methyl-*N*'-nitro-*N*-nitrosoguanidine in a TA100 bacterial assay (254). More recently, it has been demonstrated that treatment of mice with genistein and daidzein inhibits DMBA-induced sister chromatid exchange in bone marrow cells, suggesting that these isoflavones may reduce the amount of DNA damage resulting from DMBA treatment (255). Although the mechanisms through which isoflavones inhibit metabolic activation and mutagenesis have not been elucidated, each of these studies provides evidence of potential anticancer activity of isoflavones.

Occurrence

Isoflavones are broadly distributed within the plant and bacterial worlds. Leguminous plants such as soybean and clover contain large amounts of specific isoflavones. In plants, isoflavones exist primarily as conjugated glycosides. The isoflavone conjugates are hydrolyzed by glucosidases produced by the bacterial flora of the gut. The unconjugated isoflavones appear to be more readily absorbed from the gut than the conjugated forms. The structures of several biologically active isoflavones are illustrated in [Figure 81.10](#).

Common Name	Substituents			
	5	7	4'	5'
Daidzein	H	OH	OH	H
Genistein	OH	OH	OH	H
Formononetin	H	OH	CH ₃	H
Biochanin A	OH	OH	OCH ₃	H
Genistin	OH	O glucose	OH	H
Prunectin	OH	OCH ₃	OCH ₃	H
Prunetin	OH	OCH ₃	OH	H
Orobol	OH	OH	OH	OH
Tectorigenin	OH	OH	OH	H

Figure 81.10.

Phytoestrogens

Several classes of plant-derived chemicals possess estrogenic activity in mammalian species. Among these phytoestrogens, the isoflavones discussed above, have been most widely studied. Other phytoestrogens include lignans such as enterolactone and enterodiol, coumestans (e.g., coumestrol), and resorcyclic acid lactones (e.g., the fungal compounds zearalenone and zearalenol).

Epidemiologic and Clinical Studies

Several epidemiologic studies suggest that consumption of diets high in whole grains, fruits, and vegetables are associated with a relatively low risk of developing cancers at a variety of sites. Because individuals who consume diets high in whole grains, fruits, and vegetables consume large amounts of phytoestrogens, it has been hypothesized that the low risk of developing cancer is due in part to anticancer activities of various phytoestrogens ([256](#)). Studies focused on dietary isoflavones are discussed above. Summarized here are studies investigating other classes of phytoestrogens.

Enterolactone and enterodiol are present in human urine ([257](#), [258](#)). Although originally thought to be of gonadal origin, these compounds are now recognized to be derived from dietary sources ([256](#), [259](#)). Urinary excretion of the lignans enterodiol and enterolactone correlates with fiber consumption ([225](#), [260](#)). Moreover, Adlercreutz et al. ([225](#), [260](#)) demonstrated that urinary lignan excretion among various groups of women was lowest in the group with breast cancer, prompting the hypothesis that formation and adsorption of antiestrogenic lignans may protect against breast cancer. Although this hypothesis is supported by correlative data, it has yet to be directly verified.

Little information exists concerning the levels of lignans in the systemic circulation and tissues of humans. Dehennin et al. ([261](#)) reported plasma enterolactone concentrations (total) of 37 to 127 nM in a group of 6 men. Most of this lignan was conjugated.

Adlercreutz et al. (224) reported plasma enterolactone concentrations (total) of 10.4 to 74.1 nM (mean, 33.3 nM) in a group of 14 omnivorous women and 17.9 to 1078.2 nM (mean, 252.6 nM) in a group of 14 vegetarian women. Approximately 20 to 30% of total plasma enterolactone was either in the free or sulfated forms. Much lower levels of plasma enterodiol were observed in this study. Bioavailability of the various circulating lignans to peripheral tissues has not been assessed. Consumption of a diet supplemented with soy flour, red clover sprouts, and linseed, all of which contain substantial amounts of several phytoestrogens, promoted maturation of vaginal epithelial cells in a group of 23 postmenopausal women (262). Although the quantities and identities of the phytoestrogens consumed were not determined, these data nonetheless suggest that dietary phytoestrogens exert detectable estrogenic activity in the reproductive tract of the human female.

Laboratory Studies Using Animal Models

Enterolactone, administered subcutaneously, was unable to elicit an estrogenic response (stimulation of RNA synthesis) in the uterus of the immature rat (263). When administered concurrently with, or 12 hours before, 17 β -estradiol, enterolactone did not inhibit the ability of the estrogen to stimulate uterine RNA synthesis. When administered 22 hours prior to 17 β -estradiol, enterolactone partially inhibited induction of uterine RNA synthesis by 17 β -estradiol. The mechanism for this inhibition was not established, and Waters and Knowler did not conclude that the classic antiestrogenic mechanism involving competition for binding to the estrogen receptor was responsible for the observed partial inhibition (263). Based upon our present knowledge of the relative affinities of enterolactone and 17 β -estradiol for the estrogen receptor, it would appear that the dose of enterolactone administered by Waters and Knowler was inadequate to allow effective competition with 17 β -estradiol for binding to the receptor.

Coumestrol, incorporated into a semipurified diet at levels approximating those consumed by humans and fed for 4 days, elicited a significant trophic effect in the uterus of the immature female rat (264). In addition to stimulating uterine growth, coumestrol consumption increased the number of progesterone receptors in the uterus, anterior pituitary, and hypothalamus (264, 265). Coumestrol, either consumed in the diet or injected subcutaneously, did not antagonize the ability of 17 β -estradiol to increase uterine growth (266). Together, these data indicate that coumestrol displays estrogenic, as opposed to antiestrogenic, activities in the female rat.

Verdeal et al. (267) observed binding of coumestrol, zearalenone, and zearalenol to estrogen receptor (ER) in rat uterine cytosol. These investigators demonstrated that coumestrol, administered orally at doses of 0.1, 2, and 5 mg/day, was unable to support the growth of estrogen-dependent, DMBA-induced mammary cancers in Sprague-Dawley rats, suggesting that at this dose and route of administration, coumestrol was devoid of estrogenic activity. Interestingly, the orally administered coumestrol was similarly devoid of antiestrogenic activity. However, when administered by subcutaneous injection at a dose of 1.5 mg/day, coumestrol stimulated growth of these mammary tumors, indicating that this phytoestrogen exerts estrogenic activity in the rat mammary gland.

Mechanisms of Action

Regulation of Estrogen Receptor–Dependent Parameters in Cultured Cells. The abilities of various phytoestrogens to bind to the estrogen receptor (ER) have been well documented. A common method for examining binding of a potential ligand to the ER is to demonstrate that it effectively competes with 17 β -estradiol for the binding site on the receptor. It is often wrongly assumed or stated that an ability of a compound to compete with an endogenous estrogen such as 17 β -estradiol for binding to the ER is synonymous with that compound possessing antiestrogenic activity. For a ligand to be classified as an antiestrogen, the compound must bind to the ER yet lack estrogenic activity. We now review known biologic effects of phytoestrogen interactions with the ER.

Shutt and Cox (215) noted that coumestrol can bind to the ER and noted a correlation between the relative abilities of coumestrol, the synthetic estrogen diethylstilbestrol, and a variety of isoflavone phytoestrogens to bind to the ER and their uterotrophic potencies in vivo. A similar correlation was noted by Shemesh et al. (268).

Martin et al. (269) demonstrated that coumestrol, zearalenone, and zearalenol each bind to the ER in MCF-7 breast cancer cells, albeit with an affinity significantly less than that of 17 β -estradiol. Each of these compounds displayed estrogenic activity in MCF-7 cells, as evidenced by their abilities to stimulate proliferation of this cell line (269). Enterolactone also stimulates MCF-7 cell proliferation (212, 270). Welshons et al. (210) (Fig. 81.11) further demonstrated that zearalenol, zearalenone, coumestrol, and b-zearalenol behave as full agonists with respect to their ability to stimulate proliferation of MCF-7 cells cultured under estrogen-depleted conditions. Similar observations were reported by Mäkelä et al. (211). The latter study is noteworthy in that none of the phytoestrogens examined displayed antiestrogenic activity in the presence of 17 β -estradiol.

Figure 81.11. Dose-response curves for several of the estrogens. *MGA*, melengestrolacetate. (From Welshons WV, Rottinghaus GE, Nonneman DJ, et al. *J Vet Diagn. Invest* 1990;2:268–73, with permission.)

In contrast to studies discussed above (212, 270) that demonstrated a proliferative response of MCF-7 breast cancer cells to enterolactone, Mousavi and Adlercreutz (271) reported that enterolactone and 17 β -estradiol each inhibit the other's ability to stimulate proliferation of this cell line. In that study, 17 β -estradiol itself either failed to stimulate MCF-7 cell proliferation or simulated proliferation only weakly. The proliferative response to enterolactone was also small. Therefore, the validity of the stated conclusion must be questioned. Enterolactone and enterodiol have been demonstrated by Hirano et al. (272) to inhibit proliferation of ZR-75-1 human breast cancer cells. These investigators suggested that inhibition of proliferation may be due to inhibition of membrane-associated N⁺,K⁺-ATPase activity.

Coumestrol, zearalenone, b-zearalenol, and phloretin were demonstrated to enhance expression of an estrogen-responsive reporter plasmid (pERE/TK/CAT) in HeLa cells (216). This stimulation was inhibited by the antiestrogens ICI164384 and 4-hydroxytamoxifen. Moreover, no stimulation of expression was observed in the absence of cotransfected expression plasmid encoding the human ER. Together these data clearly indicate that these phytoestrogens exert their estrogenic activities by binding to and activating the ER. Although these phytoestrogens were less potent than 17 β -estradiol in this model system, coumestrol, zearalenone, and b-zearalenol were each more potent than the isoflavone phytoestrogens genistein, daidzein, and biochanin A. Mäkelä et al. (211), using a similar transfection assay, demonstrated that coumestrol and zearalenone exert estrogenic activities that are mediated through the ER.

Modulation of Estrogen Metabolism. Enterolactone and, to a lesser extent, enterodiol inhibit aromatase activity in microsomes prepared from human placenta (226). Inhibition by enterolactone is competitive. These lignans also inhibit aromatase activity in cultured preadipocytes (228) and JEG-3 human choriocarcinoma cells (226). These data suggest that certain lignans at micromolar concentrations may inhibit production of estrogens.

Another study (211) indicates that different phytoestrogens may inhibit 17 β -HSOR in an isoform-specific manner and thereby inhibit conversion of estrone to 17 β -estradiol.

Occurrence

The lignans enterolactone and enterodiol have been identified in human urine. They are formed from plant lignans matairesinol and secoisolariciresinol by intestinal flora (256, 259). Lignans are contained in whole grains, beans, and peas (269). Although not widely consumed by humans, flax seed contains the highest amount of lignan of any plant source examined (273). Coumestrol is contained in a variety of legumes. Zearalenone and zearalenol are produced by the fungus *Fusarium graminearum*. Structures of some of these common phytoestrogens are shown in Figure 81.12.

Figure 81.12. Some common phytoestrogens and metabolites.

Isothiocyanates

Occurrence

Isothiocyanates are common constituents of cruciferous vegetables (274). Volatile isothiocyanates are released from thioglucosides in vegetables and contribute to the distinctive odor and flavor of cruciferous vegetables. Allyl isothiocyanate was identified nearly 50 years ago as particularly prevalent in cabbage (274). Widely used by the food industry, it is the component that gives the horseradish bite to brown mustard (275). Sulphoraphane was recently isolated from broccoli by following its potent induction of phase 2 detoxication enzymes in cultured mouse hepatoma cells (276). Phenethyl isothiocyanate is abundant in water cress (277).

Laboratory Studies

More than 20 natural and synthetic isothiocyanates have been studied for their ability to prevent carcinogenesis, as was comprehensively reviewed (278). Isothiocyanates are generally effective in cancer prevention when administered near the time of carcinogen treatment, suggesting that their main mode of action is to enhance detoxication and inhibit activation pathways. Early investigations of the anticarcinogenicity of isothiocyanates demonstrated inhibition of liver cancer in animals treated with a-naphthyl and b-naphthyl isothiocyanate prior to, or with, 3-methyl-4-dimethylaminoazobenzene (DAB) (279).

In recent years, laboratories have focused on intervention in lung and nasal cavity carcinogenesis in rats and mice by a variety of isothiocyanates (280). The naturally occurring phenethyl isothiocyanate and benzyl isothiocyanate have been extensively studied as inhibitors of tobacco-specific nitrosamine (4-(methylnitrosamino)-1-3-pyridyl)-1-butanone; NNK) and polycyclic hydrocarbon (benzo[a]pyrene; BaP) carcinogenesis (278). Phenethyl isothiocyanate was effective in

the inhibition of lung tumorigenesis by NNK, and butyl isothiocyanate was effective against BaP-induced cancer (278).

Prevention of mammary carcinogenesis was reported for sulphoraphane and related norbornyl isothiocyanates (281, 282). Oral intubation of these compounds near the time of treatment with 9,10-dimethyl-1,2-benzanthracene inhibited development of mammary tumors. Earlier studies demonstrated inhibition of DMBA-induced mammary tumors in rats pretreated with benzyl isothiocyanate, phenethyl isothiocyanate, and phenyl isothiocyanate (283). Mixed results were observed in prevention studies of esophageal carcinogenesis (284, 285). In contrast to studies at other sites, studies of colon cancer using the azoxymethane-rat model reported no inhibition of foci of aberrant crypts in rats treated with phenyl isothiocyanate, and an enhancement of small intestinal and colon carcinomas was observed in rats fed 6-phenylhexyl isothiocyanate (286). The latter study suggested that 6-phenethyl isothiocyanate promotion of colon carcinogenesis may be due to elevated eicosanoid synthesis. Because of the extensive consumption of allyl isothiocyanate, the National Toxicology Program conducted a bioassay of this compound at maximally tolerated doses in rats and mice (275). No evidence of carcinogenicity was observed in mice or in female rats. In male rats, a small but statistically significant rate of transitional cell papilloma of the urinary bladder was observed (275). Since excessive doses of the compound were used in the bioassay, it is improbable that allyl isothiocyanate presents any risk to humans at normal dietary levels.

Mechanisms of Action

Cancer prevention by isothiocyanates generally requires that the isothiocyanate treatment be administered at or near the time of treatment with carcinogen (278). This observation predicted that isothiocyanates would modify metabolic pathways for carcinogen activation and/or detoxication and elimination. Indeed, both inhibition of cytochrome P450-mediated activation and enhancement of glutathione sulfatransferase-mediated detoxication have been demonstrated for a wide variety of isothiocyanates. However, data showing a block in cell cycle progression in cells treated with isothiocyanates (287) suggests that isothiocyanates may be able to prevent cell proliferation and thus inhibit later events in cancer.

An extensive series of investigations demonstrated that isothiocyanates inhibit oxidative metabolism of a number of carcinogens and result in reduced DNA damage. Studies focused on liver metabolism indicated that phenyl isothiocyanate and phenethyl isothiocyanate inhibited α -hydroxylation of *N*-nitrosodimethylamine and of the tobacco-specific nitrosamine NNK. This result was associated with reduced DNA methylation (288). In addition, benzyl isothiocyanate and benzyl thiocyanate suppressed DNA synthesis and cell proliferation induced by several carcinogens in the liver (289). Esophageal tumorigenesis by *N*-nitrosomethylbenzylamine and DNA methylation were inhibited by phenethyl isothiocyanate in parallel studies (284). Inhibition of DNA methylation is shown in [Figure 81.13](#). Studies have assessed isothiocyanate effects on tobacco carcinogenesis in the oral cavity and lung. A variety of isothiocyanates inhibited metabolic activation of NNK in the lung and oral cavity (290). Structure activity studies suggested that 4-phenylbutyl isothiocyanate and 6-phenylhexyl isothiocyanate were the

most effective inhibitors of NNK activation and that they were more effective than phenethyl isothiocyanate. These observations may be useful in designing increasingly effective inhibitors of tobacco-induced cancer.

Figure 81.13. Effect of dietary phenethylisothiocyanate (*PEITC*) on nitrosomethylbenzylamine (NMBA)-induced DNA methylation. Groups of 20 rats were administered control or experimental diets for 14 days before administration of [³H-methyl]NMBA. Animals were killed 24 h later. Esophageal 7-methylguanine and O⁶-methylguanine were isolated and analyzed. (Reprinted from Morse MA, Zu H, Galati AJ, et al. *Cancer Lett* 1993;72, 1–2, 103–110, with permission.)

Isothiocyanate inactivates and inhibits the enzymes necessary for NNK activation (291). Phenyl isothiocyanate was particularly effective in the inhibition of hepatic demethylase (cytochrome P450-2E1 dependent) (292) and was a potent inhibitor of cytochrome P450-1A1, which is involved in formation of oxidative metabolites of NNK (298). Recent studies with the broccoli constituent sulphoraphane demonstrated its ability to inhibit cytochrome P450-2E1 (294). Human studies assessing debrisoquine metabolism as an indicator of cytochrome P450-2D6 activity indicated inhibition by phenethyl isothiocyanate in vitro with human liver microsomes, but no evidence of inhibition was observed in the in vivo study (295).

Several lines of evidence support a role of isothiocyanates in induction of phase II metabolism, which results in reduced toxicity and accelerated elimination of many toxic and carcinogenic substances. For example, early studies reported an increase in glutathione S-transferase, the enzyme responsible for conjugation of a wide variety of electrophiles with the sulfhydryl group of glutathione, in the mouse forestomach following dietary administration of benzyl isothiocyanate (296). More-recent studies demonstrated that compounds that induce glutathione transferase also induce NAD(P)H:(quinone-acceptor) oxidoreductase (297), another important enzyme defense against toxicity and carcinogenicity of chemicals. Furthermore, isothiocyanates including sulphoraphane, benzyl isothiocyanate, allyl isothiocyanate, and phenethyl

isothiocyanate are substrates and inducers of human glutathione transferase (298).

Recent investigations demonstrated the induction of c-Jun N-terminal kinase by isothiocyanates in ovarian HeLa cells and in fibrosarcoma cells (HT1080) (299). Phenethyl isothiocyanate treatment resulted in the most-sustained induction, while 3-phenylpropyl and 4-phenylbutyl isothiocyanate stimulated transient activation. The authors speculate that c-Jun N-terminal kinase induction may be involved in induction of phase II detoxication enzymes. However, it is not clear if the cellular concentrations of the isothiocyanates in this investigation were comparable to concentrations achieved in vivo.

Diallylsulfide

Epidemiology of Allium Foods and Cancer

Allium vegetables are members of the lily family and include garlic, onions, leeks, scallions, and chives (300). These foods share the common property of generating organic molecules that incorporate sulfur atoms when the plant is cut or cooked. Many different organosulfur compounds are present in allium foods. For example, garlic contains diallyl sulfide, allyl methyl disulfide, allyl methyl trisulfide, S-allyl cysteine, diallyl trisulfide, and others (301). Allium foods have been used for centuries for their antibiotic and antithrombotic activity. They have also been shown, in animal models, to have anticarcinogenic properties (302).

Studies in human populations have evaluated the incidence of certain cancers in subjects relative to their consumption of allium vegetables. As with the micronutrients that have been studied for their chemopreventive effect, allium vegetables yield mixed results in epidemiologic cancer research. Two retrospective studies, conducted in the province of Shandong, China, which has an exceptionally high rate of stomach cancer mortality, showed that subjects who consumed garlic had a tenfold lower risk for gastric cancer than those who did not (303).

Haenszel et al. (304) compared stomach cancer risk in Hawaiian Japanese populations consuming native foods and Western foods. This study found an increased cancer risk among subjects who consumed dried and salted fish and pickled vegetables and a decreased risk among those who consumed Western vegetables, including onions. In addition to the overall lower relative risk for stomach cancer in onion consumers, the investigators found that risk declined further as the frequency of onion consumption increased.

Another investigation, in which consumption of garlic and onions together was studied, found that relative risk for gastric cancer declined as frequency of intake increased (305). This study also found that the reduced risk associated with consumption of raw onions did not exist for cooked onions, although risk was significantly decreased for consumption of cooked garlic.

In contrast to epidemiologic studies demonstrating decreased gastric cancer risk with

garlic and onion consumption, a case-control study of a Japanese cohort (306) found that consumption of certain vegetables, including onion, was associated with a significantly elevated relative risk for stomach and colorectal cancers. The increased cancer risk associated with onion consumption remained even when variables for education, smoking, alcohol, and high-salt food consumption were taken into account (306). Although most epidemiologic evidence supports a role for allium vegetables in decreasing risk for gastric and colorectal cancers, studies that show either no change or an increased cancer risk suggest the need for further investigation, particularly into possible mechanisms of action for this compound as a chemopreventive agent.

Chemoprevention by Allium Compounds in Animal Models

Administration of high doses of garlic compounds to rodents has demonstrated significant inhibition of chemically induced mammary, colon, esophageal, and other cancers in these animal models. The first study to show that dietary garlic increased latency and decreased mammary tumor incidence in rats provided organosulfur compounds (OGCs) as garlic powder added at levels of 2 and 4% to semipurified diet (307). Although specific organosulfur compounds were not identified, a dose-responsive inhibition of tumorigenesis was demonstrated following consumption of the garlic in the rat diet. Furthermore, inhibition was seen in both the initiation and promotional phases of tumor development. Similar results were obtained in subsequent studies by Amagase et al. using 20 g/kg garlic powder in semipurified diets (308, 309). These studies also established an inhibition of DMBA-DNA adduct formation in mammary tissue in animals fed the garlic-supplemented diets.

In contrast to the findings of Amagase and Milner (308), Pereira and Khoury (310) found no significant inhibition of cancer foci in the colons of mice fed 0.1% diallyl sulfide in semipurified diets. The diallyl sulfide treatment was begun 1 week prior to administration of carcinogen. Tumor inhibition by the OGCs in garlic may be the result of interaction between other compounds in the garlic powder that were not present in the diallyl sulfide-supplemented diet. Also, the level of diallyl sulfide in the diet (0.1%) may have been too low to achieve an inhibitory effect.

In studies by other investigators, garlic extracts have been administered by intragastric gavage. Sumiyoshi and Wargovich (311) and Wargovich et al. (312) administered diallyl sulfide and other OGCs in doses of 50 400 mg/kg body weight to rats in serial gavages prior to injection with carcinogen. This experimental protocol resulted in a significant decrease in chemically induced colon tumor incidence in the rats when diallyl sulfide and other lipophilic OGCs were used.

Gastric gavage delivers the OGC in a concentrated form directly to the absorptive surface of the gut. Whether this method of delivery is more effective than dietary administration has not been established. Also, dosage and timing in intragastric OGC administration can affect the outcome of chemically induced tumorigenesis. Takada et al. found that high doses (up to 150 mg/kg) of DAS and related OGCs administered intragastrically during the promotional stage increased rather than decreased the number of tumor foci and nodules in hepatic tissue of mice (313). Such varied outcomes in chemopreventive effects of OGCs suggests that these compounds function quite

differently as food components than as purified compounds administered in supraphysiologic doses.

Mechanisms of Inhibition of Tumorigenesis by Organosulfur Compounds

Organosulfur compounds may mediate tumor inhibition through various pathways. Two notable mechanisms that have been studied are the induction of cytochrome p450 enzymes and induction of glutathione S-transferase. Cytochromes p450 are a group of microsomal enzymes found in most tissues but predominantly in the liver (314). They are involved in hydroxylation reactions that result in increased solubility in metabolism and excretion of toxic compounds. However, some compounds (e.g., carcinogens) enter the p450 pathway and become activated rather than detoxified (314).

In the case of agents such as benz[a]pyrene that form DNA adducts, inhibition of certain p450 enzymes results in decreased tumorigenicity (91). However, not all organosulfur compounds are effective p450 inhibitors. Furthermore, specific OGCs inactivate certain p450 species following induction by specific carcinogens. For example, diallyl sulfoxide, diallyl sulfone, and diallyl sulfide inactivate the p450 isoform 2E1 induced by NNK and DMH, although at different rates (91).

Previous research using carbon disulfide established that p450 inactivation is due to the sulfur compound (329). This mechanism may in part account for the decreased tumor inhibitory properties of onion, which contains saturated (*n*-propyl) substituents, compared with garlic with unsaturated alkyl groups (330).

The glutathione S-transferases (GSTs) catalyze the conjugation of glutathione to electrophilic species produced from cytochrome p450 activity. These transformed metabolites are rendered less toxic and more soluble for excretion (317). GST activity has been measured following administration of chemical carcinogens. In the presence of OGCs such as diallyl sulfide, diallyl trisulfide, and others, GST activity is increased and tumor incidence is decreased (311). Glutathione may exert its inhibitory effect by conjugating carcinogenic compounds and rendering them unavailable to bind to DNA and initiate damage. However, GST activity is clearly only one of many components of the cancer inhibitory effect of diallyl sulfide and other OGCs.

Chemoprevention with Garlic Extract

Concentrated extract of fresh garlic has been used in rodent models to demonstrate inhibition of tumor growth from injected transplantable tumors and inhibition of chemically initiated and promoted tumors. Garlic was administered to mice either orally or peritoneally concomitantly with injection of tumor cells or chemical initiation and promotion (318), and survival time and tumor incidence in the mice were determined. Interestingly, garlic extract was only effective in increasing survival and decreasing tumor incidence in the group that received orally administered extract. In another study, garlic extract was injected intraperitoneally simultaneously with the cytotoxin cyclophosphamide, followed by injection of tumor cells 14 days later (319). This group was compared with mice that received only the tumor cells. The animals that received injected garlic extract, cyclophosphamide, and tumor cells survived longer than those

receiving injected garlic extract and tumor cells only. The results of the study suggest that the garlic extract could protect normal cells from the cytotoxic agent but had little or no effect on inhibiting tumor growth.

Tea and Tea Polyphenols

Epidemiologic and Clinical Studies

Epidemiologic studies on the relationship between tea consumption and human cancers have not provided clear evidence for cancer prevention by tea. However, as discussed below, studies in experimental animals and cultured cells provide strong evidence for cancer prevention by tea and its constituent polyphenols (reviewed in [320]). A number of the human studies focused on esophageal cancer because early reports indicated a causal role for tea consumption. In general, consumption of tea at high temperature, near boiling, was associated with esophageal cancer in some studies, while consumption at more moderate temperatures was protective or had no effect (320). Tea consumption was suggested to increase, decrease, or have no effect on stomach, lung, breast, colon and rectum, and kidney cancer in epidemiologic investigations (320). Urinary bladder and nasopharynx cancer were not associated with tea intake.

In a recent prospective study conducted with the Netherlands Cohort Study on Diet and Cancer, black tea consumption was not associated with rates of colorectal cancer, was positively associated with breast cancer, and was inversely associated with stomach and lung cancers. However, tea drinkers tended to smoke less and consume more fruits and vegetables. When the data were corrected for these covariants, the protective association disappeared, indicating that tea itself was not related to these cancers (321). Since green tea contains higher concentrations of many of the compounds suspected to protect against cancer, it is possible that human study designs must clearly distinguish the influences of green and black teas. Furthermore, some of the studies indicating that tea consumption was protective were conducted in areas of the world where green tea is more frequently consumed (322). It is possible that these populations are also more prone to micronutrient deficiencies, and thus tea (green or black) may be more effective in cancer prevention in populations that are deficient in micronutrients. In summary, there is no conclusive evidence that consumption of tea at normal temperature protects against cancer, and consumption at excessively high temperature may be a risk factor for esophageal cancer.

Laboratory Studies

Investigations with experimental animals provide strong evidence of cancer prevention properties for tea (320). Green or black tea, polyphenol-rich extracts from tea, or specific tea polyphenolic compounds have been shown to inhibit both chemically and ultraviolet light–induced skin cancer and chemically induced cancer of the esophagus, lung, forestomach, liver, colon, small intestine, breast, pancreas, and prostate (reviewed in [320]). Inhibition of skin carcinogenesis by tea and tea constituents has been extensively studied. Both topical and oral application of green tea or black tea extracts were effective in preventing carcinogenesis by DMBA and TPA or by UV light (320). Inhibition of UV light–induced skin tumors by black tea is shown in [Figure 81.14](#).

Furthermore, all stages of chemical carcinogenesis, initiation, promotion, and conversion of papillomas to carcinomas were inhibited by tea.

Figure 81.14. Inhibitory effect of oral administration of two doses of black tea, 0.63% (*open circles*) and 1.25% (*closed circles*), in the drinking water on the formation of UVB-induced skin tumors in mice previously initiated with DMBA; controls (*triangles*). Female SKH-1 mice were initiated with 200 nmol of DMBA. One week later, the mice were given gradually escalating doses of tea in the drinking water for 1 week, followed by full-strength tea for 1 week before and during treatment with UVB (30 mJ/cm²) twice weekly for 31 weeks. Each value is the mean from 29–30 mice; bars, SE. (From Wang ZY, Huang M-T, Con Y-R, et al. *Cancer Res* 1994;54:3428–35. *Br J Cancer* 1994;69:879–82, with permission.)

Oral administration of tea also reduced the number of spontaneous lung metastases from mouse Lewis lung carcinoma cells (323). Parallel in vitro studies demonstrated inhibition of Matrigel invasion, a proxy assay for tissue invasion, in the presence of green tea infusion or in the presence of gallate-containing catechins (323).

Most studies on tea inhibition of experimental carcinogenesis have focused on green tea and green tea constituents, probably because many of the chemicals suspected to be important in cancer prevention by tea are present in higher concentration in green tea. For example, catechins such as epigallocatechin and epigallocatechin-3-gallate have been shown to have cancer preventive properties similar to those of tea or phenolic-rich extracts from tea (320). Green tea extract is 30 to 42% catechins, while black tea is only 3 to 10% catechins (320) (Table 81.2). However, some studies found similar potency in cancer prevention by green and black tea (324) and others found that cancer prevention by tea did not appear to be consistently related to the presence of the major catechin, (-)-epigallocatechin-3-gallate (325). These results suggest that many components of green and black tea may have cancer prevention properties.

Components	Green Tea	Black Tea
Catechins	30-42	3-10
Flavonols	5-10	6-8
Other flavonoids	2-4	—
Theogallin	2-3	—
Galic acid	0.5	—
Quinic acid	2.0	—
Theanine	4-6	—
Methylxanthines	7-9	8-11
Theaflavins	—	3-6
Thearubigens	—	12-18

Table 81.2 Principal Polyphenolic Components Present in Green and Black Tea (measured in weight % of extract solids)

Mechanisms of Action

A major barrier to understanding the mechanisms of cancer prevention by tea and its constituents is that the particular compounds that contribute to cancer prevention by tea and tea extracts are not well identified. Although several components have been isolated and their activities have been studied, it appears that many compounds contribute to cancer prevention by tea. Irrespective of this barrier, a wide range of activities have been identified for tea and its constituents. Augmentation of the antioxidant defense system and phase II metabolism was reported by Khan et al. (326). Dietary administration of a 0.2% phenol-rich fraction from green tea for 30 days increased the activities of glutathione peroxidase, catalase, and quinone reductase in the small bowel, liver, and lungs. In addition, glutathione S-transferase activity was elevated in the small bowel and liver. In studies designed to assess the inhibition of colon cancer by green tea and green tea catechins, Pingzhang et al. (327) observed increased expression of colonic superoxide dismutase by immunohistochemistry. Oxidative metabolism of the tobacco-specific nitrosamine NNK and DNA methylation by lung microsomes was inhibited by tea extracts (328). The catechin (-)-epigallocatechin-3-gallate was the most effective component of the tea extracts. This compound also inhibited the catalytic activity of several p450 enzymes (328). However, in vivo studies did not provide evidence for the importance of the inhibition by tea of metabolism and DNA alkylation in vivo.

Pretreatment of mouse skin with polyphenolic-rich tea extracts inhibited epidermal inflammation induced by the phorbol ester tumor promoter TPA (329). TPA-induced edema, hyperplasia, and neutrophil infiltration were all inhibited by green tea polyphenols (329). Further research by the same laboratory demonstrated that induction of the inflammatory cytokine interleukin-1a by a number of agents that induce epidermal inflammation was inhibited by several green tea polyphenols (330).

Monoterpenes

Laboratory Studies

Experimental Mammary Tumorigenesis. Consumption of orange peel oil (5%), of which the monoterpene limonene is the predominant component, inhibited development of mammary tumors in Sprague-Dawley rats treated with DMBA (331). In that experiment, orange peel oil was fed to the rats beginning 1 week after treatment with DMBA. D-Limonene, fed to female Sprague-Dawley rats at levels of 0.1 and 1.0% (w/w) beginning 1 week before, and continuing for 27 weeks after, administration of DMBA, inhibited development of mammary tumors in a dose-dependent manner, as evidenced by an increased latency (332) (Fig. 81.15). When consumed for a 1-week period bracketing DMBA treatment, limonene (5%) increased latency and reduced the number of tumors per animal (333). Limonene consumption, beginning 1 week before initiation with DMBA and continuing for the duration of a 25-week promotion/progression phase, reduced the number of tumors per animal but had no effect on latency. These data indicate that limonene exerts anticarcinogenic effects during both the initiation and promotion/progression phases of DMBA-induced mammary tumorigenesis. Also, limonene inhibits development of mammary tumors during the promotion/progression phase in female Wistar-Furth rats treated with the direct-acting carcinogen nitrosomethylurea (NMU) (334).

Figure 81.15. Appearance of first tumor (1 × 1 mm) in rats treated with DMBA (week 0) and fed diets containing 0 ppm (*triangles*), 1000 ppm (*X*), or 10,000 ppm (*squares*) d-limonene. The diets were fed for 1 week prior to and 27 weeks after DMBA. (From Elegbede JA, Elson CE, Qureshi A, et al. *Carcinogenesis* 1984;5:661–4. *J Natl Cancer Inst* 1976;56:1237–42, with permission.)

Consumption of a diet containing limonene (10% of diet by weight) promotes regression of DMBA-induced mammary cancers in female F2 progeny resulting from a cross between F344 and Wistar-Furth rats (335). This observation has been confirmed and

extended by Jirtle et al. (336). These data suggest that limonene may have therapeutic potential. Regressing tumors displayed increased levels of immunoreactive transforming growth factor- β 1 (TGF- β 1) and mannose 6-phosphate/insulin-like growth factor II receptor (M6P/IGF-II receptor). Regressing tumors in limonene-treated animals showed approximately twice as much mRNA encoding the M6P/IGF-II receptor as nonregressing tumors from control animals or nonregressing tumors in limonene-treated animals. No effect of limonene on TGF- β 1 mRNA was observed. These investigators proposed that the observed increase in M6P/IGF-II receptor expression might enhance conversion of latent TGF- β 1 to its active form. Because TGF- β 1 exerts an inhibitory effect on mammary cell proliferation (337), Jirtle et al. suggested (336) that the increase in TGF- β 1 observed in association with regressing tumors might be the mechanism through which regression occurs. More recently, limonene (5–10% w/w) was shown to promote regression of NMU-induced mammary cancers in female Ludwig/Wistar/Olac rats (338).

Other monocyclic monoterpenes also display anticancer activities in the rat mammary gland. Russin et al. (339) demonstrated that dietary (-)-menthol (1% w/w) during the initiation phase significantly inhibits DMBA-induced mammary tumorigenesis in female Sprague-Dawley rats. Carveol and uroterpenol, two hydroxylated derivatives of limonene identified in urine of rats and humans, and sobrerol, a derivative of α -pinene, inhibit DMBA-induced mammary tumorigenesis during the initiation phase (340). When fed to female Wistar-Furth rats at a level of 1% beginning 2 weeks before, and continuing for 1 week after, treatment with DMBA, uroterpenol, and sobrerol significantly increased latency, whereas all three monoterpenes significantly decreased tumor multiplicity. Of these compounds, sobrerol appeared most active in inhibiting mammary cancer development in DMBA-treated animals. Perillyl alcohol, a hydroxylated analogue of limonene, has recently been shown to be more potent than limonene in promoting regression of DMBA-induced mammary cancers (341). Relative to limonene, perillyl alcohol produced higher circulating levels of perillic acid and dihydroperillic acid, suggesting that the differing potencies of limonene and perillyl alcohol may result from pharmacokinetic factors.

Experimental Gastric Tumorigenesis. When administered by oral intubation 1 hour prior to *N*-nitrosodiethylamine (NDEA), D-limonene and D-carvone markedly inhibited development of forestomach papillomas and carcinomas in female A/J mice (342).

Experimental Lung Tumorigenesis. Limonene, administered by weekly intravenous injections, inhibited spontaneous development of lung adenomas in A/J mice, whereas both limonene and orange oil inhibited dibenzpyrene (DBP)-induced lung tumorigenesis (343). Wattenberg (342) demonstrated that limonene and carvone, administered by oral intubation 1 hour prior to NDEA, inhibited development of pulmonary adenomas in A/J mice. Together, these data suggest that monoterpenes may inhibit lung tumorigenesis at both the initiation and promotion/progression stages.

Experimental Skin Tumorigenesis. Orange oil, as well as other citrus oils, promotes development of skin papillomas in strain 101 mice treated topically with DMBA (344). In this experiment, mice were treated weekly by topical application of the citrus oils at the site of carcinogen treatment. Skin tumors did not develop in response to treatment with

orange oil in mice that were not pretreated with DMBA, indicating that the orange oil itself was devoid of carcinogenic activity. A terpene-containing fraction of orange oil was shown to contain the active skin tumor-promoting agent. Elegbede et al. (345) demonstrated that orange peel oil and limonene, when applied topically, are each capable of weakly promoting development of skin tumors in CD-1 mice following initiation with DMBA. In contrast, neither orange peel oil nor limonene promoted DMBA-induced skin tumors when consumed in the diet.

Van Duuren and Goldschmidt (346) observed a slight inhibitory effect of limonene on DMBA-induced skin tumorigenesis in ICR/Ha Swiss mice when the two compounds were administered together. Similar results were reported by Gould et al. (347) who observed a slight, but not statistically significant, inhibitory effect of limonene on DMBA-induced skin tumorigenesis in CD-1 mice when limonene was administered for a total of 6 days flanking DMBA treatment. From these data it would appear that limonene, depending upon when and how it is administered, can either promote or inhibit DMBA-induced skin tumorigenesis.

Experimental Hepatocarcinogenesis. Mills et al. (348) recently demonstrated that consumption of perillyl alcohol (1–2% w/w) inhibits development of diethylnitrosoamine (DEN)-induced liver tumors in the male F344 rat. Tumor mass was markedly smaller in animals consuming perillyl alcohol than in animals fed the control diet. Although consumption of perillyl alcohol had no effect on proliferation of normal and neoplastic liver cell populations, the number of apoptotic cells within the tumors was significantly increased in the animals fed perillyl alcohol, suggesting that this monoterpene may inhibit hepatocarcinogenesis by promoting apoptosis within the tumor cell population.

Experimental Pancreatic Tumorigenesis. It was recently demonstrated that consumption of perillyl alcohol (3% w/w) markedly inhibits growth of a pancreatic cancer cell line (PC-1) maintained subcutaneously in male Syrian hamsters (349). Perillyl alcohol also inhibited proliferation of PC-1 (hamster pancreatic ductal carcinoma cells harboring activating mutation in the *K-ras* gene) and MIA PaCa-2 cells (human pancreatic carcinoma cell line harboring mutations in the *K-ras* and *p53* genes) maintained in culture.

Other Experimental Cancers. Orange oil administered to C57BL/6 mice by subcutaneous injection at the same site 24 hours following the carcinogen dibenzpyrene markedly inhibited development of subcutaneous fibrosarcomas (343). Limonene and a mixture of limonene and limonene hydroperoxide also inhibited DBP-induced tumor development in this animal model.

Mutations in the *p53* tumor suppressor gene are common in human malignancies. Mice in which both alleles of the *p53* gene have been inactivated by insertional mutagenesis rapidly and spontaneously develop a variety of tumors, including lymphomas. Hursting et al. (350) recently examined the effect of limonene consumption (7.5% w/w) on tumorigenesis in *p53*-knockout mice. Although limonene consumption slightly inhibited development of lymphoma, other nonhematopoietic tumors developed, and survival was not prolonged.

Clinical Studies

Although phase I clinical studies are in progress, information about the effectiveness of monoterpenes as therapeutic or chemopreventive agents in humans is not available. Crowell et al. (351) performed a study to assess toxicity and metabolism of limonene in human subjects. Consumption of limonene (100 mg/kg body weight) did not result in detectable toxicity. The ingested limonene was extensively metabolized within 4 hours, with the major circulating metabolites being perillic acid, dihydroperillic acid, and limonene-1,2-diol. Lesser metabolites included the methyl esters of perillic acid and dihydroperillic acid.

Mechanisms of Action

Chemically induced mammary cancers in rats are often associated with activating mutations in the *c-Ha-ras* gene (352). Moreover, the ability of p21 *ras* to transform NIH3T3 cells requires that this protein be farnesylated (353). Limonene has been demonstrated to inhibit, in cultured NIH3T3 cells, isoprenylation of several proteins of 21 to 26 kDa, including p21 *ras*, the product of the *c-Ha-ras* protooncogene (354). Perillic acid and dihydroperillic acid, both major circulating metabolites of limonene in the rat and human (351, 355), also inhibit protein isoprenylation in NIH3T3 cells (354). Crowell et al. (356) evaluated the abilities of a number of monoterpenes to inhibit protein isoprenylation in NIH3T3 cells. The following structure-activity relationship was observed in that study: monohydroxyl = ester = aldehyde > thiol > acid = diol = epoxide > triol = unsubstituted. Moreover, the monoterpenes displayed the same structure-activity relationship when their abilities to inhibit proliferation of HT-29 human colon carcinoma cells was examined. More recently, Gelb et al. (357) demonstrated that limonene, perillyl alcohol, and perillic acid weakly inhibit protein farnesyl transferase and protein geranylgeranyl transferase, whereas a minor metabolite, perillic acid methyl ester, markedly inhibits these enzymes. Based on these data, Gould and colleagues suggested that limonene and/or its circulating metabolites might exert their anticancer activities by inhibiting farnesylation of p21 *ras*, thereby modulating the intracellular localization and activity of this protein. Ruch and Sigler (358) demonstrated that limonene, perillyl alcohol, perillic acid, menthol, and pinene each inhibit proliferation of a *v-Ha-ras*-transformed rat liver epithelial cell line (WB-*ras*). However, inhibition of cellular proliferation by these monoterpenes could not be attributed to inhibition of *ras* farnesylation.

In the rat, limonene consumption has been shown to inhibit formation of DMBA-DNA adducts in the liver, spleen, kidney, and lung; increase urinary excretion of DMBA and DMBA-derived metabolites; and induce the levels and activities of hepatic cytochrome P450s of the CYP2B and CYP2C families as well as the activity of epoxide hydratase (EH) (340, 359). Urinary excretion of DMBA and its metabolites is also increased by consumption of sobrerol (340). Paradoxically, limonene and sobrerol increased formation of DMBA 3,4-dihydrodiol, which is considered by many to represent the proximate carcinogen of DMBA (359). Although these data indicate that limonene modulates the activities of phase I metabolizing enzymes, the relationship between

these enzymes and the anticancer effects of this monoterpene are not clear.

Consumption of diets containing limonene and sabinol resulted in increased activities of the phase II enzymes GST and uridine diphosphoglucuronosyl transferase (UDPGT) in the liver (360). Consequently, the investigators suggested that induction of phase II enzymes may be responsible for much of the anticancer actions of these monoterpenes during initiation of mammary tumorigenesis by DMBA.

ACKNOWLEDGMENTS

The authors appreciate the excellent secretarial and word processing support provided by Ms. Mary Doty, the editing assistance of Ms. Robin Amerine, and generation of structures for figures by Dr. Barry Gold.

Abbreviations: **DMBA**—7,12-dimethylbenz[*a*]anthracene; **MNU**—methylnitrosourea.

The designation cancer includes many disease conditions characterized by growth of cells that have lost their usual growth regulation and thus multiply and spread. The localized and/or distant spread interferes with the function of adjacent organs and often has detrimental systemic effects. Potent factors produced by tumor cells or by other body cells in reaction to the cancer may also have profound local and systemic effects.

HEALTH BURDEN OF CANCER

This chapter reviews the many effects of malignant diseases on the nutritional state of the patient and the roles of diet and nutrition in the management of such patients. The genetic basis of cancer is reviewed in [Chapter 78](#) and the contributions of diet to cancer development and its prevention are reviewed in [Chapter 79](#); chemoprevention of cancer is considered in [Chapter 81](#).

Mortality from Cancer

The estimated number of deaths from cancer in 1996 in the United States was 554,740, up from 331,000 in 1970 and 514,000 in 1991 (1). The total number of deaths from cancer was second only to that from cardiovascular disease (2), but this gap has been narrowing for both men and women in the United States (3) ([Table 82.1](#)). This trend is attributable to the continuing decline in deaths from ischemic heart disease and stroke. Mortality rates from cancer in the United States in persons below the age of 45 and especially below 20 years decreased markedly for men and women (4) but were more than made up by mortality in older groups prior to 1990. In 1992, cancer accounted for 23.9% of all deaths, compared with 33% of deaths from heart disease (2).

Cause	Year	Men		Women	
		Percentage of All Deaths	Probability of Dying from Cause (%)	Percentage of All Deaths	Probability of Dying from Cause (%)
Cancer	1955	14.5	14.6	17.5	15.5
	1986	22.7	22.5	21.9	19.5
IHD	1955	33.1	35.8	27.9	32.3
	1986	24.8	26.4	24.6	26.5

Data from Lopez AD. *Ann NY Acad Sci* 1990;609:70, 72 (Tables 1 and 2).

Table 82.1 Comparative Mortality in the United States from Cancer, Ischemic Heart Disease (IHD), and Stroke in 1955 and 1986

Death rates from cancer at common anatomic sites at intervals from 1930 to 1992 are presented in [Figure 82.1](#) for females and males. The striking changes over the 7 decades have been the dramatic rise in death from lung cancer and the marked decline in mortality from gastric and uterine (predominantly cervical) malignancies. The rise in lung cancer deaths has been caused primarily by cigarette smoking, while the decline in uterine cancer mortality is attributed to early detection by widespread screening with the Papanicolaou (Pap) smear. The reasons for the decrease in gastric cancer mortality,

seen throughout the world, are not completely clear. Improvements in food refrigeration and decline in use of salt, nitrates, and nitrites for food preservation are thought to have played an important role.

Figure 82.1. Changes in cancer mortality in the United States in males **(A)** and females **(B)** between 1930 and 1992. (From Anon. Cancer facts and figures, 1996. Atlanta, GA: American Cancer Society, 1996, with permission.)

After decades of steady increase, the age-adjusted mortality due to cancer has recently declined, as shown by recent data based on the Surveillance, Epidemiology and End Results Program (SEER) of the National Cancer Institute. This program collects incidence and survival data on cancer from five states (Connecticut, Hawaii, Iowa, New Mexico, and Utah) and four metropolitan areas (Detroit, Atlanta, San Francisco-Oakland, and Seattle-Puget Sound).

The American Cancer Society applies incidence rates from SEER for 1979–93 to the estimated total U.S. population (e.g., for 1996) to give current incidence rates. These rates indicate that cancer mortality declined by 3.1% between 1990 and 1995 (5), mainly because of a decrease of 3.9% in lung cancer deaths and 2% in other smoking-related cancers. The overall decrease of 3.1% has been credited to cancer prevention activities (e.g., decreased cigarette smoking, earlier detection) and improved therapies. The changes have been greatest among children and adults under 55 years of age (6). Using data from other sources, it has been estimated that cancer mortality on an age-related basis decreased by 1.0% between 1991 and 1994 (6).

The incidence, 5-year survival, and annual 1996 estimated death rates for the eight major cancers are listed in [Table 82.2](#). Treatment of some neoplasms including testicular cancer and some forms of leukemia and lymphoma has been very successful; however, in most common cancers (lung, breast, colorectal), treatments have had moderate or no success. Primary prevention measures such as avoidance of smoking and sun exposure, diet modification, control of infection, and moderation in alcohol use have decreased cancer incidence and mortality (7, 8). Significant progress in secondary

prevention by detecting and removing premalignant or early cancerous lesions can improve cure and survival rates and decrease mortality. Thus, Pap smears for detection of in situ cervical cancer and mammography for detection of breast cancer are effective early measures for reducing mortality from female cancers. Fecal occult blood testing and sigmoidoscopy can detect polyps and early cancers in the colon, and their removal reduces colon cancer mortality.

Cancer Site	Incidence	5-Year Survival (%)	Annual Death (1996)
Lung	177,000	13.4	158,700
Colorectal	133,500	61	54,100
Breast	185,700	83.2	44,560
Prostate	317,000	85.8	41,400
Pancreatic	26,300	3.6	27,600
Non-Hodgkin's Lymphoma	52,700	51	23,300
Leukemia	27,600	Variable ^a	21,000
Ovarian	26,700	44.1	14,600

Table 82.2 1996 Incidence, 5-Year Survival and Death Rates of Specific Cancers in the United States

PREVALENCE AND SIGNIFICANCE OF MALNUTRITION

An involuntary weight loss of more than 10% in the cancer patient—especially when rapid—is generally agreed to be cause for concern and is frequently an independent risk factor for survival (9). In quantitative terms, the degree of undernutrition at which survival is minimal is associated with a corrected muscle area of 9 to 11 cm² in cancer patients (10). The degree and prevalence of malnutrition, if any, in cancer patients depend on tumor type and stage, the organs involved, the types of anticancer therapy used, and patient response. Concurrent nonmalignant conditions such as diabetes and intestinal diseases can be important contributing factors.

Determining the true prevalence of malnutrition can be difficult because it depends on the sensitivity and specificity of the parameters used for nutritional assessment (Chapter 54, Chapter 55 and Chapter 56) and because of the lack of universal agreement on the validity of these parameters. Most studies in cancer patients used weight loss as the primary nutritional assessment criterion and found that between 40 and 80% of patients suffer from malnutrition (11).

The prevalence of weight loss during the 6 months preceding the diagnosis of cancer was reported from a multicenter cooperative study of patients with 12 types of cancer (9). The lowest frequency (31–40%) and severity of weight loss were found in patients with breast cancer, hematologic cancers, and sarcomas. Intermediate frequency

(54–64%) of weight loss was found in patients with colon, prostate, and lung cancers. Patients with gastrointestinal (GI) cancers (pancreas and stomach) had the highest frequency (over 80%) and severity of weight loss, with more than one-quarter of the patients presenting with weight loss exceeding 10% of body weight. The study did not report on patients with esophageal or head and neck cancers, in whom weight loss is also very frequent and severe because of dysphagia (12). Other studies revealed that over 40% of patients undergoing medical treatment for cancer were malnourished (11, 13).

Breast cancer is usually associated with relatively little or no weight loss when it is confined or metastatic to the bones only (9). In a study of 923 women newly diagnosed with breast cancer and without metastases, 13% were undernourished, 42.4% were at their desired weight, 22.1% were overweight, and 22.4% were obese. Obesity at time of diagnosis was associated with an increased risk for recurrence (14).

Among surgical patients in VA hospitals, 39% of those undergoing a major operation for cancer were malnourished, as judged by either a nutritional risk index or a combination of weight loss and low serum proteins (15). In patients with early pancreatic cancer deemed suitable for curative resection, malnutrition was common, with weight loss up to 22% of body weight and an average of 6.3% (16). As noted above, patients with more-advanced pancreatic cancer present with more-severe malnutrition and weight loss (9). The degree of malnutrition among children admitted to the hospital with malignant diseases was similar to that seen in children with benign diseases (17, 18). In a prospective study, children with newly diagnosed cancer were commonly malnourished with a significantly reduced food intake (19).

Malnutrition may have a major clinical impact on the cancer patient and is associated with increased morbidity and mortality, first pointed out in a report by Warren in 1932 (20). Studying data from autopsies, Warren concluded that cachexia was the leading cause of death among patients with various cancers. More-recent studies have confirmed the association of malnutrition with poor prognosis and quality-of-life of the cancer patient. In the aforementioned multicenter cooperative study of patients receiving chemotherapy (9), those who had experienced weight loss prior to diagnosis had decreased performance status and survival compared with those without weight loss. In a study of patients with limited, inoperable lung cancer, weight loss was a major predictor of survival (13).

The negative impact of malnutrition was also demonstrated in surgical patients with malignant diseases. Malnourished patients undergoing a major operation were at greater risk for postoperative infectious and noninfectious morbidity and mortality than well-nourished patients (15). In patients with cancer of the esophagus, significant weight loss was associated with increased postoperative morbidity including higher rates of anastomotic leak and infection (21). Analysis of prognostic factors for survival in patients with cancer of the head and neck (stages 3 and 4) undergoing chemotherapy revealed that pretreatment weight loss was the strongest predictor of survival (18). Patients with no weight loss had a median survival of 44.3 months, compared with 10.6 months for patients with more than 10% weight loss. The extent of weight loss in these patients

was also a significant negative predictor of decreased performance status.

These studies do not establish a clear causal relationship between malnutrition and poor outcome. It is reasonable to suppose that a poor nutritional state is an independent prognostic factor for a poor outcome, but malnutrition may merely indicate a more serious type and stage of illness rather than causing a poor outcome. A few studies have attempted to isolate the effect of malnutrition from the direct effects of the disease (9, 22). Without a clear demonstration that reversal of malnutrition independently improves the outcome, it is hard to establish it as an independent factor in the course of the disease. However, one *must* appreciate that in a particular patient, various ill effects result from malnutrition and will respond to nutritional support.

EFFECTS OF CANCER ON NUTRITIONAL STATUS

Malignancies can induce a number of adverse changes in nutritional status (Table 82.3). An understanding of these changes provides the basis for evaluating their causes and for planning and providing support when indicated. Malignant tumors can produce signs and symptoms at the site of the original tumor or distally, by metastasis. In addition, humoral factors produced by cells of the immune or neuroendocrine system exert local or distant effects termed *paraneoplastic syndromes*.

Table 82.3 Nutritional Problems Associated with the Presence of Neoplastic Disease

Anorexia, Wasting, and Other Paraneoplastic Effects

Loss of appetite (anorexia) in patients with various cancers occurs as a manifestation of a systemic effect but also as a consequence of infection, surgery, radiation, chemotherapy, or other medications. It is often intensified by fear and depression. Although anorexia is not unique to cancer, its high incidence and severity in certain types of malignancies can contribute to significant weight loss.

Onset of anorexia and weight loss may be insidious and may not be accompanied by specific disease manifestations. A dictum of medicine states that the patient with an unexplained weight loss should be examined for an occult neoplasm. Detailed initial medical evaluation usually reveals the cause (23).

Cancer-induced anorexia appears to be a general phenomenon exhibited by humans and other tumor-bearing species. Anorexia in these species, as in humans, is not necessarily induced by all tumor types. A comparison of the reactions of rats to transplanted tumors of different types is instructive (24). A Leydig's cell-derived tumor (LTW) caused early anorexia and growth failure when transplanted in young rats. A breast carcinosarcoma, however, was not associated with significant anorexia; tumor and host grew almost until death. Parabiotic studies were performed in which two rats were subcutaneously attached so that a small persistent blood exchange occurred. In each pair, one rat had either the LTW or the breast tumor type and the other had no tumor. Attached cancer-free rats served as controls. Over time, none of the rats with breast cancer lost weight (as expected), and neither did their parabiotic non-tumor-bearing partners. In contrast, the rats with the LTW tumor lost weight (as expected), and their parabiotic non-tumor-bearing partners also lost significant weight. Such general results have been observed by others (25).

Such studies suggest that one or more mediators from anorexia-inducing tumors can (directly or indirectly) act on the neuroendocrine system to affect food intake adversely and to induce metabolic changes characterized as paraneoplastic syndromes. Data derived from laboratory animals with a variety of transplanted human tumor cells and from cancer patients indicate that the mediators differ among tumors and that tumor burden is not necessarily correlated with degree of wasting and other effects. The nature of the mediators and their mechanisms of action are the focus of much current research as indicated below in the section on [mediators of metabolic changes affecting nutritional status](#).

Energy Expenditure

Because patients with cancer tend to lose weight, some at a relatively early stage, many measurements of resting energy expenditure (REE) have been performed to determine whether increased REE is a possible causative factor. One type of study compared the daily REE of cancer patients as measured by indirect calorimetry with values predicted by the Harris-Benedict equation. Some investigators noted a hypermetabolic rate (i.e., 10% above the predicted value) in varying degrees (26, 27). Others found that the daily REEs of patients with GI cancer were variable, with some patients hypometabolic, some normometabolic, and some hypermetabolic (28, 29). Still others found no difference in the REEs of patients with colon and rectal cancer (30).

More-relevant data have been obtained by making direct comparisons between cancer patients with different degrees of weight loss and those with nonmalignant diseases having similar weight changes.

Alimentary Tract Tumors. The data on REE are contradictory. Investigators reported a

small absolute increase in REE in patients with GI cancer who were losing weight, compared with patients without malignant disease ($P < .05$) (31); the presence of liver metastases or more extensive disease increased the REE (31). Other studies found no increase (30, 32, 33). Patients with similar cancers and weight loss (average, 17%) had a significantly higher daily REE than patients with benign disease who had lost a similar percentage of weight. This relationship held true when REE was expressed per kilogram per day or per millimole of total body potassium (34). Regardless of the presence of weight loss, the cancer patients had similar daily REEs and REEs per kilogram, but the REE in relation to total body potassium was higher in those who had lost weight (34).

Other studies have found no significant differences in REE between patients with gastric or colorectal cancer and an average loss of 18% body weight and those with benign gastric diseases and an average loss of 16% body weight, whether the loss was expressed in $\text{kg}^{0.75}/\text{day}$, kg/day , or kg lean body mass (LBM)/day (32). When a relatively large group of patients with colon and non-small-cell lung cancer with some weight loss were compared with malnourished patients without cancer and with healthy volunteers, no difference appeared in their daily REE/kg LBM (34). No significant difference existed among weight-losing or weight-stable patients with gastric or colon cancer or among weight-losing patients with benign GI diseases in their REE per day, per kilogram body weight, or per kilogram fat-free mass (FFM) (36). Patients who were in a semistarving condition with localized resectable esophageal cancer had an REE/kg body weight similar to that of better-nourished controls admitted for minor surgery (37). In contrast, cachectic patients with pancreatic cancer had an increased REE (38). Weight-stable patients with cancer and healthy volunteers had a significantly higher ($P < .001$) total daily REE than weight-losing patients with cancer or GI diseases, but no difference in REE existed among any groups in relation to body weight or FFM (33).

Sarcomas. In patients with bony and soft tissue sarcoma, those with localized tumor and a 7.2% average weight loss had a total daily REE similar to that of age- and sex-matched controls; also, the $\text{REE}/\text{kg}^{0.75}/\text{day}$ was not different (39). Four of these patients had diffuse disease and a 15.4% mean weight loss; their total daily REE was the same as that of the other two groups, but their $\text{REE}/\text{kg}/\text{day}$ and $\text{REE}/\text{kg}^{0.75}/\text{day}$ were increased. Tumor resection led to a postoperative fall in REE (39).

Several groups noted that the Harris-Benedict equation tended to underestimate the REE/day for weight-losing cancer patients (32, 34). On the other hand, Fredrix et al. concluded that this equation overestimated energy expenditure in all groups studied, with or without cancer and weight losing or weight stable (33). They found that the current FAO/WHO/UNU prediction equation reduced the predicted number of “hypermetabolic” patients (40).

Although some controlled studies indicated increased REE in patients with cancer, especially those with weight loss, the differences among patients with and without cancer were not marked, and some studies indicated no differences. Furthermore, expressing data in terms of weight or LBM tends to eliminate or decrease differences. However, some weight-losing cancer patients maintain their preweight-loss level of energy expenditure in contrast to otherwise healthy, semistarving, weight-losing

individuals, who decrease their energy expenditure (41).

Further insight into the question of energy expenditure is provided by examining cancer patients for evidence of an inflammatory response to their cancer. Cachectic pancreatic cancer patients had appreciably higher REE per kilogram body cell mass than age-matched healthy controls; REE was even greater in patients with an acute-phase response (APR) (38). Similarly, among 87 patients with primary non-small-cell lung cancer, 67 had increased REE. This response was positively correlated with increased APR and with other evidence of a systemic inflammatory response, including elevated levels of IL-6 and soluble tumor necrosis factor (TNF) receptors as well as weight loss (42).

Carbohydrate Metabolism

Glucose intolerance has been noted frequently in patients with cancer (43); it may be mild in early stages, and it increases with tumor burden (Table 82.4). This glucose intolerance results from increased insulin resistance to both exogenous and endogenous insulin and perhaps from inadequate insulin release. This may be nonspecific in part, because such nontumor factors as weight loss, bed rest, and sepsis cause similar changes in other diseases (44).

Glucose intolerance
Insulin resistance
Abnormal insulin secretion
Delayed glucose clearance
Increased glucose production
Increased glucose turnover
Variably increased CoII cycle activity

Table 82.4 Carbohydrate Metabolism Abnormalities Associated with Advanced Cancer

Gluconeogenesis and Glucose Turnover and Disappearance

The reports of an increased rate of endogenous glucose production in cancer patients are numerous. Tumor type, stage, and histology influence the rate. This increased production, combined with other changes in carbohydrate metabolism, is associated with weight loss (41, 43, 44 and 45). In contrast, weight loss caused by uncomplicated starvation is associated with reduced glucose turnover (46). Rates of glucose and urea turnover and glucose oxidation have been determined in normal volunteers, in a group

of patients with early GI (colon) cancer, and in those with advanced GI (esophagus, stomach, pancreas) cancer (47). Basal rates of glucose turnover were similar in the normal and early cancer groups but were significantly higher in the advanced cancer group. The glucose oxidation rate increased progressively in proportion to tumor burden (23.9% for controls, 32.8% for early tumors, and 43.0% for advanced tumors). After curative resection in the early tumor groups, glucose use decreased significantly.

In those with early and advanced GI cancer, glucose production was suppressed with glucose infusion by 76 and 69%, respectively, whereas in normal volunteers, glucose production was almost completely suppressed (94%) (47). Glucose infusion significantly suppressed urea turnover in the healthy control group but did not induce a significant decrease in the high-urea-turnover advanced-tumor group (47). Glucose turnover rates in patients with sarcoma and leukemia have been 2 to 3 times those of normal volunteers; on the other hand, no difference from the normal rate was observed in patients with lymphoma (48). Glucose infusion into patients with sarcoma and leukemia suppressed hepatic glucose production by less than one-third (48).

Cori Cycling. In the Cori cycle, glucose released by peripheral tissues is metabolized to lactate, which is then resynthesized to glucose in the liver (46, 49, 50 and 51). An increased rate of Cori cycling has been reported in cancer patients. The process consumes energy because six adenosine triphosphate molecules (ATP) are required for glucose resynthesis, whereas only two are produced in the glycolytic cycle; hence, the term *futile cycle*. If anaerobic glycolysis by tumor cells with release of lactate is substantial, a considerable amount of energy would be consumed by Cori cycling of lactate in the liver. Hence, increased Cori cycling could theoretically be a significant factor in the development of weight loss from diminished energy production. Increased cycle activity has been noted in patients with metastatic disease and progressive weight loss but not in patients with cancer and stable weight (49). Cycling was significantly higher in patients with cancer—fasting or fed—than in patients without cancer but with a similar degree of weight loss (50).

The source of recycled lactate that accompanies accelerated Cori cycling in human cancer cachexia has not been completely elucidated (44). Earlier work focused on glucose consumption by the tumor with lactate formation because glucose use by the tumor can be substantial. A massive tumor, however, would be required to consume the amount of glucose reportedly used; such a size is unusual for most human tumors of the type often associated with cancer cachexia (45). More-recent reports have emphasized release of lactate from glucose recycling in peripheral tissues (45). The quantitative significance of Cori cycling to cancer wasting is uncertain (50, 51).

Information on the relation of lactate production to weight loss is gained from comparison of two experimental colonic tumors. When transplanted into the animal host (52), tumor Mac 13 consumed much more glucose than Mac 16 did; however, both tumors were the largest glucose consumers after the brain. Although Mac 13 used glucose at a greater rate than Mac 16, Mac 13 did not induce cachexia whereas Mac 16 did. In this model, at least, increased glucose oxidation and lactate production by the tumor were divorced from cachexia and from glucose use by normal tissues.

Lipid Metabolism

Many reports have stated that the major portion of weight loss in many cancer patients is attributable to fat depletion (43, 53, 54). Fat metabolism abnormalities in cancer patients are listed in [Table 82.5](#).

Excess body fat depletion relative to protein loss
Increased lipolysis, free fatty acids, and glycerol turnover
Decreased lipogenesis
Hyperlipidemia

Table 82.5 Fat Metabolism Abnormalities Associated with Advanced Cancer

Fat Mobilization

Fat from adipose tissue is mobilized in the fasting state by the action of specific lipases that eventually complete the lipolytic conversion of triglycerides to free fatty acids and glycerol. The lipase that releases the first fatty acid, triglyceride lipase, is regulated by various circulating hormones, some of which, especially catecholamines, are stimulatory, whereas insulin is antilipolytic. In the nonfasting state, fatty acids are derived from chylomicrons and very low density lipoprotein (VLDL) under the influence of lipoprotein lipase (LPL).

Klein and Wolfe (55) have reviewed mechanisms that may increase lipolytic rates in cancer patients: decreased food intake, weight loss, stress response to illness with adrenal medullary stimulation and increased circulating catecholamine levels, insulin resistance, and release of lipolytic factors produced by the tumor itself or by myeloid tissue cells. Hence, these mechanisms must be controlled insofar as possible to delineate the role of the tumor per se (55). The evidence for an increased lipolytic rate is contradictory. Weight loss per se in the absence of cancer has been associated with increased lipolytic rate. Other reports concerning whole-body lipolytic rates in patients with cancer vary; rates were normal in some and increased in others (55).

Body fat is lost when both lipolysis and fatty acid oxidation are increased. Increased lipolysis without a corresponding increase in fatty acid oxidation increases

tri-glyceride–fatty acid cycling; that is, released fatty acids are subsequently reesterified to triglyceride. Although this cycle does not increase net flux of reactants, the reaction requires energy. b-Adrenergic activity stimulates both lipolysis and triglyceride–fatty acid recycling in burn patients (56); serious undernutrition may be such a stimulus as well (55).

In laboratory animal models with transplanted tumors, including those in the genetically abnormal nude mouse, carcass lipid depletion occurs with varying degrees of tumor burden (57). Assays showed that urine and plasma from mice and human subjects with cancer cachexia had higher lipid-metabolizing activity than urine and plasma from either normal controls or volunteers after a period of acute starvation (58).

Hyperlipidemia

Elevated lipid levels usually are not marked in cancer patients but do occur in association with certain tumors. One mechanism for this elevation is decreased LPL activity, which has been noted in rodents bearing transplanted tumors and in patients with lung cancer. The lowest levels of LPL activity in lung cancer patients were associated with the greatest weight loss. Patients with breast cancer had normal LPL and minimal weight loss (59).

Fat Oxidation

The considerable literature reporting that fat is oxidized at an increased rate in patients with cancer has been summarized (43). Fat oxidation rates were higher and carbohydrate oxidation rates were lower in those patients with cancer (colorectal and gastric) who had lost significant weight than in patients with cancer who had not lost weight or in patients with benign disease who had lost weight (32).

Protein Metabolism (Table 82.6)

The rates of whole-body protein turnover and the synthetic and catabolic rates of muscle protein increase with advancing stage of disease and its clinical expression of weight loss (60, 61 and 62). Whole-body protein turnover increased 50% or more in patients with small-cell sarcoma (62) and 50 to 70% in those with lung and colorectal cancer (35). On the other hand, subpopulations of patients exist with turnover rates varying from increased to normal. In malnourished cancer patients, providing nutrition by the intravenous route did not reverse the increased turnover rate (63). Whole-body protein turnover was 32 and 35% greater in a group of malnourished untreated cancer patients without liver metastasis than in malnourished patients with benign disease and in healthy subjects starved for 10 days, respectively (64). Thus, patients with cancer and weight loss usually have increased protein turnover, synthesis, and proteolysis in contrast to the reduced rates that are the normal adaptive response to acute malnutrition in benign disease states.

Increased whole-body protein turnover
Increased protein fractional synthetic rates in liver
Reduced fractional synthetic rates in muscle
Increased hepatic protein synthesis
Persistent muscle protein breakdown
Decreased plasma branched-chain amino acids

Table 82.6 Abnormalities in Protein Metabolism Associated with Advanced Cancer

By the use of labeled leucine during intraoperative periods, no significant differences were noted in whole-body protein synthesis, whole-body protein catabolism, net protein catabolism, or albumin fractional synthesis rates between groups of patients with benign disease who had maintained weight and those with cancer who had also maintained weight (65). In contrast, patients with cancer cachexia (e.g., 15% weight loss) had significantly elevated whole-body protein catabolism, somewhat elevated whole-body protein synthesis, and an increased net protein catabolic rate. They also had significantly higher fractional synthetic rates in skeletal muscle, liver, and albumin. It was concluded that patients with cancer cachexia were actively losing protein as a result of increased whole-body protein catabolism that was only partially compensated for by increased whole-body protein synthesis. Protein fractional synthetic rates did not significantly differ in the primary tumors of those patients, with or without weight loss.

A key question is the nature of the catabolic pathway(s) involved in such proteolysis in muscle. One pathway is lysosomal energy-dependent proteolysis, another involves calcium-dependent proteases, and a third is the ubiquitin-proteasome-dependent pathway (66). Skeletal muscle from rats with hepatoma had a higher proteolytic rate during in vitro incubation than muscle from non-tumor-bearing control animals. The first two pathways mentioned were not affected, but ATP-dependent proteases were involved, and ubiquitin conjugates were increased in skeletal muscle of tumor-bearing rats. Thus, the ubiquitin-protease-dependent pathway seems to play a role in cancer-related muscle wasting (67).

Cancer patients who have lost significant weight often have protein kinetics similar to those of traumatized or infected individuals, including mobilization of skeletal muscle protein with an efflux of amino acids from peripheral stores to liver and increased urinary nitrogen excretion (68, 69) (see also Chapter 96). The same changes are noted in animal tumor models (68).

Organ imaging in a small sample of patients with cancer cachexia indicated that liver size has been spared, presumably as the result of transfer of nitrogen to the liver (70).

Patients with cancer and serious weight loss had significantly decreased percentage of lean body mass, while the percentage of nonmuscle lean body mass (i.e, visceral protein) rose markedly (54). The patients had an average total weight loss of 15.2 kg over a 6-month period, which represented loss of 7.4 kg of body water, 6.2 kg of fat, and 1.6 kg of protein (71).

Taste and Appetite Changes

Many patients ascribe diminished appetite and food intake to unpleasant and unacceptable alterations in the taste of foods. Anatomic, physiologic, and other factors affecting taste and smell are complex (see Chapter 42), as are those regulating food intake (reviewed in [72] and Chapter 40). Earlier studies of altered taste in patients with cancer used the method of detecting the lowest perceptible solution concentration of sodium chloride (salt), hydrochloric or citric acid (sour), urea (bitter), and sucrose (sweet). This method has been criticized, and forced-choice methods, although more time consuming, have been recommended to eliminate some response biases (73).

An early paper in this field (74) noted that 25 of 50 patients with metastatic carcinoma of various primary sites stated that food didn't taste as good. This change was associated with an elevated taste threshold for sweetness (i.e., food tasted less sweet) and a lowered taste threshold for bitterness (74). Subsequent papers have challenged the concept of a consistent pattern of altered taste (75, 76); others have found no abnormalities (77, 78). While such findings on taste are inconsistent with respect to pattern, altered responses to the taste of foods are frequent. When such responses cause rejection of nutritious foods, they contribute to anorexia and decreased intake. Physicians and dietitians should ascertain the food preferences and dislikes of their individual patients and develop appropriate menus based on their responses.

Learned Food Aversions

The impact on appetite of fear and uncertainty engendered by the diagnosis of cancer and the stress of diagnostic procedures is exacerbated by the physiologic and metabolic effects of various antitumor interventions. One aspect of these stresses is so-called learned or conditioned food aversion, which stems from unconscious or conscious association (by person or laboratory animal) of consumption of a particular food with a concurrent or subsequent unpleasant reaction, such as nausea or vomiting. The result is avoidance of that food. In cancer patients, unpleasant reactions may be associated with antitumor therapy, such as a chemotherapeutic drug or ionizing radiation. Children who were to be given anticancer drugs that induced nausea or vomiting were tested for learned food aversion: the test group was offered an unusual flavor of ice cream shortly before drug administration, while controls were given ice cream, but not of this flavor. When tested later for aversion to the unusually flavored ice cream, controls chose it three times more frequently than did the experimental groups (79). Such studies were extended to include adult patients.

The possible role of learned food aversions in tumor-bearing animals was based on the hypothesis that tumor-bearing rats would avoid foods associated with aversive physiologic effects of the tumor itself without any relation to treatment. The results have

been variable and have depended, in part, on the tumor and diets tested ([80](#), [81](#)).

Conditioned food preferences and aversions are discussed in [Chapter 40](#), with reference to neural pathways. The conditioned aversion associated with cancer chemotherapy depends on a serotonergic mechanism, because 5-HT₃ antagonists abolish it ([82](#)). The neural pathways that mediate learned aversions depend on both forebrain and hindbrain interactions ([83](#), [84](#)).

MEDIATORS OF METABOLIC CHANGES AFFECTING NUTRITIONAL STATUS

The deleterious effects on nutritional status that occur when malignancy reaches a certain critical stage are summarized above. This section summarizes current information on specific factors that may cause such paraneoplastic changes: various hormones, cytokines (also called interleukins and, in the Japanese literature, toxohormones), and related growth factors. A later section considers the effectiveness of nutritional intervention in reversing these paraneoplastic changes in tumor growth and in host response.

Cytokines and Growth Factors

Laboratory Animal Research

Efforts to delineate a specific role for certain hormones known to reduce appetite (e.g., cholecystikinin [[85](#)] or serotonin [[86](#)]) in tumor-induced anorexia and weight loss have been unsuccessful. More recently, attention has been directed to polypeptides (cytokines and growth factors) derived from mononuclear blood cells (lymphocytes and macrophages) under the influence of tumor-derived substances. These factors provide communication between cells that influences their proliferation, differentiation, and metabolism. Individual cytokines can influence other cytokines in activated blood cells. Their production and activation is also influenced by neuro-endocrine secretions (e.g., glucocorticoids and catecholamines). Certain cytokines are produced also in response to infection or trauma; these “proinflammatory” cytokines include TNF- α , interleukin-6 (IL-6), and interferon- α (INF- α). Their regulation involves antiinflammatory cytokines (e.g., IL-10) that decrease secretion of proinflammatory cytokines and suppress macrophage and T-cell functions.

Much attention was directed to studies of TNF- α as a factor in wasting following the initial studies of Cerami and associates, who noted wasting of body proteins and fat in association with anorexia and suppression of LPL in rabbits infected with *Trypanosoma brucei* (reviewed in ref. [87](#)).

More-recent animal studies have revealed a more complex situation, namely, other mediators may be present in larger amounts than TNF- α , and the presence and levels of such mediators vary with specific tumors. In addition to TNF- α , IL-6, INF- α and leukemia-inhibitory factor (LIF) are produced by some cachexia-inducing human cancer cell lines, which may act indirectly by inhibiting LPL ([88](#)). In nude mice transplanted with

any single one of eight human cancer cell lines from widely divergent tissues, all of which induced cachexia, two had elevated IL-6, two had elevated LIF, and one had elevated LIF, IL-6, and IL-11; the three others had no increase in measured cytokines. mRNA for the *ob* gene was not expressed in any of these cell lines that induced wasting (89). Normal mice injected with leptin or rats with continuously high leptin levels had severe depletion of fat stores (90). IL-6 injected into mice with a cachexia-inducing subclone of an adenocarcinoma and into normal controls induced anemia, thrombocytosis, and visceral organ hypertrophy but not anorexia, body weight loss, or lymphocytopenia (91). These latter signs are characteristically observed in the cachexia-inducing subclone that enhances tumor growth and elevates IL-6 (91).

Investigation of murine adenocarcinoma MAC 16 led to isolation of a 24K proteoglycan from the host mouse splenocytes; this agent produced cachexia *in vivo* by inducing catabolism of skeletal muscle. It was also present in the urine of cachectic cancer patients but not in urine from patients with weight loss due to trauma and cancer patients with little or no weight loss (92).

Cachexia-inducing transplanted tumors may exert their effects through hypothalamic neuroendocrines, namely, neuropeptide Y (NPY) and corticotropin-releasing factor (CRF), which are, respectively, a stimulant and an inhibitor of feeding behavior. These neuropeptides are discussed in [Chapter 40](#) and reference 72. In Yoshida sarcoma-bearing rats, NPY activity is impaired and CRF activity is not suppressed (93).

Clinical Studies

No significant elevations of serum TNF were found in patients with solid tumors who were without sepsis or acute parasitic infections (38, 42, 94, 95). Similarly, TNF- α and IL-1 β levels were not elevated in patients with renal cell carcinoma, regardless of weight loss or fever. In contrast, IL-6 concentrations were higher in the cancer patients than in healthy individuals, and higher in those with fever or weight loss and lymph node or metastatic spread. The higher IL-6 concentrations correlated with C-reactive protein blood values (94). Elevated serum IL-6 has been related to weight loss in lung cancer patients (42) and correlated with the degree of weight loss, tumor size, tumor invasion, noncurative resectability, serum albumin and C-reactive protein levels in patients with esophageal or pancreatic cancer (96). The rise in IL-6 levels, however, was not always related to the acute-phase response (38).

Continuous infusion of low doses of recombinant human TNF into normal subjects for 4 weeks did not modify REE, body weight, serum TNF, or the level of common laboratory nutritional markers (97). Infusion of this cytokine into cancer patients for 5 days was associated with negative nitrogen balance attributed to TNF-induced anorexia rather than to a specific effect on protein metabolism (98).

Failure to observe elevated TNF levels does not necessarily signify that TNF is not involved in the wasting and other metabolic changes observed in advanced cancer. Increased production of TNF and IL-6 by peripheral mononuclear blood cells was found in patients with pancreatic cancer who had an acute-phase response, although serum TNF was not present (38). Increased soluble TNF in hypermetabolic lung cancer

patients (42) suggests that local activity at the production site, without first circulating through the blood, is important in development of the hypercatabolic state.

Data from laboratory animals support the concept of local effects. A liver tumor (LIV) weighing approximately 1% of total body weight produced anorexia, weight loss, acute-phase response, and systemic cytokine responses similar to those associated with the subcutaneous (SQ) tumor weighing approximately 10% of body weight. Neither tumor-bearing group had abnormal liver function tests or evidence of obstructive biliary pathology. TNF was detected in both tumors as well as in histologically normal liver tissue remote from the tumor of the LIV group but not in livers of animals in control and SQ groups. The proximity of the tumor to the competent tissue macrophage populations, such as hepatic Kupffer cells, may suffice to induce cachexia (99).

In contrast, TNF- α levels can be very high in the serum of children with leukemias, lower in those with pediatric solid tumors (Wilms, osteosarcoma, etc.) than in healthy controls (100, 101), and decline to undetectable levels in those with complete remission (101). In adult B-cell chronic lymphocytic leukemia, TNF- α levels were high in serum, circulating monocytes, and leukemic cells (102).

Hormone- and Cytokine-Induced Paraneoplastic Syndromes

Secretion of various polypeptide hormones by a number of malignant tumors has been known for many decades to cause distinct paraneoplastic syndromes (103, 102, 103, 104 and 105). Multiple endocrine neoplasia syndromes also occur, e.g., MEN I, II, and IIA (104a). In addition to these classic endocrine disturbances, various cytokines and growth factors are also expressed by tumors and can interact with each other.

Every known naturally occurring hormone has been reported to be produced by one or more human tumor types. Unlike the firmly regulated feedback controls of the normal endocrine system, such hormone production is more autonomous. Hence, unregulated production can have a powerful influence on adjacent and distant organs. Table 82.7 lists a number of clinical syndromes that induce hormone formation, and others are discussed below. These tumor-produced hormones were believed earlier to be abnormal with respect to source. However, many normal cells not previously considered hormone producers are now known to be capable of making small amounts of hormones (103). For example, chorionic gonadotropin made by colonic adenocarcinoma can also be produced in normal colonic mucosa; ACTH and calcitonin made “ectopically” by bronchiogenic cancer can be produced in small amounts by normal bronchial epithelial cells. Hence, tumor-derived peptide production is more appropriately designated as “eutopic”, that is, production is abnormal with respect to quantity but not with respect to source. Metabolic, nutritional, electrolytic, and other clinical problems can result from increased production of eutopic hormones.

Clinical Syndromes	Hormones*
Flushing/diarrhea	Serotonin, substance P, NKA, TCT, PP
Uter disease	Gastrin
Hypoglycemia	Insulin, TNF, IGF-II
Dermatosis, dementia, diabetes, deep vein thrombosis	Glucagon
Diabetes, steatorrhea, cholelithiasis	Somatostatin
Acromegaly	GHRH
Cushing's disease	ACTH/CRH
Hypercalcemia	PTHrP, PTH, VIP
Inappropriate antidiuretic hormone	Vasopressin, atrial natriuretic peptide
Pigmentation	Melanocyte-stimulating hormone
Silent vascular liver metastases	PP

Modified from Perry RB, Vines AJ. *Annu Rev Med* 1996;47:57-68.
 *NKA, neurexin A; TCT, calcitonin; PP, pancreatic polypeptide; TNF, tumor necrosis factor; IGF-II, insulin-like growth factor II; GHRH, growth hormone-releasing hormone; ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; VIP, vasoactive intestinal polypeptide; PTHrP, humoral hypercalcemia factor of malignancy; PTHrP, parathyroid hormone-related protein; PTH, parathyroid hormone.

Table 82.7 Clinical Syndromes That Induce Hormone Formation

Gastrointestinal Syndromes

Approximately 50% of the tumors inducing such syndromes are carcinoids, 25% are gastrinomas, 15% are insulinomas, 6% are VIPomas, 2 to 5% are glucagonomas, and less than 2.5% are a variety of rare types (104). In addition to the GI hormones listed in Table 82.7, somatostatins, enkephalins, and neurotensin may be produced. More than one can be secreted by a given tumor type, and the symptoms elicited may be intermittent and vary in severity.

The classic carcinoid syndrome (flushing and diarrhea) with elevated levels of serotonin and various peptides is associated with tumors most commonly found in the appendix and terminal ileum but can be found throughout the GI tract as well as in the pancreas and lungs. Loss of parietal cells in pernicious anemia can be associated with development of gastric carcinoid tumors (106). Secretory diarrhea occurs with (a) carcinoids; (b) VIPomas that induce the Verner-Morrison syndrome with watery diarrhea, hypokalemia, hypochlorhydria, and acidosis (107); (c) gastrinomas that occur in the pancreas, duodenum, and porta hepatitis and cause the Zollinger-Ellison syndrome, which is also associated with severe ulcers and steatorrhea [108]; (d) medullary carcinoma of the thyroid; (e) one type of somatostatinoma; and (f) secreting villous adenoma of the rectum.

Hypoglycemia from islet cell insulinomas is associated with an elevated insulin:glucose ratio and proinsulin and C-peptide levels (103). In contrast, the nonislet tumors that also induce hypoglycemia usually lack insulin. Insulin-like growth factor (IGF) II, often present in elevated amounts in this tumor and in the blood, is postulated to bind to and activate insulin receptors (105).

Some polypeptide hormones produced by tumors may have activities of other hormones because of common peptide sequences in their molecules. Many hormones produced by neuroendocrine tumors contain opioid peptide sequences. Secretion of opioid peptides has been postulated to contribute to psychiatric disturbances such as

depression, mood swings, and psychosis ([109](#)).

Several drugs have proved useful in the management of some of these gut-derived endocrine tumors when resection is not feasible. Omeprazole and H₂-blocking drugs that inhibit acid secretion by the gastric mucosa can eliminate or greatly reduce the gastrin effects in the Zollinger-Ellison syndrome. When administered in several daily subcutaneous injections, the analogue of somatostatin, octreotide, has proved beneficial in suppressing endocrine secretions associated with the Verner-Morrison syndrome (VIPomas) and the carcinoid syndrome. Octreotide has also been reported of benefit with insulinomas and glucagonomas ([110](#)).

Hypercalcemia

Hypercalcemia, one of the most common metabolic complications of cancer, is probably the most common paraneoplastic syndrome. Approximately 20 to 40% of patients with breast, squamous, bladder, and renal carcinomas, multiple myeloma, and lymphomas develop hypercalcemia at some point. The total incidence of these cancer-related effects is about one-half that seen with primary hyperparathyroidism. It is steadily progressive unless treated and may be symptomatic at calcium concentrations lower than those found in hyperparathyroidism. The more common symptoms are nausea, muscle weakness, excess urinary secretion, elevated blood pressure, anorexia, lethargy, confusion, and stupor progressing to coma. The etiologies of tumor-related hypercalcemia include the following ([111](#), [112](#)):

1. Local osteolytic hypercalcemia. This syndrome is involved in 20 to 40% of malignancy-associated cases of hypercalcemia, primarily in breast cancer, multiple myeloma, lymphomas, and leukemias. The primary cause is tumor cell secretion of paracrine factors that stimulate nearby osteoclasts to reabsorb bone. IL-1a, IL-1b, TNF-a, TNF-b and TGF-a stimulate osteoclastic bone resorption in vitro and cause hypercalcemia when infused into mice; which of these polypeptides are involved in this syndrome is not yet established ([112](#)). While serum calcium levels are elevated, serum phosphorus is normal, and PTH and calcitriol are reduced secondary to the hypercalcemia ([111](#), [112](#)). The herpesvirus that is associated with Kaposi's sarcoma, when present in the bone marrow dendritic cells of multiple myeloma patients, has been found to transcribe IL-6; the human homologue of IL-6 is a growth factor for multiple myeloma ([113](#)).
2. Osteoclastic bone resorption. This hypercalcemia results from discrete lytic lesions caused by bone-metastasizing solid tumors (breast, lung, and pancreatic).
3. Humeral hypercalcemia of malignancy (HHM). HHM is the dominant form of cancer-related hypercalcemia in 75–80% of such cases, mainly in squamous, renal, and urothelial malignancies ([112](#)). This syndrome of diffuse osteoclastic bone resorption is normally caused by a tumor distant from the skeleton. Although there may be tumor metastases to the bone, the generalized loss of calcium from bone results from secretion of a hormone designated PTH-related protein (PTHrP), which is related genetically to PTH but whose gene is much more complex than that of PTH ([112](#)). Its biochemical effects result from its interaction with PTH receptors in skeleton and kidneys; hence, the elevated serum calcium is associated with both a low serum phosphate and a high nephrogenous cyclic

AMP; PTH and calcitriol are low, and bone formation is suppressed. Patients with HHM are typically severely hypercalcemic and in marked negative calcium balance.

4. Excessive calcitriol associated with lymphomas. Although hypercalcemia in this condition is uncommon, about 50% of hypercalciuric patients with lymphomas have elevated serum calcitriol levels (114).

There have been several cases of true ectopic PTH production in patients with lung, ovarian, and neuroectodermal cancer (112).

Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

SIADH is probably the second most common endocrine-related complication in malignant conditions. It is associated primarily with the presence of small-cell carcinoma of the lung, but it may occur with intestinal and urothelial cancers. Originally, it was associated with ADH (vasopressin) excess, hence the name. Because it is now known to be associated also with production of atrial natriuretic peptide and perhaps other hormones, it might be better described as the humoral hyponatremia of malignancy (115). This syndrome with hyponatremia induced by excessive and inappropriate retention of water is discussed in [Chapter 6](#), where it is noted that other factors also induce this syndrome, including pulmonary lesions and a variety of medications.

Osteomalacia

Certain tumors are associated with reduced plasma concentrations of calcitriol, PTH, and calcium in conjunction with hypophosphatemia, renal phosphate wasting, and normal calcidiol, thereby inducing an oncogenic osteomalacia. Approximately 50 such cases were reported as of 1986. Most reported cases have involved benign nonendocrine tumors of mesenchymal origin (e.g., hemangiopericytoma) or giant cell tumors of epithelial origin (116). In addition, hypophosphatemic osteomalacia has been noted with prostatic carcinoma (117). Muscle weakness of varying degree and variable back pain have been frequent complaints. GI malabsorption of calcium and phosphate has been observed. When resection of the tumor has been possible, serum calcitriol and phosphate levels rose within 36 hours, with subsequent correction of the bone disease (117).

LOCALIZED TUMOR EFFECTS

In addition to the systemic effects of cancer, more-localized effects of various neoplasms may lead to nutritional problems ([Table 82.3](#)).

Intestinal Obstruction

The most common direct effect of alimentary tract neoplasms on nutritional status relates to partial or complete obstruction at one or more sites. Approximately 20% of surgical hospital admissions for acute abdominal conditions are associated with intestinal obstruction; the second most common cause of obstruction in adults is

neoplasm of the alimentary tract ([118](#)). Esophageal, gastric, and colorectal carcinomas are important etiologic factors in older persons. Obstructive symptoms can result from peritoneal tumor seeding and intestinal dysfunction without mechanical obstruction and may develop secondary to abdominal metastases. Acute obstruction almost always leads to immediate medical attention. Most neoplasms, however, obstruct slowly and progressively; consequently, a significant number of patients wait until one or more of their symptoms and signs (anorexia, dysphagia, weight loss, weakness, nausea, vomiting, pain, diarrhea, or anemia from chronic blood loss) cause them to seek medical care.

Malabsorption

Malabsorption occurs for numerous reasons.

Intestinal Villous Changes

Creamer ([119](#)) suggested that malignant tumors external to the gastrointestinal tract induced an abnormal intestinal mucosa with resultant malabsorption and weight loss characteristic of malignant disease. In a more definitive study, Barry ([120](#)) showed that malnourished patients with extra-alimentary-tract malignant tumors often displayed abnormal mucosal cell structure, epithelial cell loss, and decreased xylose absorption. Because he found similar changes in seriously malnourished patients without cancer, he suggested that the mucosal changes result from malnutrition rather than being a direct effect of non-GI malignant tumors ([120](#)). Once present, impaired mucosal function contributes further to malnutrition.

Blind Loop Syndrome

Blind loop syndrome occurs with partial obstruction in the small bowel, the presence of jejunal diverticula, or lack of motility in an intestinal loop. The associated overgrowth of bacteria in the small bowel may result in steatorrhea and vitamin B₁₂ deficiency. Not only is there direct interaction of bacteria with certain nutrients, but resulting abnormalities of the intestinal epithelium also cause malabsorption ([121](#)). (See also [Chapter 65](#).)

Fistula

Bypass of a significant portion of the bowel can result from fistula formation between widely separated portions of the GI tract. The degree of malabsorption depends on the site, completeness, and extent of the bypass. Severe malabsorption occurs with fistulas between stomach and large bowel (gastrocolic type), between small bowel and large bowel (enterocolic type), between small bowel and small bowel (enteroentero fistula), or from small bowel to skin (enterocutaneous fistula).

Malignancies of the Small Bowel

Malignancies of the small bowel, uncommon in the duodenum and small intestine, account for only about 1% of all malignancies of the GI tract. They may be associated with pain and bleeding (often occult, resulting in microcytic anemia), weight loss, partial obstruction, and diarrhea or steatorrhea, especially with lymphomas of the upper intestine. Celiac disease is associated with increased incidence of intestinal lymphoma and carcinoma ([122](#), [123](#)) ([Chapter 71](#)). A type of intestinal lymphoma in individuals in the Middle East involves the mesenteric lymph nodes, with resultant malabsorption ([124](#)).

Protein-Losing Enteropathy

Infiltration of the lamina propria and draining lymph nodes by tumor cells can lead to obstruction and dilation of the lymphatics within the intestinal villi; this, in turn, can lead to development of protein-losing enteropathy with hypoalbuminemia, hypoglobulinemia, and lymphocytopenia ([125](#)). This condition was described originally with intestinal lymphoma and gastric carcinoma but now is known to occur with tumors arising outside the alimentary tract (e.g., malignant melanoma, ovarian carcinoma, and metastatic lung carcinoma).

Anemia

Anemia occurs in cancer patients for a number of reasons. Nutritional deficiencies occur secondary to chronic blood loss (iron deficiency) and malabsorption (folic acid deficiency). However, in those with solid tumors, most anemias are normocytic and normochromic and are secondary to hemolysis, bone marrow failure, infection, or a paraneoplastic effect of a distant tumor ([126](#)).

NUTRITIONAL MANAGEMENT OF PATIENTS WITH SPECIFIC CANCERS

Reversal of the undesirable clinical, metabolic, and nutritional changes secondary to progressive systemic and localized effects of cancer depends primarily on its complete eradication or major palliation. As with all chronic wasting diseases, one cannot and should not expect to induce significant improvement in the nutritional state in a short period of time. Urgent antineoplastic treatment cannot and should not be postponed until nutritional rehabilitation is achieved. In such a situation, acute or chronic vitamin and mineral deficiencies, blood loss, and electrolyte and fluid imbalances can usually be corrected rapidly. When malnutrition is present or is a risk factor, nutritional therapy should be incorporated in the overall treatment program as early as possible.

When surgery, radiation, and/or chemotherapy are indicated for a debilitated patient who faces a further significant period of little or no voluntary oral intake, efforts to improve nutritional and metabolic status by adequate enteral ([Chapter 100](#)) or parenteral feeding ([Chapter 101](#)) may help decrease morbidity, thereby shortening the period of convalescence. The efficacy of such support is reviewed below.

Significant nutritional problems may arise not only from the local and systemic effects of the malignant condition but also from treatments undertaken to control the neoplastic process. The nutritional impact of such therapies is summarized in [Table 82.8](#) and in the following sections.

Table 82.8 Consequences of Cancer Treatment Predisposing to Nutrition Problems

Head and Neck Cancer

Patients with cancer of the head and neck often present with significant weight loss and malnutrition because the obstructing tumor impairs food intake. In addition, patients often have a history of chronic heavy alcohol intake and smoking; many may be nutritionally depleted prior to therapy. Treatment often involves combined surgery and radiation, with chemotherapy also used in some cases.

The overall 5-year survival rate is 52%. Radiation can induce mucositis, loss of taste (“mouth blindness”), xerostomia (dry mouth) as the result of salivary gland damage, trismus (spasm of jaw muscles) and some nerve damage, depending on the site irradiated. Injury to teeth may also occur, but this outcome can be minimized by adequate dental care. Some of these effects subside within 3 months after completion of radiotherapy, but they may persist for prolonged periods in some patients. Of 13 such patients studied 1 to 7 years after radiotherapy, 9 had measurable taste losses (especially for salt and bitter), 12 had reduced salivary flow and secretion rates, 9 complained of dry mouth, and 7 had no saliva ([127](#)).

Surgery may include partial or total glossectomy and mandibulectomy, and resection of portions of the hard or soft palate and of soft tissues of the lower face and neck. These procedures add to the difficulties in chewing and swallowing. The likelihood of chronic aspiration during swallowing may be serious enough to require tube feeding. Chemotherapy may produce serious systemic effects that can severely impair the

patient's ability to ingest, digest, and absorb food ([Table 82.9](#)).

Table 82.9 Potential Adverse Nutritional Effects of Cytotoxic Chemotherapeutic Agents

Nutritional Support

For the patient who is seriously malnourished on presentation, early nutritional intervention with appropriate diet, nutritional supplements, or enteral feeding may be desirable. Patients receiving nutritional supplements throughout radiation therapy maintained good body weight and completed radiation therapy without interruption ([128](#)). The widespread use of percutaneous endoscopic gastrostomy allows tube feeding patients with cancer of the head and neck despite severe dysphagia and obstructing tumors (see [Chapter 100](#)). Enteral feeding given prior to and during radiation therapy can prevent weight loss, dehydration, and interruption in therapy as well as minimizing admissions to the hospital. In the malnourished patient scheduled for surgery or chemotherapy, pretreatment enteral feeding can improve the nutritional state and may decrease morbidity ([129](#)). In a randomized study, malnourished patients with head and neck cancer who received enteral nutrition prior to surgery had decreased postoperative complications and hospitalization ([130](#)). In the immediate postoperative period, most patients require a short course of enteral feeding, mostly provided through a tube placed during the operation with the tip in the esophagus. Such feedings are usually required for a few days to allow healing of the operative wounds or improvement in the ability to swallow improves. In patients who continue to experience mild to moderate dysphagia postoperatively, nutritional treatment is directed to providing attractive foods with pleasant aroma, which are lubricated by gravies and salad dressings and have high caloric content. Nutritious liquid formulas that can be administered by mouth are also helpful.

For patients with significant nonresolving dysphagia, endoscopic gastrostomy tubes greatly facilitate provision of nutrition by feedings administered 3 to 4 times a day ([131](#)). For patients who are at serious risk of aspiration of regurgitated food (tendency to vomit, absent gag reflex, significant pulmonary disease), bolus feeding through a tube with its

tip in the stomach increases the risk. This danger is reduced by placing the tip of the tube in the small bowel and using a pump to infuse the formula by slow drip over several hours.

Patients who require long-term enteral feedings at home should be trained in enteral feeding techniques, including recognition of safety problems, information about nutritious formulas, and issues of cost. Regular medical follow-up is important to ensure the adequacy of the patient's regimen and allow appropriate adjustments as required (e.g., with diabetes, heart and kidney failure). These issues are reviewed further in [Chapter 100](#).

Esophageal Cancer

Malnutrition is highly prevalent in patients with carcinoma of the esophagus, primarily because of the severe dysphagia. This symptom, most commonly found on initial presentation, is seen in about 90% of all patients. In a report on 110 patients, average weight loss at presentation totaled 9 kg ([132](#)). A review of 83,783 patients from 122 studies revealed a mean weight loss of 10 kg on initial presentation ([12](#)).

Surgery is the primary treatment modality of patients with carcinoma of the esophagus, with radiation and chemotherapy often given preoperatively. The outcome is still poor, with an overall 5-year survival rate of only 11%. Surgical treatment usually involves total or distal esophagectomy requiring bilateral vagotomy, proximal gastrectomy, and anastomosis of the retained portion of the esophagus to the remaining stomach, which is placed in the chest. Frequent regurgitation, rapid satiety, decreased rate of gastric emptying of solid food (despite pyloroplasty), diarrhea, and steatorrhea (mild to moderate) are common complications of this surgery ([Table 82.8](#)). The causes of diarrhea and steatorrhea are not easily identified. If troublesome, their cause should be identified; vagotomy should be suspect ([133](#)).

Esophagectomy is often associated with short- and long-term complications that can severely limit the patient's ability to consume adequate amounts of food. Such complications include anastomotic leak, stricture, dysmotility of the stomach, early satiety, regurgitation, and vomiting. Of 46,692 patients enrolled in different studies, serious postoperative complications occurred in 36% ([134](#)). When strictures occur postoperatively, dilatation can help increase the diameter of the esophageal lumen; however, strictures often recur.

Radiation to the esophagus can induce esophagitis. Although this complication usually subsides following cessation of therapy, some patients may develop fibrosis with resultant esophageal stricture. Fistulas (particularly esophagotracheal) and hemorrhage are commonly related to regrowth of the cancer. Chemotherapy may induce nausea, anorexia, sore mouth, and odynophagia, thus further inhibiting food intake and decreasing the acceptance of tube feeding. In a series of patients receiving radiation plus chemotherapy or radiation alone, severe or life-threatening upper digestive tract complication with accompanying nutrition problems occurred in 33 and 18%, respectively ([135](#)). These complications included mucositis, ulcerations, dysphagia,

necrosis, fistulas, and perforations.

In the patient presenting with advanced, nonresectable esophageal cancer, dysphagia is usually a major problem. Dilatation and laser therapy often temporarily improve the patient's ability to swallow, but dysphagia usually recurs, requiring repeated treatments. In these patients, placement of a gastrostomy tube can be very helpful in providing nutrition.

Nutritional Support

Many patients present with significant weight loss secondary to progressive dysphagia. Weight loss and malnutrition are negative prognostic factors (136). When obstruction is mild and regurgitation is not a problem, ingestion of an adequate amount of well-planned meals and liquid formulas often prevents or ameliorates malnutrition. Dietary management of various stages of dysphagia is reviewed in Appendix [Table V-A-34-a-1](#), [Table V-A-34-a-2](#), [Table V-A-34-a-3](#), [Table V-A-34-b-1-a](#), [Table V-A-34-b-1-b](#), [Table V-A-34-b-1-c](#), [Table V-A-34-b-2-a](#), [Table V-A-34-b-2-b](#), [Table V-A-34-b-3-a](#), [Table V-A-34-b-3-b](#), [Table V-A-34-b-4-a](#), [Table V-A-34-b-4-b](#) and e. When dysphagia is moderate or severe, special oral and/or enteral feeding should be initiated. It can be administered through an endoscopically or surgically placed gastrostomy or jejunostomy tube. Because patients with esophageal cancer have functional GI tracts distally, enteral nutrition should be used rather than TPN when there is no contraindication (i.e., severe nausea, vomiting, and/or diarrhea).

Following resumption of oral intake by the patient who has undergone esophagectomy, the nutritional plan should provide for frequent small meals (to overcome easy satiety and the tendency to regurgitate). The diet should be high in carbohydrates and adequate in protein and fat.

If postoperative strictures occur, the patient may temporarily require special diets or oral or tube-fed liquid formulas to ensure adequate intake until the stricture is overcome.

Carcinoma of the esophagogastric junction creates pre- and postoperative physiologic and nutritional problems similar to those described above. Because an appreciably larger portion of the proximal stomach may be resected, early satiety may be more marked and production of gastric juice may be reduced, thereby resulting in decreased vitamin B₁₂ absorption.

Gastric Cancer

Patients with gastric cancer frequently present with weight loss, abdominal pain, anorexia, and weakness. Surgical treatment for gastric cancer involves either a radical subtotal gastrectomy (80–85%) with a gastrojejunal anastomosis or a total gastrectomy with an esophagojejunal anastomosis with or without some type of reservoir in the upper jejunum. The 5-year survival of gastric cancer patients in the United States varies from 43% for stage 1 to 20% for stage 4 (136). Long-term survival following curative surgery is better in Japan (where gastric cancer is highly prevalent) than in the United States

(137).

Radiation and/or chemotherapy are used for the treatment of patients with resected but residual localized disease. Patients who present with metastatic disease usually receive only palliative therapy; surgery is performed only to relieve gastric obstruction or to manage severe bleeding.

Removal of most or all of the stomach reduces or eliminates its reservoir, digestive, secretory, diluting, and metering functions. These modifications have both physiologic and nutritional consequences that may vary from mild to severe, depending on the extent of resection, the individual patient response, and the postoperative care (Table 82.8). The most common nutritional problems in patients postgastrectomy are early satiety and the inability to ingest adequate amounts of food during a meal. Consequently, they often exhibit weight loss and nutrient deficiencies.

Depending on the types and amounts of foods ingested postoperatively and on the response of the patient, various signs and symptoms, termed the *dumping syndrome*, can occur (138). Usually the signs and symptoms occur within 15 to 30 minutes following ingestion of a meal, termed *early dumping* (139). Vasomotor manifestations include diaphoresis, palpitations, weakness, and faintness; in addition, GI signs and symptoms include abdominal bloating, cramping, and diarrhea, which may become pronounced shortly after the meal. Another set of symptoms, which often occur in conjunction with those just mentioned but usually 1½ to 2 hours after eating (*late dumping*) (139), is characterized also by sweating, tachycardia, and faintness; confusion may also occur. This set of symptoms and signs is related to catecholamine discharge mediated by hypoglycemia induced by a heightened insulin response to rapid entry of the meal into the upper small bowel. This syndrome may be intense enough to discourage food consumption. A diagnostic provocation test consists of measuring the heart rate after oral ingestion of 50 g of glucose. The sensitivity and specificity of a positive response (i.e., a heart rate increase \geq 10 beats/min in the first hour) were 100 and 94%, respectively. An early rise in breath hydrogen in the same protocol had an 84 and 94% sensitivity and specificity, respectively (139).

Fat malabsorption occurs especially in patients who have undergone total or near-total gastrectomy (138). Deficiencies of iron, calcium, and fat-soluble vitamins may also develop. Lack of gastric acidity, intrinsic factor, and R protein inhibits both cobalamin availability and absorption from food and its absorption from a vitamin supplement unless accompanied by intrinsic factor equivalent (Chapter 27).

Numerous reports have described the benefits of somatostatin and especially of its analogue octreotide, both short and long term, in the treatment of the dumping syndrome. In dumping provocation tests induced by diet, the drug reduced or abolished the early and late signs and symptoms associated with hypovolemia and hypoglycemia, respectively (140, 141). Some patients benefited from long-term use, but many could not tolerate the drug because of diarrhea (140). The use of octreotide has provided important information on the possible cause of the dumping syndrome; the plasma levels of pancreatic polypeptide, neurotensin, and glucagon were markedly elevated during the “dump” in patients treated with placebo but were suppressed in those

pretreated with octreotide. It has been postulated that neurotensin is most likely the mediator peptide ([141](#)).

Patients with gastric cancer who do not undergo curative resection may have very severe nutritional problems because of obstruction, abdominal pain, recurrent nausea and vomiting, and bloating. In such patients, enteral feeding through a jejunostomy may play an important supporting role in providing adequate hydration and nutrition for an interim period.

Nutritional Support

Attention to dietary treatment and appropriate education of the patient and family may alleviate many of the nutritional problems that arise postgastrectomy, especially when there has been a major resection. The dumping syndrome can be greatly minimized or prevented by adherence to an antidumping diet (see Appendix [Table V-A-35](#)). Small meals should be taken five to six times per day. In general, such a diet is high in protein, adequate in fat, quite low in simple carbohydrates, and restricted in fluids at mealtime. The foods should be calorically dense and relatively low in insoluble fiber, since high fiber content both increases satiety and decreases transit time; thus, high-fiber diets can diminish food intake and increase the risk of diarrhea. Those who continue to be symptomatic should recline for a period immediately after eating. Use of a pectin derivative has been reported to prolong gastric emptying, thus decreasing dumping with its blood volume changes, to exert better control on the early serum insulin rise, and to minimize the later fall in blood sugar (see also [Chapter 43](#)) ([142](#)).

Deficiencies of vitamins and minerals can be prevented or treated by adequate oral administration of iron with ascorbic acid and by supplements containing both water-soluble and fat-soluble vitamins (high-potency vitamin formulations are usually not necessary). Monthly injections of 100 μ g of vitamin B₁₂ are necessary because of the inability to extract bound B₁₂ from food secondary to loss of gastric juice and an inability to absorb ordinary amounts of oral B₁₂ because of the absence of intrinsic factor.

Symptoms of milk (lactose) intolerance, which are common in these patients, can be prevented by lactase-treated milk or yogurt. If these approaches are unsatisfactory, the more soluble calcium salts should be taken in divided doses over the day to provide at least 1 g of this nutrient.

The weight loss seen so often in patients postgastrectomy is only partly due to malabsorption; it is primarily attributable to poor food intake. In addition to food antipathy related to early satiety and the unpleasant dumping syndrome with meals, discomfort associated with eating may result from obstructive symptoms, the afferent loop syndrome, esophagitis secondary to bile regurgitation, anorexia, depression, or the side effects of drugs and/or radiation. Hence, a careful diet history, adequate explanation of the basis for dietary modifications, and periodic review to manage new problems as they arise are important.

When the most careful dietary advice and adherence to an antidumping diet do not

prevent weight loss and dumping, nocturnal enteral feeding given via a pump that controls continuous drip into the jejunum can provide up to 1800 calories/night and provide a substantial portion of the required nutrients and fluids. Such feeding requires placing a jejunal feeding tube, which can be done endoscopically.

Pancreatic Cancer

Pancreatic ductal adenocarcinoma is an aggressive disease, and by the time of diagnosis, most patients have significant weight loss and are at a stage at which curative treatment is not feasible. Although histologically similar, adenocarcinoma of the distal bile ducts and of the ampulla of Vater usually have a better prognosis because of a higher rate of resectability ([143](#)).

The adverse impacts on nutritional status of this type of tumor and its treatments are listed in [Table 82.8](#). Pancreatic carcinoma is often associated with presenting complaints of abdominal pain, anorexia, nausea, and vomiting or of weight loss; some nausea and vomiting is associated with duodenal obstruction. Eating may aggravate pain. Carcinoma of the pancreas may cause digestive enzyme deficiency when the pancreatic duct is obstructed, and the resulting malabsorption, combined with anorexia, contributes to progressive weight loss. Bile insufficiency may result from tumor obstruction of the ampulla of Vater or the common bile duct behind the pancreatic head or at the porta hepatis. Bile insufficiency may reduce absorption of fat and fat-soluble vitamins.

Surgical resection offers the only chance of cure at present, but less than 20% of patients are resectable ([143a](#)). Pancreaticoduodenectomy was described by Whipple et al. in 1935 for the surgical treatment of carcinoma of the ampulla of Vater; this procedure is now used for surgical management of cancer of the ampulla of Vater, head of the pancreas, distal common bile duct, and duodenum. In the standard operative procedure, the distal half of the stomach is removed, the pancreas is transected (usually at its neck, but varying amounts or even the entire organ may be removed), and the entire duodenum and a few inches of jejunum distal to the ligament of Treitz are resected. Ligation of the pancreatic duct with oversewing of the transected end of the pancreas (a procedure that is occasionally done) leads to complete exocrine pancreatic insufficiency ([144](#)). Even when the remainder of the duct in the pancreatic stump is anastomosed into the small bowel in an effort to use exocrine secretions, fat malabsorption occurred in 27% ([144](#)) and 50% ([145](#), [146](#)) of patients. Total pancreatectomy is still performed in a small minority of patients.

The evolution, current status of modifications, and morbidity and mortality of this procedure in cancer patients have been summarized recently ([147](#)). Over the past 35 years, the perioperative mortality rate has declined from about 20% to less than 5% or even 2% or less. Early postoperative delay in gastric emptying (up to 6 weeks) is still a problem, as is leakage at the pancreatic anastomosis. The standard procedure is associated with the morbidities attributable to hemigastrectomy: dumping, marginal ulceration (minimized with use of H₂ blockers), and bile reflux gastritis. A pylorus-preserving modification reduces bile reflux and dumping, but its use in patients with pancreatic cancer is problematic. The 5-year survival rate following the standard

procedure for adenocarcinoma of the head of the pancreas has been poor (about 4%) in the 50 years up to 1986; more-recent large-scale studies report survivals of about 20%, but the data require confirmation ([147](#)).

Approximately 10 to 12% of patients with carcinoma of the pancreas are overtly diabetic, and depending on the site of the tumor, 10 to 35% have asymptomatic glycosuria or hyperglycemia ([145](#)). Decreased glucose tolerance has been noted in postpancreaticoduodenectomy patients with normal fasting blood sugar but an insufficient insulin response to a glucose load ([148](#)).

Patients with an unresectable tumor undergo a “double bypass,” which is performed to alleviate an actual or impending obstruction of the duodenum and bile duct. The operation consists of a gastrojejunostomy and choledochojejunostomy. Despite this procedure, patients often continue to suffer from early satiety, abdominal pain following a meal, distention, and lack of appetite. The GI tract dysfunction is due to compression of the stomach and small bowel by the tumor. Usually these patients have severe weight loss, weakness, pain, and anorexia.

Nutritional Support

Pancreaticoduodenectomy results in early satiety, rapid transit, diarrhea, and generalized feeling of anorexia. The end result is a substantial decrease in food intake and weight loss. Malabsorption and glucose intolerance can further aggravate the nutritional state. When the tumor recurs in the abdomen (usually within a year or two), generalized dysmotility of the GI tract (due to mesenteric carcinomatosis), intestinal obstruction, ascites, and liver involvement may further aggravate the nutritional state. Exocrine pancreatic secretions may be deficient following pancreaticoduodenectomy. This requires adequate amounts of pancreatic enzyme preparations, which should be administered with all meals and snacks, particularly when moderate-to-severe fat malabsorption exists ([145](#)). Dietary therapy should aim at providing sufficient amounts of calories and nutrients to compensate for the malabsorption. Because glucose oligosaccharides do not require pancreatic enzymes for their hydrolysis, their use may provide better glucose absorption than use of long-chain carbohydrates. Concern for glucose intolerance requires appropriate testing. Frequent small meals may help the patient increase intake because early satiety secondary to the partial gastric resection may limit the ability to consume large meals. In patients with or without a curative resection, nocturnal enteral feeding through an endoscopically placed jejunostomy tube can supplement the oral intake and provide significant amounts of calories and nutrients.

Colorectal Cancer

Patients with colorectal cancer usually present with little or no weight loss. Surgical therapy involves removal of the segment of the colon containing the tumor. The overall 5-year survival rate of patients is 61% ([1](#)). In patients with familial polyposis or with ulcerative colitis, the whole colon is removed. Resection of part or all of the colon does not result in significant nutritional problems. Although patients may experience transient diarrhea postoperatively, this usually subsides and does not cause significant fluid or

mineral depletion. Patients with Duke's stage B and C routinely receive a 5-fluorouracil-based adjuvant chemotherapy postoperatively, which can result in transient diarrhea that usually does not create nutritional or hydration problems.

Resection of the right colon with the ileocecal valve and a portion of the distal ileum may be associated with watery diarrhea, in large part caused by entry of increased amounts of bile salts into the colon as well as by functional loss of the valve (149). Cholestyramine binds bile salts and may markedly attenuate the diarrhea. Only a small segment of distal ileum usually is sacrificed; thus, vitamin B₁₂ deficiency is not likely.

When a significant segment of the large bowel is taken out of continuity by a diverting procedure that leaves the distal colon in place but without the stream of stool, an inflammatory process, termed *diversion colitis*, can develop in this residual area. Diversion colitis occurs at variable times after the operation and is characterized by persistent histologic features resembling those of ulcerative colitis: absent or variably symptomatic abdominal cramping with mucoid or bloody diarrhea. Resolution occurs only with reanastomosis (150). Infusion of a salt solution containing short-chain fatty acids (SCFAs) into the rectal remnant appears to have a healing effect (151). Butyric acid, one of the SCFAs, is the primary energy source for colonocytes. SCFAs are active factors in colonic cell differentiation, which may explain their role in healing the colonic mucosa.

Ileal Resection

Major resection of the small bowel because of primary GI malignant tumors is relatively uncommon, as is resection of only the jejunum. The ileum may be damaged, bypassed, or removed to varying extents in cancer patients because of involvement with metastatic disease, fistula development, or radiation enteritis. Resection of the ileum leads to significant physiologic and nutritional problems that are reviewed in [Chapter 65](#) and [Chapter 68](#) and listed in [Table 82.8](#).

NUTRITIONAL IMPACT OF CANCER THERAPIES

The nutritional impact of surgery is discussed above for specific cancer sites. The effects of radiation therapy are reviewed in [Chapter 70](#).

Chemotherapy

Combinations of chemotherapy drugs are administered cyclically in maximum tolerated dosages either as the only antitumor therapy or in combination with surgery or radiation. The therapeutic effectiveness of available agents against certain malignant tumors is significant. High percentages of cures, particularly of childhood malignancies, have been reported for acute leukemias, lymphomas, testicular tumors, Wilms' tumor, osteogenic sarcoma, and rhabdomyosarcoma. Adjuvant therapy (chemotherapy given following curative resection) is highly effective in increasing survival of patients with breast and colon tumors. On the other hand, other cancers (e.g., those of the lung, stomach, pancreas and liver) respond poorly to chemotherapy and adjuvant

chemotherapy. Major efforts continue to develop and test new agents and to vary the combinations of drugs and their dosages to obtain better responses.

Nutrition-Related Side Effects

Because the activities of chemotherapy drugs are not specific to cancer cells, side effects on host cells are common. The severity and manifestation of these side effects are related to the specific agent, dosage, duration of treatment, accompanying drugs, and individual susceptibility. Because the epithelial cells of the alimentary tract have a relatively rapid turnover, many of the drugs affecting cell division have adverse effects on this tissue, with severe nutritionally related consequences. Chemotherapeutic agents may also have pronounced damaging effects on bone marrow and renal tubules as well as on hepatic, cardiac, pulmonary, and nerve cells. Nausea and vomiting are among the most common side effects of chemotherapy, but development of effective drugs to counteract chemotherapy-induced emesis (CIE) has helped ease these problems (see below).

[Table 82.9](#) lists some of the more commonly used chemotherapeutic agents and summarizes their biochemical actions and potential side effects that influence nutritional status. Severe nausea and vomiting tend to result from usual dosages of cisplatin, cyclophosphamide, nitrogen mustard, doxorubicin, and gencytabine. Mucositis and stomatitis may be severe with 5-fluorouracil, methotrexate, paclitaxel, and docetaxel. Diarrhea may be marked with nitrogen mustard, 5-fluorouracil, and methotrexate. Vincristine may cause neurologic damage leading to severe ileus and constipation. Abdominal pain occurs with dactinomycin, cyclophosphamide, methotrexate, and vincristine. Hepatotoxicity occurs with busulfan in high doses, pentostatin, and asparaginase. Nephrotoxicity is frequent with asparaginase, cisplatin, gallium nitrate, pentostatin, and methotrexate. Cisplatin leads to renal wasting of magnesium, with resultant hypokalemia and hypocalcemia if the hypomagnesia is not corrected ([152](#)). Doxorubicin is cardiotoxic. Bleomycin and busulfan may induce pulmonary toxicity. Some hormonal agents (e.g., diethylstilbestrol and tamoxifen) may induce nausea and vomiting. Corticosteroids cause sodium and water retention and nitrogen and calcium loss. The dose-limiting toxicity of many chemotherapeutic agents is leukopenia and thrombocytopenia.

Another common effect on the nutritional status is negative nitrogen balance despite continuing nutrient supply. This was illustrated by a study of protein kinetics during parenteral nutritional support before and during multiple chemotherapy in patients with advanced testicular carcinoma. Nitrogen equilibrium before starting vinblastine, cisplatin, and bleomycin changed to negative balance; protein turnover, synthesis, and catabolism decreased by 23, 34, and 30%, respectively ([153](#)).

Chemotherapy-Induced Emesis (CIE) and Antiemetics. Distinct types of CIE occur, including acute, delayed, and anticipatory emesis ([154](#)). *Acute emesis* has its onset within 24 hours of administration of emetogenic chemotherapy. *Delayed emesis* is a syndrome of nausea and/or vomiting that begins approximately 24 hours after administration of chemotherapy, most commonly described following high-dose cisplatin. *Anticipatory emesis* is a learned behavior that develops over time, most

commonly in patients who experience acute or delayed emesis.

Certain patient-related factors are highly predictive of severe vomiting following chemotherapy (154). Female patients, young adults (40 years old or younger), and patients with no history of heavy alcohol consumption tend to vomit heavily following chemotherapy. Of greatest importance in predicting the incidence of CIE is the emetogenic potential of the chemotherapy agent or combination of agents being administered.

The discovery that serotonin receptors play a pivotal role in CIE led to development of specific serotonin-receptor antagonists (155). Ondansetron (Zofran) and granisetron (Kytril), the two serotonin antagonists licensed for use in the United States, are now routinely used as effective first-line agents for prevention of CIE. These drugs should be given just before administration of the emetogenic chemotherapy rather than after symptoms begin. Previously available agents, such as high-dose metoclopramide, are associated with disturbing side effects (dystonic reactions, agitation, and restlessness). In contrast, the side effects of serotonin antagonists are less severe, and include headache, constipation or diarrhea, and transient elevations of liver enzymes. When used in combination with dexamethasone (which improved the efficacy of serotonin antagonists by 10–15%), complete control of emesis, defined as complete absence of nausea and vomiting, has been demonstrated in 45 to 55% of patients receiving highly emetogenic chemotherapy (156, 157). The remaining patients generally experience fewer than two vomiting episodes and only mild nausea. Ondansetron and granisetron are therapeutically equivalent, and the decision to use one agent over another often depends on dosage, schedule, and cost.

Blood Cell–Stimulating Factors

Bone marrow injury with high-dose chemotherapy leads to neutropenia and thrombocytopenia, with the risk of life-threatening infections and bleeding. This can be overcome in most patients by the use of autologous bone marrow transplant or peripheral stem cell rescue. The production by recombinant DNA technology of hematopoietic colony-stimulating factors for granulocytes (G-CSF) and for granulocytes and macrophages (GM-CSF) has allowed clinical studies of their effectiveness in overcoming neutropenia induced by chemotherapy. Despite their widespread use in cancer patients and despite the fact that G-CSF does shorten the duration of neutropenia, evidence to date suggests that use of G-CSF had no clinical benefit over standard practice with antibiotics in adults (158) and children (159). GM-CSF and G-CSF may have value for patients undergoing peripheral blood stem cell transplantation after chemotherapy (160). GM-CSF has been associated with development of hypomagnesemia, hypocalcemia, hypokalemia, and hypoalbuminemia (161, 162).

Dietary Influences on Toxicity and Efficacy

Protein and Amino Acids. Numerous laboratory animal studies have addressed the effects of the nutritional state and different types of diets on toxicity of certain chemotherapeutic compounds. Protein-caloric malnutrition in rats is associated with

increased methotrexate toxicity because of reduced drug clearance (163). When protein-depleted rats were repleted with protein-enriched diets, tumor response to methotrexate administration was enhanced (164). Casein-based diets enhanced the gastrointestinal toxicity and weight loss of methotrexate, while soy concentrates or peptide-based diets offered significant protection (165). The inhibitory effect of soy-based diets on growth of various tumors in rats has been reviewed (166); part of the effect appears to be secondary to methionine deficiency (167). When methotrexate was administered to rats with transplanted mammary tumors 2 hours after initiating various nutritional regimens, tumor volumes were significantly lower in those given either adequate parenteral or oral diets or amino acid supplements than in those given a protein-depleted diet (168, 169 and 170).

Conditionally Essential Nutrients: Arginine, N-3 Fatty Acids and RNA. In a randomized study, the effects of a standard feeding formula were compared with a formula enriched with w-3 fatty acids, arginine, and RNA (Impact), which was designed to enhance the immune response (171). The group receiving the supplemented formula had fewer wound complications and infections and a shorter hospitalization; however, the results of this study have been criticized on several grounds (172). A subsequent study comparing Impact with routine intravenous fluids in postsurgery cancer patients showed no clinical benefits from routine postoperative enteral feeding with the immunity-enhancing formula (173).

Conditionally Essential Nutrients: Glutamine. The metabolic roles and clinical significance of glutamine and its precursors are discussed in detail in [Chapter 35](#), [Chapter 96](#), [Chapter 98](#), [Chapter 101](#). The evidence of its value as a supplement in affecting survival and hospital stay was considered at a recent meeting (174). Hospital stays of bone-marrow transplant patients (175, 176) and of patients resected for colorectal cancer (177) were reduced by supplementation of the parenteral solutions. Oral supplementation of glutamine to cancer patients, however, did not reduce manifestations of stomatitis (178) and intestinal and hematologic toxicity induced by chemotherapy (179, 180).

Biologic Therapies

Immunotherapy

The term *immunotherapy* has been given to various biologic strategies designed to destroy cancer cells by use of cells and cell products of the natural defense mechanisms of the immune system (181). They are mentioned here because they may either influence nutritional state or be influenced by some dietary modification.

Monoclonal Antibodies. Tumor cells often bear surface molecules that are immunogenic in the natural host or in other animal species. By immunizing animals with tumor cell preparations, antisera can be prepared that recognize the various antigens found on the surface of the tumor cell. Each clone of cells produces a single type of antibody, termed a *monoclonal antibody*, that has a single type of antigen-binding site. These cells can be grown in large numbers, and the monoclonal antibody can be highly purified in essentially unlimited amounts. Monoclonal antibodies can be used to

radiolocalize tumors and as carriers of cytotoxic substances for cancer therapy. They can also be used to purge bone marrow in vitro of either T lymphocytes (to prevent graft-versus-host disease) or tumor cells before autologous transplantation in conjunction with high-dose systemic chemotherapy (182). Monoclonal antibodies have been used in the treatment of melanoma and colorectal, breast, and ovarian cancers (183). This type of therapy is evolving, and new generations of antibodies are being evaluated.

Cytotoxic Effects of Cytokines (Interleukins). It was noted approximately 18 years ago that lymphocytes exposed to IL-2 developed the ability to kill fresh tumor cells but not normal cells (181). IL-2 was shown to be effective in the treatment of renal cell carcinoma and, to a lesser degree, melanoma. However, toxicity may be severe, resulting in hypotension; renal, hepatic, and central nervous dysfunction; nausea; vomiting; diarrhea; and, in extreme cases, death (184). A nutritional complication of both IL-2 and interferon is their induction of the enzymes that degrade tryptophan to kynurenine, with resultant decline in the concentration of this essential amino acid (185).

Interferons have also been used as therapeutic agents against a variety of tumors and viruses (particularly hepatitis B and C viruses). They are effective against chronic leukemias (particularly hairy cell and myeloid types), lymphomas, and a variety of solid tumors including melanoma, Kaposi's sarcoma, and ovarian and basal cell carcinoma. Side effects include a flulike syndrome, significant weight loss, nausea, vomiting, and neurologic disturbances (186). Other cytokines given singly or in combination with chemotherapy or interferon are currently being assessed for activity against a variety of cancers.

Differentiation Therapy

The strategy of differentiation therapy is to use chemical compounds to induce differentiation of human cancer cells rather than to destroy them.

Retinoid Analogues. Some success has been achieved with the retinoids 13-*cis*-retinoic acid (isotretinoin) (see Chapter 17) and all-*trans*-retinoic acid (ATRA). Isotretinoin caused regression of premalignant leukoplakia of the buccal mucosa and has prevented secondary primary tumors in patients with squamous cell carcinoma of the head and neck. Objective responses have been observed in patients with squamous cell carcinoma of the skin and cervix treated with isotretinoin and interferon (187).

ATRA has induced an aggregate rate of complete remission of approximately 80% in acute promyelocytic leukemia (APL); however, remissions solely by ATRA are brief, so consolidation chemotherapy must follow (188). This retinoid induces differentiation of immature neoplastic cells into mature granulocytes. ATRA has side effects similar to those of other retinoids given in high doses (see Chapter 17). In addition, APL patients are very susceptible to reactions termed the *retinoic acid syndrome*, which consists of fever, respiratory distress, edema, pleural or pericardial effusions, and episodic hypotension. Early treatment with high-dose dexamethasone resulted in prompt improvement and recovery (188).

Synthetic Vitamin D Analogues. Vitamin D analogues—including new ones that are much less likely to induce hypercalcemia—have nuclear receptors and induce tumor cells to differentiate ([189](#), [190](#)). (See also [Chapter 18](#).)

Gene Therapy

Gene therapy involves transfer of DNA into cells to correct pathologic processes that result from abnormalities in the genetic makeup of the cell. There are two major categories of gene therapy: (a) in vitro therapy, in which the gene is inserted into the target cells in vitro and then the cells are returned to the animal or patient, and (b) in vivo therapy, in which the gene is transferred into the target cell by introducing the gene directly into the body ([191](#)). Systems used to transfer the genes are mostly viruses, but nonviral systems are also used. Gene replacement has been useful in slowing growth of malignant cells in vitro and occasionally in vivo. However, major obstacles in the use of gene therapy against cancer include the presence of numerous genetic aberrations in tumors (requiring transfer of many genes) and the potential need to introduce genes into all the malignant cells to achieve effective therapy. A more promising use of gene therapy is the application of gene transfer–mediated antitumor immunotherapy. Current laboratory studies and planned clinical trials will address these issues.

EFFICACY OF NUTRITIONAL SUPPORT

Two major and apparently contradictory themes are apparent in considering the relationship of advanced cancer and nutritional support. One is the need to prevent or minimize the severe undernutrition frequently accompanying advanced cancer. The other is the altered metabolism induced by tumor-mediated cytokines in many of these patients, which renders current nutritional therapies ineffective unless the underlying malignant condition can be eradicated or significantly palliated by antitumor treatments.

In contradistinction to patients with active malignancies that require immediate therapy, a group of patients have primary nutritional support needs. Included in this category are those whose effective antitumor therapies—curative or significantly palliative—have resulted in significant short- or long-term nutritional problems (e.g., alimentary tract dysfunction of various kinds). Nutritional support of some kind is usually effective for such patients.

Evaluation of Total Parenteral Nutrition

Total parenteral nutrition (TPN) has been a primary method of ensuring continued administration of nutrients to seriously ill patients undergoing antitumor treatments. Early retrospective and uncontrolled reports suggested that with such nutritional support, undernourished cancer patients had improved nutritional status, were more responsive to radiation therapy and/or chemotherapy, and had fewer side effects from treatment ([192](#), [193](#)). Better-controlled studies followed, but they differed with respect to patient numbers, ages, and gender; the types and stages of malignant disease; the nature and duration of accompanying antitumor treatments; and the types, duration, and

frequency of administration of TPN formulations. This variability often makes it difficult to compare findings of individual studies. This section summarizes this complex field.

Chemotherapy with or without Radiation and Total Parenteral Nutrition

TPN can improve some nutritional parameters in patients receiving chemotherapy; it can yield better hydration, increase body fat and weight, and correct specific nutrient depletion (27, 194). In patients with advanced cancer, TPN does not suppress the cancer-induced increased glucose oxidation and turnover (47, 48), muscle proteolysis and protein turnover (64, 65), or redistribution of body protein and increased lipolysis (54). Although some specific nutritional parameters can be improved, the more relevant issue is whether TPN can improve morbidity rates, quality of life, and survival when given in conjunction with chemotherapy. These clinical issues have been examined in a number of randomized studies using a variety of chemotherapy drugs, with different cancer sites: lung (195, 196), colon (197), testes (198), lymphoma (199), and others (200, 201).

Patients enrolled in many of these studies were not malnourished, and some had adequate oral intake and GI function, making elucidation of a potentially favorable effect of TPN difficult. The results of such studies, judged individually or in combination, indicated that routine nondiscriminatory use of TPN in patients treated with chemotherapy offered no treatment outcome advantage and no decrease in chemotherapy-induced complications.

A metaanalysis evaluated a pool of 12 randomized studies of cancer patients receiving chemotherapy and given TPN (202). The American College of Physicians report based on this analysis concluded that TPN did not result in any improvement in overall survival or response to chemotherapy (203). This analysis supported the conclusions of an earlier analysis of 28 clinical trials indicating that TPN had little or no effect on decreasing chemotherapy toxicity (204). TPN was associated with a significant increase in risk of infection, and the data revealed no conditions for which TPN could be shown to be beneficial (203).

Eighteen trials were reviewed in which adults were given only chemotherapy and five trials in which children were treated with chemotherapy alone or with additional radiation (205). The author concluded that although weight gain or decreased weight loss can often be achieved with nutritional support, “early weight gain with nutritional support usually results from accumulation of water and fat” and that “this is of questionable benefit. Consistent improvement in other nutritional parameters has not been found in the trials. This reviewer would argue that changes in nutritional parameters without concomitant improvement in clinical outcome are of no clinical utility. ... Based upon prospective, randomized, controlled clinical trials *with the exception of bone marrow transplantation* [author's emphasis], there appears to be little support for the routine aggressive nutritional support in the nonsurgical oncology patient.” Nevertheless, the author recognized circumstances in which aggressive nutrition by any route should be provided. These circumstances include prolonged inability to eat (especially when malnutrition is secondary to poor intake), a nutritional support team to decrease

complications, and the presence of a tumor deemed likely to respond to treatment (205).

Patients treated with bone marrow transplantation (BMT) can benefit from TPN because the cytoreductive chemotherapy and radiation often cause prolonged severe GI dysfunction with mucosal injury, nausea, vomiting, diarrhea, and abdominal pain. These symptoms can severely limit oral intake for weeks. In a randomized study, BMT recipients received either TPN starting 6 days prior to cytoreductive therapy or, alternatively, intravenous fluids with minerals and vitamins until metabolic dysfunction occurred, at which point TPN was given. In the TPN group, the incidence of malignant relapse was lower and survival was longer (206). In children receiving BMT for acute nonlymphocytic leukemia, TPN improved body mass and bone marrow function (207).

In a prospective randomized study comparing TPN with ad libitum food and fluid intake in children given chemotherapy plus high-dose abdominal and/or pelvic radiation, TPN was found safe and maintained nutritional status; one-third of controls became malnourished and required TPN. However, there was no clinical benefit of “bowel at rest” or decreased toxicity. Most patients lost the weight gained on TPN when TPN was discontinued and chemotherapy was continued (208). These studies suggest that patients receiving BMT and others who cannot eat for a prolonged time (particularly if they are severely malnourished) may benefit from TPN or, if the GI tract is functioning, from enteral feeding.

Surgery and Total Parenteral Nutrition

Numerous randomized studies in surgical cancer patients examined whether TPN decreased postoperative complications and improved survival (15, 16, 209, 210). Ten days of preoperative TPN was associated with nutritional improvement and significant reduction in major postoperative complications and mortality in patients with GI cancer (209). However, these positive results could not be confirmed in other studies. In a multiinstitution Veterans Administration prospective randomized study, of whom two-thirds were cancer patients, TPN was not associated with a reduction in postoperative morbidity or in 90-day mortality (15). The authors concluded that perioperative TPN should be given only to severely malnourished patients.

Patients in one hospital undergoing curative resection for pancreatic cancer ($n = 117$) were randomized to receive TPN or intravenous fluids and electrolytes in the postoperative period (16). No benefit from routine postoperative TPN was noted. However, routine perioperative TPN in patients ($n = 144$) undergoing hepatectomy for hepatocellular carcinoma exerted a clear benefit (210). The TPN group in this randomized study had a lower overall postoperative morbidity mostly because of fewer septic complications. There was also less deterioration in liver function postoperatively.

Two early metaanalyses found that pooled results from studies in which patients received perioperative TPN showed that postoperative complications and mortality were significantly reduced in the TPN groups (202, 211). A more recent analysis concluded that routine TPN did not improve the complication rate and mortality following surgery in cancer patients (212).

It appears from various randomized studies that indiscriminate use of TPN in the surgical cancer patient offers no benefit. Severely malnourished patients may benefit from preoperative TPN because of improved nutritional status prior to possible interference with nutrient use as a result of the surgical injury. In specific operations (e.g., hepatectomy), routine perioperative TPN may offer benefits, but more studies are required to clarify this issue.

The role of TPN in patients with severe, prolonged, postoperative complications (abdominal abscess, anastomotic leak, prolapsed ileus) has not been examined specifically. Such patients are usually given TPN 7 to 10 days after the operation if gastrointestinal dysfunction persists. This practice seems warranted at the present time.

Total Parenteral Nutrition and Infection

Infection is a particularly serious matter in patients on chemotherapy because of the frequency of associated leukopenia and depressed immunity, especially in malnourished patients. The metaanalysis summary of the American College of Physicians indicated a fourfold risk of infection in patients given chemotherapy and TPN, compare with those not receiving TPN (203). However, in only four of seven studies analyzed by Koretz was there a statistically significant difference in infection rates associated with TPN in nonsurgical patients on chemotherapy with or without radiation (212). In the VA perioperative study, the increased infection rate in the TPN group (compared with controls) occurred only in borderline or mildly malnourished patients (15). In contrast, the severely malnourished group on TPN had rates of infectious complications comparable to those in the control group (15). Infection rates were not greater with TPN, chemotherapy, or undernutrition in another study (201). There is evidence in neonates that the use of Intralipid is associated with increased infection rates (213). This possible relationship with parenteral lipids has not been reported in appropriately designed studies in cancer patients nor has there been such a comparison among newer lipid formulations.

Critique of the Analyses of Standard TPN. The preceding section provides good evidence that indiscriminate use of TPN in cancer patients undergoing antitumor therapies has generally shown no statistically significant benefit. Nevertheless, the reader should be aware of specific issues that were not always adequately considered or discussed in various reviews.

One issue involves the adequacy of the TPN solutions given during the trials. Because several clinical trials were published in 1981 or earlier, most of the subjects in these studies were given TPN solutions that were not nutritionally adequate. Prior to 1981, complete vitamin formulations were not commercially available, and prior to 1983, a number of essential trace elements were not added to TPN solutions. Unless these missing nutrients were obtained or prepared separately by the pharmacist or physician, their provision to the patients was very problematic. Because common use of Intralipid in the United States began in the late 1970s, glucose-based TPN solutions were generally used in that period. Secondly, in most of the studies with cyclical chemotherapy continued at home, TPN was given for relatively short periods of 2 to 4

weeks. Thus, a number of patients were not appreciably malnourished at the outset. Furthermore, such patients were usually discharged home without receiving TPN in the intervals. Thirdly, most of the surveys did not include survival data. Failure of chemotherapy to have a significant effect on the downhill course of most advanced adult solid tumors guaranteed progressive debility and death.

Some of the studies implied that provision of TPN significantly shortened survival. An analysis of one trial is instructive. This study involved patients with advanced colorectal cancer treated with chemotherapy, randomized to receive either an ad libitum diet or TPN. One of its conclusions was that “overall median survival was significantly decreased in TPN patients (79 vs. 305 days, $P = .03$)” (197). Analyses of the protocol and results reveal that TPN was given for 14 days prior to chemotherapy and continued during the first course only, which lasted an average of 12 days. TPN was discontinued thereafter, although chemotherapy was continued every 4 weeks with oral intake. While shortened survival was attributed to TPN, there were significant other reasons for earlier demise, including major group differences in sex distribution and maldistribution of patients with liver metastases.

Another major problem lies in evaluating the significance of the findings of trial summaries and metaanalyses. The variability between and among studies in terms of patient diagnoses, disease severity, complications, medications, and outcome assessment makes statistical comparison difficult. The uncertainty has led to calls for prospective randomized intervention studies (214, 215).

Evaluation of Enteral Nutrition

Chemotherapy

A few randomized studies evaluated the efficacy of enteral nutrition in patients receiving chemotherapy. They included patients with lung (216, 217), GI (217, 218), breast (219), hematologic (220), and metastatic cancer (221). These studies did not demonstrate a clear benefit from enteral nutrition with regard to treatment toxicity, tumor response, or survival. However, the small number of patients in each study and the poor designs weaken the validity of their conclusions.

Surgical Patients

Little information is available for assessing the role of standard enteral nutrition in the perioperative period. Randomized studies in patients who had surgery for GI cancers included small numbers of patients and encountered major difficulties in providing the planned nutritional regimens because of nausea, vomiting, distention, and dysfunction of the needle jejunostomy tubes (222, 223, 224 and 225). No evidence exists currently to justify routine enteral feeding postoperatively in cancer patients. However, provision of enteral nutrition to seriously malnourished patients should be considered.

Home Nutritional Support

Long-term TPN in the home can be lifesaving and life sustaining for prolonged periods for appropriately selected cancer patients (see also [Chapter 100](#), [Chapter 101](#)). These include individuals with massive intestinal resection, those with severe radiation enteritis, and those suffering from major radiation-induced unresectable stenosis but who show good evidence that malignancy has been cured. Survival rates and TPN-related complications in such patients are comparable to those seen in patients with diseases such as the short bowel syndrome and Crohn's disease who require home TPN. However, among patients with widely metastatic disease who have failed all therapy, home TPN offers limited benefit, with only 15% of such patients surviving longer than 1 year ([226](#)). Recently developed techniques for placing feeding tubes, even in the presence of upper GI obstruction, make it possible to feed such patients enterally and thus obviate the need for TPN. Ethical issues related to administration of fluids and nutritional supplements to the terminally ill patient or to those in a persistent vegetative state are discussed in [Chapter 102](#).

PHARMACOLOGIC AGENTS

With the limited success of total parenteral or enteral nutrition in reversing the wasting of advanced cancer, there has been renewed interest in anabolic agents such as hormones, appetite stimulants, and, more recently, cytokine inhibitors.

Hormones

The effects of insulin, IGF, anabolic steroids, growth hormone (GH), and related agonists have been tested in laboratory animals and in patients with cancer and other hypercatabolic states. This literature is reviewed in [Chapter 44](#), [Chapter 96](#) and [Chapter 98](#) and by Herrington et al. ([227](#)) regarding clinical trial results in cancer and HIV patients.

Laboratory Animal Studies. In sarcoma-bearing rats treated with doxorubicin, growth hormone (GH) significantly attenuated weight loss and preserved host body composition without stimulating tumor growth ([228](#)). Rats bearing mammary adenocarcinoma given GH also had greater carcass weight, muscle weight, and protein content than did controls; deprivation of protein and provision of GH inhibited tumor growth ([229](#)).

Because IGF-I mediates many of the anabolic growth properties of GH, the influence of IGF-I has been assessed in tumor-bearing rats. In three reports using different tumor transplants, there were variable effects when rats that had the hormone (or an analogue) infused subcutaneously over many hours on a daily basis were compared with tumor-bearing controls. With a transplanted methylcholanthrene-induced sarcoma, Fischer rats receiving IGF-I had significantly better host weight and attenuated loss of host muscle protein and lean tissue without tumor growth stimulation, compared with saline-treated controls ([230](#)). Wistar-Furth rats with a dimethylhydrazine-induced colon cancer transplant were randomly assigned to IGF-I, insulin, or control solutions, with paired feeding ([230a](#)). Neither IGF-I nor insulin had any significant effect on rate of tumor growth, but IGF-I very significantly ameliorated the loss of host body mass,

compared with insulin or control infusion, with no changes in circulating glucose or insulin. In contrast, in a study using a transplanted mammary adenocarcinoma, IGF-I was associated with decreased food intake and circulating insulin and glucose, failure to promote muscle protein accretion, and increased tumor growth, compared with controls (231). Insulin infusion alone increased food consumption, decreased tumor growth, and increased carcass protein and fat. LR³-IGF-I, a potent analogue of IGF-I, had no positive effect when given alone; however, when insulin and LR³-IGF-I were infused together, there was a synergistic effect on host weight. It was postulated that IGF-I may exacerbate an insulin insufficiency with resulting decreased metabolic substrates available to the host. As noted above, experimental animal tumors may differ in their production of cytokines and growth factors, which may be of importance in accounting for the variable effects of IGF-I. In another study, insulin maintained the normal ratio of inorganic phosphorus to ATP in the liver of tumor-bearing rats, compared with non-insulin-treated controls; this was associated with better food intake and weight maintenance without increased tumor growth (232). In earlier long-term studies, insulin was not considered effective because it did not extend survival.

When the anabolic b₂ agonist cimaterol was administered, tumor-bearing and control rats exhibited large increases in muscle protein and weight resulting from increased protein synthesis and decreased degradation (233). Tumor-bearing adult mice given a similar drug, clenbuterol, had no significant change in food intake or body composition (234). When the anabolic steroid norandrolone propionate was given to tumor-bearing mice, their weight increased, but 85% of the gain was water (235).

Clinical Studies. Growth hormone and IGF-I in their recombinant human forms have been given to patients with the wasting syndrome of HIV infection, as reviewed recently (227). While there was some weight gain, most patients did not have any improvement in quality of life.

Corticosteroids of various potencies have been tested in cancer patients undergoing antitumor therapies. In most studies, the effects on nutritional indices and appetite have been either minimum or short-lived; long-term use has been associated with negative nitrogen and calcium balances, glucose intolerance, and immunosuppression (227). The anabolic steroid nandrolone did not prevent weight loss in lung cancer patients undergoing chemotherapy (236).

Inhibitors of Cytokine-Related Paraneoplastic Syndromes

Studies in Laboratory Animals. Monoclonal antibody against TNF has had variable effects when injected into animals with various transplanted or induced tumors. It decreased anorexia and loss of body protein or fat in mice but did not reverse anemia, hypoalbuminemia, or acute-phase responses in one study (237). Both anti-TNF and antibody to IL-1 decreased anorexia and tumor growth in mice, but the effects were not additive; neither changed the acute-phase responses or decreased the elevated serum IL-6 (238). Anti-TNF lowered to varying extents the rates of proteolysis of various organs in tumor-bearing rats (239). Antibody against IL-6 significantly (but only partially) suppressed cachexia in mice (240). Similarly, antibody against IFN-g prevented severe cachexia induced in nude mice bearing hamster ovary tumor cells genetically

engineered to produce this cytokine (241).

Clinical Studies. Pentoxifylline was reported to decrease TNF messenger RNA. However, a randomized double-blind, placebo-controlled trial did not demonstrate any benefit in treating cancer-associated anorexia or cachexia (242). A preliminary study with melatonin reported lower serum TNF levels and less weight loss in the treated group (243).

Summation. Agents that effectively slow or inhibit wasting in cancer patients could be very useful if their actions on tumors and paraneoplastic syndromes could be separated from the deleterious effects on normal cell growth and normal cell differentiation. This would allow (a) significant improvement in the state of well-being and function of patients primarily at home during intensive antitumor treatment and (b) increased survival by decreasing mortality from infection and improving response to therapies. This approach is still in its early stages and will require clinical application with randomized studies and adequate follow-up studies.

Appetite Stimulants

Megesterol Acetate

Megesterol acetate, a synthetic progestational agent used to treat metastatic endometrial and breast cancers, has also shown some promise in improving appetite and weight. A recent review summarized results of nine trials of this drug used as an anticachectic agent in adult cancer patients with either hormone-sensitive or hormone-insensitive tumors; daily dosages varied from 160 mg/day to 1600 mg/day. Some were randomized, double-blind placebo-controlled trials; others were randomized tests of different dosages (227). In general, the results were positive for increased appetite and weight. In some studies, edema was apparent in a minority of the patients. While the actual changes in body composition have not been studied in detail, fat accumulation was indicated. This review (227) did not mention any possible survival benefit of megesterol acetate.

This agent in daily doses as low as 60 mg has been given in conjunction with cytokines INF- α and IL-2 to a variety of patients who failed standard antitumor therapy; decreased anorexia and weight loss were reported (244). Increased appetite, weight gain, and quality of life were reported when this agent was given between chemotherapy cycles to patients with head and neck cancer; however, performance status (Karnofsky) did not improve (245). It is available (Megace) on prescription as an oral suspension at 800 mg (20 mL) once daily for treatment of anorexia and cachexia in patients with HIV infection. The manufacturer notes that cases of adrenal suppression have been observed. It may exacerbate preexisting diabetes and is contraindicated in pregnancy.

Medroxyprogesterone acetate, which was tested some years ago as an appetite stimulant, has apparently not been used further for this purpose. Similarly, cyproheptadine has failed to prevent weight loss in patients with advanced cancer (227).

Cannabinoids

Marijuana and its derivative dronabinol were claimed to enhance appetite and induce weight gain in cancer patients in two studies that were not properly randomized and controlled (227). Dronabinol has Food and Drug Administration approval for the treatment of nausea and vomiting associated with chemotherapy and for anorexia with weight loss in HIV patients. Randomized studies are needed to evaluate the effects of these agents. Despite lack of such information, several states have decriminalized the use of such agents for cancer patients.

GUIDELINES FOR NUTRITIONAL SUPPORT

While recognizing the uncertainties of a positive response of patients to nutritional support, nevertheless, the physician frequently has to make a decision concerning its initiation and withdrawal. Individual responses to such support vary, and there are no simple objective tests that will enable the physician to predict who will and who will not benefit. The following guidelines are offered to assist in decision making:

1. Early nutritional assessment and serial follow-up are indicated for patients who have developed or are at risk of developing significant and persistent nutritional deficits as a consequence of the tumor or therapy. This evaluation should be followed where indicated by appropriate nutritional intervention and periodic evaluation to ensure adequate therapy.
2. For the patient with mild-to-moderate anorexia and taste changes who may require prolonged treatment, careful evaluation of food preferences and provision of attractive solid and liquid foods and supplements, properly timed, may make the difference between weight maintenance and loss.
3. An important criterion for instituting nutritional support is progressive and serious weight loss or the likelihood of significant weight loss in a patient deemed likely to respond to therapy. The specific period of active support depends on the nature and duration of the antitumor therapy or therapies and on patient responsiveness. For example, enteral feeding may greatly benefit the patient with cancer of the head and neck with severe dysphagia who is undergoing radiation and chemotherapy.
4. Factors influencing the choice of enteral versus parenteral route are reviewed in [Chapter 100](#) and [Chapter 101](#). In general, the seriously ill leukopenic and thrombocytopenic patient with seriously impaired GI function is a candidate for parenteral nutrition through a central vein. Patients undergoing BMT are in this category. If the GI route can be safely used without significant distress to the patient, oral and tube feeding are advised. In general, if the gut works, use it. Enteral and parenteral nutritional formulations for the cancer patient are basically the same as those for the mildly to moderately ill patient without cancer. Due consideration must be given, however, to special problems related to organ failure and the effects of the various antitumor or other therapies being used.
5. For the patient requiring major surgery who has lost little (<5%) or no weight, routine fluid and electrolyte support in the postoperative period is indicated unless serious complications postpone enteral intake for at least 7 to 10 postoperative

days. In this instance, TPN is indicated unless gastrostomy or jejunostomy tube feedings are appropriate and feasible.

6. A patient requiring major surgery who has severe weight loss (15–20% body weight loss) should be considered for 12 to 14 days of preoperative nutritional therapy, usually through a gastrostomy or jejunostomy tube. Patients with carcinoma of the esophagus, stomach, or pancreas may fall in this category.
7. Enteral feeding should be used for the seriously anorectic patient who is no longer a candidate for antitumor therapy, who has a functioning alimentary tract, and whose quality of life is reasonably acceptable and likely to be maintained or improved by enteral supplementary feeding at home.
8. The patient with an aggressive malignancy and persistent intestinal obstruction or other severe intestinal dysfunction who has failed all therapy and cannot be sustained on some type of enteral feeding will experience a rapid downhill course as an inpatient or outpatient without intravenous feeding. This situation presents difficult emotional problems, especially for the family, when the patient is to be discharged home without TPN, particularly if prior use of parenteral nutrition had improved strength and weight. The physician frequently is pressured to continue this method at home despite clear indication that TPN will not benefit the patient and may induce serious complications. The physician, preferably with the assistance of other health professionals, should present to the patient and/or family members the options and drawbacks of home parenteral nutrition (including financial costs). The mentally competent patient or the family or surrogate of the incompetent patient must then make the decision. Our personal experience and recent data ([230](#)) indicate a poor outcome (mean survival £3 months) for most of these patients.
9. The cancer patient with a chronic severely dysfunctional alimentary tract (the result of radiation, surgery, chemotherapy, or a combination thereof) who is free of residual malignant disease has an entirely different prognosis from that of the cancer patient in item 8. Proper management of such patients by oral, enteral, and/or parenteral feedings can lead to prolonged survival of good quality. (See [Chapter 68](#), [Chapter 70](#), [Chapter 100](#) and [Chapter 101](#).)

UNPROVEN DIETARY AND NUTRITIONAL CLAIMS

Historically, diseases with major morbidity and mortality and a relatively poor response rate to conventional medical practice of the time have attracted therapeutic “innovations” that have little or no evidence of proof of efficacy. Cancer is no exception because (a) it ranks second in terms of mortality, (b) major cancers of solid organs at the disseminated stage currently have relatively low “cure” rates by the best medical practice, and (c) expensive conventional therapies for cancer often have unpleasant, but usually transient, side effects with no certainty of “cure.”

How many cancer patients in the United States and elsewhere are being given treatments that are not accepted by the medical profession is unknown. Although probably a minority of all cancer patients, they are a very “visible minority” ([246](#)). Such treatments are called “fraud,” “quackery,” “unproven,” or “disproved” (e.g., laetrile) by those mainly in scientific medicine, “unconventional” or “unorthodox” by those less oriented to scientific method, and “alternative” or “complementary” by those favorable to

unproven methods. The “alternative” movement embraces the postmodernist doctrine that science is not necessarily more valid than pseudoscience (247).

The nature of some of these “alternative” nutrition treatments, their claims for efficacy, and the characteristics of their practitioners are reviewed in [Chapter 110](#) with the relevant literature. Many of these unconventional treatment programs have special dietary and nutritional components and regimens and use herbal and gland extracts, purgatives, enemas, laetrile, special “immunizing” agents, and spiritual guidance, often combined to form a particular “system” of management. Some of the agents and procedures appear innocuous; others raise a concern for safety. Of special concern is the patient who decides to forgo accepted medical therapy for an “alternative” program. Physicians, dietitians, and nurses who care for cancer patients should be aware of the extent of this problem, know the details and costs of some of the more common components of unproven systems of care, and be willing to discuss this area frankly with patients who ask about such methods ([245](#), [248](#), [249](#), [250](#) and [251](#)).

The need for an informed and understanding approach to patients on this issue is underscored by data collected on cancer patients by Cassileth et al. ([251](#)). Interviews were conducted with 304 inpatients at a cancer center and with 356 cancer patients (primarily outpatients) under the care of “unorthodox” practitioners; 31% were treated with conventional (i.e., medically accepted) therapy only, 49% were treated with both conventional and unorthodox therapy, and 8% were treated with unorthodox therapy only. In addition to the 171 patients treated with both types of therapies who received chemotherapy and/or radiation and/or surgery, 10% of the remaining patients had refused recommended chemotherapy, 9% had refused recommended radiation therapy, and 2% had refused recommended surgery. Of the patients treated with unorthodox therapy only, 28% had refused recommended chemotherapy, 26% had refused recommended radiation therapy, and 28% had refused recommended surgery. Of the 325 patients treated with both types of therapies, 64% had sought conventional treatment first and then added alternative treatment an average of 24 months later; although 60% continued both systems of treatment, 40% had discontinued conventional care entirely after an average of 8 months.

This study revealed that physicians constituted 60% of unorthodox practitioners; they played an active role in prescribing unorthodox treatments for the 378 patients receiving such therapies, particularly “metabolic,” megavitamin, and “immune” treatments. Of patients treated with dual systems, 75% had informed their regular physicians of their adoption of alternative care; 39% of these physicians reacted with disapproval to this information, 30% were supportive, and 12% were neutral. Disapproval resulted in 4% of patients being denied further treatment by their physicians. No data were provided on the nature of the unorthodox treatments that led to rejection, disapproval, or approval by physicians ([251](#)).

Two major claims made by proponents of “alternative” therapies are (a) superior patient support is offered by the therapists and (b) their remedies are effective against cancer. Both aspects were examined in a prospective randomized study of patients with advanced malignant disease and an expected median survival time of not more than 1 year. One group received care at an academic cancer center and the other at a cancer

clinic that provided its “autogenous immune enhancing vaccine” plus the conventional care of the academic center (253). Survival times were the same in these two settings, but the quality-of-life scores were consistently better among those treated at the academic center beginning from the time of enrollment.

Summation. As indicated above, conventional medical treatments for cancer, while prolonging or saving life, may induce significant adverse side effects. Most patients who have chosen to explore alternative remedies first started with conventional therapy. Presumably because of dissatisfaction with the effectiveness of that therapy, because of painful side effects, or for other reasons, they initiated alternative treatment described by practitioners, friends, or the media as effective, less painful alternatives. Randomized, well-controlled studies have not been performed by their proponents to demonstrate benefit. Nonetheless, new, more effective, and less stressful modalities in the treatment of cancer are clearly needed. One hopes that their development will render ineffective alternatives less attractive.

BONE COMPOSITION AND STRUCTURE

Bone is a tissue in which cells make up only 2 to 5% of the volume, and nonliving material, 95 to 98%. It is the nonliving material that gives the bone its mechanical properties of hardness, stiffness, and resiliency. This nonliving material consists of a mineral-encrusted protein matrix (also called *osteoid*), with the mineral comprising about half the volume and the matrix the other half. Unlike other connective tissues, there is virtually no free water in the bony material itself. Embedded in this solid material are

cells, called *osteocytes*, residing in lacunae in the matrix, and communicating with one another through an extensive network of long cellular processes lying in channels called *canaliculi* that ramify throughout the bone. As a consequence of this arrangement, virtually no volume of normal bone is more than a few micrometers distant from a living cell. Furthermore, even in the dense bone of the shafts of long bones, there is an extensive network of vascular channels, so that the most remote osteocyte is typically no more than 90 μm away from a capillary.

Bone Mineral

The mineral of bone is a carbonate-rich, imperfect hydroxyapatite with variable stoichiometry. Calcium comprises 37 to 40%, phosphate 50 to 58%, and carbonate 2 to 8% of this mineral. These values vary somewhat from species to species, and the carbonate component is particularly sensitive to systemic acid-base status (decreasing in acidosis and rising in alkalosis). In addition, bone mineral contains small amounts of sodium, potassium, magnesium, citrate, and other ions present in the extracellular fluid at the time the mineral was deposited, adsorbed onto the crystal surfaces and trapped there as the water in the recently deposited matrix is displaced by the growing mineral crystals.

Protein Matrix

The protein matrix of bone, as for tendons, ligaments, and dermis, consists predominantly of collagen, which comprises about 90% of the organic matrix. For bone, the collagen is type I. Collagen is a long fibrous protein, coiled as a triple helix. For the molecules of the protein to coil tightly, there can be no side chains projecting off the peptide backbone on the side facing inward; hence every third amino acid in the body of the collagen molecule is glycine. Projecting outward, however, are the side chains of various amino acids, such as lysine, which allow posttranslational formation of tight covalent bonds between collagen fibers. This cross-linking helps prevent fibers from sliding along one another when bone is stressed along the axis of the fibers.

Noncollagenous Matrix Proteins (1)

Noncollagenous proteins make up about 10% of the organic matrix of bone. They include a family of proteins in which glutamic acid residues are carboxylated in the γ position, called *gla-proteins*, the best studied of which is osteocalcin (or bone gla-protein, BGP), which comprises about 1.5% of the matrix. Other proteins include osteonectin, fibronectin, matrix gla-protein, osteopontin, and bone sialoprotein. The functions of these many constituents are unclear. Some doubtless serve as chemoattractants for osteoclasts, while others stimulate osteoblasts to lay down new bone. Because of these properties of the matrix proteins, bone seems to contain the chemical signals for its own remodeling (see below).

The shape and three-dimensional structure of bone is determined by its protein matrix. A bone that has been completely demineralized in the laboratory (by soaking in acid or EDTA) looks entirely normal, and when sectioned, stained, and examined under a microscope, reveals all the fine structure of bone. In fact, prior demineralization has

been the traditional first step in studying bone histologically (since mineralized bone tends to damage the microtome knives used by histologists to make their sections).

BONE CELLS AND THEIR FUNCTIONS

There are four principal bone cells: lining cells, osteoblasts, osteoclasts, and osteocytes. They are responsible both for maintaining the mechanical properties of bone and for mediating the calcium homeostatic function of bone.

Lining cells are flat, fibrocyte-like cells covering free surfaces of bone. They are probably derived from, or closely related to, the osteoblast cell line. They form a membrane that completely covers free bone surfaces and insulates them from the cells and hormones in the general circulation.

Osteoblasts, derived from marrow stromal cells, are the cells that lay down bone, first synthesizing, depositing, and orienting the fibrous proteins of the matrix, then initiating changes that render the matrix capable of mineralization. Osteoblasts lay down this matrix between and beneath themselves on a preexisting bone surface, thereby pushing themselves backward as they add new bone.

Bone matrix, when freshly deposited, consists of about half protein and half water and is not immediately mineralizable, just as the similar collagen-based structures, tendon and ligament, do not normally calcify. So the osteoblast still has more work to do after forming and depositing the matrix. The details of the process are not completely clear, but they involve secretion of proteins by the osteoblast into the matrix that it had previously laid down. These somehow help create a three-dimensional configuration that attracts calcium and phosphate ions and arranges them in the apatite crystal habitus. Osteoblasts also secrete an enzyme called *alkaline phosphatase* that hydrolyzes organic phosphate compounds in the vicinity, which would otherwise inhibit mineralization. Finally, as mineral is deposited, it displaces the water of the original matrix. The apatitic crystals that form are spindle shaped and are oriented parallel with, and lie between, the collagen fibers.

Osteoclasts are derived from the monocyte-macrophage line of cells, are usually multinucleated, and are the cells that resorb bone. They do this by attaching firmly to a microscopic bony surface, walling off a small region of that surface, and then secreting acid and proteolytic enzymes into this confined space. These dissolve the mineral and digest the matrix. The osteoclasts then release the breakdown products into the extracellular fluid around the resorption site, from whence they are carried away by the circulating blood. The calcium and phosphorus released into the bloodstream are usually used to mineralize other bone-forming sites elsewhere in the skeleton, while the protein fragments are metabolized or excreted. After working for a short time (a few days), the osteoclasts undergo programmed cell death (apoptosis), leaving their excavation to be refilled by osteoblasts.

Osteocytes are osteoblasts that have stopped matrix synthesis and have become embedded in bone as other bone-forming cells around them continue to add new layers of matrix. Osteocytes are responsible for monitoring the amount of strain (bending)

occurring in their domains when bone is mechanically loaded and for reporting that information to lining cells on nearby anatomic bone surfaces, which may then initiate local bone remodeling projects.

The activity of these bone cells is influenced by a large number of both systemic and local hormonal agents. Additionally, the cells influence the activity of one another. [Table 83.1](#) lists a few of the many agents influencing osteoblasts and osteoclasts. This is a rapidly developing field of investigation with much still to be learned. Osteoblasts or cells of the osteoblast lineage occupy a central position, not just in forming bone, but in processing systemic signals to the bone-remodeling apparatus (see below, "[Revision of Bony Material](#)"). Thus, although parathyroid hormone (PTH) is responsible for stimulating bone resorption, there are no PTH receptors on the osteoclast. Rather they are found on osteoblasts (and related cells) which, in response to PTH-binding, release agents that stimulate osteoclast activity. By contrast, the osteoclasts do possess calcitonin (CT) receptors and are thus able to respond very rapidly to the antiresorptive stimulus provided by CT.

Osteoblasts	Osteoclasts
Parathyroid hormone	Calcitonin
1,25(OH) ₂ D	Bisphosphonate drugs
Glucocorticoids	Interleukin-1
Insulin-like growth factors (IGFs)	Colony stimulating factor (CSF-1)
Transforming growth factor- β (TGF- β)	TGF- α
Interleukin-6	TGF- β
Parathyroid hormone-related peptide (PTHrP)	Gallium nitrate

Table 83.1 Humoral Factors Acting on Bone Cells

BONE ARCHITECTURE

Bone consists of a dense outer shell, or cortex, and an internal, chambered system of interconnected plates, rods, and spicules called *cancellous, or trabecular bone* ([Fig. 83.1](#)). In the shafts of the long bones the cortical component predominates, creating a hollow tube, while nearer the joints the cortex becomes thinner, and the interior is made up of an extensive latticework of cancellous bone. Bones such as the vertebrae, pelvis, sternum, and shoulder blades possess a thin outer rind of cortex and a more or less even distribution of cancellous bone on the inside.

Figure 83.1. Gross and microarchitecture of a typical long bone. (Copyright Robert P. Heaney, 1996; used with permission.)

The proportions both of mineral and matrix and of calcium and phosphorus are essentially identical in cortical and cancellous bone. The issue has been sometimes confused in the literature because of the difficulty of removing adherent marrow elements from cancellous bone samples prior to analysis. Fundamentally, however, bone is bone. Cancellous bone, however, turns over (remodels) much more rapidly than cortical bone. This is partly because of the much greater surface area of cancellous bone. (Remodeling always proceeds from a microanatomic bone surface into the bony material. See below, [“Revision of Bony Material.”](#)) It is also partly due to the generally greater contact with hemopoietic marrow in cancellous bone. In fact, the partition between bone with and without red marrow is probably more important than the partition between cortical and trabecular bone.

The end segments of bones are called *epiphyses* ([Fig. 83.2](#)). The shafts of long bones are called *diaphyses*, and the flared portion of the shaft merging with the region of the growth plate is called a *metaphysis*. The lining cells on the outside of the bone form a tough sheet or membrane, called the *periosteum*, while the cells on the inside surfaces of both cortical and trabecular bone are called the *endosteum*.

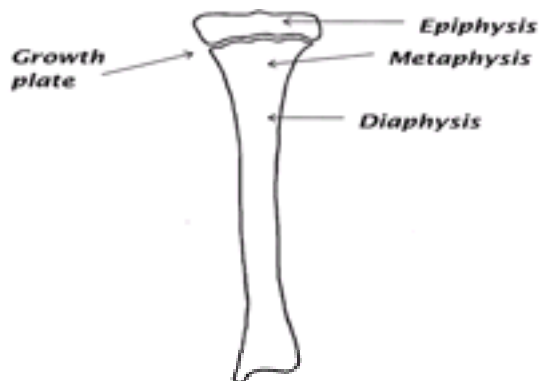

Figure 83.2. Principal regions of a growing long bone. (Copyright Robert P. Heaney, 1996; used with permission.)

The spaces between the trabecular plates and spicules are filled with bone marrow. Early in life much of that marrow is hemopoietic, but later the blood-producing marrow is confined to the bones of the trunk, and the peripheral skeletal marrow spaces are filled mostly with fat.

In dense cortical bone, remodeling over the years produces a series of internal structures called *osteons* or Haversian systems, in which concentric cylindrical layers of bone are laid down along the course of a capillary. These are produced by the usual remodeling process (see below, "[Revision of Bony Material](#)"). First a tubular hole is created in the bone by osteoclastic resorption; then it is filled in by successive waves of osteoblasts moving from the outside inward.

At their ends, where bones meet one another, is a joint; the bony surface is covered with a layer of cartilage, rather than with periosteum. In health, this cartilage is highly hydrated and is lubricated by synovial fluid held there by a tough connective tissue sac called the *joint capsule*. This arrangement ensures that the bones move on one another smoothly.

BONE DEVELOPMENT

In utero, most bones are formed first as cartilage models that are gradually replaced by bone. In this process, blood vessels invade the cartilage, calcification ensues, and the calcified cartilage is then removed by osteoclasts and replaced by bone laid down by osteoblasts. In infancy and childhood, bone development is somewhat similar. However, to accommodate growth, most bones possess one or more plates of cartilage perpendicular to the main axis of growth, separating, for example, the bone at the ends of a long bone from the bone of the shaft. This structure, called a *growth plate* ([Fig. 83.2](#)), consists of rapidly proliferating cartilage cells that, as they multiply, push the ends of the bones away from the shafts. Blood vessels invade these columns of proliferating cartilage cells from the shaft side and initiate calcification of the cartilage and bone replacement in a process similar to that occurring in utero. Meanwhile, the ends of the bone are being pushed still farther away, so that there continues to be an anatomic and temporal sequence consisting of growth plate, proliferating cartilage, calcifying cartilage, and bony replacement, progressing down the metaphysis from the epiphyses toward the diaphysis.

Growth stops when the ossification process catches up with the formation of new cartilage and bony bridges develop across the growth plate, firmly anchoring the ends to the shaft of the bone. This closure process is initiated by the high levels of estrogen produced at puberty in both girls and boys. During the time when growth in length is

occurring, the process of modeling (see below) shapes the outsides of the bones to keep them in proper proportion with the growth in length. At midshaft this typically involves periosteal new bone formation and endosteal resorption.

REVISION OF BONY MATERIAL

Although the intercellular bony material, which makes up 95 to 98% of the volume of bone, is nonliving, nevertheless it is capable of being revised and replaced, just as are soft tissues, whose cellular constituents are constantly and invisibly turning over. With bone, the revision process occurs at discrete locations and can be readily visualized microscopically. The process normally follows a stereotyped sequence of activation first, then resorption, then reversal, and finally formation. This sequence is shown diagrammatically in [Figure 83.3](#).

Figure 83.3. Schematic diagram of some of the major bone cells, indicating their role in the bone remodeling sequence. In the resting state, the bone surface is covered by lining cells. These retract at activated sites. Multinucleated osteoclasts move in and excavate a cavity. Then, after reversal, columnar osteoblasts deposit new bone matrix. Finally, the resting state is reestablished. (Copyright Robert P. Heaney, 1996; used with permission.)

In the activation step, lining cells on a bone surface retract, exposing the bony substance directly to the circulating blood. Mineralized bone serves as a chemoattractant for osteoclast precursors, which migrate to the exposed site, coalesce, attach to bone as osteoclasts, and begin to erode into the bone. After removing a suitable volume of bone, osteoclasts undergo apoptosis and disappear from the scene. A reversal phase follows. Then osteoblasts move in and begin to replace the bone removed from the cavity. They orient the collagen fibers in parallel arrays, layer by layer, often alternating direction of the fibers every few micrometers. In this way they build what is termed *lamellar bone*, which is similar in a sense to plywood (in which the grain of the wood runs in different directions in different layers). In the adult, osteoblasts advance at a rate of about 0.5 $\mu\text{m}/\text{day}$, and mineralization lags about 10 days behind

the advancing matrix deposition. Some of the osteoblasts, as noted above, stay behind in cavities within the bone and become osteocytes.

When this revision process is finished at a particular site, the remaining surface osteoblasts become quiescent, flatten out, and turn into lining cells, effectively sealing the new bone surface until, at some later time, a new remodeling project is initiated locally. In healthy adults, this sequence, from start to finish, takes about 3 months at any given site. The resorptive phase takes about 2 to 3 weeks and formation, 2 to 3 months. The process is more rapid in infants and small children and slower in the elderly.

The process just described is technically called *remodeling*. One of its principal purposes is to replace damaged bone with fresh new material. But during growth, and indeed at any time when the shape of the bone is being revised, the resorptive and formative processes occur, not at the same site, but in different parts of the bone. For example, the small shafts of the long bones of a child enlarge to adult size by osteoblastic formation on the periosteal surface and corresponding osteoclastic resorption on the endosteal surface. This process is technically called *modeling*, and is similar to remodeling in most respects except that the new bone is laid down at a location different from the site of resorption.

One of the ways this revision process can be readily visualized is by administration of carefully timed doses of a fluorescent compound such as one of the tetracycline antibiotics. The molecules of these markers bind to mineralizing bone sites and are trapped as the site is buried by layers of new bone. The markers become readily visible when, on undecalcified bone biopsy, specimens are viewed microscopically under ultraviolet illumination ([Fig. 83.4](#)).

Figure 83.4. Section through trabecular bone obtained from the iliac crest. *M*, marrow; *O*, osteoid; *T*, trabecular bone; *1* and *2*, first and second tetracycline labels. The *distance between the arrows* represents the amount of bone deposited during the time between administration of the two tetracycline labels. (From Fallon MD. Morphology and dynamics of bone nutritional interactions. In: Shils ME, Olson JA, Shike M, eds. Modern nutrition in health and disease. 8th ed. 1994;889.)

BONE FUNCTIONS

Bone serves two distinct functions: provision of mechanical rigidity and stiffness to our bodies, and provision of a homeostatic buffer, particularly to help our bodies maintain a constant level of calcium in the circulating body fluids and to provide a reserve supply of phosphorus. The mechanical function is necessary so that we can resist gravity and move about on dry land. (Strictly speaking a rigid skeleton would not be necessary in a fully buoyant medium such as water. For example, some originally bony fish, such as the sturgeon, have lost nearly all of their skeleton over the millennia of evolution. Still they function mechanically perfectly well.) The homeostatic function is the older of the two from the standpoint of evolution and is, in a sense, the more fundamental, since the body will sacrifice the structural function before it will risk losing the homeostatic one. In other words, the body will weaken the bone structurally to maintain the calcium levels of the blood and extracellular fluid.

Mechanical

In the mechanical function of bone, nature strikes a balance between a skeleton so massive that it would resist most forces but be too heavy to carry around and one so flimsy that while adequate to meet calcium homeostatic needs would be too fragile to sustain the mechanical forces of exertion or of minor injuries. Bone finds the middle ground by adjusting its mass, using a classic negative-feedback loop so that it bends under routine use by about 0.1–0.15% in all dimensions (Fig. 83.5). This bending setpoint is a major determinant of bone *size* during growth and bone *density* during adult remodeling.

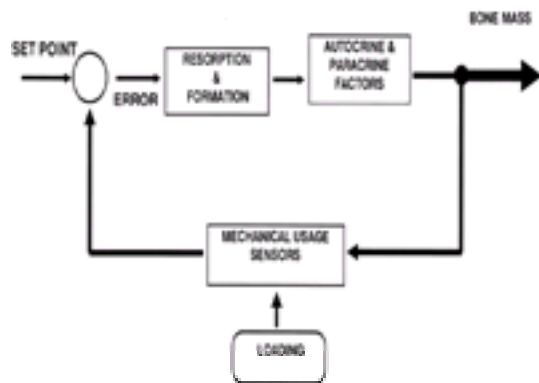

Figure 83.5. Feedback loop regulating bone mass. Mechanical sensors detect the amount of bending occurring under loading, compare that with the reference level, or setpoint, and if the two differ, send signals to the remodeling apparatus, either to initiate remodeling or to adjust the balance between resorption and formation. (Copyright Robert P. Heaney, 1990. Reproduced with permission.)

In the operation of this control loop, the osteocytes detect the amount of bending (or strain) in a local region of bone and send signals to nearby cells of the remodeling apparatus, which mediate the balance between resorption and formation. The result is that when bone is loaded locally so heavily that its strain is greater than the reference amount (as with an increase in strenuous exercise), the processes of modeling and remodeling work to increase local bone density. And when bone is loaded less heavily, so that its strains are less than this reference amount, remodeling removes more bone than it replaces, thereby lightening the structure and making it less stiff. For example, the bones in the dominant arm tend to be denser than those on the nondominant side, and the bones of athletes denser than those of nonathletes. This effect on bone mass is illustrated in [Figure 83.6](#), which shows how this difference in bone mass between the dominant and nondominant arms is exaggerated in world-class tennis players relative to nonathletes.

Figure 83.6. Difference in humeral and radial bone mass between dominant and nondominant arms of world class tennis players and nonathletic controls. Note that, even in the controls, the greater use of the dominant arm results in more bone on that side. This difference is greatly amplified in the tennis players. (Adapted from Kannus P, Haapasalo H, Sievanen H, et al. *Bone* 1994;15:279–84; copyright Robert P. Heaney, 1996; used with permission.)

The strength of a bony structure is proportional to approximately the square of the bony density. This relationship makes bone strength sensitive to relatively small changes in density and helps explain why fracture risk doubles at bone density values only 10 to 15% lower than normal.

It is important to grasp the meaning of this doubling of fracture risk. If an average individual's risk of fracture is, for example, one chance in 100 in any given year, doubling the risk means simply two chances in 100. The average individual will not perceive any difference, since the typical individual will not actually experience fracture

(i.e., 98 of 100 will be fracture free). Nevertheless, at a population level, the group of all individuals experiencing this decline in bone mass will have twice as many fractures, and health care costs or demands on the health care system will rise accordingly.

Homeostatic

The bone remodeling process also mediates the homeostatic function of bone. While the pattern of strain under loading is the major determinant of *where* bone remodeling occurs, parathyroid hormone (PTH) is the principal determinant of *how much* remodeling is occurring and how readily bone cells in any given locus respond to local stimuli to initiate a remodeling project. PTH secretion is directly responsive to the body's need for calcium. It is important to note that calcium is never simply removed from bone. Instead whole volumes of bone are removed and their calcium then scavenged to meet body needs.

As noted above, resorption precedes formation. This produces local asynchrony of mineral movement: remodeling at any given site first makes its calcium and phosphorus available to the body (as mineral is removed during resorption). The same site later creates a demand for calcium and phosphorus as the mineralizing site extracts mineral from the blood flowing past. Averaged over the whole skeleton, these processes are about equal at any given time: new remodeling sites are releasing as much calcium as the older sites are depositing. However, this local asynchrony also means that when remodeling activity is increased, resorption changes first and more calcium is released from bone than previously initiated remodeling sites need. Thus, an additional supply of calcium is made temporarily available to the body. Conversely, when remodeling is acutely suppressed, resorption drops immediately, while previously initiated formation continues, and thus the skeleton can soak up a temporary excess of calcium from the blood ([Fig. 83.7](#)). Modulation of remodeling in this way by the hormones PTH and calcitonin (CT) is a major part of the basis of the regulation of blood calcium levels by the skeleton.

Figure 83.7. Positive bone remodeling transient in a healthy individual who is not calcium deficient, in response first to a large increase in calcium intake (sufficient to suppress remodeling by 50%) and then to its later withdrawal. The vertical axis is bone mass (i.e., either bone mineral content, *BMC*, or bone mineral density, *BMD*),

expressed as percentage of the baseline value. Note that the initial rise in bone mass does not continue past one remodeling cycle (40 weeks in this illustration), and that the bone gained by remodeling suppression is lost once again when remodeling returns to its previous level. (Copyright Robert P. Heaney, 1996. Reproduced with permission.)

Two examples with nutritional relevance illustrate how this system operates. During the absorption of large quantities of calcium from milk in infant feeding, CT is secreted to suppress osteoclastic resorptive activity, thereby reducing release of calcium from bone. This allows the demands of rapidly mineralizing bone to be met by absorbed calcium from the milk, and at the same time prevents the absorbed calcium from causing a dangerous increase in blood $[Ca^{2+}]$. Later, during the postabsorptive phase, CT levels drop, and PTH levels rise to stimulate resorption again. This action sustains the blood $[Ca^{2+}]$ at normal levels despite the ongoing mineral demands of bone formation and wide swings in calcium input from the intestine. Another example is found during antler formation in deer. Each spring the demands of the growing antler exceed the calcium available from the late-winter foliage that makes up the deer's diet. So a burst of PTH-mediated remodeling occurs throughout the skeleton at the time antler mineralization begins. This creates a temporary surplus of calcium from skeletal remodeling, which is used to mineralize the bone of the rapidly forming antler. Later, when the new bony remodeling sites throughout the skeleton enter their own formation phase, they are filled in with calcium made available from the calcium-rich summer grasses and foliage.

NUTRIENTS IMPORTANT TO SKELETAL INTEGRITY

Total nutritional status influences bone cell function just as it does the function of other tissues. However, cellular malnutrition affects mainly bone currently being remodeled, while the strength of bony structures at any given time depends not so much on current cell function as on the mass of bony material accumulated by bone cellular activity over many years. For that reason, acute nutritional stresses or deficiencies rarely produce overt skeletal symptoms in adults, even when they severely compromise bone cell function. Children and growing animals show effects more promptly, both because they have less skeletal capital in their bone banks and because they are revising it much more rapidly. Nevertheless, a few nutrients are more likely than others to produce skeletal manifestations when deficient: calcium, phosphorus, vitamin D, vitamin K, and certain of the trace minerals.

Calcium and Phosphorus

In addition to buffering absorptive oscillations in blood calcium levels, bone serves as a nutrient reserve for both calcium and phosphorus. This reserve is to the calcium (and phosphorus) functions of the body as body fat is to energy metabolism. But unlike most nutrient reserves, this one (bone) has acquired a distinct function in its own right, i.e., mechanical/structural support. In other words, we walk around on our calcium reserve. It follows that any influence, nutritional or otherwise, that alters the size of the calcium

reserve will alter bone strength.

Bone is a very rich source of calcium. Total skeletal calcium averages 1100 to 1500 g, and each cubic centimeter of bone contains more calcium than the entire circulating blood in an adult. Thus, in comparison with other nutrients, the calcium reserve is huge. While low-calcium diets usually deplete the bony reserves, they do so slowly. Thus, while *population-level* risk of fracture rises immediately, it will take many years for bone strength to be sufficiently reduced to lead to a detectable increase in an *individual's* risk of fracture (see above). The slow expression of the effect of calcium deficiency has led many nutritional scientists in the past to the erroneous conclusion that calcium was not important for adult bone strength. Nevertheless, a nutritional deficiency that develops over 30 years is just as much a deficiency as one that develops over 30 days.

Low intakes of calcium and phosphorus can both limit bone acquisition during growth and cause bone loss after maturity. Calcium intake operates most directly through modulation of remodeling, as described above. In the antler example previously cited, if summer foliage were not calcium rich, each cycle of antler formation would deplete the skeleton, bony replacement would fail to occur, and bone mass would fall progressively over the animal's adult life. Because human calcium requirement rises with age (3) and because calcium intakes tend to fall in the elderly, precisely such depletion occurs in most human populations as they age.

Inadequate phosphorus availability also affects bone, but in a different way. The osteoblast environment is one of continuous mineralization, with the matrix extracting phosphate (as well as calcium) from the fluid bathing the bone-forming cells. While calcium makes up about 40% of the bone mineral, phosphate accounts for nearly 60%. Thus, phosphorus is fully as important for bone building as is calcium. Rapid growth is not possible without a high blood phosphate level, which explains the substantially higher blood phosphate values in children. When phosphate levels in the blood entering bone are low, mineralization extracts as much phosphate as it can from the fluid around the osteoblast. In so doing, it creates a local environment severely depleted of phosphate. But osteoblasts, like all cells, need phosphate for their own metabolism. The result is serious interference with osteoblast function; matrix deposition is slowed and osteoblast initiation of mineralization is reduced even more. These abnormalities produce the typical histologic pattern in bone of rickets and osteomalacia (see below).

Vitamin D

Vitamin D has many bony effects, such as facilitating development of osteoclast precursors at an activated remodeling locus and augmenting osteoclast response to resorptive stimuli. The vitamin also stimulates synthesis and release of osteocalcin by osteoblasts (see above). But its major importance for bone is to facilitate absorption of calcium (and to some extent phosphorus) from the diet. Severe vitamin D deficiency causes rickets and osteomalacia (see below). Milder shortages of the vitamin reduce calcium availability to the body and produce a situation of calcium deficiency. Because of the traditional (if simplistic) identification of vitamin D *deficiency* with rickets and osteomalacia, it is customary to refer to less extreme degrees of vitamin D shortage as

insufficiency.

Vitamin K

Vitamin K functions in the γ -carboxylation of the glutamic acid residues of three bone gla-proteins, the best studied of which is osteocalcin. Vitamin K deficiency results both in undercarboxylation of osteocalcin and in reduced osteocalcin synthesis. The net effect of these changes on bone strength or integrity is not certain.

Micronutrients

Vitamin C and certain trace minerals (notably copper, zinc, and manganese) are important cofactors for synthesis or cross-linking of matrix proteins. Copper and vitamin C are perhaps the best studied in this regard. Copper is the cofactor for lysyl oxidase, the enzyme responsible for cross-linking collagen fibrils. Interference with cross-linking results in structurally weak bone. Ascorbic acid is also a required cofactor for the cross-linking of collagen fibrils, and in its absence bone strength is impaired. In the face of deficiencies of these micronutrients during growth, severe bone abnormalities can result. These abnormalities include stunting of growth, deformity of bones, and epiphyseal dysplasia. Whether adults can develop sufficient deficiencies of these nutrients to interfere significantly with bone integrity remains unknown.

SKELETAL DISORDERS AND THEIR NUTRITIONAL CORRELATES

Osteoporosis

Osteoporosis is a multifactorial condition of the skeleton in which skeletal strength is reduced to such an extent that fractures occur on minor trauma (see also [Chapter 85](#)). Generally, osteoporosis exhibits reduced bone mass (i.e., both matrix and mineral) as well as various microstructural disturbances of bony architecture (4). A simple decrease in quantity of bone is sometimes called “osteopenia” (literally, “shortage of bone”). By current World Health Organization standards, osteopenia is a bone mass value between -1 and -2.5 standard deviations below young-adult normal values. Bone mass or density values more than 2.5 standard deviations below young-adult normal are now called osteoporosis, whether or not a fracture is present.

Lack of exercise, alcohol abuse, smoking, gonadal hormone deficiency, and inadequate intakes of calcium and vitamin D can all contribute to development of this disorder. Given diets typical of the elderly in Europe and North America, it can be estimated that inadequate calcium intake accounts for one-third to two-thirds of osteoporotic fractures. (This is why the U.S. Food and Drug Administration allows an osteoporosis health claim on labels of certain calcium-rich foods.)

Rickets and Osteomalacia (5)

Rickets is a disorder of the growth apparatus of bone (see above) in which the growth cartilage fails to mature and mineralize normally. Growth is stunted, and various

deformities about the growth plates occur. Osteomalacia is the corresponding disorder of adults, in which the newly deposited bone matrix fails to mineralize adequately. New matrix formation is slowed in both conditions, but mineralization is retarded even more; thus unmineralized matrix accumulates on microscopic bone surfaces. For this reason, the proportion of mineral to matrix drops. In severe cases, unmineralized bone may constitute so large a proportion of the skeleton that individual bones lose their stiffness and become severely deformed.

The stereotypical forms of rickets and osteomalacia are those associated with vitamin D deficiency. The principal pathogenesis of these common forms follows from insufficient intestinal absorption of calcium and phosphorus from the diet. In attempting to keep blood calcium levels close to normal levels, the body raises PTH secretion. Because one of the effects of PTH is to increase renal clearance of phosphate, this adaptive response drives the already reduced blood phosphate concentrations down to levels such that severe phosphate deficiency develops—first locally in the vicinity of the osteoblasts and chondrocytes, and then in other tissues as well (producing, e.g., muscle weakness, tenderness, and pain).

Rickets and osteomalacia develop for other reasons beside vitamin D deficiency, including fluoride toxicity and cadmium poisoning, as well as in association with certain rare vascular malignancies. Presumably the toxins or some product of tumor metabolism interferes with normal osteoblast function. More important is a group of heritable abnormalities of renal phosphate transport, the most common of which is X-linked hypophosphatemia (6). These share the inability to maintain the blood phosphate levels required for growth. Such forms of rickets produce their bony effects solely because of severe hypophosphatemia. This group of disorders in the past has been called vitamin D-resistant rickets. They do not respond to usual doses of vitamin D (hence their name). Therapy is directed at elevating serum phosphate levels.

Paget's Disease of Bone

Paget's disease is a local, but often multifocal, disorder of the bone remodeling process of uncertain etiology. Resorption proceeds erratically, with formation filling in with new bone behind it. Architecture and even external bone shape is disordered. During the early resorptive phase, the bone is excessively fragile and may fracture readily. The high level of bone remodeling is usually accompanied by high levels of remodeling markers (see below), particularly serum alkaline phosphatase. When the process involves the skull, bony growths may constrict the cranial nerve passages and lead to, for example, deafness. There are no known nutritional correlates of this disorder.

Parathyroid Dysfunction

Since PTH is the principal determinant of the amount of remodeling activity in the skeleton, one might expect significant skeletal manifestations of parathyroid functional disorders. The reality, however, is complicated. Patients with hypoparathyroidism have reduced remodeling, slightly greater than average bone mass, and probably fewer fractures. By contrast, patients with severe, longstanding hyperparathyroidism may have reduced bone mass, subperiosteal bone loss, widespread, very active bone remodeling,

and even cysts in bone filled with osteoclast-like cells. Such cases are extremely rare today, and generally patients with primary hyperparathyroidism have no abnormalities of the skeleton detectable by ordinary x-rays. In fact, when PTH hypersecretion is pulsatile and the peaks are short-lived, PTH is actually trophic for bone and can produce quite large increases in spine bone density. For that reason, PTH is now an investigational therapy for osteoporosis.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a group of heritable disorders in which there may be one of several mutations in the genes encoding for the collagen molecules that comprise the bulk of bone matrix (7). Patients with OI have fragile skeletons with reduced bone mass. In one of the common forms of OI, long bones typically have narrow shafts as well as reduced mass. Patients with OI commonly suffer many fractures throughout life, often starting in utero. When some other amino acid replaces glycine in the collagen molecule, the triple helix will not coil properly, collagen synthesis is reduced, and the matrix is abnormal. The severity of the defect depends upon the position of the substitution in the collagen molecule chain. Fractures heal normally. Other collagen-based connective tissues are also affected in certain forms of the disease, including dentin, ligaments and tendons, and the sclerae. Despite the manifest abnormality of the bone matrix, the reason for the reduced bone mass is unclear.

Bony Manifestations of Diseases of Nonskeletal Systems

Patients with chronic liver disease, especially biliary cirrhosis, commonly have a bone disease that is basically osteoporosis (8). Patients coming for liver transplant often have severe osteoporosis, attributable to a combination of the underlying disease, the immobilization that inevitably accompanies the severe disability of these very sick patients, and the treatments they have received.

Patients with end-stage renal disease often have a complex bone disease consisting of a varying mixture of osteosclerosis, osteomalacia, and hyperparathyroid bone disease (9). Exact expression of these varied abnormalities depends upon the medical regimens the patients have received, specifically on how these regimens have managed calcium, phosphorus, and vitamin D metabolism for the patient.

Patients with a variety of disorders of the small intestine, but especially those with gluten-sensitive enteropathy, malabsorb fat-soluble vitamins and hypersecrete calcium and magnesium into the digestive juices. As a result, they are commonly deficient in vitamin D, calcium, and magnesium. They often have severe osteoporosis and may have osteomalacia as well.

Patients who have had organ transplants commonly have osteoporosis (10), in part because they come to transplant with already reduced bone mass, and in part because the immunosuppressive therapy used to sustain the transplant itself causes bone loss.

Aluminum and Bone

Aluminum (Al) is not strictly speaking a nutrient, but it is extremely common in the environment, is a major component of antacids, and is widely used as cookware. Only a small portion of ingested Al is absorbed, and in healthy individuals, absorbed Al is promptly excreted in the urine. However, in patients with severely compromised renal function, particularly in those treated with large doses of Al-containing antacids to block phosphorus absorption, Al accumulates at the mineralizing sites of the bone remodeling process. It was thought at one time to be responsible for the unique bony pathology of end-stage renal disease, but Al is now considered to be at most only a minor contributor to renal osteopathy. Experimentally, Al has shown an ability to increase trabecular bone density in animals, particularly in combination with fluoride. The ultimate significance of this finding remains uncertain.

SKELETAL MANIFESTATIONS OF SYSTEMIC NUTRIENT DEFICIENCIES

Protein-Calorie Malnutrition

As noted above, the cells of bone are as dependent upon total nutrition as are other cells, and bone suffers in starvation just as do other tissues. However, bone strength is not immediately affected in acute malnutrition, especially in adults. There are two situations in which the bony effects of protein-calorie malnutrition are most obvious. One is during growth, when both growth rates and bone mass accumulation are retarded by malnutrition. The other is in repair of fractures, especially in the elderly. Protein-calorie malnutrition is common among the old elderly, and when they break a bone, such as the hip, serious complications and even death may develop. Protein supplementation reduces these complications substantially and is an important and necessary component of the treatment of most patients with hip fractures ([11](#)).

Magnesium Deficiency

Magnesium deficiency occurs with severe intestinal malabsorption (such as gluten-sensitive enteropathy, fistulas, or ileal resection, especially with high-fat diets) or with urinary losses from renal tubular defects. Initially, magnesium deficiency impairs bony responsiveness to PTH and thus leads to hypocalcemia despite a rising PTH level. As deficiency progresses, parathyroid response falters, and PTH secretion falls. The hypocalcemia of magnesium deficiency is thus due to impairment of the calcium regulatory system and is unresponsive to calcium supplementation ([12](#)) (see also [Chapter 9](#)). Less severe degrees of magnesium deficiency in these same syndromes are associated with reduced bone mass, also unresponsive to calcium supplementation. In addition to other needed treatments (such as calcium), magnesium supplements may be helpful in these patients.

INVESTIGATION OF NUTRIENT EFFECTS ON THE SKELETON

As noted above, the effects of nutrient deficiencies on the skeleton are expressed slowly in the adult. For this same reason, nutrient effects on the skeleton of any kind are difficult to detect and easy to misinterpret.

Change in Bone Mass

As noted above, bone is a composite of mineral and matrix, and “bone mass” refers, technically, to the quantity of such bone present in the whole organism (or in a body region). Technically, changes in bone mass itself cannot be measured *in vivo*, since there are no ways of detecting the organic component of the composite. However, in conditions of health, and in fact in most bone diseases, the proportion of mineral and matrix is about the same (50:50, by volume), and there are quite good methods for measuring bone mineral. Mineral content can be measured either for the whole skeleton or for various regions of interest by absorptiometric methods (see below). Change in bone mass is measured either by classic metabolic balance methods or by serial absorptiometry.

The classic nutritional approach to nutrient status is measurement of a metabolic balance, in this case, calcium (or phosphorus) balance. Since better than 99% of body calcium is in the skeleton, total body calcium balance reflects predominantly bone. And, since calcium is essentially never removed from or added to preformed bone tissue (rather units of tissue itself are removed or added), it follows that body calcium balance is a direct measure of bone tissue balance. The balance method is theoretically the ideal way of assessing change in bone mass, but it is expensive, and balance studies are difficult to perform accurately. The principal source of this difficulty, for poorly absorbed nutrients such as calcium, is that net absorption is low, and most of the ingested calcium ends up in the feces. Accurate timing of fecal excretion is nearly impossible. Moreover, lag time between ingestion and fecal excretion averages several days in healthy adults, and failure to take that lag into account leads to serious misinterpretation of calcium balance results (13). Colored dye markers demarcating treatment periods are not adequate safeguards. Rather, continuous intake markers (such as PEG 4000) are required, and fecal output must be adjusted both for its PEG content and for the time lag.

A newer approach, ideally suited to measurement of the quantity of bone present, is the direct measurement of bone mineral (13), either in a specific region or in the skeleton as a whole, by the technique of dual-energy x-ray absorptiometry (DEXA). A tightly collimated beam of x-rays is passed back and forth across the body (or one of its regions), and absorption of its photons is measured by a detector on the side opposite the x-ray source. Absorption is a function of the amount of mineral present in the path of the beam. This method measures, for example, spine mineral content in as little as 2 to 5 minutes and has a reproducibility on the order of 1 to 2%.

Because total body calcium in an adult is in the range of 900 to 1500 g, and because change in bone mass (in other words, positive or negative calcium balance) is rarely more than ± 100 mg/day (and usually much less), it follows that closely spaced, repeat measurements by DEXA will produce results within the reproducibility error of the

method. For that reason, measurements in individuals must usually be separated by 12 to 24 months (less time will not allow measurable change to occur). Thus, while DEXA permits rapid and accurate measurement of bone *mass*, it is not very sensitive to the sorts of *change in mass* that have physiologic or nutritional significance.

The Remodeling Transient

Any intervention, nutritional or otherwise, that alters bone remodeling activity will produce a transient change (15) in calcium balance (or bone mass) which is due to the asynchrony of the remodeling cycle (see above). Because of the temporal separation of resorption and formation at each remodeling site, suppression of remodeling will produce a prompt but temporary increase in bone mass (Fig. 83.7). If this follows, for example, administration of supplemental calcium, phosphorus, or vitamin D, the retention of bone mineral should not be interpreted to indicate a preexisting deficiency. (There may be such a deficiency, of course, but positive balance will occur whether or not deficiency is present, simply because, initially, the resorptive component of remodeling is reduced more than the formative component.) Since the remodeling cycle lasts at least 3 months in healthy young adults, bone mass (and calcium balance) continues to change under the influence of this asynchronous remodeling for at least that long. It may actually take a year or more in the elderly for formation and resorption once again to come into equilibrium. Response to nutritional interventions can only be interpreted *after* the transient is complete. If, at that time, balance is more positive (or bone mass by DEXA is still increasing), only then can one safely conclude that the subjects needed more of the nutrient than they had previously been receiving.

Bone Histomorphometry

The term *histomorphometry* means the measurement of shapes on histologic specimens of bone (16). As noted above, many substances attach to bone crystals as they are forming and then become trapped as more bone is laid down on top of them. Some of those substances, like the tetracycline antibiotics, fluoresce brilliantly when illuminated by ultraviolet light. Histomorphometry takes advantage of that property by giving patients paired, timed doses of tetracycline several days before obtaining a bone biopsy (typically from the iliac crest). Specimens are sectioned on special microtomes without first removing the mineral and then examined with an ultraviolet microscope. Figure 83.4 presents a typical photomicrograph from such a labeled biopsy. Since the distance between fluorescent lines can be measured with a calibrated eyepiece and since the times of administration are known, one can derive a reasonably precise estimate of the rate at which the remodeling cells are working and how active the remodeling process may be. Among other histologic features, measurements are made not only of the distance between labels but of the extent of bone surface covered with a label. This method is very useful for studying bone biology and disease but has limited applicability to the study of nutritional problems affecting bone.

Biochemical Markers of Bone Remodeling

In the synthesis of bone collagen, the ends of the collagen molecules are clipped off as the triple helix is assembled, the proline molecules in the peptide chain are converted to

hydroxyproline, and cross-links are developed between collagen molecules. Additionally, both alkaline phosphatase and the noncollagenous proteins are secreted into the matrix; in this process, some of these substances leak into the bloodstream. Later, when bone is broken down, the hydroxyproline residues and the cross-links, since they cannot be recycled, are metabolized or excreted. All these activities leave residues or produce effects that can be measured in serum or urine. Collectively, these circulating or excreted substances are called biochemical biomarkers of bone remodeling (17). They reflect in a general way the level of bone remodeling activity. [Table 83.2](#) summarizes the principal markers currently in use, together with the component of remodeling they are thought to reflect most directly. It is important to note, in this connection, that, when remodeling activity changes, *both* resorption and formation generally change, almost always in the same direction, and often to nearly the same extent. So, for most situations, a marker for either formation or resorption may be used as an index of remodeling activity.

Formation	Resorption
Serum alkaline phosphatase	Urine hydroxyproline
Bone specific	Urine pyridinium cross-links
Total	Pyridinoline
Serum osteocalcin	Deoxypyridinoline
Serum procollagen type I propeptide	Urine peptide cross-links
Carboxyterminal (P1CP)	Amino terminal (NTx)
Amino terminal (P1NP)	Carboxyterminal (crosslaps)

Table 83.2 Biochemical Markers of Bone Remodeling

While measurements of bone biomarkers can be a relatively inexpensive way of assessing bone remodeling activity under differing nutritional conditions, they are at best only semiquantitative. In other words, a 50% drop in a resorption marker does not mean a 50% reduction in the amount of bone resorbed. Also, the markers exhibit important discrepancies among themselves. For example, serum alkaline phosphatase is high in nutritional rickets despite a generally low level of new bone apposition, and 1,25(OH)₂ vitamin D elevates serum osteocalcin without, apparently, altering actual bone-forming activity (18).

The effects of nutritional deficiencies on the relationship between marker level and the process it reflects have not been studied. Nevertheless, to the extent that a nutritional deficiency alters bone remodeling, one can expect to find corresponding changes in remodeling marker levels. Thus, the accelerated bone loss of the aged, which is due to calcium deficiency, is associated with elevated excretion of deoxypyridinoline and hydroxyproline. Calcium supplementation both stops or slows the bone loss and

reduces urinary excretion of deoxypyridinoline

The nutritional requirements of healthy humans are relatively well described and are the basis of nutrient intake recommendations of several governmental and health agencies. However, rheumatic diseases represent an important deviation from the norm, and vital issues relevant to nutrient intakes need to be resolved. Are the nutrient requirements recommended for normal healthy children and adults sufficient to minimize the progression and destructive effects during development of these various pathologic conditions? Does the rheumatic disease condition represent a significantly altered physiologic state in which the spectrum and balance of nutrients recommended for normal healthy children and adults are no longer adequate? Rheumatic diseases represent a serious health hazard to a large minority of the adult population, and relatively little attention has been paid to the role of diet in the progression of this family of diseases, the severity once established, or the effect of the diseases on nutrient requirements. Nevertheless, the role of particular foods in mitigating disease severity has been widely speculated in folk medicine, and many individuals alter their diets in the hopes of beneficial effects. Rheumatic and inflammatory conditions are now known to increase demand on proteins because of increased turnover, on minerals because of increased mobilization, on antioxidant vitamins because of free radical scavenging, and on particular vitamins because of altered metabolism and bioavailability.

NUTRITIONAL IMBALANCE

Protein-Energy Malnutrition

Malnutrition in variable degrees is a common finding in patients with rheumatic

diseases, including rheumatoid arthritis (RA), rheumatoid spondylitis, systemic necrotizing vasculitis, systemic sclerosis (SSc), and systemic lupus erythematosus (SLE) (1, 2 and 3). Such data have profound implications for patients with chronic disease and may be a predisposing factor for infection and morbidity. For instance, results of a 2-year prospective study of hospitalized adult patients with RA found that malnutrition was associated with a poor prognosis, as assessed by rehospitalization and/or mortality rate (4).

Cytokine-Mediated Catabolism

Lean body mass, consisting of the body cell mass and connective tissue, accounts for nearly all metabolic activity of the body (5). Loss of body cell mass in chronic disease is associated with deficient immune competence (6) and has been shown to be a major predictor of outcome in certain critical illnesses. The mechanism of these effects is not clear, but inflammatory cytokines, such as interleukin-1b (IL-1b) and tumor necrosis factor-a (TNF-a), are associated with hypermetabolism and loss of body cell mass in animals (7). Similar effects have been shown following cytokine infusion studies in humans.

Adults with RA have significantly reduced body cell mass (8), and high levels of TNF-a and IL-1b have been demonstrated in synovial fluid and in the circulation of these patients (9, 10). A decrease of approximately one-third of the body cell mass was noted in patients with RA (11), which was associated with elevated levels of circulating IL-1b and TNF-a; the latter were associated with elevated energy expenditure (hypermetabolism). Significantly, this association was noticed even in a group with low disease activity, suggesting that hypermetabolism, a feature of chronic inflammation, lingers even when good clinical control of RA is achieved.

Anorexia

Poor appetite, a common finding among different chronic diseases, including SLE (12), and RA (11), appears to be more prevalent during periods of active disease. Although the contribution of drugs used in the treatment of these disorders should not be ignored, inflammatory cytokines appear to play a critical role. The proinflammatory cytokines IL-1 and TNF cause profound anorexia in experimental animals and humans (13) and, as discussed above, are present in elevated levels in patients with RA (14). Further support of this view comes from the recent report that documents an inverse association between IL-1b production and dietary intake in patients with RA (11). Perhaps, the anorexia induced by IL-1b aggravates the loss of body cell mass that occurs in the hypermetabolic state by preventing these patients from increasing their intake to meet their higher energy needs.

Gastrointestinal Involvement

Oral Cavity Abnormalities. Involvement of the oral cavity in rheumatic disease represents an additional impairment to adequate nutritional intake. Reduction of the oral aperture in SSc and arthritis of the temporomandibular joint and hypoplasia of the

mandible in juvenile RA limit mouth opening, cause pain with chewing, and difficulty in swallowing. For these reasons, foods requiring extensive mastication should be avoided. Patients with Sjögren's syndrome exhibit several dietary problems. Inadequate amounts of saliva to properly masticate and mix food makes swallowing solid aliments difficult. Many patients tend to reduce dietary variety and rely on the few foods that do not cause discomfort to eat, a practice that is invariably detrimental for adequate nutrition. Maintenance of proper hydration by drinking plenty of fluids, avoidance of caffeine and other beverages that exert a diuretic effect, sucking on noncaloric "candies," and preparation of food with a consistency agreeable to these patients are among possible nutritional strategies (15). Artificial saliva is currently available, and its use has been helpful in selected cases. Oral ulcerations, a common manifestation of systemic vasculitis and SLE, may decrease the palatability of foodstuffs and thus contribute to impaired food intake. Moreover, many fruits, juices, and some vegetables of higher acidic content are not well tolerated.

Esophageal Dysfunction. Abnormal esophageal motility is observed in nearly 90% of patients with SSc and has also been observed in a subset of patients with mixed connective tissue disease (MCTD). Uncoordinated peristalsis of the lower two-thirds of the esophagus often causes dysphagia and odynophagia for solid foods. The potential complications arising from gastroesophageal reflux include *Candida* esophagitis, erosive esophagitis, Barrett's metaplasia (with its accompanying potential for adenocarcinoma), strictures, and aspiration (16).

Malabsorption. Malabsorption has been described as a manifestation of many rheumatic syndromes, including RA, Behçet syndrome (17), and polyarteritis nodosa (18). In advanced SSc, in which nutrition is usually a major management problem, malabsorption can be the immediate cause of death (19). In SSc, malabsorption may result from bacterial overgrowth of the small intestine, abnormalities of the intestinal absorptive surface, and pancreatobiliary insufficiency (20). There is no predictably effective therapy other than treatment of bacterial overgrowth and nutritional support. Antibiotics and nutritional supplementation with fat-soluble vitamins, vitamin C, low-residue and elemental diets, and medium-chain triglycerides, are the foundation of therapy (16). In extreme circumstances, when oral intake is not adequate to sustain normal nutrition, tube feeding or total parenteral nutrition might be indicated (21).

Protein-Losing Enteropathy. Increased protein loss from the bowel is a rare manifestation of SLE (22, 23). This diagnosis should be suspected when diarrhea and severe hypoalbuminemia without proteinuria are found. Although infrequent, identification of this condition is important because of its deleterious nutritional implications and because many patients improve with corticosteroid therapy (23).

Nephrotic Syndrome

The kidney is one of the organs most commonly affected in SLE (24). In many instances, glomerulonephritis may be associated with the nephrotic syndrome (NS), a condition characterized by increased glomerular permeability to protein, often resulting in loss of more than 3 g of albumin per day in the urine. An important feature of NS is hyperlipidemia, characterized by increased plasma levels of potentially atherogenic

lipids such as very low density (VLDLs), intermediate-density, and low-density lipoproteins (LDLs) and, as the disorder progresses, also by hypertriglyceridemia and decreased concentrations of high-density lipoproteins (HDLs) (25, 26). These abnormalities are associated with an increased risk of coronary heart disease and may predispose to more rapid progression of renal disease. Moreover, uncontrolled NS can be complicated by increased susceptibility to infection, renal vein thrombosis, and protein-energy malnutrition (27).

In the past, high-protein diets were often prescribed for NS patients in an attempt to compensate for urinary protein losses and to restore normal serum albumin levels. More recently, however, it has become clear that increased dietary protein does not correct low serum albumin levels satisfactorily but does increase urinary protein excretion and may accelerate renal damage (28). The current general approach is to offer a diet with moderate protein restriction (containing no less than 0.6 g/kg body weight per day of protein of high biologic value), supplemented with an amount of protein equal to urinary loss. This strategy delays the progression of further loss of renal function (28, 29 and 30). The energy intake, nevertheless, should be closely monitored to avoid overt nutritional deficiency and be adjusted upward if concurrent infection or another condition increases energy output.

The effect of a vegetarian soy diet on hyperlipidemia was studied in 20 patients with longstanding NS (31). After a baseline control period of 8 weeks on their usual diets, patients were given a vegetarian soy diet (low fat, cholesterol free, and rich in monounsaturated and polyunsaturated fatty acids and fiber) for 8 weeks. After the diet period, patients resumed their usual diet for another 8 weeks (washout period). During the soy-diet period there were significant decreases in serum cholesterol (total, VLDL, HDL) and urinary protein excretion.

Obesity

Osteoarthritis

Several earlier studies have suggested that obesity is associated with osteoarthritis (OA), particularly knee OA (32, 33, 34 and 35). Obesity also aggravates joint dysfunction in patients with rheumatic diseases whose joint function has been compromised by articular damage. Diseases of weight-bearing joints are particularly affected by obesity, which further compromises already impaired ambulation.

Intestinal Bypass Arthritis

In the past, patients with morbid obesity were subjected to jejunocolic or jejunoleal bypass to limit intestinal surface for absorption. Follow-up of these patients revealed that up to 54% of them developed arthritis (36), presumably related to chronic bacterial overgrowth, immune complex formation and deposition on the synovial tissue, and complement activation (37, 38 and 39). The arthritis in these patients had a predilection for small joints of the upper and lower extremities (39). Oral antibiotics given intermittently or continuously reduce symptoms by reducing bacterial overgrowth (40). Surgical reversal of the intestinal bypass is usually associated with prompt and

invariable remission of the arthritis (36) and, in some instances, correlates with a decline of circulating levels of immune complexes (37).

METABOLIC DISORDERS AFFECTING CONNECTIVE TISSUE

Gout

Diet and alcohol are among the common and important environmental factors that contribute to hyperuricemia. Studies of patients with gout have not revealed any significant difference in dietary intake from control groups, with the exception of a greater intake of beer by patients with gout (41). Prolonged consumption of alcohol increases urate synthesis, presumably by enhancing the turnover of adenine nucleotides (42), while acute intoxication produces transient lacticacidemia and ketosis, which might lead to inhibition of renal secretion and consequent hyperuricemia (43). A diet rich in purines is well known to raise serum uric acid level. Nevertheless, when compared with dietary sources as the origin, more than 80% of the urate formed each day comes as an end product of tissue nucleic acid turnover.

A purine-free diet is unpleasant, difficult to follow, and largely unnecessary because of the effectiveness of drug therapy. The only consideration currently given to diet is avoidance of purine-rich foods such as liver, kidney, sardines, fish roe, anchovies, and sweetbreads, particularly by patients with massive tophaceous deposits (44). Control of obesity, reduction in alcohol intake, and, when necessary, control of hyperlipidemia, remain important aspects of the nutritional management of gout. However, abrupt loss of weight induced by severe dietary restriction for control of obesity can lead to ketosis accompanied by a fall in urate excretion and thus should be avoided (45).

Hyperlipidemia

Since the first description of a series of patients with an apparently distinct hyperlipidemic arthropathy (46), the true existence of such an entity has been controversial. Support from epidemiologic studies is largely lacking (47, 48 and 49), and if any agreement emerges from them, it is that features of inflammatory arthropathy are uncommon in patients with primary hyperlipidemia. In a clinical study, 18 patients homozygous for type II hyperlipidemia were identified among 14 families (46); 10 (56%) of them experienced a transient migratory polyarthritides with a pattern similar to that observed in rheumatic fever. Large joints were most frequently involved, and no relationship could be established between the joint affected and concomitant presence of xanthomas. Subsequent studies, although occasionally describing some of these features, contrasted with others, particularly the high incidence of rheumatic complaints reported. For heterozygotes, the evidence for an association is even scantier. Indeed, studies that support an association between type II hyperlipidemia and arthropathy show considerable diversity in the rheumatic syndrome reported. Of all possible associations with type II hyperlipidemia, the evidence for periartthritis, particularly Achilles tendinitis, is strongest (50, 51 and 52). The predilection of xanthomas for the Achilles tendon suggests a possible causal relationship (53).

An oligoarthropathy with or without symptoms suggesting inflammation has been reported in some patients with type IV hyperlipidemia (54, 55). There is an accepted association between gout and type IV hyperlipidemia (familial hypertriglyceridemia), although the basis of the association is not entirely delineated. In contrast to the controversy regarding the existence of a unique arthropathy resulting from primary hyperlipidemic conditions, the occurrence of rheumatic syndromes secondary to lipid-lowering drugs is well established. The most frequently implicated drugs are the fibric acid derivatives (e.g., clofibrate) and hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (e.g., lovastatin, simvastatin) (56, 57). The myopathy may manifest simply as asymptomatic increases in muscle enzyme levels, such as creatine phosphokinase (CPK) and aldolase, or alternatively as pain and predominantly proximal muscle weakness. Less commonly, this process can be so severe as to result in renal failure secondary to rhabdomyolysis.

Alkaptonuria (Ochronosis)

Alkaptonuria is a rare autosomal recessive disorder characterized by complete deficiency of the enzyme homogentisic acid oxidase (58), which causes accumulation of homogentisic acid in various tissues, leading to major sequelae. Because such pigment is preferentially deposited in cartilage, a degenerative arthropathy is an inevitable complication. Clinical manifestations are generally apparent in the fourth decade, when severe disability usually occurs secondary to articular and cardiovascular complications.

SPECIFIC NUTRIENTS IN RELATION TO RHEUMATIC DISEASES

Trace Minerals

Iron

Anemia is a frequent finding in patients with chronic inflammatory rheumatic diseases and may arise from different mechanisms. Most commonly, it is the anemia of chronic disease (ACD). A cytokine-mediated failure of the bone marrow to increase red blood cell production in response to erythropoietin and an impaired release of iron from the reticuloendothelial system are the most likely underlying mechanisms (60). Less commonly, true iron deficiency anemia due to poor dietary intake or gastrointestinal blood loss secondary to medication might occur in RA patients.

Numerous investigators have observed deposition of large amounts of iron in the synovial tissue of patients with RA (61, 62 and 63) and associated them with the occurrence of persistent joint inflammation (60). It has been hypothesized that excessive iron deposits may catalyze the formation of reactive oxygen species and thus contribute to inflammation and tissue injury in RA (64, 65). Intravenous infusion of iron produces synovitis in murine models (66) and precipitates flares of joint inflammation, with evidence of oxygen-free radical reaction products in serum and synovial fluid, in patients with RA (67, 68). Degradation of hyaluronate in RA synovial tissue was completely inhibited by iron chelators (69). Ferric nitrilotriacetate increased the production of

collagenase and prostaglandin (PG) E₂, as well as the number of rabbit synovial fibroblasts in vitro (70). Iron stimulated the DNA synthesis by synovial cells in vitro and exerted an additive effect on the activity of human cytokines (IL-1b, IL-7, TNF-a, IFN-g) for RA synovial cell proliferation (71).

Zinc

Plasma zinc levels are reduced in patients with many chronic inflammatory diseases including RA (72). The modifications in zinc status produced by inflammatory processes, however, appear to differ from that observed in subjects depleted of zinc by diseases such as alcoholic cirrhosis, diabetes, or renal insufficiency. With inflammation there is a redistribution of this element within the body compartments, characterized by decreased plasma zinc concentrations and increased zinc concentrations in mononuclear leukocytes, urine, and synovial fluid (73, 74, 75 and 76). These modifications significantly correlate with the degree of inflammation.

The clinical effects of zinc supplementation in RA were first examined by Simkin in 1976, who reported clinical improvement in patients suffering from chronic refractory RA by using 660 mg/day of zinc sulfate (77). These results could not be confirmed by several subsequent trials. The fad of zinc supplementation is not exempt from side effects (78). Significant impairment of lymphocyte and neutrophil functions (79) and a potentially harmful increased LDL:HDL ratio (80) have been described in healthy adults with excessive intake of zinc (³150 mg/day, a 10-fold excess of the recommended dietary allowance [81]).

Copper

Copper, along with zinc, is a constituent in cytoplasmic superoxide dismutase (SOD). Both ceruloplasmin and SOD possess antioxidant properties and have an essential protective role against free radical-mediated tissue damage observed in inflammatory states (82, 83). Copper bracelets were used by the ancient Greeks to relieve aches and pains (84) and presently are used as a folk remedy for RA. Open trials using copper salts to treat RA and OA have been reported (85, 86). Although uncontrolled observations account for mild improvement in some of these patients, many side effects have been reported, and it is unlikely that copper compounds will play any relevant role in RA or OA therapy (87). Elevated copper levels have been observed in both serum and synovial fluid of patients with RA (88, 89, 90 and 91), with most studies showing a positive correlation with disease activity (89). Normalization of levels along with acute-phase reactants has been reported following pharmacologic control of disease (89).

Selenium

The antiinflammatory and immunomodulatory properties of selenium prompted studies of its role in RA, juvenile RA (JRA), OA, psoriatic arthritis, and SLE. In most of the studies of RA (92, 93, 94, 95 and 96) and JRA patients (97, 98), plasma levels of selenium were significantly lower than those of healthy controls. In one study, selenium

levels in the serum of patients with psoriatic arthritis were significantly lower than those of healthy controls (99). In another study, plasma selenium levels were within the normal range in patients with SLE, although a trend to lower values was observed in active disease (100). However, most selenium supplementation trials, (usually using organic selenium compounds) failed to demonstrate any significant improvement in any of these diseases, even when the deficient selenium status was corrected (101, 102 and 103). While selenium supplementation (250 mg/day) significantly increases selenium concentration in serum and red blood cells of both RA and control subjects (101, 102), it does not increase selenium levels in PMN leukocytes from patients with RA as it does in PMNs from control subjects (104). Moreover, while selenium supplementation substantially increased glutathione reductase (GSH-Px) activity in serum, red blood cells, and platelets from RA patients, activity did not reach control levels in PMN leukocytes of these same patients. Given the important role of PMN leukocytes in the inflammatory process in RA, these findings agree with the lack of a benefit from selenium supplementation in controlled studies of RA patients. Altogether, these observations suggest that altered selenium metabolism rather than dietary deficiency underlies the observed levels.

Vitamins

Vitamin A and Retinoids

Both isotretinoin and etretinate have been associated with development of hyperostosis, especially in the cervical spine, and extraspinal calcifications of tendons and ligaments (105). These spinal changes at times resemble those seen in diffuse idiopathic skeletal hyperostosis (DISH), often developing in individuals younger than those usually afflicted with spontaneous DISH. Growth retardation and premature epiphyseal plate closure have been described in children under chronic therapy with large doses of vitamin A and, in a few instances, after administration of isotretinoin or etretinate (106).

Vitamin C (Ascorbic Acid)

Ascorbic acid is essential for the synthesis of collagen, the main extracellular protein of connective tissue. Its deficiency, such as seen in patients with scurvy, accounts for inadequate synthesis of collagen and consequent impaired wound healing and capillary fragility. An accurate differential diagnosis is needed because scurvy lesions in the skin can, at times, mimic those seen in cutaneous vasculitis (107). Decreased synthesis of collagen, however, is not a key feature in any of the rheumatic diseases. Low levels of ascorbic acid, in plasma, blood cells, and synovial fluid have been described in RA patients, irrespective of drug therapy. In the 1940s, vitamin C was used to treat RA. Nevertheless, large vitamin C supplements given to normalize serum levels had no effect on the clinical course of RA or laboratory parameters of inflammation (108).

Vitamin B₆ (Pyridoxine)

Low vitamin B₆ levels in the circulation is a well-described metabolic abnormality in patients with RA (11, 109). Low plasma levels of pyridoxal-5'-phosphate (PLP), the

metabolically active form of B₆, also occur in these patients (110) and appear to be related to the degree of inflammation and the levels of inflammatory cytokines such as TNF- α (109). Given its role as a cofactor in numerous enzymatic reactions involving aminoacids and proteins, including nucleotide and protein synthesis and cellular proliferation (111), altered bioavailability of B₆ has been hypothesized to affect the balance between protein synthesis and degradation (109). Vitamin B₆ administration to patients with RA, including those with low serum levels of PLP, failed to show any clinical improvement in disease activity (110).

Vitamin E

While peroxidative damage has been associated with the loss of certain T-cell receptor activities (112), human lymphocytes have been shown to be protected from lipid peroxidation when cultured with vitamin E (113). Data from studies assessing the plasma levels of vitamin E in patients with RA conflict; some studies found a normal baseline (114, 115), while others reported significantly lower levels (116) than those in normal individuals. Concentrations of α -tocopherol in the synovial fluid significantly lower than those of paired serum samples have been observed in patients with RA (115). In one study, multiple regression analysis indicated that depletion of α -tocopherol was largely independent of the concomitant lower concentrations of cholesterol, triacylglycerol, and LDL in the inflamed joint (117). At least in vitro, the antioxidant activity of vitamin E is regenerated by electron donation from vitamin C (118, 119). Because vitamin C levels are low in RA joint fluid, it has been hypothesized that this is caused by local consumption of α -tocopherol (117). Nonetheless, whether low levels of α -tocopherol in the synovium contribute to oxidative damage of the joint or are an indirect marker of the local oxidative stress remains to be properly addressed. Fish oil preparations used in clinical trials of RA (discussed below) are enriched in α -tocopherol, which prevents peroxidation of its polyunsaturated fatty acids (PUFAs). Since the degree of unsaturation of the cell membrane increases the risk for lipid peroxidation and generation of toxic-free radicals, the α -tocopherol requirement depends on the amount of PUFA consumed. Data from several studies, however, show that despite a substantial increase in consumption of fish oil PUFAs, the amount of α -tocopherol added to fish oil capsules usually suffices to prevent deficiencies in cellular and plasma levels of vitamin E (114, 118, 119 and 120). The clinical benefit of dietary fish oil supplementation in RA does not depend on the antioxidizing properties of the low dose of α -tocopherol (10.3–12.9 mg/day) in fish oil capsules (114, 121). In fact, aside from subjective parameters, no significant clinical improvement was observed even when patients with RA were supplemented with 1200 mg/day of α -tocopherol (122).

Histidine

Several studies have demonstrated a selective low level of serum histidine in patients with RA, compared with normal subjects including family members (123). The extent of reduction of histidine levels correlates with the degree of disease activity as assessed by clinical and laboratory parameters (124). Available in health food stores, L-histidine has been used empirically to treat patients with RA; however, a placebo-controlled trial, failed to demonstrate any convincing benefit of a dietary supplement of L-histidine in RA

(125).

FOOD AND RHEUMATIC DISEASES

Diet has been hypothesized to affect rheumatic diseases by two possible mechanisms that are not mutually exclusive. First, food-related antigens might induce hypersensitivity responses leading to rheumatic symptoms. Second, nutritional factors might alter inflammatory and immune responses and consequently modify manifestations of rheumatic diseases.

Food Hypersensitivity

The belief that food-related antigens might provoke hypersensitivity responses leading to rheumatic symptoms is not a recent one (126, 127). This thesis has gained some support from sporadic but convincing case reports of the reproducible onset of a selected rheumatic syndrome shortly after ingestion of certain aliments. For a response to food to be linked plausibly to a hypersensitivity reaction resulting in a rheumatic symptom, food antigens would have to cross the gastrointestinal barrier and circulate in an antigenic form until recognized by effector or intermediary cells in the immune system. Although large molecules with antigenic proprieties are known to have very limited access to the circulation, some food antigens do cross the gastrointestinal barrier and circulate not only as food antigens but also as immune complexes (128, 129). The M cell, a specialized epithelial cell that covers the intestinal lymphoid tissue, being free from glycocalyx, is in direct contact with the intestinal contents. These cells, by active pinocytosis, randomly pick up foreign antigenic material from the intestinal lumen and present it to the underlying macrophages and lymphocytes (130). Antigenic molecules may also pass through the intestinal mucosa, in a less controlled manner, through gaps in the epithelium caused by allergic, infectious, or toxic processes (130). Nonsteroidal antiinflammatory drugs (NSAIDs), largely used for symptomatic management of pain, might lead to a loss of intestinal integrity, thus facilitating food antigen absorption (131). Because no reliable laboratory test is available, the diagnosis of food hypersensitivity still rests mostly on clinical grounds (see Chapter 92).

Food Hypersensitivity Associated with Inflammatory Arthritis

A relationship between food intake and inflammatory (rheumatoid or rheumatoid-like) arthritis has been suggested by a number of clinical observations (132, 133, 134, 135, 136 and 137). It is possible that cases are underreported, because patients may not necessarily be aware of possible sensitivities to commonly ingested foods in the diet. The small number of documented cases in the literature, however, suggests that the syndrome is probably rare.

Food Hypersensitivity Associated with Systemic Lupus Erythematosus

In the late 1970s, alfalfa meal was shown to reduce plasma cholesterol levels significantly and induce regression of atherosclerotic lesions in cholesterol-fed monkeys (138) and rabbits (139). Subsequent studies indicated that ingestion of alfalfa seeds

was also associated with reduced plasma cholesterol levels in humans (140). In one study, however, after prolonged ingestion of alfalfa seeds, one human volunteer developed clinical and serologic features of SLE (141). Upon cessation of the dietary supplement of alfalfa seeds, these abnormalities reverted to normal. Because alfalfa sprouts had become an increasingly popular diet constituent in humans, further studies were undertaken to investigate potential side effects of their ingestion, in particular the induction of autoimmunity. These studies confirmed that alfalfa triggered an SLE-like syndrome in normal monkeys fed with alfalfa seeds and reactivated disease in susceptible animals (142). Isolated reports also suggest a similar role of alfalfa in inducing or reactivating human SLE (143). A nonprotein amino acid, L-canavanine, has been proposed to be the alfalfa component responsible for triggering an SLE-like syndrome (142). Canavanine is the principal free amino acid of a number of legumes such as clover and alfalfa, and it has also been reported to be a constituent of several food crops, including onions and soybeans (144). Interestingly, most of the toxic properties of L-canavanine appear to be destroyed by heating or cooking (145), which might explain why humans have not been affected more adversely by its toxicity (144). Altered synthesis of messenger RNA with resultant altered transcription has been hypothesized as the mechanism by which L-canavanine induces the generation of autoantibodies (144). Also, antibodies to alfalfa seeds appear to cross-react with DNA (146).

Food Hypersensitivity Associated with Other Systemic Rheumatic Diseases

Walnut extract has been reported to exacerbate Behçet's syndrome within 48 hours of its ingestion (147). In ex vivo studies, lymphocytes from these patients exhibited significantly decreased reactivity to both walnut extract and *Candida* antigens, which was associated with an increase in frequency and severity of their symptoms. Although it has been suggested that this transient suppression of lymphocyte reactivity may be responsible for the deleterious effects on the course of the disease, the mechanism by which English walnuts exacerbate Behçet's syndrome remains unknown.

Hypersensitivity to different foods has been hypothesized to be the cause of at least some cases of palindromic rheumatism and, in one instance, occurred secondary to sodium nitrate in food preservatives (148). Rarely and mostly in anecdotal reports, food hypersensitivity has been implicated as a cause of vasculitis. In 1929, Alexander et al. reported six patients with Henoch-Shöenlein purpura that improved when certain foods were excluded and recurred when those foods were reintroduced (149). Twenty-three patients with allergic purpura related to ingestion of certain foods were reported by Akroyd in 1953 (150). Azo dyes, particularly tetrazine, has also been occasionally implicated as a cause of purpura in a few patients (151, 152).

Eosinophilia-Myalgia Syndrome (EMS)

L-Tryptophan (LT) is an essential amino acid found in meats, dairy products, and some vegetable protein sources. Dietary supplementation with LT is associated with a unique rheumatic disease (EMS). Marketed as an over-the-counter food supplement in the United States since 1974 (153), LT became popular among health professionals and nutrition enthusiasts as a natural remedy for depression, insomnia, and premenstrual

symptoms (154). The rationale for use was based partly on evidence that serotonergic activity is decreased in patients with depression. However, the clinical data that support its use are scant and at times conflicting (155, 156). In fall 1989, an outbreak of eosinophilia and severe myalgia was associated with ingestion of tryptophan (157, 158); this syndrome became known as eosinophilia-myalgia syndrome. Within 6 months after the initial description, 1511 cases (including 38 fatal cases) were reported to the Centers for Disease Control and Prevention (CDC) (159). Intensive epidemiologic investigation has established that all traceable EMS cases were linked to ingestion of L^T produced by a single manufacturer (160) and that most likely identified contaminants such as 1,1'-ethylidenebis[tryptophan] play a role in the pathogenesis of EMS, although the mechanism remains unclear (161, 162).

Dietary Therapy

Dietary therapy for rheumatic diseases can be divided into two modalities: (a) *elimination therapy*, which includes both removal of selected foods from the diet and fasting, and (b) *supplementation therapy*, in which foods are added to the diet.

Elimination Therapy

The use of different diets to treat RA has been the subject of numerous studies and endless speculation. In 1983, Panush et al. (163) studied the effect of a commercially popular diet (the Dong diet [164]) in a 10-week placebo-controlled blinded study of 26 patients with active RA. This diet consists of simple Chinese foods, free of additives, preservatives, fruit, red meat, herbs, dairy products, and alcohol. The authors found no significant differences between patients on the Dong and placebo diets. However, two patients on the Dong diet experienced considerable clinical improvement and had recurrences of symptoms when they deviated from it. In 1986, Darlington et al. published the results of a nonblinded, placebo-controlled study of 6 weeks of dietary elimination therapy in 53 patients with RA (134). After a washout period during which no treatment was prescribed, the patients randomly received either the trial diet, which excluded cereal, or a placebo diet. No significant objective differences were observed between the two groups.

The role of diet in the treatment of RA remains controversial, partially because existing trials do not provide clear-cut results. Such trials have difficulty in ensuring compliance and in the ever-greater problem of blinding the trial and placebo diets. Moreover, the trial design might be inappropriate if the study population is heterogeneous and only a small number of patients are capable of being improved (165). In this context, studies with individual patients who have their symptoms exacerbated on a sufficient number of occasions by exposure to the alleged offending food provide more compelling evidence that in fact selective patients might benefit from exclusion of the offending food. In general, however, especially until methodologic impediments can be overcome, patients should be encouraged to follow balanced healthy diets and avoid elimination diets and fad nutritional practices that can lead to, or increase, preexisting nutritional deficiencies (166).

In 1979, Sköldstam et al. (167) reported that fasting for 7 to 10 days resulted in

objective improvement of disease in 5 of 15 patients with classic RA, whereas only 1 of 10 control subjects improved. Equivalent results were subsequently presented by other investigators (168, 169, 170 and 171). The mechanism by which fasting improves RA symptoms is not fully understood. In a controlled trial conducted by Kjeldsen-Kragh et al. (168), 7 to 10 days of fasting, followed by an individualized vegetarian diet for a year, resulted in sustained advantage for the diet group. Nonetheless, in the vast majority of studies, the antirheumatic effects of fasting disappear shortly after eating is reinstated, whether the patients return to an ordinary Western diet (170), lactovegetarian diet (167), or strict vegetarian diet (vegan) (172). Complete fasting for periods beyond 1 week is considered unsafe (even for patients with no complicating disorders), with potential risk for protein-energy malnutrition (PEM) and renal and cardiac complications (172, 173).

Supplementation Therapy

Among dietary supplements, the most extensively investigated in rheumatic diseases are the w-3 and w-6 polyunsaturated fatty acids. Increasing experimental and clinical data supports the use of oral-feeding antigens in an attempt to treat RA. The use of vitamins and trace elements in treatment of rheumatic disorders was discussed above in this chapter.

w-Fatty Acids. Fatty acids in the cellular membranes are substrates for the production of prostaglandin (PG) and leukotriene (LT) species fundamental for many biologic activities, including modulation of the inflammatory and immune responses; w-3 (w-3) and w-6 (w-6) fatty acids can only originate from diet and are considered essential because their deficiency can result in growth retardation and death. The composition of phospholipids in cellular membranes is determined by nutritional intake, and alterations in dietary lipids can cause major changes in the synthesis of lipid-derived mediators of inflammation. By far the most common polyunsaturated fatty acid constituents in the Western diet are the w-6 fatty acids, predominantly from terrestrial sources. This represents a great departure from the nutritional habits throughout most of human evolution, which were characterized by consumption of a higher percentage of polyunsaturated fat, more w-3 fatty acids, more fiber, and less total fat than the present Western diet. This relatively recent change in dietary patterns may have affected the development of some major chronic diseases in industrialized society. Epidemiologic studies, for example, have shown a lower incidence of myocardial infarction, asthma, diabetes mellitus, and psoriasis in Greenland Eskimos than in European controls (174). A study from the Faroe Islands reported that RA takes a milder course in this population than in other Nordic countries (175). Such evidence suggests that these findings are, at least in part, attributable to a high dietary intake of marine oils containing w-3 polyunsaturated fatty acids.

In Western societies, arachidonic acid (AA) (20:4, w-6) is predominantly present in cellular membranes and leads to the formation of the most potent PGs ("2" series), via the action of cyclooxygenase, and LTs ("4" series), via the action of 5-lipoxygenase. Marine polyunsaturated w-3 fatty acids, such as eicosapentanoic acid (EPA) (20:5, w-3) and docosahexanoic acid (DHEA) (22:6, w-3), competitively inhibit the use of AA and become a substrate for the production of alternative biologically active products through the cyclooxygenase and 5-lipoxygenase cellular metabolic pathways. As a result,

generation of PGs of the “3” series and LTs of the “5” series increases, both of which have considerably less proinflammatory effects than the corresponding AA metabolites. LTB₅, for instance, which is usually undetectable in humans consuming a Western diet, has only approximately 10% the potency of LTB₄ (176). Platelet-activating factor–acether (PAF-acether) generation of stimulated monocytes is also significantly diminished after fish oil ingestion (177). This is of considerable interest in the context of inflammation because PAF can stimulate endothelial cell generation of TNF and is 1000 times more potent than histamine in inducing vascular permeability. Alteration of the cell membrane composition by PUFAs may also result in changes in the signaling pathways critical for regulation of immune responses and cell adhesion. Of particular interest, eicosanoids modulate the immune system either directly by stimulating target cells or indirectly by modulating the production of other soluble regulatory factors such as cytokines. Normal individuals given a diet enriched with fish oil exhibit significantly reduced monocyte production of IL-1 and to some extent TNF (177).

The benefit of dietary supplementation with marine w-3 fatty acids has been demonstrated in some, but not all, models of chronic inflammatory disease (178, 179 and 180). The most striking results were observed in New Zealand Black x New Zealand White F1 hybrid mice (NZB/W), which spontaneously develop SLE-like features such as hemolytic anemia, antinuclear autoantibodies, and glomerulonephritis. NZB/W mice fed a diet rich in EPA experience notably lower levels of proteinuria, significantly lower levels of antibodies binding native DNA, and a greatly improved survival rate. The beneficial effect on glomerulonephritis is observed even if dietary supplements are withheld until after the kidney disease is established. Importantly, fish oil reduction of autoimmune disease severity in NZB/W mice does reduce immune competence, at least not in terms of susceptibility to bacterial, yeast, or viral attack.

Because this strain provides a good model in several respects, the use of marine lipids has been postulated to be of therapeutic value for human SLE. Unfortunately, this assumption has been to date only seldom, and inadequately, tested. A placebo-controlled study of 39 patients with SLE failed to show significant improvement in disease activity after 12 months of fish oil administration (181). However, the heterogeneous population enrolled in this study makes interpretation difficult. In another study, Westberg and Tarkowski (182), using a double-blind, crossover design, evaluated for a period of 6 months the effect of EPA in 17 patients with moderately active SLE. Significant improvement of clinical and serologic parameters was observed in the treated group after 3 months, but at 6 months no differences could be observed between this and the group control, suggesting a short-lived effect of EPA on SLE.

Kremer et al. pioneered the systematic study of essential polyunsaturated fatty acid supplementation (EPA and DHA) in patients with RA, and showed a significant improvement in the number of tender joints and morning stiffness in the treated group (183). Since then, several other studies have been carried out (184, 185, 186 and 187), most of which reported findings similar to those of Kremer's original study. Taken together, they indicate that w-3 fatty acid supplementation exerts significant but modest antiinflammatory effects in patients with RA. These benefits appear to be dose dependent, more consistently observed after 18 to 24 weeks of fish oil administration, and in some instances accompanied by a decrease of LTB₄ and/or IL-1, and elevation of

LTB₅. A modest sparing effect was observed in the studies that used reduction or discontinuation of NSAID therapy as the measure of outcome.

Raynaud's phenomenon, a condition marked by increased vascular reactivity to cold exposure, can be a primary disorder or part of the constellation of symptoms in SSc. Episodes of blanching or cyanosis of the fingers are the most characteristic clinical features. Infarction of tissue at the fingertip, however, may also lead to digital pitting scars or frank gangrene. DiGiacomo et al. observed that some of the biologic effects of w-3 fatty acids in cardiovascular disease could potentially benefit such patients (188). These effects include decreased plasma viscosity, a more favorable vascular response to ischemia, a reduced vasospastic response to catecholamines and angiotensin, an increase in the levels of tissue plasminogen activator, and an increase in the endothelium-dependent relaxation of arteries in response to bradykinin, serotonin, adenosine diphosphate, and thrombin. A single prospective, double-blind controlled study of the effect of dietary supplementation with 3.96 g of EPA and 2.64 g of DHA was conducted for 3 weeks in 32 patients with primary or secondary Raynaud's phenomenon (188). Patients with primary, but not secondary, Raynaud's phenomenon who ingested fish oil showed significant improvement in the time-to-onset of Raynaud's phenomenon triggered by hand immersion in cold-water baths.

w-6 Fatty Acids. Other fatty acids also exhibit antiinflammatory and immunomodulatory effects in experimental models and preliminary clinical trials. gLinolenic acid (GLA) (18:3, w-6), a fatty acid found in seeds from the evening primrose (EPO) and borage, has been the focus of substantial investigation. GLA is a precursor of other w-6 fatty acids, including AA, and may be converted by an elongase enzyme to dihomogamma-linolenic acid (DGLA) (20:3, w-6). In humans, the delta 5 desaturase that converts DGLA to AA is inefficient. Since GLA is rapidly converted to DGLA, concentrations of AA do not increase appreciably. Hence, DGLA competes with AA for cyclooxygenase, reducing the generation of prostanoids derived from arachidonate (see Chapter 4). While AA leads to the formation of PGs of the "2" series, DGLA, as a substrate for cyclooxygenase, generates prostaglandins of the "1" series, for which it has been shown to hold beneficial antiinflammatory and antithrombotic properties. Although the biologic activities of corresponding members of the monoenoic ("1" series) and dienoic ("2" series) are qualitatively similar in many instances, in some respects they differ considerably. For example, PGE₁ inhibits aggregation of human platelets in vitro, whereas PGE₂ does not influence this activity. Also, PGE₁ is much more effective than PGE₂ in increasing levels of cAMP in human synovial cells in culture and in suppressing synovial cell proliferation.

Along with its influence on the generation of PGs, it is of considerable importance that DGLA cannot be converted to inflammatory leukotrienes by 5-lipoxygenase (189). Instead, DGLA is converted to hydroperoxyl DGLA, which has additional aptitude to inhibit 5-lipoxygenase activity (190). Independent of its role as a prostaglandin precursor, DGLA may have an important role in regulating immune responses by suppressing IL-2 production by human PBMC and proliferation of IL-2-dependent T lymphocytes. GLA dietary supplementation suppresses acute and chronic inflammation, as well as joint tissue injury, in several experimental animal models (191). In ex vivo studies, addition of DGLA to human synovial cells grown in tissue culture inhibits

IL-1 β -stimulated growth fivefold, compared with cell growth in medium supplemented with AA (192). Compared with cells in control medium, those incubated with DGLA displayed a 14-fold increase in PGE₁ and a 70% decrease in PGE₂ levels.

Studies of dietary supplementation with GLA in humans have yielded somewhat mixed results. EPO used in short-term studies (12 weeks), with a small number of patients ($n = 20$) with RA has shown no apparent clinical benefit (193). GLA (in the form of EPO) was also used in a 12-month placebo-controlled, double-blinded study (193) in which 49 patients with active RA were randomly allocated in three groups receiving (a) 540 mg/day GLA, (b) 240 mg/day EPA and 450 mg/day GLA, or (c) an inert oil as placebo. In both treated groups, reduction of pain, together with a reduction or even termination of NSAIDs therapy, was reported. Nevertheless, no significant objective changes in clinical or laboratory parameters were demonstrated. Pullman-Moore et al. (194) used a higher dose of GLA (1.1 g/day), in the form of borage seed oil, to treat seven patients with active RA for 12 weeks. The authors reported significant clinical improvement in morning stiffness and in the number of swollen and tender joints. Although the larger dose of GLA used might explain the apparent favorable results, the lack of a placebo control in this study makes this assumption impossible to assess. More recently, two prospective double-blinded, placebo-controlled studies observed significant clinical improvement in RA patients taking GLA (195, 196). Although the initial study design was well conceived, the study included a limited number of patients, limited follow-up duration, possible interference by concomitant use of other medications, and a high number of dropouts, making further controlled studies necessary.

Because phosphatidylinositol (PI), a critical source of AA, is remarkably insensitive to dietary modification by ω -3 PUFAs, it has been hypothesized that alternative strategies to replace PI could displace a more significant amount of cell membrane AA and therefore exert a more potent antiinflammatory and immunomodulatory effect (196). Dietary *Platycladus orientalis* seed oil, which is rich in 5,11,14-eicosatrienoic acid and 5,11,14,17-eicosatetraenoic acid, alters the fatty acid composition of PI in the cell membrane (197), displacing a significant amount of AA (198). Moreover, *P. orientalis* seed oil suppresses antierythrocyte autoantibodies, and significantly prolongs the survival of NZB mice, suggesting that the use of unique exotic oils might have a place in the nutritional therapy of autoimmune-mediated diseases. No clinical studies with such derivatives have been reported to date.

In summary, convincing clinical evidence supporting the therapeutic use of ω -6 fatty acids in rheumatic diseases has yet to be demonstrated. The choice of an appropriate placebo for clinical studies on both EPO and fish oil has been the focus of evolving dispute. Because some fatty acids, such as olive oil, are thought to have potentially significant immunologic effects, it has been hypothesized that some of the so-called placebo fatty acids used in different studies could produce beneficial effects. The controversial issue of the ideal placebo dietary intervention to compare with EPO or fish oil remains to be settled.

NUTRITIONAL ASPECTS OF PEDIATRIC RHEUMATIC DISEASES

Pediatric rheumatic diseases are a heterogeneous group of illnesses that cause

inflammation in a variety of tissues, including joints, muscles, skin, and visceral organs. Juvenile rheumatoid arthritis (JRA) is the most common pediatric rheumatic disease and one of the more prevalent chronic diseases of childhood (199). Other relatively less common disorders include SLE and juvenile dermatomyositis (JDM). In spite of the fact that growth retardation was noted over 90 years ago in the original description of JRA (200), not until recently have studies addressed the nutritional status of pediatric populations suffering from rheumatic diseases and the possible association between nutrition and growth in these patients (201). The developmental abnormalities observed in this group include generalized short stature in JRA, SLE, and JDM; diffuse muscle atrophy in JDM and JRA; and localized asymmetric growth abnormalities in JRA and JDM (202).

Protein-energy malnutrition has been identified in up to 50% of patients with JRA (202, 206). Multiple factors contribute to increase nutritional risk in children with JRA. Intermittent or persistent anorexia, at least in part mediated by overproduction of IL-1 and TNF, occurs most commonly in periods of increased disease activity. In one study, dietary analysis revealed that the mean caloric and selected nutrient intakes (calcium, iron) of patients with JRA ranged from 50 to 80% of those of healthy children of comparable age and sex, as reflected in the U.S. recommended allowances (203). As in adult patients with RA, decreased serum levels of selenium, vitamin C, iron, and zinc have been reported in JRA. Additional risk for malnourishment arises from mechanical feeding difficulties. Up to 30% of JRA patients develop arthritis of the temporomandibular joint and hypoplasia of the mandible, which limit mouth opening and can cause pain with chewing. Nearly 30% of these patients develop hypoplasia of the mandible, resulting in malalignment of the teeth and difficulty swallowing (204).

Children with rheumatic diseases are also at high risk for developing osteoporosis (205). This increased risk is due to multiple factors including limited physical activity, immobility, limited sunlight exposure (especially for those suffering from SLE in which sunlight is known to trigger relapse of disease), inadequate dietary intake of calcium and vitamin D, low body weight, and use of corticosteroids. In a preliminary crossover study with 10 corticosteroid-treated children with rheumatic disease and osteoporosis, the use of calcium and vitamin D supplementation significantly improved spinal bone density (205). Corticosteroid therapy also intensifies the preexisting risk for growth retardation of JRA patients during childhood and into adulthood.

When planning nutritional intervention in pediatric patients with rheumatic diseases, potential changes in nutrient requirements for children with a great degree of persistent inflammation should be considered; patients with active disease often require increased dietary energy and protein. Although PEM and growth abnormalities ameliorate as the underlying inflammatory process is controlled through medication, most rheumatic disorders are chronic, and they may remain active for several years or for a lifetime. National statistics reveal that the pediatric rheumatology patient population is nutritionally largely underserved; only 8% of these patients are seen by a dietitian. In fact, this is probably an overestimation, since these studies were conducted on university-based pediatric rheumatology centers where there is more likely to be a dietitian. Pediatric dietitians must be included in the interdisciplinary team involved in the care of these patients, to ensure prompt and effective management of nutritional

problems ([206](#)).

One and a half million osteoporotic fractures of the spine, hip, wrist, and other sites occur each year, primarily in postmenopausal white women. The number of osteoporosis cases among men and nonwhite individuals, however, is expected to rise substantially in the next several decades as life expectancy increases and the world population expands. In the United States, direct medical costs of fractures among the population aged 45 and older totaled nearly 14 billion dollars in 1995 (1). Treatment of men accounted for approximately 3 billion dollars, or 20% of the total amount. In addition, fractures of the hip and spine often contribute to disability, dependence, and increased risk of death.

Osteoporosis is typically defined as a reduction in bone mineral mass that results in decreased bone strength and increased susceptibility to fracture with only mild-or-moderate trauma. For a discussion of normal bone development, metabolism, and composition and the roles of various nutrients in bone health and disease, see

[Chapter 83](#). Osteoporotic bone tissue is characterized by demineralized, disconnected trabeculae and thinning of the outer cortical surfaces ([Fig. 85.1](#)). The etiology and symptoms of osteoporosis and its link to the menopause were first described by Albright et al. more than 50 years ago ([2](#)). Several causes were known or suspected at that time, including immobilization, diet, and metabolic diseases. In subsequent years, the list of risk factors has grown, and it is now recognized that bone mass throughout the life span and the risk of osteoporotic fracture are determined by heredity and a large number of environmental factors. Diet remains of critical interest in this multifactorial disease because it is one of the few determinants that can be safely modified.

Figure 85.1. Electron micrographs of iliac crest biopsies illustrating normal bone (*upper panel*) and osteoporotic bone (*lower panel*). Normal bone consists of a series of plates (*P*) interconnected by thick rods (*B*). The osteoporotic bone has few plates, and several rods are fractured or disconnected (*arrow*). (From Dempster DW, Shane E, Horbert W, et al. *J Bone Miner Res* 1986;1:15, with permission.)

BONE DENSITY ASSESSMENT

Much of our knowledge of the influence of nutrition and other factors on bone status and fracture risk has been gained since the introduction of precise, noninvasive methods to measure bone mineral density (BMD). Widely used methods for both clinical diagnosis and research purposes include single photon or single x-ray absorptiometry, which is appropriate for measuring sites without much overlying fat and muscle tissue (e.g., wrist and heel), and dual photon or dual x-ray absorptiometry for sites such as the hip, spine, and whole body, where thicker layers of soft tissue surround the bone. Bone density is proportional to the amount of energy that is absorbed as it passes from an energy source located on one side of the bone to a detector on the opposite side. Low-radiation x-ray absorptiometry has largely replaced the older technologies that used a photon energy source. A bone density scan of the hip is shown in [Figure 85.2](#).

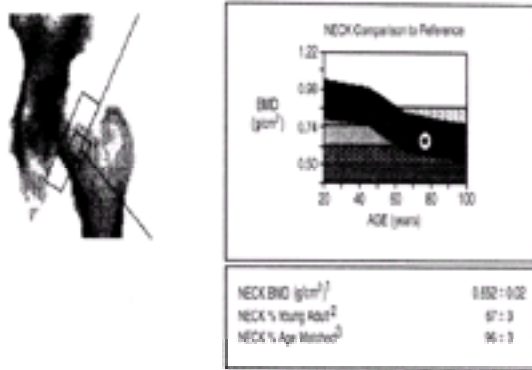

Figure 85.2. Dual-energy absorptiometry of the femur site of a 78-year-old woman. The femoral neck is the area outlined by the *large box* in the picture on the *left*. The graph and percentages on the *right* compare the subject's bone mineral density (*BMD*) with the mean value of 20-year-old women (*% young reference*) and the mean value for women the same age as the subject (*% age-matched*). The total width of the *dark band* in the center of the graph encompasses 1 standard deviation (SD) above and 1 SD below the mean BMD at various ages.

Quantitative computed tomography (QCT) and quantitative ultrasound are two alternative research techniques for assessing bone status. QCT is primarily used to selectively assess trabecular bone, which is metabolically more active than cortical bone. Quantitative ultrasound measures the attenuation and velocity of sound waves as they pass through bone and other tissues. These measures are thought to assess qualitative factors such as bone architecture and elasticity in addition to bone mineral mass. Advantages of ultrasound are the lack of radiation exposure and the compact size of ultrasound units, which allows bone status measurements in field settings.

EPIDEMIOLOGY OF OSTEOPOROSIS

The descriptive epidemiology of osteoporosis depends to some extent on the method used to define the disorder. Fractures resulting from moderate trauma (e.g., a fall from standing height or less) are the most important clinical outcome of osteoporosis. The incidence of fractures rises sharply in the fourth decade of life and, at the hip and spine, continues to rise exponentially with age in men and women. At age 50, a white woman has a 30% chance of suffering a nonvertebral fracture sometime during her remaining life, and a man has about a 13% chance of fracture. Osteoporosis in women can also be defined solely in terms of BMD, regardless of whether an individual has suffered a fracture. There is a continuous inverse relationship between BMD and risk of fracture (3), as shown in [Figure 85.3](#). The fracture rate for a given decrease in BMD is greater in older than in younger individuals (*left panel*), which indicates that qualitative properties of bone that are not measured by BMD are important in determining fracture risk.

Figure 85.3. Relationships between bone mass of the radius, age, and rate of all nonvertebral fractures in women. For a given age, the risk of fracture increases with progressively decreasing bone mass (*left panel*). The relationship between fracture risk and age is stronger, however, as seen by the steeper rise in risk with advancing age at a given level of bone mass (*right panel*). (From Hui SL, Slemenda CW, Johnston CC Jr. *J Clin Invest* 1988;81:1804–9, with permission.)

Overall, the likelihood of fracture increases 1.5- to 3-fold for each standard deviation decrease in bone density. The WHO Consensus Development Conference criteria for the definition of osteoporosis are based on this relationship: BMD that is not more than 1 standard deviation below a young female reference value is considered normal; osteopenia (low BMD) is defined as BMD more than 1 but less than 2.5 standard deviations below the reference value; and osteoporosis is present when BMD is more than 2.5 standard deviations below the reference value. Using these criteria, it is estimated that 7 to 9.4 million women in the U.S. have osteoporosis, and at least 13 million are osteopenic (4). Less than 15% of white women aged 50 have BMD in the osteoporotic range, but the prevalence rises to 70% among women aged 80 and older. Accepted definitions of osteopenia and osteoporosis based on BMD need to be developed for men.

Patterns of Peak Bone Density and Bone Loss

BMD in the older adult has been influenced by the peak bone mass achieved in young adulthood as well as the rate of bone loss in later years. The patterns of peak BMD, rates of bone loss, and fracture incidence vary with sex, age, ethnic group, and possibly skeletal site. Women, on average, have lower BMDs than men. This sex difference becomes evident in adolescence and is enhanced in later adulthood by several years of rapid bone loss surrounding the menopause. Blacks tend to have higher BMDs than whites and Asians, and this difference is first apparent in early childhood (5).

Growth in childhood is accompanied by an increase in bone mass. Bone mass accumulates rapidly during the growth spurt that normally occurs between the ages of 11 and 14 years in girls and 13 to 17 years in boys. After the growth spurt, bone

continues to increase in density but at a slower rate until peak bone mass is achieved sometime in young adulthood, about the same time that the bones cease to grow in length and the epiphyses close (6). Small increments in bone mass may continue until the late 20s or 30s.

Bone loss in young adults is believed to be minimal, and the age of onset may vary by skeletal site (7). Longitudinal studies of women indicate that bone loss at the spine and radius occurs before menopause, but the rate is not greater than 1%/year. Within the first 1 to 5 years after the onset of menopause, the rate of bone loss is two to six times premenopausal levels, but it gradually returns to about 1% annually about the 10th year after menopause. In older women, bone loss continues at a rate of approximately 1% annually into advanced ages (8, 9), although the rate may accelerate again after age 75 (8). An apparent increase in lumbar spine density with age has been reported in elderly women and men, but this is attributed to coexisting osteoarthritis or calcification of soft tissue in the region of the spine, such as the aorta, which interferes with bone density measurement.

Until recently, men were frequently excluded from studies of osteoporosis and bone loss. The higher average bone mass seen in men beginning at puberty is maintained throughout the life span, and it is not clear at what age bone loss begins in men. Cross-sectional studies indicate that decreases in bone density at various skeletal sites among men over 50 are similar in magnitude to the declines seen in women more than 10 years postmenopause (10, 11). These findings have been confirmed in several longitudinal studies in men in which rates of bone loss from the hip (9) and radius (12) were approximately 1%/year.

Epidemiology of Fractures

The incidence of fractures peaks in childhood and then declines until age 40, when rates begin to rise again. Most fractures among children and young adults result from severe trauma and are not highly dependent on bone density, but after age 40, an increasing proportion of fractures result from mild or moderate trauma. Patterns of fracture incidence in older adults generally reflect the variations in bone mass and rates of loss by age and race, although there are distinct patterns of incidence at different skeletal sites.

Radius

The incidence of fractures of the forearm or distal radius (Colles' fracture) rises after age 40 and tends to level off by age 55 in men or age 65 in women. The incidence of Colles' fractures among women in Rochester, Minnesota, increased from 107/100,000 person-years between the ages of 35 and 39 to a maximum of 640/100,000 person-years at ages 60 to 64 (13). Among men, the rate increased from 44/100,000 person-years at ages 35 to 39 to a maximum of 118/100,000 person-years at ages 50 to 54. The ratio of forearm fracture in females and males varies from 2:1 at age 35 to more than 8:1 after age 80.

Femur

Beginning at age 40, the rate of hip fracture doubles about every 6 or 7 years in men and women in the United States, and this exponential rise continues among the very old (14). Among white individuals aged 85 years, the annual incidence rate of femoral fracture is approximately 2300/100,000 in women and 1200/100,000 in men. By age 95, the rates rise to 3600/100,000 in women and 2500/100,000 in men. The risk in black women is 50% higher than in black men at age 85 (900 and 600/100,000, respectively). Men and women of Asian descent living in the United States also have a reduced risk of hip fracture, comparable to that in blacks. International comparisons indicate that incidence rates of hip fracture in black and Asian men and women are approximately one-quarter to one-half those of white women in northern Europe and the United States. On average, an Asian women has half the risk of hip fracture of a white male living in the United States or northern Europe. Among white women aged 80 years and older, 20% of all fractures are hip fractures, which are nearly four times more common than fractures of the extremities. Of all osteoporotic fractures, those at the hip are associated with the highest risk of death and disability.

Spine

A vertebral compression fracture is typically diagnosed when the height of the vertebra decreases by 20% or more. As a result, the normally cube-shaped vertebra frequently becomes concave or wedge shaped. A severe consequence of vertebral fractures is kyphosis, or the curved spine known as "dowager's hump." Vertebral fractures arising from mild or moderate trauma occur more than three times more frequently in women than in men in the United States, 137 versus 44 fractures per 100,000 population per year, respectively (15). There is considerable geographic variation in the prevalence of this type of fracture. Estimates of the prevalence of vertebral fractures in the population over age 65 years vary from less than 3% in Finland to more than 20% in the United States (16). Because vertebral fractures can be asymptomatic or easily misdiagnosed, rates of vertebral compression fracture estimated by radiographic evaluations are much higher than those obtained from hospital admissions and clinical presentation.

Other Sites

Osteoporotic fractures at sites other than the radius, spine, or hip account for approximately half of all fractures among women aged 65 and above. Pelvic fracture resulting from moderate trauma in women in Rochester, Minnesota, rose from 17/100,000 person-years at ages 35 to 54 to 446/100,000 over age 85 (17). In men, the rate reached 64/100,000 by age 85. Fractures of the humerus display a similar gender-specific pattern, rising from 120/100,000 at ages 50 to 69 to 317/100,000 above age 70 in women, and from 27 to 51/100,000 in men (18). In contrast, fractures such as those of the ankle, ribs, patella, and hands do not appear to follow the age- or sex-specific incidence patterns of other osteoporotic fractures (14).

Falls

More than 90% of fractures among the elderly are caused by falls. Factors associated with an elevated risk of falling include use of sedatives, diminished muscle strength, gait and balance difficulties, arthritis, poor vision, Parkinson's disease, and disabilities of the lower extremities (19, 20). The chance of falling increases as more risk factors are present. In addition to bone density, biomechanical and individual characteristics influence the likelihood of fracture due to a fall. Hip fractures occur more frequently after a fall to the side (21), while Colles' fractures are more often associated with forward falls. The height of the fall is directly related to the force of impact and risk of fracture, but individuals with a high body mass index are less likely to sustain a fracture (21). Most falls occur after tripping or slipping on environmental hazards (19), which implies that nonmedical interventions can significantly reduce the number of falls and fractures.

NUTRITIONAL DETERMINANTS OF BONE DENSITY AND FRACTURE RISK

Many nutritional factors have been examined for associations with osteoporosis and bone mass. Calcium, phosphorus, trace minerals, and protein are components of bone tissue. Vitamin D regulates calcium balance, and various other nutrients interact with calcium absorption and excretion. Thus, dietary intakes of these nutrients may affect bone mass, although the strength of associations may be expected to vary according to developmental phase, menopausal status, and habitual intake by the subjects studied.

Calcium

Calcium Intake and Bone Mass in Childhood

Bone mass during childhood and adolescence can be increased by raising calcium intake to the level of the 1989 RDA or above (1200 mg or 30 mmol per day for ages 11–24 years) or to the 1997 Food and Nutrition Board adequate intake (AI) values of 1300 mg (32.5 mmol) per day for ages 9 through 18 years and 1000 mg (25 mmol) ages 19 through 50 years for both males and females (see Appendix [Table II-A-2-a-2](#) and [Table A-2-b-1](#)). A 3-year randomized, double-blind, placebo-controlled trial was conducted in twins aged 6 to 14 years, during which the usual daily calcium intake (22.5 mmol, or 900 mg) of one of each pair was supplemented with 17.5 mmol (700 mg) daily (22). In prepubertal twins, the child taking the calcium supplement gained a total of 3 to 5% more bone mass at the radius and spine than his or her sibling, but there was no clear benefit of supplementation among older children. In another randomized study, calcium supplementation in girls, mean age 11.9 years, a daily calcium intake of 32.8 mmol (1314 mg) was associated with 2.6% higher bone densities at the spine and whole body bone density at the end of 2 years (23). A daily calcium intake of 30 mmol achieved with dairy foods instead of supplements was associated with larger gains in BMD at the spine and whole body in 9- to 13-year-old girls than in a control group (24). Intakes of phosphorus, vitamin D, and protein were also increased, and it is not certain if calcium or a combination of nutrients was responsible for the gains in bone mass. The

benefit to bone mass of 18 months of added calcium in prepubertal children disappeared when supplementation was halted (25), suggesting that adequate calcium intake may need to be maintained throughout childhood and adolescence to have a meaningful impact on peak bone mass. Gains in peak bone mass may afford some protection against fracture in later life.

Calcium Intake and Bone Loss in Adult Women

Increased calcium intake causes a short-term reduction in bone turnover in adult women, but whether initial beneficial effects on the rate of bone loss can be maintained for an extended period of time is questionable. The bone remodeling rate generally returns to a steady state within a year after the introduction of calcium. In addition, early and sustained effects may differ in trabecular and cortical bone.

Premenopausal. Prospective studies indicate that increasing calcium intake may reduce the rate of bone loss in premenopausal women. Spinal bone loss was significantly lower in a group of women who used dairy foods to raise calcium intake from 22.5 to 37.5 mmol (900 to 1500 mg) daily (26). A similar level of calcium intake (37 mmol) attained through supplementation slowed bone loss from the humerus but not the radius or ulna (27). The effect of calcium on bone density at other skeletal sites such as the hip in young women is unknown.

Postmenopausal. The responsiveness of bone to nutritional intervention is blunted in the first few years of menopause, as falling endogenous estrogen levels create a new “set point” of bone metabolism. Thus, results of calcium supplement trials in older women vary according to the menopausal status of the participants. Findings of recent randomized, placebo-controlled trials in early and late postmenopausal women (28, 29, 30, 31 and 31a) are summarized in Table 85.1. A 3-year study of early menopausal women found that the effect of supplementation on the femoral neck was sustained during the 2nd and 3rd years (28). Calcium supplementation also slowed the loss of total body calcium in that study. A 2-year controlled study of women aged 46 to 55 years found that daily supplements of 25 or 50 mmol (1 or 2 g) retarded spinal bone loss only within the 1st year (32). In the 2nd year, rates of loss in all groups were similar. Nevertheless, BMD in both supplemented groups remained higher than in the control group throughout the study, because of the benefits accrued in the 1st year. Calcium had no benefit on metacarpal bone mineral. Limited responses to added calcium were also observed in early menopausal women with low usual calcium intakes, under 16.2 mmol, or 650 mg (33).

Investigator (ref. no.)	Description of Subjects	Study Length	Mean Daily Calcium (mg/day)	Intervention ^a	Effect on Bone Loss
Alpert et al. 1984 (28)	107 women, age 40-52 years, 6 months-8 years postmenopausal	2 years	<600	1000 mg/day Ca 400 IU vitamin D ^b	Total body calcium ↓ Femoral neck ↓ Spine n.s. Radius n.s.
Reid et al. 1988 (29)	70 women, mean age 58 years, mean 8.5 years since menopause	4 years	760	1000 mg/day Ca	Spine ↓ Whole body ↓ Hip ↓
Prince et al. 1988 (30)	100 women, age 50-70 years, at least 10 years postmenopausal	2 years	800	1000 mg/day Ca as supplement or with products	Intertrochanteric hip ↓ Ankle ↓
Chesnut et al. 1984 (31)	70 women and men, age 62-87, previous bone fractures, no previous hip fractures	18 months	<700	800 mg/day Ca ^c	Hip ↓ Spine n.s.
Cauley-Jones et al. 1987 (31a)	300 healthy men and women, age 65 years or older	2 years	<800	500 mg/day Ca 500 IU vitamin D ^b	Hip ↓ Whole body ↓ Spine ↓

Abbreviations: Ca, calcium.
^aAs reported + (1000 mg Ca + 400 IU vitamin D) or 1000 mg Ca.
^bCaution: calcium supplements reduced the rate of bone loss compared to placebo, i.e., appeared to be beneficial, although these studies
^cPatients in placebo group also received 400 IU vitamin D daily.
^dBoth subset of treatment and placebo groups were given 1000 IU of intertrochanteric hip fractures.

Table 85.1 Summary of Recent Randomized Trials of Calcium Supplementation

The recent controlled trials of calcium supplementation in later postmenopausal women (29, 30, 31 and 31a) shown in Table 85.1 confirm earlier studies that demonstrated a reduction in bone loss (33, 34). Several also suggest that the benefits can be maintained over an extended period of time. In a 4-year study in which total calcium intake was raised to 42.5 mmol/day (1700 mg), a reduction in whole-body bone loss became apparent after the 1st year but continued at a slower rate throughout all remaining years of the study (29). Other factors have emerged in addition to menopausal age that may modify the effect of calcium intake on bone loss. The level of usual calcium intake affected the degree to which a supplement containing 500 mg (12.5 mmol) elemental calcium retarded bone loss among late menopausal women participating in a randomized, placebo-controlled study (33). The largest reductions in bone loss from the spine, hip, and radius were observed in women with usual daily calcium intakes below 10 mmol (400 mg). And, the benefit of increased calcium intake on weight-bearing sites such as the hip appears to be enhanced in women who also have high levels of physical activity (30, 34).

Calcium Intake and Bone Loss in Men

Daily milk consumption as a teenager, recalled several decades later, was associated with higher hip BMD among men aged 50 to 88 years (10). To date, there are few longitudinal studies of calcium supplementation among men to confirm the association (31a). A placebo-controlled study in men aged 30 to 87 found that added calcium did not reduce bone loss at the spine over 3 years (12). These men habitually consumed a high level of calcium, over 27.4 mmol (1100 mg) per day, and the treatment group received an additional 25 mmol/day. It is possible that there is a threshold of calcium intake above which more calcium has no measurable effect. Calcium supplementation benefited older men with lower usual dietary levels at multiple skeletal sites (31a).

Calcium Intake and Fracture Rates

Previous epidemiologic associations of increased calcium intake and reduced fracture

rates are supported by placebo-controlled trials (29, 31, 35). The incidence of hip fractures and of all nonvertebral fractures in over 3000 elderly French women was reduced by 26% in a group supplemented with 30 mmol (1200 mg) of calcium and 20 mg (800 IU) of vitamin D (35). The control group received placebos of both calcium and vitamin D, so it is not certain which agent contributed more to the reduction in fractures. The results of supplement trials of calcium only and the known function of vitamin D in promoting intestinal calcium absorption suggest calcium had a critical role. Three smaller studies are consistent with the French study (29, 31, 31a). Calcium supplementation reduced the rate of all fractures in a 4-year study of postmenopausal women, but the total number of fractures was small (29). Three years of calcium and vitamin D supplementation was associated with a reduction in nonvertebral fractures in elderly men and women (31a). In an 18-month trial, the rate of vertebral compression fractures was about 32% lower in the treatment group than in a placebo group, but again the number of fractures was small, and the difference was not statistically significant (31). The reduction in risk may have continued over a longer follow-up time.

Summary of Calcium Intake and Bone Mass

Observational studies and controlled trials with children, young adults, and the elderly all support the important and measurable role of calcium intake in building and maintaining bone mass and reducing bone loss. Studies in children demonstrate that increasing calcium intake to the RDA or above augments bone density. Dietary or supplemental calcium reduces bone loss, although it may not eliminate it, in premenopausal and postmenopausal women and reduces the risk of fracture. Our knowledge of the effect of calcium intake on rates of bone loss in older men is limited. Variations in the response to calcium at different skeletal sites may be related to the proportions of trabecular and cortical tissue in bone, usual calcium intake level, and the interaction of calcium with other dietary and lifestyle characteristics.

Vitamin D

Vitamin D is obtained from the diet in the forms of ergocalciferol and cholecalciferol as well as from cutaneous synthesis after exposure to sunlight. It is hydroxylated to 25-hydroxyvitamin D (25(OH)D, or calcidiol) in the liver and then to the active metabolite, 1,25-dihydroxyvitamin D (1,25(OH)₂D, or calcitriol), in the kidney. 1,25(OH)₂D stimulates calcium absorption across the intestine and is necessary for maintenance of healthy bone. Plasma level of 25(OH)D is a widely used clinical indicator of vitamin D status. Although it reflects both dietary and endogenous contributions, sunlight exposure appears to have a stronger influence on 25(OH)D level than diet at vitamin D intake levels typically consumed in the United States and Europe. However, diet takes on increased importance in wintertime at high latitudes in healthy adults and throughout the year in individuals who have limited sun exposure or a diminished ability to synthesize the vitamin. In the United States and Europe, the elderly ingest an average of 2.5 μg (100 IU) per day, which is only half the RDA in the United States.

The concentrations of parathyroid hormone (PTH), 25(OH)D, and 1,25(OH)₂D vary with

season. In the northern hemisphere, PTH is higher and levels of 25(OH)D and 1,25(OH)₂D are lower in winter than in summer. The most striking seasonal variability is seen in individuals with dietary vitamin D intake below 5 µg, or 200 IU (36). Rates of bone loss have also been reported to vary by season, with more rapid loss during the period in which PTH is elevated and vitamin D levels are low (37).

The role of vitamin D insufficiency in osteoporosis is increasingly recognized. The lower intestinal calcium absorption and blood levels of 25(OH)D and 1,25(OH)₂D seen in many osteoporotic patients compared with healthy age-matched controls may result from inadequate dietary vitamin D or impaired 1,25(OH)₂D action. Plasma 1,25(OH)₂D and calcium absorption can be corrected by administration of calcitriol, but previous studies with small numbers of subjects did not agree on the impact on bone density and fracture rates. Spine BMD and total-body calcium were maintained by elderly osteoporotic women after treatment with calcitriol (despite the fact that dietary vitamin D was replete), but there was no effect on the rate of vertebral fracture (38). A large multicenter trial found that treatment with 0.5 µg/day of calcitriol reduced vertebral fractures in osteoporotic women, compared with treatment with 25 mmol (1000 mg) calcium (39). The benefit was greatest in women with mild-to-moderate preexisting spinal fractures.

Vitamin D supplementation appears to be effective in preventing fracture in the frail elderly. Annual intramuscular injections of ergocalciferol to institutionalized and free-living elderly persons in Finland reduced the number of upper body fractures (e.g., radius, humerus, ribs) but surprisingly had no apparent effect on lower limb fractures (40). Injections overcame the problems of poor intestinal absorption and noncompliance. The large controlled trial of 20 µg cholecalciferol and calcium supplementation in elderly French women showed a substantial reduction in risk of fracture (35). Compared with the placebo group, there was a 26% reduction in the number of hip fractures and other nonvertebral fractures with vitamin D treatment. There was also a significant 6% difference between treatment and placebo groups in bone density of the hip in a subset of women measured over the 18-month interval. In contrast, rates of hip and other types of fracture were similar in a placebo group and a group supplemented with a lower dose of vitamin D (10 µg) without calcium in a large study in the Netherlands (41). Major differences in the population characteristics and treatments in these two trials that could have contributed to the contradictory findings are condensed in Table 85.2. The overall risk of fracture may have been lower in the Dutch study because of the inclusion of men, noninstitutionalized persons, and individuals with high usual calcium intake. The French study suggests that a large segment of the population with low calcium intakes would possibly benefit from increased vitamin D intake.

	France (25)	The Netherlands (41)
Subjects	3270 women	1916 women 662 men
Residence type	All institutionalized	60% institutionalized 40% free living
Daily supplement ^{a,c}	20 µg vitamin D with 1200 mg calcium and 690 mg phosphorus	10 µg vitamin D
Usual dietary calcium ^b	511 mg/day	888 mg/day
Duration of trial	18 months	3.5 years
Effect of intervention on fracture rate	26% reduction in hip fractures and all nonvertebral fractures	None

^a 20 µg vitamin D = 40 IU.

^b 1 mg calcium = 0.025 mmol.

^c 1 mg phosphorus = 0.030 mmol.

Table 85.2 Summary of Differences in Two Large Intervention Trials of Dietary Vitamin D on Fracture Rates in Elderly Subjects

The 1997 FNB adequate intake (AI) values for vitamin D were doubled to 10 µg/day for women aged 51 and above, compared with the 5 µg (as cholecalciferol) in the 1989 RDA (see Appendix [Table II-A-2-a-2](#) and [Table II-A-2-b-4](#)).

Phosphorus

An increase in serum phosphorus concentration arising from high dietary phosphorus intake stimulates PTH secretion, which in turn suppresses 1,25-(OH)₂D production and intestinal calcium absorption. As a consequence, excess phosphorus intake may be a concern. Increased phosphorus has an opposing effect on calcium balance, however, by reducing the amount of calcium lost through the urine, and this action may adequately offset the adverse effects on calcium absorption and bone metabolism in healthy adults. The phosphorus:calcium ratio may be more important than the level of phosphorus alone. A diet high in phosphorus (55 mmol or 1700 mg/day) and low in calcium (10 mmol/day) produced an increase in PTH secretion ([42](#)). If extended over a long period of time, it is suspected that this common dietary pattern could lead to unfavorable bone balance, but this has not been demonstrated.

Prolonged dietary phosphorus deficiency can deplete the serum level and result in enhanced resorption of this mineral from the bones. For a portion of the elderly population, phosphorus deficiency is a concern. Low serum phosphorus levels can result from malnutrition, excessive use of phosphorus-binding antacids, and intestinal malabsorption. The phosphorus content of calcium triphosphate supplements may have contributed to some degree to the reduction in fracture rate in the French study of vitamin D and calcium intervention ([35](#)). The 1997 FNB RDA for phosphorus in men and women above 19 years (700 mg/day) is lower than the 1989 RDA of 1200 mg at 19 to 24 years and 800 mg thereafter (see Appendix [Table II-A-2-a-2](#) and [Table II-A-2-b-2](#)).

Protein

The average protein intake in many industrialized countries is at least 50% above recommended levels. Excess protein intake has been proposed as a reason for the high incidence of osteoporosis in such populations despite moderate-to-high average calcium intakes. The proposed mechanism is the calciuric effect of protein. Over a wide range of protein intake, an average increase in dietary protein of 1 g results in the loss of an additional 1 mg of calcium in the urine. The effect of protein is rapid and is not balanced by a change in calcium absorption. Calcium losses of this magnitude could be very important in individuals with a low usual calcium intake or impaired calcium absorption. The importance of the protein effect in healthy adults is less clear. The interactions of protein, calcium, and phosphorus at various intake levels of these nutrients require further study.

Although reducing protein intake conserves calcium, intakes below the RDA can have serious adverse effects in the elderly. Patients with hip fracture are frequently protein and calorie malnourished. Protein-rich dietary supplements administered to hip fracture patients reduced the rates of complications and death immediately after surgery, and the rates remained lower than those of nonsupplemented patients for a period of 6 months ([43](#)).

Sodium

Sodium causes an increase in renal calcium excretion. At the high levels of sodium intake typical in the United States, over 90% of ingested sodium is excreted, and urinary sodium is a valid estimate of dietary intake. For each 500-mg increment in sodium excretion (or sodium intake) there is approximately a 10-mg increase in the amount of calcium lost in urine. Because, on average, only 25% of ingested calcium is absorbed, this means calcium intake must be raised 40 mg to compensate for a 500-mg increment in sodium intake. The impact of sodium intake on the rate of bone loss at the hip was evaluated in postmenopausal women ([44](#)). Over a wide range of sodium excretion (1–6 g/day), there was an increasingly negative change in hip bone density with higher levels of urinary sodium. In that population, optimal intakes to minimize bone loss were estimated at approximately 25 mmol (1000 mg) of calcium and no more than 87 mmol (2000 mg) of sodium daily.

Caffeine

Caffeine ingestion causes a short-term (within 1–3 h) increase in urinary calcium loss, but controlled studies have failed to document sustained effects of caffeine on urinary or fecal calcium excretion ([45](#), [46](#)). Such a temporary increase may be expected to have a minor effect on net calcium balance. However, among older individuals with low calcium intakes, the effect may possibly take on relatively greater importance as the body fails to adequately compensate for the additional calcium loss. A study of postmenopausal women found that coffee intake of two or more cups per day was associated with lower BMD in those who did not drink milk on a daily basis ([47](#)). Bone loss was more rapid in a subgroup of women with calcium intake below the RDA of 800 mg/day and caffeine

intake of more than two to three cups of brewed coffee per day (46). Coffee consumption has also been associated with greater risk of hip fracture (48) in elderly women.

Alcohol

Chronic alcoholism and osteoporosis commonly co-occur in men (49). Ethanol directly affects bone tissue by suppressing bone formation. Its use is also associated with multiple nutritional deficiencies, hepatic damage, and hypogonadism, all of which have deleterious effects on bone metabolism. Moderate or social use, on the other hand, appears to have the opposite effect on BMD and bone loss. Several population studies have reported that moderate alcohol use is associated with higher mean bone density levels (50) and reduced rates of bone loss (51). Alcohol stimulates the conversion of androstenedione to estrone, an estrogenic compound with bone-preserving properties. A potential reduction in fracture risk among alcohol users arising from a modest increase in bone density may be offset by an increased likelihood of falling, however.

Fluoride

Fluoride stimulates osteoblast activity and can replace hydroxyl ions in the hydroxyapatite structure of bone. This substitution results in bone with increased crystalline size but decreased elasticity and quality. Thus, although the compression strength of fluoride-enriched bone is greater, the tensile quality may decline. An association between increased bone density on radiographs and naturally occurring high fluoride in drinking water, at concentrations between 0.21 and 0.30 mmol (4–5.8 mg) per liter, was observed in an early study (52). In contrast, fluoridated drinking water that supplies 0.05 to 0.16 mmol (1–3 mg) per day has neither beneficial nor deleterious effects on bone density (53) or hip fracture rates (54).

When used in high doses as a therapeutic agent for osteoporosis, fluoride increases spinal bone density, but the effect on fracture incidence is less clear. No protection against vertebral fractures was found in two trials of 3.9 mmol (75 mg) fluoride, and there was a suggestion that nonvertebral fractures might have increased on fluoride therapy (55, 56). More recently, a lower dose of slow-release sodium fluoride (1.3 mmol or 25 mg/day) administered cyclically increased bone density of the spine and hip and decreased the rate of vertebral fracture (57).

Trace Minerals

Increasing boron intake may result in a drop in urinary excretion of calcium, phosphorus, and magnesium and a simultaneous increase in serum estradiol level (58). Such findings suggest that boron may play a role in maintaining calcium balance. Although the mechanism is unknown, it is postulated that boron is necessary for formation of certain steroid hormones or hydroxylation of 25(OH)D. More information is needed on usual dietary intakes and boron requirements before its importance in the development of osteoporosis can be fully understood.

Bone tissue contains approximately half of the body stores of magnesium. In animals, dietary magnesium restriction is associated with increased bone resorption and decreased formation. When magnesium depletion is induced in humans, decreased PTH secretion, hypocalcemia, hypocalciuria, and a positive calcium balance result. Reports of altered levels of magnesium in bone of osteoporotic and control subjects have not been substantiated.

Manganese, zinc, and copper are cofactors for enzymes essential to bone tissue. The effect of these three trace minerals on bone loss at the spine, alone or in combination with calcium, was evaluated in a 2-year trial of postmenopausal women (59). Spine BMD in the group supplemented with a combination of 25 mol (1 g) calcium, 0.09 (5 mg) mmol manganese, 0.04 mmol (2.5 mg) copper, and 0.23 mmol (15 mg) zinc showed no decline compared with that in the control group, which lost an average of 3.5% of bone mass. The role of these trace minerals in maintaining bone mass has not yet been established.

OTHER RISK FACTORS FOR OSTEOPOROTIC FRACTURE

Body Weight and Body Composition

Bone loss that occurs during prolonged immobilization and weightlessness in space flight demonstrates the importance of gravitational force in preserving bone density. Body weight is directly correlated with bone density, and higher weight protects against fracture (60). Apart from the contribution of total weight on bone mass, the two major components of body weight, fat-free mass (primarily muscle) and fat tissue, may influence bone through other mechanisms. Fat tissue is a source of endogenous estrogen. In postmenopausal women, this source takes on increased importance as gonadal hormone production declines. Muscle size is influenced by some of the same factors that stimulate bone formation, such as physical activity, insulin, growth hormone, and androgens. There is no agreement on whether the fat (61) or fat-free (62) component of body weight is more important in building and preserving bone density. However, excess body fat is strongly associated with increased risk of numerous chronic diseases.

Smoking

Cigarette smokers often possess characteristics associated with low bone density independently of their exposure to tobacco. These include lower body weight, greater consumption of caffeine and alcohol, and, in women, earlier menopause. Controlling for some or all of these factors, women who smoke have lower bone density and more rapid rates of bone loss than nonsmokers (63, 64). The effect of smoking is thought to be related, in part, to alterations in estrogen metabolism. Smoking increases the hepatic conversion of estradiol into biologically inactive metabolites at the expense of active hormones estrone and estriol (65). Although one population study of hip fracture in elderly women reported that smoking reduced the benefit of hormone replacement therapy (66), another found no difference in bone loss rates between smokers who did

use supplemental estrogen and those who did not (64). Smoking is associated with lower BMD, increased rate of bone loss, and higher fracture risk in men, as well (67). It is not known if smoking affects circulating androgen levels or has other direct effects on bone tissue.

Physical Activity

Part of the decrease in bone density that accompanies aging may be due to declining physical activity levels in later life. Vigorous, high-impact activity in young men and premenopausal women results in modest increases bone mass. Evidence suggests that initiating an exercise regime in older, previously sedentary individuals will increase bone density or slow bone loss. It is not known if any one type of activity is best for maintaining bone health. Vigorous aerobic activity and muscle-strengthening exercises have each been associated with increased or maintenance of bone density, particularly at skeletal sites that are directly stressed by the activity (68, 69). In postmenopausal women, aerobic exercise for 20 minutes, three times a week in conjunction with muscle-strengthening exercise is recommended to help stabilize bone density. Physical activity also improves muscle function and may play a role in reducing fall-related fractures.

Heredity

Like many anthropometric traits, bone density displays a family resemblance. The similarities arise from the influences of genetic factors and shared environment on peak bone mass, rates of bone loss, or both. Family and twin studies have reported moderate-to-strong correlations of bone density among relatives over a wide age range (70, 71 and 72), indicating a substantial genetic component to peak bone mass and possibly rates of bone loss.

A genetic marker, the vitamin D receptor (VDR), has been associated with bone density and rates of bone loss in several different populations (73, 74) but not in others (75, 76). Interactions of VDR alleles with calcium intake have been reported (77, 78). Women with the low-bone-density genotype exhibit more-rapid bone loss when their usual calcium intake is very low (77) and lack a compensatory increase in calcium absorption in response to a reduction in dietary calcium (78). These relationships have yet to be confirmed. Other hormone receptors such as the estrogen (79) and PTH receptors are also potential markers of bone density.

Glucocorticoid Medications

Glucocorticoids are a class of drugs used to treat a range of chronic inflammatory diseases such as rheumatoid arthritis, inflammatory bowel diseases, asthma and other respiratory disorders, and systemic lupus, and to suppress the rejection of transplanted organs. Adverse effects associated with their use include decreased intestinal absorption and increased urinary excretion of calcium, reduced gonadal hormone levels, inhibition of osteoblast function, and increased bone resorption; each of these mechanisms can result in accelerated bone loss and increased risk of fracture. Osteoporosis occurs in more than half of patients who receive long-term glucocorticoid

treatment. It is estimated that 4 million cases of osteoporosis in the United States, or 20% of the total number, are attributable to corticosteroid use (80).

THERAPIES FOR OSTEOPOROSIS

Diet modification alone is not sufficient treatment for established osteoporosis, although adequate dietary calcium and vitamin D intakes are necessary components of therapy. For patients with osteoporosis, the most promising treatments are estrogen replacement, calcitonin, and bisphosphonates. These commonly prescribed medications are described briefly below.

Estrogen

Estrogen receptors have been identified in normal human osteoblast-like bone cells in vitro, providing a means by which estrogen can directly influence bone turnover (81). Estrogen enhances calcium absorption through its trophic effect on $1,25(\text{OH})_2\text{D}$ and perhaps also directly.

Conjugated equine estrogens are the most commonly prescribed hormone replacement for postmenopausal women in the United States. A dosage of 0.625 mg of conjugated estrogens, alone or in combination with progestins, prevented bone loss at the hip and spine in early postmenopausal women and increased BMD in older women participating in a 3-year randomized, double-blinded, placebo-controlled trial (65). Most of the increase in BMD occurred within the 1st year, but smaller increments were observed in the 2nd and 3rd years as well. Another estrogen, ethinyl estradiol, at doses ranging from 3.7 to 37 nmol (1–10 μg) reduced bone loss in early postmenopausal women (82). Hormone therapy also reduces fracture rates at the hip (83). Estrogen replacement must be maintained to prevent the onset of rapid bone loss; when therapy is discontinued, bone loss similar to that seen immediately after menopause ensues. Estrogen has widespread effects on other body tissues, including the cardiovascular system, serum lipids, the uterus, and breast.

Calcitonin

Calcitonin, a small peptide hormone produced by the C cells of the thyroid gland, is secreted in response to increased serum calcium concentration. Its primary function is to inhibit bone resorption. Women with osteoporosis have an attenuated calcitonin response to a calcium challenge.

Salmon calcitonin is a more potent inhibitor of bone resorption than is human calcitonin and is more effective therapeutically. Treatment with calcitonin prevented bone loss from the proximal radius and reduced the rate of loss at the distal radius by 65% in osteoporotic patients (84). A similar trend was seen at the spine. Calcitonin does not appear to be effective at the hip. It is commonly administered as a nasal spray.

Bisphosphonates

Bisphosphonates are structural analogues of pyrophosphate. Their metabolic actions include inhibition of hydroxyapatite formation, inhibition of bone resorption through a direct dose-related effect on osteoclasts, and alteration of serum phosphorus levels. The bisphosphonates were developed to treat disorders such as Paget's disease, ectopic calcification, and metastatic disease of the skeleton. They have recently been approved for treatment of osteoporosis. Therapy involving intermittent cyclic administration of etidronate and phosphorus (as a bone "activator") and continuous calcium increased spinal bone density by about 4% and femoral bone density by 2% over controls and decreased the rate of new vertebral deformities among women with previous spine fractures (85). The treatment effect was even greater in a subgroup of women with low spinal bone density and a history of multiple vertebral fractures.

An aminobisphosphonate, alendronate, is more potent than etidronate, selectively inhibits bone resorption without accompanying detrimental effects on bone matrix mineralization, and does not require intermittent administration. Alendronate given to postmenopausal women with osteoporosis produced gains in bone density of the whole body, hip, and spine over a 24-month period and a 48% reduction in new vertebral fractures (86).

Abbreviations: **BMD**—bone mineral density; **25(OH)D**—25-hydroxyvitamin D;
1,25(OH)₂D—1,25-dihydroxyvitamin D.

Diabetes mellitus afflicts 18 million persons in the United States and is emerging as a major health problem throughout the world. In the U.S., it is the fourth leading cause of

death by disease and a major cause of blindness and kidney disease. The estimated costs of diabetes in the U.S. exceed \$100 billion and are increasing (1). Medical nutritional management is the cornerstone in management of all persons with diabetes, since appropriate dietary practices decrease all the risks and complications associated with diabetes and can potentially restore normal life expectancy. Central to management of diabetes and lipid risk factors is a high-carbohydrate, high-fiber, low-fat diet. Exercise is second in importance in diabetes management. Self-monitoring of blood glucose levels and appropriate adjustment of food intake, exercise, and medications lead to good glycemic control with a minimum of hypoglycemic episodes. Because of the high risk for atherosclerotic cardiovascular disease, persons with diabetes should develop a preventive program to normalize serum lipid levels and consider regular use of aspirin and antioxidant vitamins. Healthcare team members counsel diabetic individuals to enable them to manage their diabetes and lifestyle to maintain optimal health.

HISTORICAL OVERVIEW

Ancient civilizations in Egypt, Greece, Rome, and India recognized diabetes and the effect of dietary intervention. The Roman Aretaeus, AD 70, noted polydipsia and polyuria and named the condition *diabetes*, meaning “to flow through.” Thomas Willis, a London physician, later introduced the term *mellitus* or “honeylike” after noting the sweet taste of urine. Early dietary recommendations were based on theory rather than on scientific fact. As today, debate raged on the amount of carbohydrate allowed. Champions of low-carbohydrate, high-fat diets argued that excess sugar present in blood and urine required restriction of carbohydrate. Proponents of high-carbohydrate diets argued that dietary carbohydrate was needed to replace that lost in urine. Universally agreed, and still relevant today, was that diabetes is best treated by energy-restricted diets (2).

Frederick M. Allen (3) of New York developed the famous “Allen starvation treatment” of diabetes in 1912. Using 1000-kcal diets containing 10 g carbohydrate, he sustained the lives of a few young men until insulin became available. Thus, just prior to the discovery of insulin, diabetes was treated with low-carbohydrate, semistarvation regimens (2). Over the years, many sources of carbohydrate were identified as therapeutic including milk, vegetables, rice, potatoes, and oatmeal. Even after insulin was discovered in 1921, most Western diabetes specialists used low-carbohydrate, high-fat diets to treat lean diabetic individuals. The few clinicians to report that high-carbohydrate, low-fat diets benefited diabetic individuals included Geyelin et al. (4) in 1935, Sansum et al. (5) in 1926, and Kempner et al. (6) in 1958.

Recent scientific data analyzed by the British (7), Canadian (8), and American Diabetes Associations (9) support recommendations of a generous carbohydrate, fat-restricted diet. Table 86.1 lists major changes in nutritional recommendations in America over 50 years. Recommended carbohydrate intake increased steadily since 1930 and recently reached a plateau. Total fat intake steadily declined, and protein intake has remained about the same. Recommended fiber intake has increased dramatically (2).

Nutrient	1930	1955	1970	1990	1997
Carbohydrates, total, g/day	70	175	225	290	290

CLASSIFICATION

Diabetes mellitus can result from a variety of genetic, metabolic, and acquired conditions eventuating in hyperglycemia. Metabolic derangements in glucose metabolism and profound abnormalities in metabolism of fat, protein, and other substances characterize the pathology of diabetes. Current research recognizes that diabetes mellitus has several antecedents, though each type has a similar outcome once established. A heterogeneous disorder both genetically and clinically, all classifications of diabetes have in common, hyperglycemia, due to either insulin insufficiency or insulin resistance. The traditional classification segregates hyperglycemic conditions into the following groups: insulin-dependent diabetes mellitus (IDDM or type I); non-insulin-dependent diabetes mellitus (NIDDM or type II); impaired glucose tolerance (IGT), and gestational diabetes mellitus ([Table 86.2](#)). Other conditions leading to diabetes mellitus are malnutrition-related diabetes mellitus, and a variety of other genetic, drug-induced, and acquired conditions ([10](#)).

Diabetes Class	Subclass	Comments
Diabetes mellitus		
Type I (insulin-dependent diabetes mellitus, IDDM)	1A Classic	
Type II (non-insulin-dependent diabetes mellitus, NIDDM)	1B Autoimmune Nonobese NIDDM Obese NIDDM	May be insulin-treated or non-insulin-treated
Malnutrition-related diabetes mellitus (MRDM)	Malnutrition diabetes of the young (MODY) Pituitary/pancreatic diabetes Pancreatic disease	
Other types	Normal ecology Drug- or chemical-induced Genetic syndromes Insulin receptor antibodies	
Impaired glucose tolerance (IGT)	Other conditions IGT in nonobese IGT in obese IGT in NIDDM IGT in other conditions	
Gestational diabetes (GDM)		

Modified from Figure 85. Definition and classification of diabetes including malnutrition-related diabetes of the young. In Latham G, Foster D, editors. *Diabetes Mellitus*. Diabetes Mellitus. Humana: Lawrence, 1983:739–42.

Table 86.2 Classification of Diabetes Mellitus and Glucose Intolerance

Type I diabetes accounts for approximately 5% of diabetes and is manifested in insulin deficiency caused by destruction of the pancreatic b cells. Type II diabetes accounts for about 90% diabetes and is characterized by two primary defects: insulin resistance (diminished tissue sensitivity to insulin) and impaired b-cell function (delayed or inadequate insulin release). Other causes account for the remaining 5% of diabetes in the U.S.

Impaired glucose tolerance affects more people than have type I and type II diabetes combined. It is a serious public health problem because affected persons often progress to overt diabetes and frequently have other cardiovascular disease risk factors, such as hypertension, dyslipidemia, and obesity. The onset of gestational diabetes typically occurs between the 24th and 28th weeks of pregnancy, when the body's demand for insulin is dramatically increased. It affects about 2 to 4% of all pregnancies. Nutritional intake and glycemic control influence the outcome of pregnancy. Other forms of diabetes are detailed elsewhere (10).

EPIDEMIOLOGY

An estimated 18 million persons in the United States have diabetes. Over 600,000 persons are newly diagnosed with diabetes each year. Only 750,000 (about 5%) have type I diabetes; the remainder have type II. Of those with type II diabetes, approximately half, or 7 million, are undiagnosed (1). Type I diabetes is much more common in northern Europeans (Caucasians) and is uncommon among African Americans and Native Americans (11). While the prevalence of diabetes has increased dramatically over this century in the U.S., it has stabilized since 1980 and remains fairly constant (1). In the U.S., the prevalence of diabetes is highest among Native Americans; adult Pima Indians have a prevalence of about 50%. African Americans and Hispanics have substantially higher rates of diabetes than do U.S. white individuals (12).

The prevalence of diabetes varies widely around the world; certain Chinese populations have very low rates, and Micronesian populations have very high rates. The prevalence of diabetes is increasing steadily in emerging or developing countries and parallels the increase in obesity; both diabetes and obesity increase progressively as the percentage of energy from fat increases. By the year 2000, an estimated 100 million persons in the world will have diabetes (13).

Genetic and environmental factors contribute to development of type II diabetes (14). A genetic predisposition to diabetes is usually present but not required. Environmental factors contributing to development of type II diabetes are obesity, lack of physical exercise, and high-fat, low-fiber diets (13, 15, 16). Obesity, clearly the overriding risk factor, may be responsible for more than 75% of the emergence of type II diabetes (13).

DIAGNOSIS

Classic symptoms such as polydipsia, polyuria, and rapid weight loss associated with gross and unequivocal elevation of blood glucose (over 11.1 mmol/L, or 200 mg/dL) make the diagnosis of diabetes mellitus. A fasting plasma glucose level above 7.0 mmol/L (126 mg/dL) on two occasions is diagnostic. An oral glucose tolerance test (OGTT) can be performed for impaired fasting plasma glucose (6.1–7.0 mmol/L, 110–126 mg/dL), when 2-hour postprandial plasma glucose exceeds 7.8 mmol/L (140 mg/dL) or for individuals at high risk of diabetes ([10](#), [10a](#)).

The OGTT identifies individuals with diabetes, impaired glucose tolerance, and gestational diabetes. For proper interpretation, the individual must be ambulatory, otherwise healthy, and taking no medications that impair glucose tolerance ([10](#)). For at least 3 days before the test, individuals use a weight-maintaining diet providing at least 150 g of carbohydrate daily. After an overnight fast of 10 to 16 hours, an oral glucose load of 75 g (or 40 g/m²) is given. The subject remains seated during the test. Water is permitted, but smoking is not. Blood is taken before glucose administration and 0.5, 1, 1.5, and 2 hours later for plasma glucose determination ([17](#)).

Nondiabetic adults have fasting plasma glucose levels below 7.0 mmol/L (126 mg/dL) and values during the OGTT below 7.8 mmol/L (140 mg/dL) at 2 hours and below 11.0 mmol/L (200 mg/dL) at 0.5, 1, and 2 hours. Diabetes mellitus is present in nonpregnant adults when two OGTT results are abnormal, with plasma glucose levels exceeding 11.0 mmol/L (200 mg/dL) at 2 hours and one other time (0.5, 1, 1.5 hours). The diagnosis of gestational diabetes is established when two or more of the following criteria are met or exceeded after the glucose tolerance test: fasting, 105 mg/dL; 1 hour, 190 mg/dL; 2 hours, 165 mg/dL; and 3 hours, 145 mg/dL ([10](#)).

Glycosylated hemoglobin levels are convenient screening tests for diabetes. A glycosylated hemoglobin level more than three standard deviations above the “normal” mean indicates diabetes, but this test is much less sensitive than the OGTT ([17](#)) ([Table 86.3](#)).

Fasting or Hour after Glucose	Normal	Impaired (IGT)	Diabetes ^a	Gestational Diabetes ^b
Fasting	<110	<126	≥126	≥105
0.5 and/or 1 and/or 1.5	<200	≥200	≥200	≥190
2	<140	140–199	≥200	≥165
3				≥145

Table 86.3 Diagnosis of Diabetes and Related Conditions

BODY FUEL REGULATION

Role of Hormones

Cleavage of proinsulin results in the C-peptide (31 amino acids) and insulin (51 amino acids). Insulin is the hormone primarily responsible for the metabolism and storage of ingested body fuels. The body secretes insulin in response to increased blood glucose after a meal. This postprandial secretion of insulin promotes glucose, amino acid, and fat uptake by tissues (primarily liver, adipose, and muscle tissue) where the glucose is used or stored. Insulin production drops as the blood glucose level decreases (18).

Amylin, the most recently discovered pancreatic hormone, affects the rate of gastric emptying. This 37-amino-acid peptide is stored in pancreatic b cells with insulin, is cosecreted with insulin, and acts to affect the rate of intestinal absorption of nutrients (18).

Genuth (19) calculated insulin secretion rates in nondiabetic and diabetic subjects. Healthy lean adults secrete approximately 31 U insulin daily. Because of peripheral insulin resistance, obese nondiabetic adults secrete about 114 U daily. Type I diabetic individuals release only up to 4 U insulin daily, on average, whereas lean type II diabetic individuals with diabetes for more than 10 years produce only about 14 U daily. These estimates support other evidence that diabetes usually results from an absolute or relative deficiency of insulin.

Insulin is the main signal to the body for the “fed” or “fasting” states. After a large meal, high serum insulin levels stimulate fuel and energy storage. After an overnight fast, low serum insulin levels permit mobilization of fuel and energy from storage depots. Glucagon, the pancreatic a cell hormone, facilitates fuel and energy release with low blood insulin levels (Fig. 86.1). Under stressful circumstances, hypoglycemia, or trauma, glucagon and other “counterregulatory” hormones that oppose or counter insulin action are released. These hormones—glucagon, catecholamines, glucocorticoids, and growth hormone—act specifically to decrease glucose use, promote glucose production, and mobilize fatty acids. During fasting, exercise, and stress, fatty acids are a major source of energy (17, 18).

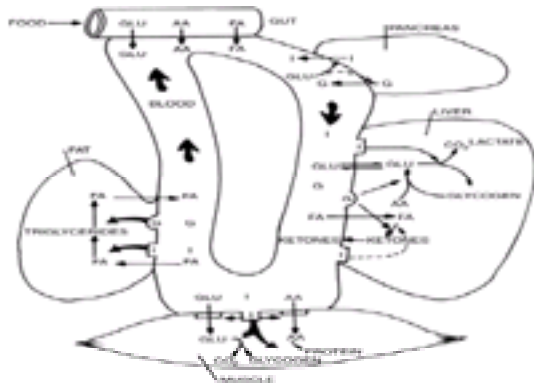

Figure 86.1. Action of insulin and glucagon shown schematically. *GLU*, glucose; *AA*, amino acids; *FA*, fatty acids; *I*, insulin; *G*, glucagon.

Energy Stores

A healthy 70-kg man stores approximately 70 g of liver glycogen, 200 g of muscle glycogen, and 30 g of glucose in body fluids, totaling 5023 kJ (1200 kcal). Available glucose stores can meet energy needs for only 12 to 18 hours. However, adipose tissue triglycerides typically represent energy deposits of 502,320 kJ (120,000 kcal), 100 times the glucose energy reserves. During starvation or stress, fatty acids are released for energy. Body proteins, skeletal and visceral structures, and other vital components are unavailable for energy except under conditions of prolonged starvation or severe stress (17).

Fed State

A multifaceted system of hormones, nervous tissue, and digestive tissue is necessary to sustain the fed individual. This state begins as food travels down the digestive tract and is enzymatically broken down into smaller units, such as amino acids, sugars, glycerol, and fatty acids. These smaller particles are absorbed by the small intestine and then transported further. The portal blood carries amino acids and sugars to the liver. Lymph carries lipids as chylomicrons from the small intestine to the circulatory system where they are transported to numerous tissues (17).

Pancreatic β cells release insulin in response to perfusion by blood enriched with glucose, amino acids, pancreatic hormones, and other secretagogues. The same action of glucose decreases production of glucagon by pancreatic α cells. Various processes that occur in response to insulin release ensure that nutrients are taken up and stored in cells and tissues (18). Insulin stimulates glycogen synthesis, aerobic and anaerobic glycolysis, protein synthesis, and fatty acid synthesis in liver. Insulin inhibits glycogenolytic, gluconeogenic, proteolytic, and lipolytic processes. After activation by phosphorylation, glucose enters glycogen depots, generates energy in glycolytic and Krebs cycle pathways, and yields precursors for fatty acid and protein synthesis. Other

simple sugars enter the glycogen pool, generate energy, or become precursors for synthetic processes. Amino acids enter precursor pools for protein synthesis (17).

Muscles and adipose tissue receive a large percentage of glucose and amino acids released after large meals. High serum insulin concentrations specifically stimulate transport of glucose and amino acids into muscle cells and glucose into adipose tissue. In muscle cells, under the influence of insulin, glucose enters glycogen depots and generates energy, while amino acids serve as precursors for protein synthesis. Insulin also facilitates conversion of glucose products to fatty acids for storage as triglycerides in fat cells. Most other tissues are freely permeable to glucose as well as amino acids and use the nutrients for glycogen formation, energy, and protein synthesis (17, 18).

Gut, liver, and other tissues handle ingested fat differently from glucose and amino acids. Gut hydrolyzes fats to fatty acids, glycerol, cholesterol, phospholipids, and other constituents. Short- and medium-chain fatty acids are absorbed and enter the portal vein for use in the liver. Long-chain fatty acids, cholesterol, and phospholipids are repackaged by gut mucosa and enter lymphatics as chylomicrons, which enter the superior vena cava through the thoracic duct. In the systemic circulation, chylomicrons release fatty acids for use by liver, muscle, fat, and other cells (17).

High serum insulin levels affect lipid metabolism in several ways. Insulin stimulates synthesis of lipoprotein lipases, which are secreted onto capillary membranes. These lipases extract fatty acids from triglyceride-rich circulating lipoproteins and facilitate entry of fatty acids into various tissues. In the fed state, a large proportion of these fatty acids are extracted by adipose tissue and incorporated into triglyceride storage. Liver cells exposed to generous amounts of insulin extract fatty acids from chylomicrons and repackage them as very low density lipoprotein (VLDL) particles, which are secreted into the systemic circulation. VLDLs also deliver fatty acids to adipose tissue for deposition (17, 18).

Fasting State

When the level of nutrients in the blood is decreased, as in a 12-hour fast, the individual is said to be in the postabsorptive, or fasting, state. This phase commences as nutrients cease to move from the intestines to the liver (17), accompanied by a gradual fall in serum insulin concentrations and a rise in serum glucagon levels. When the insulin:glucagon ratio decreases, the liver switches its enzyme machinery from glucose use to glucose production through gluconeogenesis and glycogenolysis. After 12 or more hours of fasting, half the liver glycogen is depleted. During longer starvation, hepatic glycolytic rates and activities of key glycolytic enzymes decline over 48 to 96 hours and then stabilize; hepatic gluconeogenesis rates and key gluconeogenic enzyme activity increase. After 72 hours of fasting, the liver has low glycolytic rates and has retooled for maximal gluconeogenesis (17).

Brain, other nervous tissues, red blood cells, and renal medulla have ongoing requirements for glucose for energy, whereas other tissues begin using fatty acids and ketones for energy. Low serum insulin levels stimulate lipolysis in adipose tissue; fatty acids are released at rates required for energy by various tissues. Lipolysis is further

stimulated by high serum concentrations of glucagon and catecholamines. Liver burns fatty acids to meet energy needs and to fuel gluconeogenesis. Ketones are hepatic byproducts of fatty acid oxidation. Glucogenic amino acids released by muscles and other tissues are major substrates for active gluconeogenesis. When glycogen reserves of liver and muscle are exhausted, most tissues depend on fatty acids and ketones to meet their energy needs (17).

High levels of free fatty acids decrease the number of insulin receptors on various tissues and act in other ways to block insulin action. Because of low serum insulin and high serum free fatty acids, glucose and other amino acids are not transported into muscle cells. Protein synthesis stops, and proteolysis is activated, with amino acids released into circulation. Glucocorticoids also foster release of amino acids to support gluconeogenesis in liver (17).

During a short-term fast, serum insulin and glucagon orchestrate changes in fuel homeostasis resulting in a steady supply of glucose to brain and other glucose-dependent tissues while mobilizing free fatty acids to meet energy needs of other tissues. After a 7- to 10-day fast, brain develops the capacity to use ketones for fuel and the need to convert amino acids to glucose abates, allowing adjustment to long-term fasting with sparing of skeletal and visceral proteins (17).

METABOLIC DERANGEMENTS

Diabetes resembles fasting, especially in the responses of liver, muscle cells, and adipose tissues. With low serum ratios of insulin to glucagon and high levels of fatty acids, liver produces glucose while other tissues use fatty acids and ketones instead of glucose. Muscle cells and adipose tissue respond by using ketones and fatty acids. Although the resemblance between fasting and diabetes is striking, pathologically low serum insulin levels disrupt the efficiency seen during fasting (17).

With low insulin, key glycolytic enzyme activities decrease. Glucose use falls far below levels seen during fasting. Concurrently, hepatic gluconeogenic enzyme activities increase and gluconeogenic rates rise. Bombarded with free fatty acids, the liver increases gluconeogenesis, secreting large amounts of VLDLs, and accumulates fatty acids in droplet form. A long-term toxic effect of diabetes is accumulation of 25% more lipid than normal. In the diabetic state, the liver oxidizes these fatty acids and produces acetone, acetoacetate, and b-hydroxybutyrate (17).

Muscle cells and adipose tissue also show major metabolic changes in diabetes. Muscle glycogen almost disappears, and muscle protein is broken down to support gluconeogenesis. Cardiac and skeletal muscles meet their energy needs from ketones and fatty acids. Fat cells actively release fatty acids under the lipolytic stimuli of glucagon, catecholamines, and insulin deficiency (17).

Non-insulin-dependent tissues respond to diabetes totally differently. Hexokinase, the key stimulus of glucose use, is increased in jejunal mucosa, renal cortex, and peripheral nerves of diabetic animals. In hyperglycemia, glucose use increases, and sugars accumulate. Excess glucose accumulation leads to tissue damage. Diabetic rats have

30% more total body glycogen than nondiabetic rats. Glycogen accumulates in renal tubules to values 50 times those in nondiabetic rats. Glycogen accumulation may contribute to tubular dysfunction and susceptibility to damage from x-ray dyes. Unimpeded entry of glucose into many tissues increases cellular glucose, producing linkage of glucose to tissue proteins (glycosylation). The diabetic state damages non-insulin-dependent tissues, including glomeruli, retinal vessels, nerves, and circulating blood cells (17).

DIABETIC COMPLICATIONS

Acute Problems

Diabetes can first manifest with either symptomatic hyperglycemia or a medical emergency caused by severe hyperglycemia, ketoacidosis, or severe hyperlipidemia. Most symptoms of diabetes are related to hyperglycemia or accumulation of glucose in various tissues. As hyperglycemia develops, individuals have increased polyuria, thirst, lack of energy, irritability, blurred vision, and weight loss. Adults usually develop these symptoms over weeks to months, whereas children may develop them in hours or days. If hyperglycemia goes undetected or if stress or illness intervenes, the individual develops stupor or coma (Table 86.4).

Complication	Pathophysiologic Considerations
	Acute
Hypoglycemia	Excess insulin
Mild-to-severe hypoglycemia	Headache, irritability, weight loss, fatigue, blurred vision
Severe hypoglycemia	Hyperglycemia, metabolic acids
Severe ketosis	Diabetic ketoacidosis
Hyperglycemia	Diabetic ketoacidosis syndrome with neurologic, skin, or genitourinary manifestations
Diabetes	Diabetes
Proteinuria	Increased aging of collagen, skin, and other tissue proteins; functional abnormalities of hormones, lipoproteins, and membranes
Susceptibility to infection	Contributes to atherosclerosis, premature aging, and susceptibility to cancer
Fluid accumulation	Nerve, lens, and kidney dysfunction
Microangiopathic abnormalities	Impairment of arterial walls
Stroke accumulation	Renal tubule and thyroid lesions
Dyslipidemia	Accelerated atherosclerosis
Renal permeability abnormalities	Protein leakage from capillaries
Microvascular disease	Impaired renal, muscle, and cardiovascular flow
White blood cell abnormalities	Altered response to infection and immune challenges
Protein abnormalities	Contribution to micro- and macrovascular complications and thrombosis
Endocrine abnormalities	Diffuse and altered oxygen transport
Nerve dysfunction	Decreased nerve conduction velocity
Kidney dysfunction	Hyperkalemia leading to nephropathy
	Long-term
Renal (glomeruli)	Nodular or diffuse thickening
Retinal vessels	Hemorrhage, ischemia, new vessel formation
Neurologic disorders	Neurologic defects affecting central, peripheral, and autonomic nervous systems
Capillary (myocardium)	Basement membrane (thickening and microangiopathy) abnormalities
Arterial (arteries)	Generalized and accelerated atherosclerosis affecting coronary arteries, cerebral vessels, and peripheral vessels

Table 86.4 Diabetic Complications and Pathophysiologic Considerations

The most frequent complication for diabetic individuals treated with insulin is hypoglycemia. Below-normal levels of blood glucose characterize this complication. Insulin administration may decrease the blood glucose concentration, which necessitates replenishing circulating glucose; otherwise, brain function will be permanently altered. Hypoglycemia may be triggered by missed or late meals, consumption of insufficient quantities of food, consumption of alcohol without food, or physical work. The symptoms of a hypoglycemic reaction differ for each patient; however, an individual's incidents resemble one another. Some symptoms of hypoglycemia are confusion, headaches, deficient coordination, irritability, shakiness,

anger, sweating, and even coma or death. Desired treatment for hypoglycemia is 15 g of carbohydrate administered to raise the blood glucose level between about 50 or 100 mg/dL; this rise usually takes about 15 minutes (20).

Individuals with type I diabetes are vulnerable to diabetic ketoacidosis (DKA) characterized by hyperglycemia and ketonemia, which results from either insulin deficiency or stress. Either hyperglycemic nonketotic state or ketoacidosis can be fatal. DKA is most frequently caused by lack of patient education or inadequate compliance with instructions. Symptoms of DKA include nausea and confusion. Therapy for DKA includes administration of electrolytes, fluid, and insulin, because untreated DKA could result in coma or death (21, 22).

Adults with type II diabetes are likely to develop the hyperglycemic nonketotic state characterized by plasma glucose values above 750 mg/dL without significant ketonemia. These individuals may be protected from ketoacidosis by circulating insulin in spite of low-normal or low levels. The hyperglycemic nonketotic condition can be precipitated by excessive sugar intake, dehydration, heat exposure, illness, or drug therapy. Impaired renal function, hyperosmolarity, lack of ketosis, and/or central nervous system problems may occur with this condition. Usually, the hyperglycemic nonketotic state is seen in individuals with type II diabetes. In addition, these individuals have decreased, but not completely deficient, insulin levels released from the pancreas. The hyperglycemic nonketotic state is often caused by dehydration or by diabetes associated with a coexisting illness. Symptoms of this condition include dehydration, hypotension, decreased mental ability, confusion, seizures, and coma. Therapy for the hyperglycemic nonketotic state includes insulin therapy and electrolyte and fluid replacement as well as treating basic causes (21).

Severe hypertriglyceridemia can be a serious medical emergency. Serum triglycerides exceed 22.6 mmol/L (2000 mg/dL) and may be accompanied by neurologic symptoms, skin lesions, or abdominal symptoms from pancreatitis. Treatment includes intravenous fluids or a clear liquid diet to lower serum triglycerides, insulin to control hyperglycemia, and appropriate therapy for other medical problems (23).

Short-Term Complications

Sustained hyperglycemia alters glucose metabolism in virtually every tissue. Cells that are non-insulin-dependent are particularly vulnerable because sugar alcohols (polyols) accumulate and proteins are glycosylated. Most tissues gradually convert glucose to polyols, which are used slowly. Hyperglycemia causes high intracellular glucose concentrations, leading to rapid formation of polyols (Fig. 86.2) that accumulate rapidly but are degraded slowly. Sorbitol and fructose, the major polyols, accumulate and cause cell distention and toxicity. Blurred vision, for example, is caused by distention of the lens. Polyol accumulation can alter the function of peripheral nerves (18, 24).

Figure 86.2. Polyol pathway.

Excess glucose affects production of glycoproteins, proteins containing sugar side chains (Fig. 86.3). The condensation reaction between glucose and an amino acid component of protein has two stages: (a) the aldehyde group of glucose links to the amino group of an amino acid forming an aldimine (Schiff base) and (b) the unstable aldimine releases glucose or undergoes an Amadori rearrangement to form the stable ketoamine linkage. This process occurs spontaneously without enzyme action and is termed *nonenzymatic glycosylation*. Hemoglobin, serum albumin, and many other proteins are glycosylated. In diabetes, glycosylation is related to the magnitude and duration of hyperglycemia (18).

Figure 86.3. Pathway for nonenzymatic glycosylation.

The sugar content of hemoglobin, the best-characterized glycoprotein, is normally less than 6%. In diabetes, the percentage of glycosylated hemoglobin can exceed 25% of total hemoglobin. When erythrocytes are incubated with glucose, glycohemoglobin

doubles within hours. Most glucose is attached by the unstable aldimine linkage, which can be dissociated if erythrocytes are incubated in low glucose solutions. Long-term exposure to high glucose levels causes formation of irreversible ketoamine linkages that persist until the cell is degraded. Thus, glycohemoglobin measurements reflect glycemic control over the previous 6 to 8 weeks. In patients with excellent glycemic control, glycohemoglobin concentrations are normal. Poor diabetic control yields glycohemoglobin values exceeding 9%. The degree of glycosylation of circulating proteins, hormones, lipoproteins, plasma membranes of cells, basement membranes, and other proteins in diabetes has not been determined. This may contribute to basement membrane thickening, vascular permeability, microcirculation defects, and functional abnormalities of erythrocytes, leukocytes, and platelets ([18](#), [25](#)).

Hyperglycemia induces a host of other metabolic derangements. Glycogen accumulates in non-insulin-dependent tissues. Increased flux of glucose through insulin-insensitive pathways such as mucopolysaccharide synthesis leads to abnormalities of mucopolysaccharides, possibly contributing to atherosclerosis. Hyperglycemia alters the orderly formation of glycoproteins in the kidney and other tissues, contributing to diabetic glomerulosclerosis. Many short-term problems of hyperglycemia can be avoided by maintaining satisfactory plasma glucose concentrations, and in some cases, derangements can be reversed by good glycemic control ([18](#)).

Long-Term Complications

The pathogenesis of the long-term manifestations ([Table 86.4](#)) of diabetes is still under intense study and remains poorly understood. Metabolic, genetic, and other factors affect major diabetic complications: retinopathy, nephropathy, and neuropathy ([24](#), [26](#)). Most authorities believe that chronic hyperglycemia accelerates development of these complications. Long-term complications cannot be prevented, but risks can be lowered with good diabetic control. The Diabetes Control and Complication Trial (DCCT) was a landmark study of type I diabetes documenting that improved control decreases development of diabetic retinopathy, nephropathy, and neuropathy ([27](#), [28](#)).

Pirart ([29](#)) carefully documented the prevalence of diabetic complications among 4400 diabetic patients ([Fig. 86.4](#)). After 25 years, most patients had complications of some type; however, complications were less frequent in patients who maintained fairly good glycemic control than in those who had maintained poor diabetic control. Individual genetic tendencies toward complications also affect their frequency. Some diabetic individuals develop complications at an accelerated rate despite reasonable glycemic control, whereas others show little tendency toward these complications.

Figure 86.4. Prevalence of diabetic complications over time. (Redrawn from Pirart J. *Diabetes Metab* 1977;3:97–107).

The DCCT was a carefully controlled clinical study conducted by the National Institute of Digestive and Kidney Disease in the U.S. The study shows that keeping blood glucose levels as close to normal as possible slows the onset and progression of eye, kidney, and nerve diseases caused by diabetes. This was the largest and most comprehensive diabetes study ever conducted and included 1441 type I diabetic subjects at 29 medical centers in the U.S. and Canada. Over a 7-year period, the study compared the effects of a standard treatment regimen with an intensive treatment regimen. The study showed that lowering blood glucose concentrations reduced risk for diabetic retinopathy by 76%, for diabetic nephropathy by 50%, and for diabetic neuropathy by 60%. [Figure 86.5](#) compares the effects of standard therapy and intensive control on development of diabetic retinopathy ([27](#), [30](#)).

Figure 86.5. Effect of glycemic control on development of diabetic retinopathy in the Diabetes Control and Complication Trial (DCCT). Subjects had no evidence of retinopathy at entry and developed retinopathy at the indicated rate. Intensive therapy was associated with a 76% reduction in risk compared with conventional therapy.

Atherosclerosis

Atherosclerosis is the most common complication of diabetes. Diabetic men have a two- to threefold higher risk of coronary heart disease, stroke, and peripheral vascular disease, whereas diabetic women have a three- to fourfold higher risk than matched nondiabetic individuals. Mechanisms responsible for accelerated atherosclerosis are not understood, and many interacting factors contribute. [Figure 86.6](#) illustrates major risk factors for atherosclerosis in diabetes and indicates the influence of nutrition. Reducing risk of vascular disease requires improved glycemic control, avoidance of cigarette smoking, normal blood pressure, and desirable serum lipoprotein levels. Hypertension is the major risk factor for coronary heart disease in type I diabetes. Diabetic individuals, particularly women, develop hypertension more frequently than the general population. Hypertension-related factors may act synergistically with arterial wall abnormalities, cellular dysfunction, lipoprotein abnormalities, and platelet derangements to accelerate atherosclerosis ([25](#)).

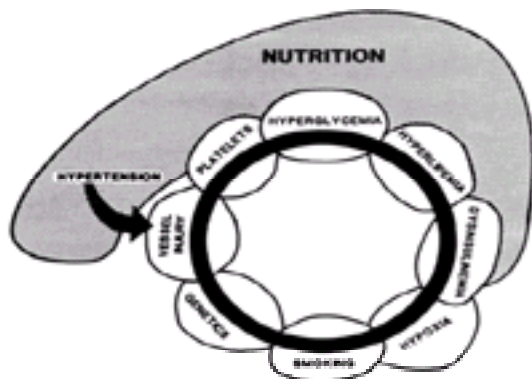

Figure 86.6. Relationship of diabetes, nutrition, and atherosclerosis.

Lipoprotein abnormalities play a major role in atherosclerosis. Serum low-density lipoprotein (LDL) abnormalities, decreased serum high-density lipoproteins (HDL), and increased serum triglycerides contribute to accelerated atherosclerosis in diabetes. LDL may be glycosylated or altered in other ways to enhance atherogenicity in diabetes. Many lipoprotein alterations in diabetes increase the risk of atherosclerosis ([25](#)).

In addition to hypertension and lipoprotein derangements, diabetic individuals have increased prevalence of other cardiovascular risk factors ([Table 86.5](#)): elevated serum insulin ([31](#)), elevated fibrinogen and von Willebrand factor ([32](#)), platelet function abnormalities ([33](#)), glycosylation of proteins throughout the body, leukocyte abnormalities contributing to vascular endothelial dysfunction and coagulation,

macrophage dysfunction leading to foam cell formation, increased susceptibility to oxidation of LDL, and HDL dysfunction. The nutritional plan focuses on reducing the risk of atherosclerosis by reducing saturated fat intake, achieving desirable serum lipoproteins, and reducing other cardiovascular risk factors (17).

Nonmodifiable Risk Factors	Modifiable Nonlipid Risk Factors	Modifiable Lipid Risk Factors	Risk Factors Unique to Diabetes
Male gender	Obesity ^a	High LDL cholesterol ^a	Platelet aggregation ^a
Age	Hypertension ^a	Low HDL cholesterol ^a	Increased coagulation ^a
Atherosclerotic disease ^a	Cigarette smoking	High triglycerides ^a	Fibrinogen elevation ^a
			Leukocyte dysfunction ^a
			Macrophage dysfunction ^a
			Susceptibility to oxidation ^a
			HDL dysfunction ^a

^aNot necessarily preventable.

Table 86.5 Risk Factors for Atherosclerotic Cardiovascular Disease in Diabetes

GOALS FOR MEDICAL NUTRITIONAL THERAPY

Medical nutritional therapy is pivotal in the management and care of diabetes. The objective is to provide diabetic individuals with an approach to diet that enables them to maintain a near-normal metabolic state. Glycemic control goals are outlined in [Table 86.6](#). Nutritional intervention provides a cost-effective strategy for reducing the complications, hence the morbidity and mortality, of diabetes. Recent results from the DCCT (34) indicate the following: persons who reported following their prescribed meal plan more than 90% of the time had average glycohemoglobin levels 0.9% lower than those who followed their meal plan less than 45% of the time; overconsumption of food to treat hypoglycemia was associated with significantly higher glycohemoglobin values, emphasizing the importance of appropriate treatment of hypoglycemia; glycohemoglobin values were also lower in persons who said they responded to high blood glucose levels and changes in planned meals by adjusting their insulin dose according to meal size and content; and eating extra nighttime snacks was associated with higher glycohemoglobin levels than eating the prescribed evening snack more consistently.

Measurement	Nondiabetic ^a	Goal (diabetes)	Action Suggested ^b
Preprandial glucose, mmol/L (mg/dL)	<6.4 (115)	4.4–6.7 (80–120)	<4.4 (80) >7.8 (140)
Bedtime glucose, mmol/L (mg/dL)	<6.7 (120)	5.6–7.8 (100–140)	<5.6 (100) >8.9 (160)
Glycohemoglobin, %	<6.0	<7 ^a	>8

^a<15% above normal limit for laboratory; these values are for nonpregnant adults.

^b"Action suggested" is tailored to the individual.

Table 86.6 Glycemic Control for Persons with Diabetes

The DCCT model establishes the following mandates for medical nutritional therapy (34):

1. Nutritional self-management education begins with a nutritional assessment. For persons taking insulin by injection, insulin can be integrated into usual eating and exercise habits. Goals, not rules and regulations, should be emphasized. Recommendations must be practical, achievable, and acceptable for the person with diabetes.
2. A variety of meal-planning approaches and educational tools were used in the DCCT. Educational tools that persons with diabetes can easily understand and use should be selected. Consistent follow-up for evaluation and continued self-management education is essential.
3. A team approach is necessary to promote positive nutritional behaviors. Optimal glycemic control was achieved only when patients applied nutritional principles learned through diabetes-nutrition self-management education.

The American Diabetes Association (ADA), in 1994, revised its nutritional recommendations and principles for persons with diabetes (9, 35). [Table 86.7](#) lists specific and general targets of nutritional therapy. Specific guidelines apply to the diabetic individual, while general guidelines apply to all individuals. The first and preeminent goal is achieving and maintaining blood glucose levels as near normal as possible by balancing food intake with insulin (either endogenous or exogenous) or antidiabetes agents. Optimizing glucose use, normalizing glucose production, and enhancing insulin sensitivity will also regulate safe levels of fatty acids, ketones, and amino acids. Immoderate hyperglycemia, as well as ensuing hypoglycemia, is hazardous and should be minimized by diet. Second in priority is achieving and maintaining optimal serum lipid levels. Cardiovascular disease is the most common complication of diabetes. Lipoprotein abnormalities play a major role in atherosclerosis. Except for enhancing glycemic control, we do not know how to tailor the diet to reduce specific complications of diabetes; emerging research suggests that a diet moderate in protein (10–12% of energy) or one substituting vegetable protein for animal protein may

decrease risk for diabetic nephropathy (36). Measures to retard development of atherosclerosis include maintaining desirable body weight and sustaining a diet high in dietary fiber, soy protein, and antioxidants and low in fat, saturated fat, and cholesterol (37). Regardless of the type of diabetes present, utmost consideration must be given to individual preferences, cultural or social mores, and ability to understand and follow the prescribed diet. All the nutritional planning in the world will do no good if it is not implemented.

Specific
Achieve physiologic blood glucose levels
Maintain desirable plasma lipids
Reduce likelihood of specific diabetic complications
Retard development of atherosclerosis
General
Provide optimal selection of nutrients
Attain and maintain desirable body weight
Meet energy needs in a timely manner
Address special requirements (such as pregnancy)
Tailor for therapeutic needs (such as renal disease)

Table 86.7 Goals for Nutritional Therapy for Diabetes

General goals consider the provision of variety, balance, and moderation. *Dietary Guidelines for Americans* (38) and the *Food Guide Pyramid* (39) summarize and illustrate nutritional guidelines and nutrient needs for all healthy Americans and can be used by people with diabetes and their family members (35). Optimal selection of nutrients is addressed through food-value exchanges, allowing individual preferences to reign yet including foods from each of the food groups. Energy needs are met by distributing meals throughout the day, with allowances for snacks when indicated. Meal distribution and close monitoring of blood glucose levels limit the frequency of hyper- or hypoglycemic episodes. Eliminating excessive calories and fats is indicated to attain and maintain a reasonable weight for adults, especially non-insulin-dependent diabetics. However, provision of adequate calories is crucial for normal growth and development of children and adolescents, increased metabolic needs during pregnancy and lactation, or recovery from catabolic illnesses. Medical nutritional therapy aims at reducing and preventing complications of diabetes during short-term illnesses, exercise-related problems, and long-term complications such as renal disease, hypertension, and atherosclerotic cardiovascular disease. Special tailoring is needed for existing complications such as renal failure.

The DCCT (27) substantiated that goal achievement results from a coordinated team effort by the physician, nurse, dietitian, and diabetic individual. Effective self-management training requires an individualized approach, appropriate for the personal lifestyle and management goals of the diabetic individual. To facilitate

compliance, sensitivity to cultural, ethnic, and financial considerations is of prime importance. Monitoring blood glucose and glycohemoglobin levels, serum lipids, blood pressure, and renal status is essential to evaluate nutrition-related outcomes (35). If goals are not met, changes must be made in the overall diabetes care and management plan. Nutritional assessment is used to determine what the individual with diabetes is able and willing to do. A major consideration is the likelihood of compliance with nutritional recommendations.

Methods of Diet Prescription

Nutritional Therapy and Type I Diabetes

Usual food intake and pattern preference should be determined and used as the basis for insulin requirement prescriptions (34). Eating at consistent times is vital for appropriate use of insulin. Intensified therapy may be considered for those willing and able to comply and can provide considerably more flexibility in meal planning. Individuals can be taught to adjust premeal insulin to compensate for changes in their meal plans, to delay premeal insulin for meals that are late, and to administer insulin for snacks that are not part of their meal plan. Insulin can also be adjusted for changes in physical activity. Intensified therapy may include carbohydrate counting with adjusted multiple injections or use of an insulin pump. The individual's skill and educational level must be considered.

Nutritional Therapy for Type II Diabetes

Emphasis should be placed on maintenance of desired weight and glucose, lipid, and blood pressure goals. Loss of 10% of current weight was shown to improve diabetes control (18). Strategies may be aimed at improving food selection (e.g., reducing dietary fats and saturated fats), spreading meals throughout the day, and incorporating regular exercise habits. If dietary and behavioral intervention is not successful, an antidiabetes agent may be needed. Stopping or changing oral agents is preferable to dietary manipulation for type 2 diabetic patients who are experiencing hypoglycemia. Insulin therapy should be a last resort after all combinations of oral medications have been exhausted, as it may exacerbate concomitant hyperinsulinemia and promote weight gain.

NUTRITIONAL PLAN

Consensus recommendations, though still somewhat controversial, have evolved considerably over the past few years. Areas of debate remain, and dogmatic or narrow recommendations would be inappropriate (7). Probably, there is more than one suitable diet composition. Wolever et al. (40) reported results in a randomized, controlled study, consistent with the recent move away from universal recommendation of high-carbohydrate diets toward individualizing the nature and amount of dietary carbohydrates. Associations between diet and glucose control varied in different groups of subjects with type II diabetes; higher carbohydrate or higher dietary fiber intakes were associated with improved blood glucose control in those treated by diet alone, insulin, or

metformin, but not in subjects on sulfonylureas. Low glycemic index was associated with improved glucose control only in subjects treated by diet alone. Nutritional recommendations are outlined in [Table 86.8](#).

Nutrient	ADA ^a	NIDDK Nutrition Facts ^b
Carbohydrate, % of kcal	about 50% ^c	50-60%
Protein, %	10-20%	10-15% (0.8 g/kg)
Fat, total, %	<30% ^d	<30% ^e
Saturated, %	<10%	<10%
Monounsaturated, %	10-20%	10-15%
Polyunsaturated, %	<10%	<10%
Cholesterol, mg/day	<200 mg/day	<200 mg/day
Fiber, g/day	20-35 g/day	about 35 g/day
Sodium, mg/day	<2400 mg if hypertensive	115-25 g/1000 kcal <1000 mg/1000 kcal
Alcohol	≤2 drinks/day	Men ≤2 drinks/day Women ≤1 drink/day
Vitamin supplements	Not recommended	Hydroxycortisone mineral daily Antioxidant supplements

^dRecommendation recommended: More fat permitted and less carbohydrate acceptable.
^eUp to 35% of energy from fat can be used for moderate individuals with acceptable serum triglyceride values if the additional fat comes from monounsaturated sources and saturated and polyunsaturated fats remain low. 10% each.

Table 86.8 Nutritional Recommendations for Persons with Diabetes

Carbohydrates

Carbohydrates should provide 50 to 60% of energy intake. Greater amounts, up to 70%, are tolerated in research studies and by highly committed individuals but are not generally recommended for most persons with diabetes. Simple carbohydrates (not as severely restricted in the past) should make up less than 1/3 of total carbohydrate intake. Unrefined carbohydrates, with natural fiber intact, have distinct advantages over highly refined versions because of their other benefits such as a lower glycemic index, greater satiety, and cholesterol-lowering properties.

Amount

About 1980, the American and the British Diabetes Associations finally relinquished the antiquated strategy of carbohydrate-restricted diets for diabetic individuals, aiming instead for a diet restricted in fat but higher in complex carbohydrate and dietary fiber (2). While considered radical by some, many other countries introduced essentially identical policies. The enthusiasm for high-carbohydrate, high-fiber diets has waned somewhat, but these diets still have the strongest scientific basis for recommendation. Under certain circumstances, especially with low fiber intake, high-carbohydrate, low-fat diets can worsen blood glucose control, increase serum triglyceride concentrations, and lower HDL-cholesterol concentrations (41, 42). The fiber content of the diet appears critical in preventing these problems (17, 43). (See Appendix [Table IV-A-20](#) for fiber contents of many foods.) The popularity of the “Mediterranean diet” has led some to recommend lower-carbohydrate, higher monounsaturated fat intake to alter serum lipid concentrations favorably and reduce risk for oxidation of LDL. However, only a few controlled studies support this recommendation, and the effect of higher fat intake on

obesity in type II diabetes is a major concern (17, 44).

Glycemic Response

Carbohydrates in foods have traditionally been classified as either “simple” (sugars) or “complex” (starches). Simple carbohydrates from commonly used foods raise blood glucose concentrations more than complex carbohydrates from starchy foods. The glycemic response to 50 g glucose is much greater than the response to a variety of foods providing 50 g starch. Whereas glucose, maltose, and sucrose produce large increases in the blood glucose level, fructose does not (Fig. 86.7). Fructose, metabolized without insulin, evokes little increase in serum insulin in nondiabetic individuals; it produces only minimal increases in blood glucose levels in nondiabetic and diabetic persons with reasonable glycemic control. Fructose may play a role as a sweetener for selected individuals with diabetes (17). Although simple carbohydrate worsens glycemic control and promotes weight gain, the ADA has suggested that “modest amounts of sucrose and other refined sugars may be acceptable, contingent on metabolic control and body weight” (45).

Figure 86.7. A. Glycemic response of nondiabetic individuals to 50 g carbohydrate from new potatoes or kidney beans. B. Glycemic response of healthy individuals to 50 g of glucose, sucrose, or fructose.

Complex carbohydrates in different forms also evoke different glycemic responses. Bread and potatoes raise blood glucose levels much more than beans (Fig. 86.7). Many investigators have compared the glycemic response of foods rich in complex carbohydrates (46, 47). Jenkins et al. introduced the term *glycemic index* to describe these responses, comparing test foods to the glycemic response from a reference food such as bread or glucose (46). Table 86.9 compares the glycemic responses to selected foods (see Appendix Table V-A-26-a for more quantitative data).

Class I (Higher: GI >90)	Class II Intermediate: GI = 70-90	Class III (Lower: GI <70)
Most breads	All bran	Pumpernickle bread
Plain crackers	Oatmeal	Most pasta
Most breakfast cereals	Most cookies or biscuits	Parboiled rice
Most potatoes	Polished rice	Most dried legumes
Millet	Buckwheat	Nuts
Corn chips	Sweet corn	Barley
	Boiled new potatoes	Bulgar (cracked wheat)
	Yams	
	Sweet potatoes

Table 86.9 Glycemic Index (GI) Ranking of Selected Starchy Foods

Many factors influence the glycemic response to foods ([Table 86.10](#)). Sipping 50 g of glucose slowly over several hours produces a much smaller increase in blood glucose than rapid intake of the same amount. Eating three apples takes 15 minutes, whereas their juice can be consumed in 1.5 minutes. Differences in fiber content and ingestion time influence the resultant glycemic response. Fat, protein, water-soluble fiber, and other factors influence gastric emptying time. Food form has a major impact on digestion time; bread can be digested more rapidly than pasta. Methods of processing and cooking foods (and in the case of fruit, degree of ripeness) influence glycemic response. Foods with higher ratios of amylopectin to the amylose form of starch are digested more rapidly than those with low ratios ([17](#)).

Table 86.10 Factors Affecting the Glycemic Response to Food

Fiber is only one of many components of food that influence the glycemic response. Beans have lower glycemic indices than any other group of carbohydrate-rich foods.

The low glycemic response to beans is probably related to their high soluble fiber content, food form (usually eaten as cooked rather than in bakery products), and naturally occurring starch blockers (inhibitors of digestive enzymes responsible for hydrolysis of starch). Finally, fiber fermentation products such as short-chain fatty acids are absorbed from the colon into the portal vein; in the liver, they may directly affect glucose metabolism (48). Factors influencing the glycemic response to foods require more investigation. The complexities of teaching and applying the glycemic index concept to individual patients make practical application difficult at this time. However, when using carbohydrate counting, more insulin is required for higher glycemic foods than for lower glycemic foods.

Proteins

The adult recommended dietary intake (RDI) of 0.8 g protein/kg body weight meets metabolic and nutritional needs. Though current ADA recommendations allow 10 to 20% of energy intake as protein, we recommend a more conservative 10 to 15% of total energy needs as protein. Diabetic individuals, on average, consume more protein than nondiabetic individuals, (49) and excessive protein intake has been linked to diabetic nephropathy (36, 50). According to current guidelines, in the presence of diabetic nephropathy, protein should not exceed 0.8 g/kg or 10% of total calories (9, 35).

At present, there is insufficient evidence to support protein allowances higher or lower than that for the general population. Protein of high biologic value should be given consideration, though protein should be included from both animal and vegetable sources. With the onset of nephropathy, protein intake should be no greater than the recommended dietary allowance (RDA) of 0.8 g/kg. Ten percent of daily calories should be sufficiently restrictive and is recommended for individuals with evidence of nephropathy (9). Higher amounts (over 12%) are likely in diets with greater emphasis on vegetable sources of protein, particularly the cereals and legumes, which are recommended for diabetes from other considerations. Further work is required to establish whether a higher protein intake is acceptable from the renal point of view if it comes mainly from vegetable sources (36). Current research indicates that soy protein diets reduce hyperfiltration in diabetic individuals, and substituting soy protein for animal protein should be considered as a preventive measure for diabetic individuals (36).

Fat

Fat intake generally should not exceed 30% of energy. Most importantly, saturated fats, because of their atherogenic potential, should be held at a maximum of 10% of energy needs. Polyunsaturates, with their tendency to lower HDL-cholesterol values and their susceptibility to oxidation, should also be held under 10%. However, up to 35% of energy from fat can be used for nonobese individuals with acceptable serum triglyceride values if the additional fat comes from monounsaturated sources such as canola or olive oils. Cholesterol intake, though less influential than saturated fats on serum lipid values, should be held under 300 mg/day; we recommend less than 200 mg/day. These recommendations are consistent with those of the American Heart Association and other groups (17, 44).

Amount

In 1928, Dr. Elliott P. Joslin (51) stated that “with an excess of fat diabetes begins and from an excess of fat diabetics die.” The weight of scientific evidence still supports this prescient observation. Excessive fat intake contributes to obesity, insulin resistance, hypertension, and atherosclerotic cardiovascular disease. Maintaining serum lipid levels is one of the most important goals in diabetes management. Hyperlipidemia, common in type II diabetics, is a major risk factor for cardiovascular disease. Epidemiologic evidence indicates that high-fat diets contribute to atherosclerosis. In fact, almost all risk factors for cardiovascular disease occur more frequently in diabetics. Hyperlipidemia, glycosylated lipoproteins, platelet dysfunction, arterial wall changes, hyperinsulinemia, hypertension, and obesity are correlated with atherosclerosis in diabetics. High-fat diets cause insulin resistance and impaired intracellular glucose metabolism. High-fat diets decrease the number of insulin receptors in several tissues, decreasing glucose transport into muscle and adipose tissue and decreasing activities of insulin-stimulated processes. Glycogen synthesis rates, glycogen accumulation, and glucose oxidation are also lower with high-fat diets (17).

Fat reduction has been identified as the most difficult dietary recommendation for diabetic patients to follow. Reducing fat intake may be relatively more important in type II diabetes, whereas limitation in protein intake may be more important in type I diabetes.

Type

The long-term effects of altering the type of fat in the diabetic diet are not well documented. One long-term (30-week) study compared diets rich in polyunsaturated fat with diets rich in saturated fat in patients with non-insulin-dependent diabetes. Compared with the saturated-fat diet, the polyunsaturated-fat diet significantly lowered cholesterol and LDL cholesterol without affecting triglycerides, HDL cholesterol, or apoproteins (52). A high-carbohydrate diet was compared with a diet high in monounsaturated fat in patients with non-insulin-dependent diabetes; after 4 weeks, the monounsaturated-fat diet significantly decreased insulin dose, glucose, triglycerides, and VLDL cholesterol while significantly increasing HDL cholesterol and apolipoprotein A-I (42). Although increased intake of fat usually leads to decreased insulin sensitivity, this preliminary short-term study suggests that this may not occur with monounsaturated fat intake.

Monounsaturated Fats. There is a growing consensus that diets for diabetic individuals should include only modest amounts of saturated fat but could include moderate-to-high levels of monounsaturates. Partial replacement of complex carbohydrates with monounsaturates in NIDDM patients does not increase the level of LDL cholesterol and may improve glycemic control and triglyceride and HDL-cholesterol levels (42, 53). If triglycerides and VLDLs are elevated, a moderate increase in monounsaturated fat intake may be liberalized to include up to 20% of calories with a more moderate intake of carbohydrate (9). However, increased monounsaturated fat intake may enhance

insulin resistance and, in obese individuals, may perpetuate or aggravate the obesity.

Polyunsaturated Fats. Some increase in polyunsaturates and the polyunsaturated/saturated ratio can be expected as saturated fatty acids are reduced (7). Artificially high intakes and supplemental polyunsaturates are not advised, and the ADA recommends restriction to below 8% of energy. The World Health Organization (WHO) recommendation for the general population is 3 to 7% of energy from polyunsaturates. High intakes of polyunsaturates have been suggested to be potentially damaging, relating to increased production of lipid peroxides (43).

w-3 Fatty Acids. Certain essential fatty acids of the w-3 class lower serum cholesterol moderately and serum triglyceride levels markedly (54). These w-3 fatty acids, popularly known as fish oils, may also decrease platelet aggregation, which may potentially reduce the cardiovascular disease risk in diabetes. Initially, fish oil supplementation in individuals with non-insulin-dependent diabetes appeared to improve their insulin sensitivity. The most potentially beneficial effects of w-3 fatty acids are on plasma triglycerides, commonly elevated in type II diabetic patients. In pharmacologic quantities, w-3 fatty acids reduce elevated plasma cholesterol and triglyceride concentrations and blood pressure. Diabetic patients may experience disadvantages associated with higher doses of w-3 fatty acid supplements. Intake of more than 4 g/day may aggravate hyperglycemia and elevate serum LDL-cholesterol concentrations. Dietary supplementation with 10 g/day of fish-oil capsules in a prospective double-blind placebo-controlled study improved hypertriglyceridemia but with deleterious effects in factor VII and blood glucose levels in NIDDM subjects (55). Recent research indicates that the benefits of fish-oil supplements outweigh the disadvantages and that these supplements can benefit carefully monitored subjects (54). More studies are needed to be conclusive. Increased intake of oily fish is reasonable as an alternative to foods such as meat and cheese products with high saturated fat content. Higher intake of total fat, mostly from olive oil, occurs in Mediterranean countries and is associated with lower risk of heart disease (7).

Fat Substitutes. Olestra, a sucrose polyester, is a fat substitute recently approved by the Food and Drug Administration (FDA). While release of this food ingredient generated considerable attention, it seems well tolerated by most consumers; gastrointestinal side effects probably will limit overuse by persons who do not tolerate it well. Olestra is a nondigestible fat made from sucrose bonded with eight long-chain fatty acids into a molecule too large to be hydrolyzed in the small intestine. It currently is available in potato chips and similar snack foods.

Another product, Simplese, is made from the protein of egg white and milk. Manufactured by a microparticulation process, it imparts a creamy smooth sensation much like that of fat. Since this product is a protein, it contains only 3.8 kcal/g instead of the 9 kcal/g in actual fats. Oatrim, is a product produced from oat bran. Clinical tests indicate that this product is useful in decreasing glycemic responses and in lowering serum cholesterol concentrations in nondiabetic subjects.

Controlled studies using these fat substitutes in the diabetic diet are needed to establish their potential usefulness. If results are positive, fat substitutes may foster improved

dietary fat compliance in the diabetic population (35).

Fiber

Fiber has emerged as a major dietary component in the management of diabetes. It has therapeutic value and may reduce the prevalence of diabetes. The ADA currently recommends 20 to 35 g/day. We recommend approximately 35 g/day or 15 to 25 g/1000 kcal for our patients (44). In 1960, Trowell reported that diabetes was rare in African hospital patients (56). Walker then postulated that increased cereal fiber intake might prevent development of diabetes (57). Walker et al. documented that healthy Bantu school children in South Africa had lower glycemic responses than urban children and that these differences were related to dietary fiber intake (58). Trowell speculated that prolonged intake of fiber-depleted starch promoted development of diabetes and formulated the dietary fiber hypothesis of the etiology of diabetes (59). Epidemiologic data indicate that low fiber intake correlates with a higher prevalence of diabetes (15, 16, 57).

The therapeutic value of fiber in diabetes emerged in 1976 when the Oxford group reported that fiber supplements reduced postprandial glycemic responses (60), and we (61) reported that high-fiber diets decreased the insulin requirements of lean diabetic individuals. Many others confirmed that either fiber-supplemented diets or high-fiber diets benefit diabetic individuals (7, 62, 63 and 64).

O'Dea et al. (64) compared the impact of different diets for 2 weeks on blood glucose and lipid values in type II diabetic individuals (Table 86.11) and showed the detrimental effects of high fat intake on blood glucose and lipid values and the beneficial effects of a high-carbohydrate, high-fiber, low-fat diet. Although a low-carbohydrate, low-fat, high-protein intake providing 221 g of protein daily was used to test the effects of low carbohydrate and low fat intake, this diet is impractical and contraindicated in diabetic individuals at risk of diabetic nephropathy. This study demonstrates the clear superiority of a high-carbohydrate, high-fiber diet to either a high-carbohydrate, low-fiber diet or a low-carbohydrate, high-fat diet.

Parameter	High Carbohydrate, High Fat	High Carbohydrate, Low Fat	Low Carbohydrate, High Fat	Low Carbohydrate, Low Fat

Table 86.11 Effect of Diets on Glycemic Control and Serum Lipids

[Table 86.12](#) lists the pros and cons of recommending increased dietary fiber intake in diabetic individuals. For many individuals, the advantages outweigh the disadvantages. In addition to its effects on the gastrointestinal tract, fiber enhances peripheral sensitivity to insulin ([65](#)). Increasing dietary fiber intake offers these major advantages: improved glucose control with decreased swings in blood glucose resulting in less hyperglycemia and less hypoglycemia; decreased requirements for insulin or sulfonylureas; lower atherogenic lipoproteins; and other health benefits such as lower blood pressure ([64](#)), reduced risk of coronary heart disease ([66](#)), enhanced weight management ([67](#)), and reduced risk of colorectal cancer ([68](#)). Generous intake of dietary fiber from fruits, vegetables, legumes, whole-grain cereals, and breads also fosters intake of many nutrients such as vitamins and minerals.

Advantages

- Slow nutrient digestion and absorption
- Decrease postprandial plasma glucose
- Increase tissue insulin sensitivity
- Increase insulin receptor number
- Stimulate glucose use
- Attenuate hepatic glucose output
- Decrease counterregulatory hormone release (e.g., glucagon)
- Lower serum cholesterol
- Lower fasting and postprandial serum triglycerides
- May attenuate hepatic cholesterol synthesis
- May increase satiety between meals

Disadvantages

- Increase intestinal gas
- Temporarily may cause abdominal discomfort or gastrointestinal distress
- May alter pharmacokinetics of certain drugs

Table 86.12 High Fiber Intakes: Advantages and Disadvantages

Different types of fiber are distinguished by their physiologic properties and systemic effects. Water-insoluble fiber, found primarily in wheat, vegetables, and most grain products, alters gastrointestinal function by decreasing intestinal transit time and increasing fecal bulk. Insoluble fiber generally does not lower blood glucose or cholesterol levels. Soluble fiber becomes viscous or gummy when mixed with water, increasing intestinal transit time, delaying gastric emptying, and slowing glucose absorption. These actions lower postprandial blood glucose concentrations and decrease blood cholesterol, both important goals for individuals with diabetes. Food sources of soluble fiber include fruits, oats, barley, and legumes. Research into fiber supplements such as pectin, guar, and psyllium has documented the beneficial effects of these substances in diabetes control ([69](#)), but fiber supplements are not commonly used in clinical practice. Newly developed, safe, and palatable fiber supplements may help patients to reach recommended levels of fiber intake and improve metabolic control.

The major disadvantages of increased fiber intake relate to gastrointestinal symptoms. Theoretical concerns about detrimental effects on vitamin or mineral availability have not been documented (70, 71). The mild abdominal discomfort experienced by some individuals can usually be avoided by gradually increasing fiber intake, and it usually disappears after a few days. Most individuals have more flatulence with increased fiber intake; this usually persists but is better tolerated in time. Increased fiber intake increases fecal bulk and usually increases frequency of bowel movements. Individuals with irritable bowel syndrome often do not tolerate an abrupt increase in fiber intake well and should increase fiber intake slowly to avoid gastrointestinal symptoms. Individuals with autonomic neuropathy of the gastrointestinal tract need special consideration. Increased soluble fiber may aggravate delayed gastric emptying. Increased fiber intake may benefit diabetic diarrhea and also promote laxation for individuals with constipation. In our experience, dietary fiber has a beneficial effect in most diabetic individuals with autonomic neuropathy. Most diabetic individuals who gradually increase fiber consumption have net beneficial effects.

Many national health organizations recommend that healthy adults increase their dietary fiber intake by 50 to 100%. Because the average fiber intake of American adults is approximately 13 g/day for women and 18 g/day for men, this recommendation suggests that an intake of 20 to 35 g/day would be healthy and desirable (72). In 1987 the ADA recommended that diabetic adults consume approximately 40 g/day of dietary fiber or 15 to 25 g/4186 kJ (1000 kcal) (45). These recommendations are appropriate for diabetic individuals because of such fiber-related benefits as increased insulin sensitivity, better glycemic control, and lower atherogenic serum lipids. This level of fiber intake can easily be achieved using high-carbohydrate, high-fiber (HCF) exchanges (Table 86.13) or ADA exchanges (Table 86.14), with an emphasis on higher-fiber choices such as whole-grain breads, high-fiber cereals, generous intake of fruits and vegetables, and regular use of legumes (73). While foods rich in dietary fiber have many health benefits for diabetic individuals, the ADA recently decreased the amount it recommends and now recommends 20 to 35 g/day, the recommended level for the general population (9).

Food Group	Energy (kcal)	Carbohydrate (g)	Protein (g)	Fat (g)	Fiber (g)
Starches	70	15	2	—	2

Beans	95	17	7	—	5
Vegetables	25	5	1	—	2
Fruits	60	15	—	—	2.5
Skim milk	85	12	8	—	—
Fats	45	—	—	5	—

Table 86.13 Nutrient Values per Serving: 1987 High-Carbohydrate, High-Fiber (HCF)

Exchange List

Food Group	Energy (kcal)	Carbohydrate (g)	Protein (g)	Fat (g)
Starchy/bread	80	15	3	trace
Meat and substitutes				
Lean	55	—	7	3
Medium-fat	75	—	7	5
High-fat	100	—	7	8
Vegetables	25	5	2	—
Fruit	60	15	—	—
Milk				
Skim	90	12	8	trace
Low-fat	120	12	8	5
Whole	150	12	8	8
Fat	45	—	—	5

*Multiplying the grams of carbohydrate and protein by 4 in the starchy/bread and skim milk lists will not yield the total number of calories given for these two lists. These exchanges contain less than a gram of fat per serving and the term trace is used to make teaching easier. Diabetics may wish to use 1 g of fat in their calculations to achieve the total caloric value for the exchange group.

Table 86.14 Nutrient Values per Serving: 1986 American Diabetes Association (ADA) Exchange List^a

Sweeteners

Traditionally, diabetic individuals have been advised to curtail intake of foods that aggravate hyperglycemia, increase serum triglyceride concentrations, and foster additional weight gain. Often, these same foods contain excessive amounts of fat and calories contributing to poor metabolic control. Much of the focus has been on limiting refined sweets and processed foods. Recently, the ADA and others have eased their restrictions on the use of sweets in the diet. However, this should not be construed as a recommendation to increase the amount of sweets consumed in the total diet. It merely illustrates that a variety of foods may be included as they fit into a well-balanced meal plan. It is still wise to limit the consumption of sugar in patients with diabetes to that recommended for the general population (35). This represents a major change in eating habits for many people. Up to 25 g of added sucrose may be allowed, provided it is part of a low-fat, high-fiber diet and that it substitutes for an isocaloric amount of fat or high-glycemic-index food or other nutritive sweeteners. There is no strong reason to recommend fructose in preference to sucrose within this limit.

There are two basic categories of sweeteners: nutritive (calorie containing) and nonnutritive (noncaloric). Nutritive sweeteners, such as fructose found in fruits, and common sugar alcohols, the polyols (sorbitol, mannitol, or xylitol), are acceptable in modest amounts in the diabetic meal plan.

Fructose as a natural component of foods is sweeter than other sugars and is metabolized without the use of insulin, thus producing less hyperglycemia. Though fructose may increase an already high blood glucose level in poorly controlled diabetics,

its effect is minimal in those with adequate control. Substituting fructose for sucrose or glucose lowers average blood glucose levels, producing a glycemic response of 20% and 33%, respectively. When we incorporated 50 to 60 g of fructose/day in a prudent diet for 14 diabetic men for 24 weeks, no adverse effects were noted in plasma glucose, glycohemoglobin, cholesterol, triglycerides, lactate, or uric acid concentrations. Inclusion of fruits containing fructose in accordance with the dietary guidelines for Americans, 2 to 4 servings per day according to calorie and activity level, should provide balance and variety in the diabetic individual's diet.

The polyols are formed by partial hydrolysis and hydrogenation of edible starches. Polyols also produce a lower glycemic response than sucrose and other carbohydrates. There appear to be no significant advantages of the polyols over other nutritive sweeteners. Excessive amounts of polyols may, however, have a laxative effect (35).

Alternative sweeteners, noncaloric, are an acceptable means of checking the amounts of excess refined sugars in the diet. Though adequately safe, to avoid excesses of any one type, a multiple-type approach is recommended. Each sweetener has its distinctive taste, advantages, and risks. Saccharin, aspartame, and acesulfame K are approved by the FDA for use in the United States. The FDA also determines an acceptable daily intake for approved additives, including nonnutritive sweeteners. Nonnutritive sweeteners approved by the FDA are safe to consume by all people with diabetes (35).

Saccharin, one of the first artificial sweeteners, is a petroleum derivative with potential association with bladder cancer when ingested in excessive quantities. Though the typical diet certainly would not exceed a moderate amount, pregnant women are advised to avoid saccharin, and children should not exceed two cans of saccharin-sweetened soft drinks daily. Aspartame, a dipeptide containing aspartic acid and phenylalanine, is present in a large variety of foods and is contraindicated only for individuals with phenylketonuria. Its use is limited to foods that do not rely on heat exposure in processing or for baking (35). Acesulfame potassium, a derivative of acetoacetic acid, is approved for broad product applications. In-take of artificial sweeteners should be limited to established safe levels. Practical resources are available to assist in counseling patients with diabetes in regard to sweeteners (35).

Diabetic Foods

So-called diabetic specialty foods are not recommended for people with diabetes or for anyone else. There is no evidence that the foods or drinks offer any advantage to people with diabetes, compared with conventional products. They often contain large amounts of sorbitol or fructose and similar energy to the conventional equivalent. The term *diabetic* attached to a food for promotional purposes has been interpreted by patients and relatives as meaning freely available and even therapeutically beneficial. The main arguments for their use relate to risks of dental caries and of becoming overweight. Reduced-sugar products labeled “diabetic” are usually more expensive; ordinary reduced-sugar products should be used. There also is a risk of hypoglycemia if reduced-sugar foods are taken inadvertently by insulin-treated patients (35).

Alcohol

Because of its potential hypoglycemic effects, heavy alcohol use is not recommended in the diabetic population. However, if alcohol is included in the diet, it should be limited to no more than 2 drinks per day for men and no more than 1 drink per day for women. One drink consists of a 1.5-oz shot of distilled spirits (i.e., whiskey, scotch, vodka, gin, rum), a 4-oz glass of wine, or 12 oz of beer (see Appendix [Table IV-A-19](#)). Alcohol does not require insulin to be metabolized; it is directly absorbed from the stomach, duodenum, and jejunum. The liver is the site of alcohol metabolism and oxidation. Excessive alcohol enters the general circulation and exerts its effects on the central nervous system.

In diabetics, alcohol induces fasting hypoglycemia by inhibiting gluconeogenesis. If consumed, it should be ingested with a meal. Alcohol also provokes hypertriglyceridemia and interacts with concurrent medications (particularly the disulfiram reaction of flushing, nausea, and dizziness that may occur when alcohol and chlorpropamide are used). Impaired judgment from alcohol intake may disrupt otherwise stable eating patterns and insulin dosage.

Alcoholic beverages provide 7 kcal/g, similar to fat and metabolized much the same. This may result in excessive energy intake without corresponding nutritive value. For insulin-dependent diabetes, the caloric value should be counted in the meal plan. In the non-insulin-dependent diabetic diet, alcohol is best substituted as a fat exchange (one alcoholic beverage equals two fat exchanges). Additional calories from mixers must be included ([44](#)).

A thorough assessment of a diabetic should include inquiry about alcohol use. Individuals may not be aware of the effects of alcohol and should be provided with at least the following guidelines: (a) potential or current intake should be discussed with the physician and nutrition counselor; (b) alcohol should be consumed slowly and with food to lessen hypoglycemic episodes; (c) identification should be worn indicating diabetic diagnosis since the symptoms of insulin reaction and intoxication are similar; (d) drinking to the extent of impaired judgment or operating a motor vehicle should be avoided; (e) poorly controlled diabetics should abstain from alcohol use, and of course pregnant women, diabetic or not, should not use alcohol ([35](#)).

Micronutrients

Two minerals commonly mentioned in relation to diabetes are chromium and magnesium. Animal studies have also examined vanadium, but only one clinical study ([74](#)) is available for humans. Chromium deficiency has been related, hypothetically, to development of diabetes in humans for many years, but persuasive studies in Western people are not available for recommendation of chromium supplementation for diabetic individuals. The only clear-cut circumstance in which chromium replacement has any beneficial effect on glycemic control is for people who are chromium deficient as a result of long-term chromium-deficient parenteral nutrition ([35](#)). However, it appears that most people with diabetes are not chromium deficient, and thus chromium supplementation

cannot be routinely recommended. Similarly, although magnesium deficiency may play a role in insulin resistance, carbohydrate intolerance, and hypertension, the available data suggest routine evaluation of serum magnesium levels only in patients at high risk for magnesium deficiency. Magnesium should be repleted only if hypomagnesemia is demonstrated. The magnesium question is controversial, and the ADA held a consensus conference in 1992 and recommended measuring serum magnesium in persons at risk for magnesium deficiency ([75](#)) (see also [Chapter 9](#)). Potassium loss may be sufficient to warrant dietary supplementation in patients taking diuretics. Hyperkalemia sufficient to warrant dietary potassium restriction may occur in patients with renal insufficiency or hyporeninemic hypoaldosteronism or in those taking angiotensin-converting enzyme inhibitors.

ADDITIONAL CONSIDERATIONS

Children

Diabetic children have unique needs. It is important to address their fears, their level of understanding, and family support. Each stage of childhood requires revision of the diabetic management plan. Both child and parent should participate in the learning process. As therapy progresses, the child should be allowed to assume increased responsibility for the management goals. Restoring the sense of wellness, of “feeling good,” is the primary goal. Eliminating the hallmark signs of diabetes such as polydipsia, polyuria, and polyphagia; preventing ketoacidosis, hypoglycemia, and hyperglycemia are specific preliminary objectives to be covered with the child and caregiver.

Growth should be monitored and can be plotted on standardized charts appropriate for the child's age and gender several times yearly, especially during the initial learning phase. An individualized plan including adequate nutrition with consideration for preferences and eating habits and normal-for-age levels of physical activity are the cornerstone of child diabetes management.

A generous carbohydrate and fiber intake coupled with limited fat provides the same advantages for children as for adults with diabetes ([35](#), [76](#)). During periods of rapid growth or increased energy requirements, more carbohydrates may be added. Consistent levels of food intake are more important than carbohydrate distribution for the insulin-dependent diabetic child. Three meals, each providing approximately 20 to 25% (65% total) of energy needs, and an additional three snacks using the remaining 35% of energy needs are appropriate. The dietitian may develop a meal plan based on the child's food preferences and daily schedule, and then insulin doses are tailored to achieve good glycemic control.

Simple guidelines should be provided about appropriate glycemic range and increasing snack intake for increased physical activities. Self-monitoring of blood glucose is extremely important in preventing hypoglycemic or hyperglycemic episodes experienced with physical activity, changes in meal intake, and sedentary or sick days. By trial and error, the child and caregiver will learn which variables require adjustment or closer monitoring. Autonomy and acceptance are necessary in development of a healthy well-adjusted adult without physical or psychosocial limitations. Periodic nutritional

reassessment is needed to adjust requirements for growth and physical activity. Changes in insulin dosage and meal planning should evolve as the child matures (35, 76).

Elderly Patients

Diabetes is a major chronic problem for a growing elderly population. The prevalence of diabetes is almost 10% for Americans over age 60 and approximately 20% for those over 80 years old. Diabetic individuals over age 65 have a relative risk of mortality approximately 1.5 times that of nondiabetic individuals. Factors that contribute to glucose intolerance and development of diabetes in the elderly include decreased physical activity, intake of less complex carbohydrate and a higher percentage of energy from fat, and increased adiposity with decreased lean body mass. Other illnesses or medications may contribute to development of diabetes in the elderly (35).

Because the elderly have multiple defects, including impaired insulin secretion, decreased action of insulin to suppress hepatic glucose output, and peripheral insulin resistance, treatment should first focus on increasing sensitivity to insulin through nutrition and physical activity. For consideration, an α -glucosidase inhibitor may be tried as the first antidiabetes agent in older individuals, since these agents do not cause hypoglycemia and may enable sluggish insulin secretion to keep pace with slowed absorption of carbohydrates. When required, second-generation sulfonylureas should be given. If insulin is necessary, a single injection of NPH or a premixture of NPH and regular (e.g., 70/30 insulin) often supplements endogenous insulin secretion adequately. Commonly, the sulfonylurea agent is continued after insulin is instituted to minimize the amount of insulin required. The goals for blood glucose control are tailored to each individual's circumstances.

Eating a nutritious diet providing adequate energy from a variety of foods is extremely important. Fat intake should be less than 30% of energy, with limited saturated fat and cholesterol. The generous carbohydrate intake can include simple and complex carbohydrates rich in dietary fiber. Fruits, juices, and sweeteners usually do not need to be limited if fat guidelines are followed. The antidiabetes agent or insulin regimen can usually be adjusted to allow individuals to follow meal plans that suit their preferences or circumstances. Special teaching skills and patient involvement are required to optimize learning for elderly diabetic individuals. Nutritional counselors need a positive attitude, patience, and use of praise to enable elderly individuals to change lifelong dietary and exercise habits successfully.

Pregnancy

Pregnancy changes eating habits, exercise patterns, emotional state, insulin sensitivity, and hormone secretions. These changes alter glucose control and insulin requirements. In the nondiabetic woman, as placental and ovarian hormones decrease insulin sensitivity, more insulin is secreted to maintain satisfactory glucose levels. Two to 4% of women lack the pancreatic reserve to meet this challenge and develop gestational diabetes. This condition usually abates after delivery, but these women are much more likely to develop diabetes during subsequent pregnancies or later in life, particularly if

they are obese. For all diabetic women, reduction of maternal, fetal, and perinatal risks requires excellent glucose control (17).

Insulin requirements change dramatically during pregnancy. To sustain a healthy fetus, the diabetic woman must adjust her nutrient intake and insulin dose to control glucose levels and avoid ketosis. During the first half of pregnancy, insulin requirements drop by 20 to 30% because of decreased food intake and increased glucose uptake by the fetus and placenta. During the second half of pregnancy, insulin requirements rise by 60 to 100% above prepregnancy levels because of placental hormone production and insulin resistance related to other factors. After delivery and removal of the placenta, insulin requirements drop precipitously; much smaller doses are required the week after delivery, but insulin requirements gradually increase to prepregnancy levels by 6 weeks after delivery. Proper adjustment of insulin therapy during pregnancy and the postpartum period requires careful blood glucose monitoring (17).

Pregnant women have lower fasting glucose levels than nonpregnant women; normal fasting blood glucose is 55 to 65 mg/dL. This level normally peaks at 140 mg/dL 1 hour after a meal; the 24-hour average is 80 to 85 mg/dL. To ensure the best possible outcome, normal glucose levels are the goal for diabetic pregnant women. Goals during pregnancy include meeting the nutritional needs of both mother and fetus while maintaining excellent blood glucose control. Specifically, these goals are to achieve glucose control before gestation and during the early weeks of pregnancy to reduce the risks of congenital malformations; to provide energy intake for appropriate weight gain (a range of 6.8 to 18.1 kg [15 to 40 lb], based on prepregnancy body mass index [BMI]), to meet increased protein needs; to provide carbohydrate to minimize ketosis, meeting the needs of the fetus and placenta; to optimize tissue sensitivity to insulin; and, during the critical 3 to 4 weeks prior to delivery, to maintain excellent glucose control to reduce neonatal risk and fetal macrosomia (17, 35).

Requirements for most nutrients increase with pregnancy and are similar for diabetic and nondiabetic women. During the first trimester, most women should gain 0.9 to 1.8 kg (2–4 lb); this can be achieved by increasing energy intake by 419 kJ (100 kcal) per day. During the second and third trimesters, a gain of about 1 lb/week depending on prepregnancy BMI is the goal. This is achieved by increasing energy intake by 15%, or 1256 kJ (300 kcal) per day. To meet increased needs, intake of high-quality protein is increased by 30 g/day to at least 1.3 g protein/kg body weight. Carbohydrate should provide at least 50% of the energy intake; some individuals benefit from higher intakes of complex carbohydrate and fiber. Fat provides the remaining energy intake. Most women require supplemental iron and folic acid; a multiple vitamin and mineral supplement including these is usually prescribed if evidence indicates that usual intake is low enough to produce adverse effects on maternal or fetal health or on the outcome of the pregnancy (17).

Gestational Diabetes (GDM)

Onset of GDM and duration during pregnancy occur in about 2 to 4% of all pregnant women, or approximately 90,000 American women each year (1). This makes it the most common medical disorder affecting pregnancy. It appears to occur only rarely in

women under 20 years of age. Although the vast majority of these women return to normal glucose tolerance after delivery, 40 to 60% of them may develop NIDDM in 15 to 20 years. Those who maintain a reasonable body weight and exercise regularly have a decreased incidence of developing NIDDM. From the 24th to the 28th week of pregnancy, the body's need for insulin increases dramatically. Risks for GDM include occurrence of GDM during an earlier pregnancy, delivery of a previous macrosomic infant (>9 lb birth weight), a family history of diabetes, and maternal obesity (>120% of ideal body weight) (17).

Pregnancy in Overt Diabetes

A successful diabetic pregnancy requires planning and commitment of time and money. Because poorly controlled diabetes threatens the health of the mother and safety of the fetus and newborn, most women make these commitments. To reduce the risks of congenital malformations, excellent glycemic control prior to conception and during early pregnancy is necessary. Maintaining excellent glycemic control throughout pregnancy demands careful attention to diet, exercise, and insulin adjustments. Health professionals educate women about special needs during pregnancy, with the patient, physician, dietitian, and nurse educator working as a team to accomplish goals.

Nutritional management plans for pregnant and nonpregnant women with overt diabetes are similar, but pregnancy necessitates greater attention to the day-to-day nutritional plan. Guidance during early pregnancy includes special consideration of food cravings or nausea. An individualized nutritional plan that evolves throughout pregnancy is essential to meet changing nutritional needs and insulin requirements. Three meals and three snacks supply energy requirements in the timely fashion necessary to prevent hypoglycemia.

The pregnant diabetic woman requires intensive management to achieve a successful outcome. Frequent office visits and vigorous nutritional therapy are important. Using frequent home blood glucose measurements, the individual strives to maintain normal fasting and postprandial glucose values while avoiding frequent or severe hypoglycemic reactions. The healthcare team monitors the fetus and assesses fetal maturity to select the optimal time for, and mode of, delivery. Hospitalization may be necessary to reestablish blood glucose control; early hospitalization for glycemic control prior to delivery is advisable. Finally, intensive neonatal management is essential. Use of these principles can reduce maternal risk to near that of nondiabetic women and their offspring.

Diabetic women should be encouraged to breast-feed their infants, while paying special attention to changing insulin and food requirements. A caloric intake of 31 kcal/kg maternal body weight is associated with the ability of mothers with insulin-dependent diabetes to sustain lactation (35).

Renal Disease

Renal disease is a major complication that affects 30 to 50% of type I and over 20% of type II diabetic individuals. Diabetic nephropathy is accompanied by proteinuria,

decreased glomerular filtration rate, and hypertension. Development of *microalbuminuria*, urine protein of 40 to 300 mg/24 hours, is the forerunner of overt nephropathy. Hypertension accelerates development and progression of renal disease, whereas poor glycemic control and high protein intake may contribute to development and progression of nephropathy (36).

Protein restriction in management of chronic renal failure is discussed elsewhere (see [Chapter 89](#)). High protein intake is thought to lead to renal damage in diabetic individuals by various mechanisms. Extensive protein feeding increases glomerular filtration rate, renal blood flow, single-nephron glomerular filtration rate, and transcapillary hydraulic pressure in laboratory animals (36).

Unlimited protein intake is inappropriate in patients with diabetic nephropathy. Protein restriction decreases the progression of chronic renal failure in nondiabetic individuals and perhaps in diabetic nephropathy. At present, it appears prudent to restrict protein intake to 0.6 g/kg body weight for individuals with established diabetic nephropathy, with appropriate adjustments for proteinuria and careful clinical monitoring. Carbohydrate should provide at least 50% of energy intake, and saturated fat and cholesterol intake should be restricted. Recent research indicates that substitution of soy protein for animal protein may decrease risk for developing diabetic nephropathy (36). Furthermore, substituting soy protein for animal protein may reduce proteinuria and slow progression of nephropathy. Further research is required to rigorously test this “soy protein for diabetic nephropathy” hypothesis (36).

Hyperlipidemia

Most diabetic individuals have lipoprotein abnormalities. There are multiple abnormalities of VLDL, LDL, and HDL composition and metabolism. Hypertriglyceridemia and low HDL-cholesterol values are seen more commonly in diabetic than nondiabetic individuals. Hypertriglyceridemia appears to confer a higher risk of atherosclerotic cardiovascular disease on diabetic than on nondiabetic individuals; low HDL-cholesterol values are another major risk factor (25, 77).

Serum lipid and lipoprotein goals for diabetic individuals are still being actively discussed. To minimize the risk of atherosclerotic cardiovascular disease, the following desirable or goal fasting values for diabetic individuals are recommended: total cholesterol, <200 mg/dL (<5.2 mmol/L); LDL cholesterol, <100 mg/dL (<2.6 mmol/L); triglycerides, <150 mg/dL (<1.7 mmol/L); and HDL cholesterol for males, >45 mg/dL (>1.2 mmol/L) and for females, >55 mg/dL (>1.4 mmol/L). Because abnormally low HDL-cholesterol levels are difficult to increase by dietary or pharmacologic measures, LDL cholesterol should be decreased to achieve ratios of LDL:HDL cholesterol below 2.2 for males and below 1.8 for females (44, 78).

The diabetes nutritional plan outlined in this chapter and elsewhere is the basic approach for most hyperlipidemic individuals (44). Good glycemic control, attaining and maintaining a desirable body weight, regular exercise, and moderation in alcohol intake—practices recommended for all diabetic individuals—reduce hyperlipidemia. Approach to hyperlipidemia can focus on management of elevated LDL cholesterol,

elevated triglycerides, decreased HDL cholesterol, or combinations of these disorders.

Elevated LDL-cholesterol levels occur with the same frequency in diabetic and nondiabetic individuals; treatment is similar. A high-carbohydrate (55–60% of energy), high-fiber (25 g/4186 kJ [1000 kcal]), low-fat (about 25% of energy with less than 10% saturated), low-cholesterol (<200 mg/day) diabetes diet is the first step. This diet should include generous amounts of soluble dietary fiber from oat and bean products. Increasing soluble fiber intake by 6 g/day without other changes in diet can decrease LDL cholesterol by 10 to 20% (44, 79, 80). The second step is daily inclusion of 4 to 12 g of psyllium, a well-tolerated concentrated source of soluble fiber (80, 81). When desirable LDL-cholesterol levels are not achieved, a bile acid sequestrant is added. Bile acid sequestrants and psyllium can be mixed together in 8 to 12 oz of fluid and taken two or three times daily. Hydroxymethylglutaryl coenzyme-A (HMG-CoA) reductase inhibitors are the second pharmacologic agent of choice (44).

Because of the accelerated risk for atherosclerotic disease in diabetic individuals, some authorities recommend LDL-cholesterol goals below 2.6 mmol/L (100 mg/dL) for diabetic adults. These authorities also recommend low-dose HMG-CoA reductase inhibitor therapy for adults with LDL-cholesterol values above 2.6 mmol/L (100 mg/dL). Further study is required to justify this aggressive therapy.

Hypertriglyceridemia is more common in diabetic individuals, especially in type II diabetes, than in nondiabetic individuals and carries a greater risk of atherosclerosis. Almost all individuals can be managed effectively with a high-fiber, high-carbohydrate diet if they decrease their fat intake to a low enough level (44, 82). Figure 86.8 illustrates the responses of serum triglyceride values to intensive high-carbohydrate, high-fiber, low-fat diets for diabetic individuals at our medical center. Persistently elevated triglyceride levels usually are due to excessive dietary fat intake, because triglyceride levels plummet when individuals are hospitalized and receive a low-fat diet. Sometimes excessive alcohol or simple sugar intake aggravates hypertriglyceridemia. Fibric acid derivatives, nicotinic acid, or a combination of HMG-CoA reductase inhibitors with nicotinic acid are pharmacologic choices for those not responding to diet.

Figure 86.8. Response of serum cholesterol and triglyceride concentration to high-carbohydrate, high-fiber (*HCF*) and high-fiber-maintenance (*HFM*) diets in lean and

obese diabetic individuals. *Open circles* represent individuals with elevated fasting serum triglyceride values on an American Diabetes Association (ADA) diet. Duration of follow-up is indicated in months.

Type II diabetic individuals commonly have decreased HDL-cholesterol levels. Regular physical exercise such as walking 2 to 3 miles daily and not smoking are important lifestyle practices to increase HDL cholesterol. Dietary measures to decrease serum triglycerides and the regular use of oat products may increase HDL cholesterol by 10 to 20% (83). HDL cholesterol usually decreases when intensive nutritional measures are used. Decreases in HDL cholesterol may parallel decreases in LDL-cholesterol levels for several months before HDL cholesterol levels begin to increase. The increase in HDL cholesterol with exercise and diet occurs slowly over 3 to 6 months. However, most individuals cannot increase HDL-cholesterol levels by more than 0.13 to 0.26 mmol/L (5–10 mg/dL) by these lifestyle measures. Often, LDL-cholesterol levels must be decreased to below goal levels to achieve desirable LDL:HDL ratios below 2.2 for males or 1.8 for females. Pharmacologic agents that increase HDL cholesterol somewhat are fibric acid derivatives and HMG-CoA reductase inhibitors. These agents are introduced when LDL-cholesterol or triglyceride concentrations do not reach goal levels with dietary measures.

The hyperlipidemia of most diabetic individuals responds well to nutritional measures. Most individuals with LDL-cholesterol levels of 4.13 mmol/L (<160 mg/dL) can be managed effectively with high-fiber diets including generous amounts of soluble fiber. Most hypertriglyceridemic individuals respond to a high-fiber diet moderately or severely restricted in saturated and total fat. New nutritional considerations include use of soy protein to decrease LDL-cholesterol and triglyceride concentrations (84) and antioxidant supplements (85). Regular exercise (e.g., walking 2 to 3 miles daily) and achieving and maintaining a desirable body weight also enhance the lipoprotein response to nutritional measures.

Obesity

About 75% of type II diabetic individuals in the United States are obese; obesity is a major contributor to development and maintenance of the diabetic state. Achieving and maintaining a desirable body weight through diet and exercise is the treatment of choice. Antidiabetes drugs and insulin are important adjunctive measures, but they cannot be substituted for exercise and a diet appropriate in energy, fat, and complex carbohydrate.

Weight-Loss Programs

The healthcare team sets the stage for effective weight loss by being empathetic and supportive while continuing to emphasize the detrimental effects of overeating on diabetes and health. However, the obese individual must be committed to losing weight before nutrition counseling is effective. Our team offers a variety of weight-loss

programs, including instruction in a hypocaloric diet; referral to a community program; an intensive high-fiber, weight-reduction diet with frequent medical and dietetic follow-up; and medically supervised low-calorie or very low calorie diet programs. Diabetic individuals with a BMI above 30 kg/m² or who need to lose more than 22.7 kg (50 lb) should have medical supervision during the weight-loss phase and should not enroll in medically unsupervised programs (44).

Weight Maintenance

Weight loss is not the cure for obesity. This chronic condition requires a long-term maintenance program and access to lifelong counseling about lifestyle changes important in weight maintenance. After nonsurgical weight-loss programs, long-term weight maintenance as a percentage of initial weight loss is reported to be about 36% at 2 years and about 5% at 5 years. Most obese individuals who complete community weight-loss programs, behavioral modification programs, and very low calorie programs regain all the weight they lost within 2 to 5 years. Newer very low calorie diet programs that stress physical activity, use the best available behavioral techniques, and facilitate achievement of desirable body weights are obtaining better long-term weight maintenance. Obese individuals completing the HMR Fasting Program at the University of Kentucky (UK) are maintaining about 63% of their initial weight loss 2 years after completing the weight-loss phase (86). Recent data indicate that “graduates” of the UK program are maintaining about 20% of their weight loss at 7 years; approximately 25% are maintaining a loss of at least 10% of their initial weight (i.e., maintaining more than 10 kg of weight loss) (Anderson JW, unpublished observations). The best predictors of good weight maintenance are low fat intake and good levels of physical activity such as walking 20 miles/week. Much further development is required to enable formerly obese individuals to maintain desirable weights for long periods.

High-Fiber Weight-Loss Programs

High-carbohydrate, high-fiber, weight-reducing diets are excellent choices for diabetic individuals with BMIs ranging from 28 to 35 kg/m² (62). The diet is individualized to provide 5 to 7 kcal/lb actual weight, so many women receive 4186- to 5023-kJ (1000- to 1200-kcal) diets and many men receive 5023- to 6698-kJ (1200- to 1600-kcal) diets. These diets provide 55 to 60% of energy from carbohydrate, 50 to 70 g protein, the remainder of energy from fat, and about 15 to 25 g fiber per 4186 kJ (1000 kcal). Patients also are encouraged to walk 2 to 3 miles/day and keep records of food intake, exercise, and blood glucose values. Initially, patients are seen every 2 weeks, then every 3 to 6 weeks during the weight-loss phase, and then every 4 to 8 weeks during the 1st year after completing the weight-loss phase (44, 68).

Low-Calorie and Very Low Calorie Weight-Loss Programs

Intensive low-calorie or very low calorie diet programs are the treatment of choice for obese diabetic individuals with BMIs exceeding 35 kg/m². Responsible very low calorie diet programs provide careful medical evaluation and ongoing medical supervision by trained physicians; a high-quality supplement adequate in protein, carbohydrate, vitamins, and minerals; a weekly program providing the most current behavioral and

lifestyle education; an emphasis on physical activity that enables average participants to achieve and maintain the expenditure of 8372 kJ (2000 kcal) per week in physical activity such as walking; and a maintenance program of 18 or more months (87, 88).

Medication Adjustment with Low-Calorie Diets

Because high energy intakes sustain hyperglycemia and requirements for insulin or sulfonylureas, energy-restricted diets reduce requirements for these medications. Figure 86.7 shows insulin-dose reductions over 12 weeks when 20 insulin-treated type II diabetic individuals were given low-calorie or very low calorie diets providing 2093 to 3349 kJ (500–800 kcal) per day. Insulin doses decreased about 50% during the 1st week. We routinely decrease insulin doses by 50% when we initiate low-calorie or very low calorie diets. With less severe energy restriction, we reduce insulin doses by 10 to 30%, based on prior glycemic control and extent of energy restriction. Subsequent doses are decreased as required on the basis of home glucose monitoring. Similarly, sulfonylurea doses must be reduced when diabetic individuals initiate energy-restricted diets. Usually, we reduce sulfonylurea doses by 50% when initiating low-calorie or very low calorie diets. Individuals treated with either insulin or sulfonylureas must monitor their glucose when initiating energy-restricted diets, to avoid serious hypoglycemia (87) (Fig. 86.9).

Figure 86.9. Reduction in insulin dose for type II individuals treated for 12 weeks with low-calorie diets. Subjects designated *non-insulin* were able to discontinue insulin during the 12-week study.

EXERCISE

A routine exercise program is important for all people. Exercise is excellent for weight control, enhanced physical and psychologic fitness, better capacity to work, improved body composition, and increased HDL concentration (44). Diabetics prosper in additional ways, including better glucose tolerance, raised insulin sensitivity, reduced atherosclerosis risk factors, decreased blood pressure (44), and improved

cardiovascular fitness.

The most beneficial exercise program differs for each person, but walking is best for obese individuals. A good way to ease into an exercise regimen is to start walking 10 to 20 minutes once or twice each day, increasing this gradually over a few weeks to 30 minutes twice a day. On average, most diabetics should walk 12 to 14 miles/week.

Other exercises such as bicycling, stair climbing, swimming, and aerobic dancing are good alternatives to walking, but more time should be spent on these machines to equal desired walking time (Table 86.15). It is beneficial to use the upper body during exercise. A Cardioglide or E-Force machine is an excellent choice for persons who are limited in the exercises they can perform with their lower extremities. These machines allow cardiovascular exercise without working the legs. With the vast selection of exercise equipment available, all individuals can find something appropriate for their needs and physical condition. After patients have set an exercise goal and selected an appropriate program, they should keep a written reminder of the goal. In addition, a personal exercise journal keeps patients focused and helps them remember what they have done (43).

Exercise	Time or Distance Equivalent to Walking One Mile
Jogging or running	1 mile
Outdoor bicycling	3 miles
Stair climbing	25 flights
Stair machine (fast pace)	8 min
Cross-country skiing machine	8 min
Swimming	10 min
Sitting rowing machine (E-Force)	10 min
Rowing machine (20 strokes/min)	10 min
Stationary bicycle	12 min
Aerobic dancing	12 min
Basketball (noncompetitive)	12 min
Golf (not riding a cart)	20 min

Adapted from Anderson JW, Brackner MM. Dr. Anderson's antioxidant, antiaging health program. New York: Carol & Graf; 1996:110:1-276.

*Amount of aerobic activity achieved (or activity equivalent to walking 1 mile) depends on the intensity of the exercise for most activities.

Table 86.15 Various Exercises That Are Equivalent to Walking One Mile

While exercise has definite benefits, there are also hazards to vigorous exercise, such as irritation of poorly regulated hyperglycemia, hypoglycemia or ketonemia, or unexpected death during exercise. Therefore, exercise safety for diabetics is of the utmost importance. Diabetics should monitor their blood glucose levels so food intake or insulin adjustment can be determined. Packing a snack while exercising outside prepares patients for times when they feel poorly. Also, an exercise partner who is educated on the patient's condition or having the patient wear identification can be useful in cases of hypoglycemia or an insulin reaction (89).

INSULIN THERAPY

Although insulin replacement therapy has been used for about 70 years, physiologic replacement of insulin for diabetic individuals remains an elusive goal. In lean, nondiabetic adults, insulin is secreted into the portal system in the basal state at a rate of approximately 1 U/h. After food intake, the rise in blood glucose and gastrointestinal hormones triggers a five- to tenfold increase in insulin secretion rates. Basal plus food-related insulin secretion totals approximately 40 U/day for lean, nondiabetic adults. Even though human insulin is available, this physiologic response cannot be mimicked (18).

Both diet and exercise have major effects on insulin sensitivity in type I and type II diabetic individuals. High-carbohydrate, high-fiber diets increase insulin sensitivity and decrease insulin requirements, whereas high-fat diets have opposite effects (65, 66). For example, a slender 38-year-old farmer required 57 U of insulin daily for good glycemic control on a conventional high-fat (37% of energy), low-carbohydrate (43% of energy), low-fiber diet in 1974 (44). After 16 years of good adherence to a high-carbohydrate (about 60% of energy), high-fiber (about 45 g/day), low-fat (less than 25% of energy) diet, he takes 36 U of insulin daily to maintain fairly good control as an outpatient. Regular physical activity appears to act similarly by increasing skeletal muscle sensitivity to insulin. For example, when a family-practice physician trains for marathons by running over 60 miles/week, he requires only 20 U of insulin daily, but when not in training, he requires about 50 U daily. Physiologic considerations, risks, and benefits of exercise are reviewed elsewhere (44).

These two case studies indicate that algorithms based on body weight have limited accuracy. The farmer had a 37% reduction in insulin dose related to diet without change in body weight or physical activity. While in his busy practice, the physician required 250% of the insulin dose needed when in training for marathons, without significant changes in body weight. Likewise, algorithms for premeal insulin doses used for carbohydrate counting are better based on total insulin dose of the individual than on body weight. For example, if someone takes 50 U of insulin daily, about 40%, or 20 U, is related to basal insulin needs and should be provided as intermediate (e.g., NPH) or long-acting (e.g., Ultralente). Thus, 30 U is assigned to premeal and presnack doses. If the person consumes 2400 kcal/day and 300 g of carbohydrate, one can “guestimate” a carbohydrate:insulin ratio of 10:1 and initiate carbohydrate counting and premeal insulin on this basis.

The insulin regimen is usually tailored to the nutritional plan and the physical activity of the individual. Some nutritional guidelines for insulin-treated type II diabetic individuals, type I diabetic individuals receiving conventional insulin therapy, and type I diabetic individuals receiving intensive insulin therapy are presented. [Table 86.16](#) compares insulin preparations widely used in the United States.

Type	Onset (h)	Peak (h)	Maximum Duration (h)
Lyspro	0.25-0.5	1-1.5	2-3
Regular	0.5-1	2-3	4-6
70/30 ^a	0.5-1	2-3,4-10	14-18
NPH	2-4	4-10	14-18
Lente	3-4	4-12	16-20
Ultralente	6-10	"peakless"	20-30

^aMixture of 70% NPH and 30% Regular

Table 86.16 Usual Timing and Action of Human Insulins

More than 2 million type II diabetic individuals receive insulin therapy in the United States. Many receive sulfonylurea therapy as well as insulin because this combination decreases the amount of insulin required (44, 90). About 75% of these insulin-treated type II individuals are obese. When diabetes and obesity occur together, termed *diabesity*, overeating is the major cause of hyperglycemia. Any reduction in energy intake promptly reduces insulin requirements. When starting any weight-reduction diet, reduced insulin need should be anticipated.

Insulin therapy in type II diabetes usually supplements endogenous insulin and often is given as a single injection before breakfast or at bedtime. When doses exceed 50 U/day, injections are usually given twice daily, before breakfast and the evening meal. Some patients mix NPH insulin and regular insulin for these injections or use premixed combinations of 70% NPH insulin and 30% regular insulin (70/30 insulin). Most insulin-treated type II diabetic individuals can be managed with three meals and a bedtime snack. The major adverse effects of insulin therapy in type II diabetes are hypoglycemic attacks and weight gain. Because overeating is the major contributor to hyperglycemia, undereating predictably produces hypoglycemia in the insulin-treated, obese type II diabetic individual. Avoiding hypoglycemia and weight gain in these individuals challenges both the physician who counsels the patient on insulin dosage and the dietitian who counsels on diet.

Conventional insulin management in type I diabetes usually involves two daily injections of a mixture of NPH and regular insulin and a meal plan including three meals and two to three snacks. Many individuals can achieve fairly good glycemic control if they self-monitor the blood glucose (SMBG) and make appropriate adjustments in food intake, physical activity, and insulin doses on the basis of their blood glucose level. Because most type I diabetic individuals do not adjust their own insulin doses based on twice-daily SMBG, energy intake at meals and snacks must be consistent from day to day. Most of these individuals benefit from a meal plan based on exchanges (91).

Intensive insulin therapy is now used more widely by type I diabetic individuals and is

the treatment of choice for most. An intensive therapy program includes multiple daily injections of insulin or use of an insulin infusion pump; multiple SMBG daily; careful balance of food intake, physical activity, and insulin dose through self-monitoring and self-adjustment of these parameters; and careful and frequent coaching and support by the health care team. The diet plan for these individuals is highly tailored to their needs, and patients must be able to make daily adjustments in food intake in response to blood glucose values and physical activity.

Carbohydrate counting is a popular adjunct to intensive insulin therapy (92, 93 and 94). While the time-honored method of intensive insulin therapy relates to eating a standardized diet from day to day and adjusting insulin on the basis of blood glucose deviations from target values, carbohydrate counting provides more flexibility. However, this does complicate the insulin regimen, since premeal insulin doses must be adjusted for anticipated carbohydrate intake as well as current blood glucose level. For highly motivated, highly trainable type I individuals, this regimen brings flexibility to the treatment plan.

ANTIDIABETES DRUG THERAPY

The 1990s ushered in several new antidiabetes agents that allow better tailoring of therapy to the presumed pathologic defect. [Table 86.17](#) outlines current thinking about the pathogenesis of type II diabetes and how the various antidiabetes agents approach these defects. As previously outlined (95), three organs—the liver, pancreas, and skeletal muscle—play a major role in the pathophysiology of diabetes. Recently added on the basis of emerging evidence related to amylin, is the gut. Currently, these four organs are considered to play major roles in the pathobiology of diabetes. Briefly, the liver exhibits excessive and uncontrolled gluconeogenesis and the skeletal muscles are resistant to the action of insulin. Because of hypertrophy related to hyperphagia and hyperglycemia, the intestines absorb glucose more rapidly than normal. The pancreas, of course, has defective secretion of insulin. As newer antidiabetes agents become available, we will be better able to tailor the agent to the presumed major pathophysiologic defect of the individual.

Organ	Defect	Sulfonylurea Action	Metformin Action	Acetone Action
Pancreas	Decreased insulin secretion	Increases insulin release in response to glucose	No action	Allows slowly released insulin to work better!
Liver	Increased gluconeogenesis	Decreases gluconeogenesis	Decreases gluconeogenesis	No action
Muscle	Decreased insulin sensitivity	Increases sensitivity	Increases sensitivity	No action
Gut	Accelerated glucose absorption	No action	Decreases glucose absorption	Slows glucose absorption

Table 86.17 Pathophysiologic Derangements in Type II Diabetes and Proposed

Mechanisms of Action of Antidiabetes Agents

Within recent years, several new hypoglycemic agents have become available and a few are still in the research stage, awaiting approval. However, for years, sulfonylureas were the only oral hypoglycemic agents available in the United States. The sulfonylureas lower blood glucose principally by stimulating insulin secretion from the pancreatic β cells. These agents may also enhance peripheral sensitivity to insulin by unknown mechanisms. Persons of normal weight and obese individuals who develop diabetes after age 40, those who have had diabetes for less than 5 years, or those whose diabetes is well controlled on 20 U of insulin for lean persons or 40 U for obese persons are likely to respond well to sulfonylurea agents.

Nearly 40% of type II diabetic individuals take sulfonylureas; chlorpropamide, glipizide, and glyburide account for 75% of the market. (1). The two second-generation sulfonylureas are the preferred agents for initiating therapy. All sulfonylureas have the same mechanism of action, but they differ in potency, duration of action, and metabolic fate. The second-generation agents, glipizide and glyburide, are more potent than the first-generation agents, have fewer side effects, and may have other advantages (91). A significant disadvantage of sulfonylureas is the tendency for individuals to gain weight as they achieve good glycemic control. An overview of antidiabetes agents available or available shortly in the U.S. is presented in [Table 86.18](#).

Agent	Class	Usual Starting Dose	Maximum Dose	Mechanism of Action
Glibenclamide	Sulfonylurea	2.5 mg b.i.d.	10 mg b.i.d.	Enhances insulin secretion and increases muscle sensitivity to insulin
Glibenclamide	Sulfonylurea	2 mg b.i.d.	12 mg b.i.d.	Enhances insulin secretion and increases muscle sensitivity to insulin
Glibenclamide	Sulfonylurea	5 mg b.i.d.	20 mg b.i.d.	Enhances insulin secretion and increases muscle sensitivity to insulin
Glibenclamide GTS	Sulfonylurea	5 mg b.i.d.	20 mg b.i.d.	Enhances insulin secretion and increases muscle sensitivity to insulin
Glibenclamide	Sulfonylurea	1-2 mg b.i.d.	8 mg b.i.d.	Enhances insulin secretion and increases muscle sensitivity to insulin
Glipizide	Sulfonylurea	50 mg t.i.d.	600 mg t.i.d.	Decreases hepatic output of glucose, decreases intestinal glucose absorption, and increases muscle sensitivity to insulin
Acarbose	α -Glucosidase inhibitor	25 mg b.i.d.	100 mg t.i.d.	Delays digestion of ingested carbohydrates
Troglitazone	Thiazolidinediones	200 mg b.i.d.	600 mg b.i.d.	Enhances peripheral sensitivity to insulin
Irisin	Agonist	not available	not available	Enhances peripheral sensitivity to insulin

Table 86.18 Antidiabetes Drugs

The combination of insulin and sulfonylureas is widely used for type II diabetes because it lowers insulin requirements and frequently improves glycemic control. Theoretically, the sulfonylureas increase peripheral sensitivity to insulin and reduce hyperinsulinemia. When insulin doses exceed 70 to 100 U/day for obese type II diabetic individuals, we

incorporate sulfonylureas into the regimen (91).

Diet and exercise retain central importance in the management of type II diabetes. Our experience indicates that approximately three-fourths of type II individuals treated with insulin, sulfonylureas, or the combination can be managed with diet and exercise alone. Whether insulin or sulfonylureas are used or not, overeating is the major cause of hyperglycemia in type II diabetes; a mildly energy-restricted diet generous in complex carbohydrate and fiber and restricted in fat almost universally improves glycemic control as it facilitates weight loss (44, 91).

Metformin, another new oral hypoglycemic agent, is effective for the control of hyperglycemia without causing weight gain or hypoglycemia. Metformin is used to treat NIDDM when control of glucose levels cannot be achieved solely by diet. It is also used in combination with sulfonylureas when either drug alone is ineffective. There are several advantages to using metformin. It does not exhaust the pancreas. Instead of stimulating the pancreas to make more insulin (and later causing the pancreatic cells to become depleted) as sulfonylureas do, metformin makes insulin receptors more sensitive. Metformin reduces insulin resistance in the cells so the body can use the insulin it has already produced. Other benefits of metformin are its appetite suppressant effect, as well as its ability to decrease the concentrations of blood lipids, especially triglycerides. Nausea, gastrointestinal discomfort, diarrhea, metallic taste, and anorexia are common side effects of metformin use. Side effects tend to lessen with decreased dosage. One important precaution is that metformin should not be used by individuals with kidney disease, since they are at higher risk for lactic acidosis (96, 97, 98 and 99).

Acarbose, a new antidiabetes agent available in the U.S. since early 1996, inhibits hydrolysis of complex carbohydrates and dietary disaccharides. In addition, it reduces the normal increase of insulin and blood glucose seen after a meal by impeding glucose release from disaccharides and complex carbohydrates. The recommended dosage of 25 to 50 mg should be taken at the beginning of each meal, totaling three doses daily. Side effects of acarbose include cramps, flatulence, borborygmus, abdominal distention, and diarrhea. However, these adverse effects lessen with time. This medication may also cause anemia and lower absorption of iron, but decreased weight is not an adverse effect of this medication. Administration of acarbose with metformin is *not* recommended, (100, 101).

Combining use of metformin and sulfonylureas is effective. Sulfonylureas cause the pancreas to make more insulin as metformin causes cells to better use the insulin produced. Also, addition of metformin to existing sulfonylurea therapy improves lipid levels and glucose metabolism (97, 98).

Troglitazone is another oral hypoglycemic agent recently approved for use in the U.S., specifically for type II individuals treated with insulin. This agent increases peripheral sensitivity to insulin. When troglitazone is administered to patients with type II diabetes, hyperglycemia and resistance to insulin are reduced (102, 103).

EDUCATION AND COUNSELING

The social and cultural importance of eating behavior has often been neglected, and the difficulty in making permanent changes to entrenched eating habits is still greatly underestimated. Many diabetic patients consider diet to be the most traumatic aspect of their treatment. Compliance with diabetic diets is notoriously poor, as is probably the case with any therapeutic diet where the short-term penalties for noncompliance are not always apparent and the reward for keeping to the diet is a negative one (absence of complications) in the distant future.

Full goals are probably attained by rather few patients. The degree to which dietary advice can be implemented varies between individuals. All patients should, with guidance, be able to improve their diets significantly, but not all will be willing or able to achieve the full goals, and certainly not overnight. Finding the right balance where nutritional goals are desirable, beneficial, and attainable is key. Dietary goals should continue to be presented, consistently, by all members of the diabetes care team.

About 64% of diabetics in the 1989 NHIS reported following a diet for their diabetes, but 87% believed that diet is important in control of their diabetes (1). A variety of situations were problematic in maintaining the diet, most notably the desire to eat foods that are not on the diabetes diet. Of importance, two situations were not issues: lack of support from family and friends and being unsure about what foods they should eat. In general, difficulties with following a diet for diabetes were expressed less frequently as age increased. Patient education can translate into increased self-management skills, but only 35% of people with diabetes in the 1989 NHIS had ever attended a diabetes educational class or course.

It is important to identify the types of situations that make nutritional adherence difficult for a particular person. Clinically, the idea of adherence barriers allows us to improve patient education and intervention efforts—teaching beyond generalized information.

1. Ensure that the healthcare team realizes that nutritional intervention is an important component of intensive therapy; many physicians and nurses are unaware that diet is vital in optimizing glycemic control.
2. Individualize the diet to include lifestyle and food preferences and expand counseling beyond nutritional requirements. Social and environmental influences greatly affect choices; the patient needs to have options to address these situations. “Ideal” meal plans that are generic for all patients are often never implemented.
3. Teach IDDM patients how to estimate food intake. Patients adjusting insulin doses to match intake must be able to identify portions and/or grams of carbohydrate.
4. During the initial stages of intervention, have the patient keep food records that can be correlated with glycemic control and adjusted accordingly.
5. Remind patients able to implement intensive therapy that though they may “cover” any food with insulin, weight gain carries considerable risk if it causes increased caloric consumption (101).

Simplified systems of nutritional education are again coming of age and should be considered for certain individuals. Some nutritional experts no longer use formal

carbohydrate exchange lists. The British Diabetic Association notes that although these lists have some reference value and give confidence to some patients, such as the newly diagnosed, they are probably unnecessary for most routine management and are not essential in the initial stages (7). Recommendations may instead involve general nutritional goals such as quenching thirst with water or other drinks without sugar; having regular meals, avoiding fried and very sugary foods; eating plenty of vegetables with cereal, bread, pasta, potato, or rice as the main part of each meal; having meat, egg, or cheese as a small part of each meal; and remembering fish and legumes as alternatives (34).

One attractive approach is the “plate model” advocated by the Swedish Diabetic Association and the Community Nutrition Group of the British Dietetic Association (7). A simple system of fat exchanges might be useful for limiting fat intake. Identifying or naming a nutrient in a dietary prescription always carries the connotation of restriction. Since fat is the nutrient principally restricted and complex carbohydrate intake is generally encouraged, identifying the fat components of the diet might be preferable to the current system of defining the diet in terms of carbohydrate content.

Education and management of diabetes have become oriented more toward prevention and less toward crisis intervention. Whichever educational approach is deemed appropriate, dietary guidelines for the diabetic remain similar to nutritional principles of the general American population. Reduction in saturated fat and total fat and increased fiber intake are among the most important of these recommendations (Table 86.19).

Survival Skills
 Relation of food to insulin and activity
 Importance of good nutrition in the control of blood glucose and lipid levels
 Necessity of maintaining normal weight
 Types and amounts of food in meal plan
 Modification of food intake during brief illnesses

In-depth counseling
 Meal planning
 Types of nutrients, their functions, relation to insulin, and effect on blood glucose and lipid levels
 Caloric level of meal plan and percentages of carbohydrate, protein, and fat
 Food sources of fiber
 Importance of reducing total fat, saturated fat, and cholesterol in the diet
 Relation of sodium to hypertension
 Proper serving sizes
 Changes in food intake based on activity level
 Eating out and special occasions
 Label reading and grocery shopping
 Use of sweeteners, alcohol, and “diabetic” foods
 Food modifications for other disorders
 Incorporation of favorite recipes

Table 86.19 Diabetes Nutritional Education Topics

INDIVIDUALIZATION

To be effective in the long term, the nutritional plan must be individually tailored. Readily available, preprinted diet sheets provide clues to changes in eating habits, but they allow no flexibility and are doomed to eventual failure. Although the effects of dietary components such as carbohydrate and fat have been extensively studied, diet

implementation has received much less attention. The best nutritional plans will not work if they are not followed.

Initially, team members must realistically assess the motivation and capability of the patient and family or support group. An optimistic approach is imperative; previous failures do not necessarily predict failure with a nutritional plan at this point. An individual unable to learn an exchange system should be taught a “no-added-sugar” plan. Shortly after the diagnosis of diabetes, some individuals are best taught a simplified “survival” diet, with more-detailed nutritional education provided when they are better able to cope with their condition.

After initial evaluation, the dietitian assesses exercise habits, work schedule, socioeconomic level, living situation, and past eating habits. Diet recalls, food records, or food-frequency checklists provide useful information. A history of food eaten in the past 24 hours is a practical way to estimate energy intake and the percentage contributions of carbohydrate, protein, and fat. A 7-day food-frequency survey offers a better overview of food in-take. To obtain accurate information, the interviewer should ask nonjudgmental questions. Finally, food preferences are elicited. Information about prior food habits forms the foundation for building a solid nutritional plan.

Desirable body weight estimations are made during the initial nutritional assessment. After obtaining a weight history (lightest and heaviest adult weights, recent weight changes, prior use of weight-reducing regimens), we often ask individuals how much they would like to weigh. Ideally, the individuals identify “good” weight goals, and we avoid designating a weight they consider unrealistic. Desirable body weight estimations from tables or formulas provide guidance in setting weight goals. The diabetic individual and dietitian work together to develop targets for short- and long-term weight. The simple process of establishing an estimate of desirable body weight signals diabetic individuals that management of their condition is a partnership venture.

Developing the specific nutritional plan is the next step. Based on the available information, the dietitian and physician decide which nutritional strategy best suits the individual. For some, a plan avoiding sucrose and foods rich in sugars works best. Simplified educational materials have been developed for this purpose. For others, a plan using food exchanges is more appropriate. Some individuals are good candidates for high-fiber diets. Once the team establishes a basic plan, it must be modified for other conditions such as hyperlipidemia, congestive heart failure, or weight loss.

Tailoring the diet to the specific individual is probably the most difficult task in the management of nutrition in diabetes. In doing so, the dietitian considers the treatment regimen (frequency and type of insulin injections or use of oral hypoglycemic agents) as well as other factors. The individualized nutritional plan should be as compatible as possible with the food habits and lifestyle of the patient, but an effective nutritional plan usually requires change. The dietitian's goal is to develop the most therapeutically effective plan and to train the diabetic individual and support group to put this plan into practice.

FOOD EXCHANGES

Flexibility has slowly become an integral part of the diabetes nutritional plan. The American Diabetes Association and American Dietetic Association Exchange Lists for Meal Planning, first released in 1950, have remained the most acceptable, universal method of meal planning. To better reflect current nutritional recommendations for people with diabetes, these exchanges were revised in 1986 (17). Other specialized exchange plans have been developed based upon the same principles (44). Exchange-based nutritional plans provide flexibility and choice while maintaining consistency from day to day.

Exchange groups include foods of similar nutrient composition; all serving sizes or portions in one exchange provide similar amounts of energy, carbohydrate, protein, and fat. Using an exchange diet, an individual chooses a certain number of items from each food group daily. Because each exchange group includes many different foods, the diet can be quite varied (Table 86.20) (see Appendix Table V-A-25-a, Table V-A-25-b, Table V-A-25-c, Table V-A-25-d, Table V-A-25-e, Table V-A-25-f, Table V-A-25-g, Table V-A-25-h, Table V-A-25-i, Table V-A-25-j and Table V-A-25-k). Although several methods of dietary instruction are available, exchange nutritional plans are widely used by health professionals. When individuals change healthcare providers, use of a universally understood nutritional plan facilitates communication and continuity of care.

Exchange	Servings	Energy (kcal)	Carbohydrate (g)	Protein (g)	Fat (g)
Starchy/bread	8	640	120	24	trace
Meat and substitutes	3	165	—	21	9
Vegetables	7	175	35	14	—
Fruit	7	420	10	—	—
Milk	2	180	24	16	trace
Fat	10	450	—	—	50
Total	—	2000	284	75	59
Target	—	2000	290	75	60

Table 86.20 Worksheet for Developing 2000-kcal Exchange Meal Plan

Step-by-Step Guide to Exchange Diet Calculations

1. Estimate energy requirements. The Harris-Benedict equation may be used or an allowance of kilocalories per pound of current body weight. For middle-aged persons, the following approximations apply: sedentary individuals, 10 to 12 kcal/lb is adequate; for moderately active adults, 13 to 15 kcal/lb; and for very

- active adults, 16 to 20 kcal/lb. For weight reduction, subtract 500 kcal/day for a weight loss of 1 lb/week.
2. Calculate desired energy intake for each macronutrient based on caloric level. If following suggested guidelines, carbohydrate is calculated at 50 to 60% of energy needs, protein at 12 to 15%, and fat at about 30%. For example, with an energy requirement of 1500 kcal: $1500 \times 0.55 \text{ CHO} = 825 \text{ kcal from carbohydrate}$.
 3. Convert kilocalories to grams, dividing by the appropriate conversion factors: protein and carbohydrate each have 4 kcal/g; fat has 9 kcal/g. Using the above example: $825 \text{ kcal of carbohydrate} \div 4 \text{ kcal/g} = 206 \text{ g of carbohydrate}$
 4. Exchange lists are readily available for all caloric levels and include variations for individual preferences. However, it is a good idea to tailor each exchange on the basis of individual preferences and eating habits. Compliance is much greater if the diet is based on cultural, ethnic, and personal eating habits. Begin by estimating servings of starch/bread, vegetables, fruit, and milk to meet the carbohydrate goal. Add the meat and meat substitute required to meet the protein goal. Finally, add the fat exchanges. In tailoring personal exchange plans, vegetarian, nondairy, or other dietary preferences can be accounted for.
 5. Assign exchanges to the meal/snack plan. Our meal plans routinely include three meals and an evening snack. Most persons taking insulin need midmorning and midafternoon snacks. Distribute energy intake according to the following guidelines. The three main meals should provide at least 65% of energy and snacks up to 35%. Breakfast has 20 to 30%, the noon meal 20 to 35%, and the evening meal 25 to 40% of energy intake. Snacks provide 0 to 15% each at midmorning, midafternoon, and evening. Insulin-treated individuals should be taught how to increase their food intake in response to exercise or hypoglycemia.
 6. Finally, calculate the fiber content of the diet. The exchange worksheet diet provides 18 g of fiber from starches/breads, 12 g from vegetables, and 15 g from fruits, for a total of 45 g fiber. These values are based on fiber values developed for the high-carbohydrate, high-fiber (HCF) exchange list ([104](#)). This is a generous-fiber meal plan, a goal of approximately 35 g of fiber/day is currently recommended.

Carbohydrate Counting

Carbohydrate counting is an effective method of allowing diabetic patients to obtain needed nutrition while attaining the desired blood glucose values. This approach focuses on carbohydrate intake because carbohydrates have the most significant effect on blood glucose levels ([93](#), [94](#), [105](#)). Patients with an insulin pump or daily injections of insulin or individuals who desire more choices in food selection are good candidates for this method ([94](#)).

There are several methods of carbohydrate counting, each with advantages and disadvantages that would be considered for each individual. The patient should feel comfortable with the math involved and satisfied with the blood glucose levels that result. Carbohydrate counting can involve difficult or simple math; more-complex math allows greater freedom in choosing a food plan ([93](#)).

DEFINITION AND CLASSIFICATION

Obesity, characterized by an excess accumulation of fat, is a detriment to good health and well-being. It is easy for individuals to take on excess fat as soon as enough food and leisure are available in a society, because of an imbalance between energy intake and energy expenditure. Although there continues to be disagreement as to which side of this energy equation is more important in the epidemic of obesity, both sides certainly play a role.

Criteria for Weight Normality

A population cannot be precisely divided into normal and obese, because with gradually increasing fat accumulation, there is not a biphasic distribution with a “normal” and an “abnormal” group, nor is there a normal bell-shaped curve of weights in Western industrialized societies. Rather, the curve is skewed to the right, with excess weights trailing out.

Even in a genetically homogenous population, weight is variable. In the modern world, with the great intermixing of ethnic and racial groups, wide genetic heterogeneity exists. The heterogeneity is manifested by differing heights, body circumferences (chest, waist, hips), and heaviness of frame. It is undesirable to focus on a single number of kilograms for height in centimeters as the “normal” weight, particularly because it is not clear what the criterion for “normal” weight should be. Should it be low mortality, low morbidity, a combination of the two, or the longest extended “optimal health” or “well-being” of the individual?

For lack of a better database, life insurance industry statistics have been used widely to develop tables of normality. These tables give weight ranges for height and frame size and are associated with the greatest longevity in individuals who were healthy at the time of initial examination when their height and weight were measured. (See Appendix [Table III-A-12-a-1](#), [Table III-A-12-a-2](#), [Table III-A-12-a-3](#) and [Table III-A-12-a-4](#) for a history of their development and [Tables III A-12-b-I](#) for actual tables.)

Although these (Appendix [Table III-A-12-a](#) and [Table III-A-12-b](#)) are some of the best data available, they are inadequate in several ways. They predominantly reflect data from upper-middle-class white groups. They are sex and height specific but not age specific. As such, they provide data on the basis of the predictive longevity of relatively young persons generally weighed in their 20s and 30s and followed to their death. These tables have been used on the assumption that whatever weight is desirable at age 21 years is also desirable at age 45 or 65. Yet, in Western society, weight changes with age in a normal population, gradually increasing in women from 20 to 60 years and more gradually increasing for men from 20 to 50 years, with a fall after that (1). In addition, body composition changes with age, with gradual accretion of fat and loss of lean body mass even if weight remains stable (see Appendix [Table III-A-12-c-1](#), [Table III-A-12-c-2](#), [Table III-A-15-a](#), [Table III-A-15-b](#) and [Table III-A-15-c](#)). It is unclear whether the “normal” weight should be the same as age advances or whether it can rise somewhat as the proportion of body fat increases, so that lean body mass remains as constant as possible.

A classification that is useful clinically is based on two simple measurements: height without shoes and weight with minimal clothing. The weight/height² (W/H²), called the body mass index (BMI), is then calculated, with weight expressed in kilograms and height in meters. The population, whether male or female, can be divided by extent of obesity as follows:

Normal weight	W/H ² 20–24.9
Overweight	W/H ² 25–29.9
Grade I: obesity	W/H ² 30–34.9

Grade II: obesity
Grade III: severe obesity

W/H²35–40
W/H²>40

The major weakness of the use of W/H²(originally proposed by Quetelet in 1871) (2) is that some muscular individuals may be classified as obese when they are not (3). The number of such persons will be small, however. BMI is a relative weight index that shows a reasonable correlation with independent measures of body fat (4). The BMI range of 20 to 24.9, classified as normal, coincides well with the lowest level of mortality derived from life insurance tables. The mortality ratio increases at BMI levels above 25 and more steeply above 27, and it is at this level that health professionals must be concerned (5).

Although the increase in mortality with overweight (W/H² = 25–29.9) is not great, it is important because it is transitional to obesity grades I to III, which truly create health risks for the individual (5). Data on BMI by percentiles in U.S. males and females aged 1–74 years and a nomograph for estimating BMI are given in Appendix [Table III-A-13-a](#) and [Table III-A-13-b](#), respectively.

Other Relative Weight Measures

Skinfolds

Over half the fat in the body is deposited under the skin, and the percentage increases with increasing weight. The thickness of this subcutaneous fat can be measured at various sites by using standardized skin calipers. The distribution and amount of subcutaneous fat change with age and are also quite different by sex. One difficulty with skinfold measurement is that there is no agreement on the number and sites that best reflect actual body fat content. Also, an inexperienced or careless observer can easily make large errors, particularly if the patient is too obese.

Data on skinfolds for children have been obtained in cross-sectional population studies and are less reliable than those for adults. Arbitrary definitions of obesity (e.g., 85th percentile and above of weight) have been set (see Appendix [Table III-A-18-b-1](#), [Table III-A-18-b-2](#) and [Table III-A-18-b-3](#)). Sex differences in percentage total body fat occur early in life, so that by 5 years of age, different standards are necessary for males and females. In adults, sex differences are marked. Subcutaneous fat is about 11% of body weight in lean men and 18% in women (6). Tables are available for triceps and subscapular percentile distributions for ages 1–74 years (see Appendix [Table III-A-16-a](#) and [Table III-A-16-b](#) and references [7a](#) and [7b](#)).

Because the amount of fat distributed from place to place in the body varies, some investigators have suggested that the sum of skinfolds from different areas better reflects total body fat. For example, Durnin and Womersley (8) derived tables relating the sum of four skinfolds (biceps, triceps, subscapular, and suprailiac) to the fat content of the body. Other sets of skinfold thicknesses have been used to estimate body fat stores (see Appendix [Table III-A-17-a](#), [Table III-A-17-b](#), [Table III-A-17-c](#), [Table](#)

[III-A-17-d-1](#) and [Table III-A-17-d-2](#) and [Chapter 49](#) and [Chapter 56](#)).

Other measurements to estimate body fat and other body compartments are more difficult, expensive, and time consuming and have generally been used for research purposes. These include indirect estimates of body fat by measuring the weight of the fat-free compartment and subtracting this amount from total body weight to derive the weight of fat.

Density

The density of the whole body is derived from the density of the various body components (bone, water, fat, protein), which are all slightly different. It is easier to think of the body as divided into fat and fat-free masses, with fat having a density of 0.900 g/mL and the fat-free mass a density of 1.100 g/mL. Therefore, as the proportion of fat in the body increases, the density decreases. The amount of fat in the body can be determined by measuring the density of the entire body. This requires total submersion of an individual and accurate correction for lung and abdominal air ([9](#)).

Tritiated or Deuterated Water

Total body water can be measured by dilution of tritiated ($^3\text{H}_2\text{O}$) or deuterated (D_2O) water. Both deuterium and tritium oxides rapidly equilibrate in body water, so the test can be done in 2 to 3 hours. Deuterium is nonradioactive and thus is preferentially used in children and women of childbearing age. Water is then assumed to be a fixed proportion of fat-free mass (FFM); that is, $\text{FFM} = \text{water mass}/0.73$. The calculated FFM is subtracted from total body weight to obtain total body fat ([10](#)). Alternatively, the naturally occurring ^{40}K in the body can be counted in a whole body counter. Total body ^{40}K can be measured as an index of lean body mass because potassium is present only in the fat-free compartments of the body. ^{40}K makes up 0.012% of the total potassium, and since it is naturally radioactive, it can be detected by a sensitive counter. Using an estimated value for the meq of K in lean body, one can calculate the lean body mass and once again derive total body fat ([11](#)) (see also [Chapter 49](#)).

Bioelectrical Impedance

Bioelectrical impedance is based on the passage of an electrical current through the body (see [Chapter 49](#)). Differing proportions of fat to lean tissue cause differing speeds of transmission of the signal. By appropriate calibration, the transmission can be converted to the proportion of fat and lean tissue in the body ([12](#)). This method is not as accurate as hydrodensitometry, total body water, or ^{40}K , but it is cheaper and more convenient and can be used in doctors' offices and for epidemiologic studies.

Inert Gases

The most tedious method for estimating fat uses an inert gas, such as krypton or xenon, which is soluble in fat but poorly soluble in water. The gas must be breathed for several

hours to allow equilibration with tissues. The proportion of gas retained reflects the amount of fat in the body (13).

PREVALENCE

Standards of Normality

Efforts to produce standards of obesity for the population, against which individuals can be compared, have generally concentrated on weight and have taken two forms. The first is the use of “desirable” weight, that is, weight (stratified for sex, height, and frame size) correlated with the greatest longevity. These weights come from life insurance data. The 1983 tables of the Metropolitan Life Insurance Company (14) are presented in Appendix [Table III-A-12-a-2](#) and [Table III-A-12-a-4](#). The second is the use of average weights of subsamples of a general population stratified by sex, age, and height. Examples are the Health and Nutrition Examination Survey (NHANES) tables produced by the National Center for Health Statistics in 1960 to 1962 (15), 1971 to 1974 (16), 1976 to 1980 (17), and 1988 to 1991 (18). The data are presented in Appendix [Table III-A-14-a](#), [Table III-A-14-b-1](#), [Table III-A-14-b-2](#), [Table III-A-14-c-1-a](#), [Table III-A-14-c-1-b](#), [Table III-A-14-c-2-a](#), [Table III-A-14-c-2-b](#), [Table III-A-14-d-1-a](#), [Table III-A-14-d-1-b](#), [Table III-A-14-d-2-a](#), [Table III-A-14-d-2-b](#), [Table III-A-14-e-1](#), [Table III-A-14-e-2](#), [Table III-A-14-f-1](#), [Table III-A-14-f-2](#), [Table III-A-14-g-1](#) and [Table III-A-14-g-2](#) (graphs) for infants, children, and adolescents (Appendix [Table III-A-14-a](#), [Table III-A-14-b-1](#), [Table III-A-14-b-2](#), [Table III-A-14-c-1-a](#), [Table III-A-14-c-1-b](#), [Table III-A-14-c-2-a](#), [Table III-A-14-c-2-b](#), [Table III-A-14-d-1-a](#), [Table III-A-14-d-1-b](#), [Table III-A-14-d-2-a](#), [Table III-A-14-d-2-b](#), [Table III-A-14-e-1](#), [Table III-A-14-e-2](#), [Table III-A-14-f-1](#), [Table III-A-14-f-2](#), [Table III-A-14-g-1](#) and [Table III-A-14-g-2](#)), youths and adults. The data are given as means and as percentiles.

In these tables, it is necessary to designate a percentile level at which values are considered abnormal. The National Center for Health Statistics defines overweight as a BMI at or above the 85th percentile for the 20- to 30-year-old groups measured in 1960 to 1962 and severe overweight as at or equal to the 95th percentile (17). Appendix [Table III-A-18-a](#) and [Table III-A-18-b](#) provide such graphic and tabular data for ages 1–74 years. Age-adjusted percentages of overweight persons by ethnicity and sex in the United States are shown in [Table 87.1](#).

	Male Overweight (%)	Female Overweight (%)
White	32.0	33.5
Black	31.5	49.6
Mexican	39.5	47.9

From Kuczmarski RJ, Flegal KM, Campbell SM, Johnson CL. JAMA 1994;272:205-11.

Table 87.1 Age-Adjusted Percentages of Overweight Persons Aged 20 to 74 Years from the National Health and Nutrition Examination Survey (NHANES) II and the NHANES by Ethnicity and Sex

Two facts are evident from the Metropolitan Life tables and the NHANES tables. First, as a rule, the desirable weights on the insurance tables are lower than the average weights describing the U.S. population, although this is less true of the 1983 Metropolitan Life tables, which were set considerably higher than the 1959 tables (Appendix Table III-A-13-f). Second, the NHANES data show weight increasing by age from 18 years to 54 years, then a plateau, followed by a fall. Thus, in the U.S. population, weight is not static with age once maturity is reached but is actually a function of age.

The insurance companies used the terms *ideal weight* or *desirable weight* to describe weights that actuarially were associated with the least mortality. In subsequent use of these tables, overweight has been defined as 10% above an ideal or desirable weight and obesity as 20% or more above this point. Using such criteria, researchers found a high incidence of overweight in the NHANES survey of 1960 to 1962 (15). Data from the NHANES surveys of 1971 to 1974 and of 1976–1980 show that U.S. adults measured at that time were comparably obese (16, 17). The latest survey available (1988 to 1991), however, found a continuing obesity trend (18). These latest data are shown in [Table 87.2](#) and [Figure 87.1](#).

NHANES Survey Year	Male				Sex			
	1962	1974	1976	1979	1962	1974	1976	1979
Male	23.1	23.8	24.2	23.1	22.1	23.9	25.2	23.3
Female	23.6	24.0	24.4	23.5	41.6	42.1	44.5	43.2

Table 87.2 Age-Adjusted Percentages of Overweight Persons Aged 20 to 74 Years by Race and Sex in the United States

Figure 87.1. Age-adjusted percentages of overweight persons aged 20 to 74 years by sex in the United States. (From Kuczmarski RJ, Flegal KM, Campbell SM, Johnson CL. JAMA 1994;272:205–11.)

Figure 87.1 makes clear that an alarming percentage of Americans are overweight. As shown in Table 87.3, this percentage increases with age, particularly among women. What constitutes “healthy weight” at various ages is controversial. It has been suggested that as a person ages, some increase in weight is acceptable and not harmful (19). The NIH geriatrics tables allowed for such an increase (20) (Appendix Table III-A-12-b). The 1990 weight guidelines of the U.S. Departments of Agriculture and Health and Human Services also reflected this point of view (21). However, these more liberal tables have been vigorously attacked as unjustifiably lenient (22). The most recently released recommended dietary allowances from the U.S. Department of Agriculture make no allowance for weight gain with age, and acceptable weight for height is set as a constant for adult life (23).

Age (years)	Sample Size	Prevalence of Overweight (SE) %	Mean BMI (SE)
Men			
20–29	858	20.2 (2.25)	24.9 (0.21)
30–39	759	27.4 (2.28)	26.1 (0.29)
40–49	643	37.0 (2.73)	27.3 (0.36)
50–59	493	42.1 (2.05)	27.6 (0.16)
60–69	588	42.2 (2.84)	26.9 (0.22)
70–79	495	35.9 (3.06)	26.5 (0.29)
≥80	373	18.0 (2.24)	24.7 (0.24)
Women			
20–29	755	20.2 (2.17)	24.1 (0.29)
30–39	771	34.3 (2.46)	26.4 (0.39)
40–49	624	37.6 (2.70)	26.7 (0.29)
50–59	454	52.0 (2.53)	29.5 (0.41)
60–69	595	42.5 (2.43)	27.3 (0.27)
70–79	446	37.2 (2.57)	26.7 (0.29)
≥80	396	26.2 (2.11)	24.6 (0.23)

Obesity in Children

The prevalence of obesity in the Western world begins in infancy. Available studies, though imperfect, suggest that one-third or more infants in the Western industrialized world are too heavy (24, 25 and 26). Data for schoolchildren are less available, and estimates vary between 6 and 15% (24, 27, 28). Adolescent obesity rates have been calculated at 20 to 30% (26, 28, 29 and 30). Studies suggest that young women are more likely to be obese than are young men. The most recent national data are shown in Figure 87.2, with comparisons of previous surveys. As in adults, overweight prevalence is increasing in children and adolescents (31) (see also Chapter 63).

Figure 87.2. Overweight prevalence in American children and adolescents over time. (From MMWR 1997;46:198–202.)

Whether childhood obesity leads to obesity in the adult has been widely debated. Some retrospective studies have suggested a direct progression from a fat child to a fat adult (32). Rimm and Rimm report that 50% of adult women in every age group weighing more than 18% of ideal body weight were obese adolescents (33). In addition, it has been stated that 30% of obese adults become obese during childhood. About 80% of obese adolescents become obese adults (34), and they have been reported to be fatter than those who become obese as adults (33). Of obese infants and children, 26.5% were still obese two decades later, compared with the 15% expected by chance (35). The more severe the obesity in childhood, the greater the likelihood of persistence to adulthood (36).

Socioeconomic Influence

Epidemiologic studies have shown a strong association between socioeconomic status and the prevalence of obesity. This relationship is much stronger in women. The effect

of social environment on obesity was investigated many years ago in the “Midtown Manhattan Study,” which in 1965 studied a population with both high- and low-income groups. Socioeconomic status and the prevalence of obesity were found to be inversely related (37). As many as 30% of women of lower socioeconomic class were obese, 16% of middle-status women, and 5% of upper status. Men showed similar but less exaggerated trends. Similar socioeconomic trends have been found in other countries (38, 39). In the Manhattan study, obesity was also related to ethnicity (40), with Eastern Europeans being particularly heavy. Others have also found ethnicity to be an important variable (41). Religious affiliation was also important (42).

In the NHANES data, persons below the poverty line have a significantly greater prevalence of obesity (43). Although a relationship exists in the United States between increasing prevalence of obesity and socioeconomic status, it is not all clear-cut. For example, an English study showed a low prevalence of overweight in males of lower socioeconomic status engaged in heavy manual labor (44).

Race also affects obesity. The prevalence of overweight in whites, blacks, and Mexican Americans in the United States is shown in Figure 87.3. Mexican American men and both black and Mexican American women have higher prevalences of overweight (17). The reason for these findings is not presently evident, though it is thought to be partly socioeconomic, partly cultural, and possibly partly genetic.

Figure 87.3. Prevalence of overweight by age and race/ethnicity for men and women, U.S. population 20 years of age and older, 1988–1991. (From Kuczmarski RJ, Flegal KM, Campbell SM, Johnson CL. JAMA 1994;272:205–11.)

MORTALITY AND MORBIDITY

Overweight has been associated with excess mortality in many studies (45, 46, 47, 48 and 49). Table 87.4 summarizes mortality data for three such studies: the Build and Blood Pressure Study of 1959 (47), the Build and Blood Pressure Study of 1979 (48), and the American Cancer Society study (49). All three studies show increasing mortality

with increasing overweight, with higher mortality risks in men than in women.

Weight Group	Suited and Blood Pressure Study 1969		American Cancer Society Study		Suited and Blood Pressure 1979	
	Male	Female	Male	Female	Male	Female
20% Underweight	85	87	110	110	125	110
10% Underweight	86	88	103	85	94	97
10% Overweight	110	109	107	108	111	107
20% Overweight	125	121	121	122	128	110
30% Overweight	142	138	127	128	125	125
40% Overweight	167		152	152	153	138
50% Overweight	200		210		177	148
60% Overweight	250				210	187

From Table 13 in J. G. A. (1972, 1973) who assessed the Influence of Circulation

^aNot only insured (persons from 10% or 10% overweight, when mortality was 100)

Table 87.4 Mortality Ratios According to Variations in Weight^a

The American Cancer Society study, which was not an insurance study, counteracts the objection that it is not valid to relate weight at insurance to death some 35 years afterward because insured lives are not typical of the general population, as insured individuals tend to be richer and predominantly white. The American Cancer Society data are similar to the insured data, and they help validate the use of actuarial data of insured lives. Because insurance companies relate only to healthy persons, their data generally exclude ill people. On the other hand, the American Cancer Society study in all likelihood overstated the mortality of underweight persons, because it only lasted 12 years, and the general population it studied no doubt included some persons with illness and unintentional weight loss that could have caused early death.

The mortality rate increase is not linear with increasing weight. Accelerated mortality occurs as people get heavier, particularly males (50). In addition, in the insurance data, the relative mortality is higher in males who are overweight than in females, whereas this is not so in the general population, as reflected by the American Cancer Society study. Many studies do not show increased risk of mortality at relative weights up to 20% above desirable level (50, 51, 52, 53 and 54). In the extensive Norwegian study, which took weights and heights in a large proportion of the population between 1963 and 1975, relative mortality increased as the BMI increased above 27 (55). The so-called J-curve of mortality in relation to BMI is shown in Figure 87.4 (56).

Figure 87.4. J-Curve of mortality.

Evidence exists that the relationship between weight and mortality differs at different times of life. The Whitehall study of 18,000 English civil servants showed that the relationship between weight quintile and mortality changes with age; for the youngest men, coronary heart disease (CHD) mortality increases linearly from lowest weight quintile to highest, whereas no relationship is evident for the oldest men (57). Other studies have investigated the relationship of weight and mortality in the elderly. All seem to agree on a protective effect of moderately increased weight in old age (58, 59 and 60).

The relationship of obesity and mortality may be obscured by the fact that fatness may relate to the type of death as well as to overall mortality. That is, with increasing obesity, individuals are at greater risk of death from cardiovascular disease and diabetes but not from cancer (61). Thus, it may not be possible to assign a single optimum weight or an optimum level of fatness. There may be “different optima for different causes of death at different time periods and ... no single value of weight or fatness is optimal for all” (62).

Causes of Death and Morbidity

The causes of death in men 20 and 40% above average weight as derived from the data of the American Cancer Society study (49) and the Build Study of 1979 (48) are shown in [Table 87.5](#).

Cause of Death	Men 25% above Average Weight		Men 40% above Average Weight	
	Built Study 1979	American Cancer Society	Built Study 1979	American Cancer Society
Coronary heart disease	148	138	169	175
Cerebral "hemorrhage" (stroke)	110	116	164	161
Cancer	180	185	185	124
Diabetes	290	210	360	300
Digestive diseases	135	168	220	240
All causes	130	121	160	162

Table 87.5 Mortality Ratios (Factor of Increased Risk)^a

Cardiovascular Disease

Prospective studies of cardiovascular morbidity and mortality have shown an association with obesity. Studies that control for smoking show lowest mortality in the leanest weight category (63, 64, 65 and 66). The effect of obesity on cardiovascular disease has not always been independent but has generally involved exacerbation of other risk (64) such as hypertension, diabetes, and dyslipidemia (65). This finding is not surprising because blood pressure, blood lipids, and glucose values increase when individuals gain substantial amounts of weight (67). The predictable increase in cardiovascular risk factors by increasing weight was well quantified in the Framingham study. For every 10% rise in relative weight, systolic blood pressure rises 6.5 mm, plasma cholesterol rises 12 mg/dL, and fasting blood glucose rises 2 mg/dL (68). Although the association of these cardiovascular risk factors is not as strong in women as in men, the association of obesity to cardiovascular disease is as strong in women as in men. The Nurses Health Study (66) showed this clearly.

Evidence indicates that obesity that occurs at an earlier age (20–40 years) has a greater influence on cardiovascular disease than later-onset obesity (69). The Manitoba Study, which compared the 26-year incidence of CHD and had a young average entry age of 30.8 years, found that BMI was significantly related to CHD (70). Myocardial infarction, sudden death, and coronary insufficiency were all associated with a high BMI. This association was not evident until the 10th year of follow-up. This was also true in the Framingham study, in which the effect of obesity on cardiovascular mortality increased with time of follow-up (71). Thus, short-term studies or studies concentrating on older individuals may not show an independent effect of obesity because they are too short or have not focused on the correct age group.

Finding a relationship between obesity and increased mortality at a young age (<40 years of age) and no such relationship at an older age implies that it is continuous obesity over many years that affects health and can lead to death. Moreover, as people

grow older, other risk factors for death take on increased importance.

Studies by Chapman et al. using ponderal index ($W^{0.33}/H$) as a measure of obesity found a higher rate of myocardial infarction in men under age 40 and not in those older (72). In the Whitehall study, 10-year CHD mortality increased from the lowest- to the highest-weight quintiles for younger men but showed no effect of weight in older men (57). In addition, the effect of weight is small when blood pressure, cholesterol, and smoking are accounted for. For older men, the highest mortality is in the lowest weight quintile.

Numerous studies now show that the pattern of body fat distribution affects morbidity and mortality from cardiovascular diseases (73, 74, 75 and 76). In fact, this risk factor is as important as smoking, hypertension, and hypercholesterolemia (77). The effect is more important at younger ages and tends to lose importance after the seventh decade (77).

Blood Lipids

Triglycerides. Although hypertriglyceridemia has been associated with obesity (78), the association is not strong. Triglycerides are transported predominantly as very low density lipoproteins (VLDLs) (79). Hypertriglyceridemia may be related to the insulin resistance and consequent hyperinsulinemia of obesity (80), which increases hepatic triglyceride synthesis and secretion (79, 81). In addition, because free fatty acid (FFA) levels are raised in obesity, the increased hepatic uptake of FFA may increase the rate of triglyceride secretion (82). Enhanced triglyceride production may also come from more glucose precursors extracted by the liver (82). Despite this increased triglyceride production, the triglyceride level in obese persons is often normal or only slightly elevated. Because lipoprotein lipase activity is elevated in obesity (83) and rises higher after weight loss (84, 85), it is possible that this activity enhances VLDL clearance at the periphery. After weight reduction, plasma triglycerides that were high tend to fall (79). This change is associated with decreased VLDL-triglyceride production and decreased insulinemia (79). In families carrying the combined hyperlipidemia trait, obese relatives tend to manifest high levels of VLDL, whereas nonobese relatives show elevated low-density lipoproteins (LDLs) (86).

Cholesterol. Much less evidence exists of cholesterol elevation in obesity. Only marginally significant correlations have been shown (87, 88). High-density lipoprotein (HDL) cholesterol is usually low in obesity, and because of this, the LDL:HDL ratio is elevated, which enhances the risk of CHD. Low HDL-cholesterol concentrations are a risk factor for CHD, independent of the concentration of LDL-cholesterol (89, 90).

While LDL-cholesterol levels may be normal, the quality of the particles is different. Persons with insulin resistance tend to have small dense LDL particles (91, 92), which are considerably more atherogenic than larger particles, enhancing CHD risk (93, 94).

Diabetes Mellitus

A strong association exists between obesity and diabetes mellitus. In fact, obesity can be considered the most important “environmental” determinant in the manifestation of diabetes. In epidemiologic studies including many geographic areas, races, and cultures, West and Kalbfleisch noted a marked correlation between prevalence of diabetes and overweight (95). This has also been shown in other, more recent studies (96). Even moderate obesity can raise the risk of diabetes tenfold (96). In the Framingham study, women in the upper quintile of weight were four times as likely to develop glucose intolerance as women in the lower quintile (97). In the Nurses Study (98), in which the nurses have been followed for 16 years, there is a gradually increasing risk with increasing BMI as shown in Figure 87.5. Also, the gain from baseline is important, with increased risk for the same amount of weight gain as baseline BMI increases (98).

Figure 87.5. Risk of NIDDM using BMI (Nurses Study). (From Colditz GA, Willett WC, Rotnitzky A, et al. *Ann Intern Med* 1995;122:481–6, with permission.)

Body fat distribution has been implicated as a predictor of glucose intolerance and hyperinsulinemia (99, 100, 101, 102 and 103). It is also a predictor of frank diabetes (104, 105). Why the abdominal area is related to metabolic disturbance while the thigh area is not is unclear. This increased risk with abdominal fat suggests that a “male” pattern of fat distribution poses a greater risk for diabetes than a “female” pattern. The important factor is intraabdominal or visceral obesity (106). Possibly, visceral fat is more lipolytic, delivering more FFAs to the liver in a setting of high glycerol and insulin levels which make for enhanced VLDL production, small dense LDL particles, decreased HDL production, and enhanced gluconeogenesis (107, 108).

Hyperinsulinemia and Insulin Resistance. Obesity is associated with hyperinsulinemia (109); in general, the fatter an individual, the higher the basal or fasting insulin level (80). In addition, in nondiabetics, the height of the insulin response to glucose or other stimuli is related to basal insulin and therefore is closely correlated with the degree of obesity (80). In obese subjects with abnormal glucose tolerance,

however, the percentage increase of insulin over basal values is actually lower than that of lean subjects. Thus, the impairment of glucose disposal can often be explained by an accompanying impairment of insulin secretion. This impairment is first observed in the early phase of insulin response, but as carbohydrate tolerance deteriorates, the entire time course of the insulin response is affected.

The phenomenon of excessive blood insulin levels in obesity, both basal and after stimuli, demonstrates that insulin resistance or insensitivity is present. This is manifested by tissue resistance at the muscle and liver level, decreasing glucose uptake at the periphery and increasing hepatic glucose output ([110](#), [111](#)); adipose tissue sensitivity remains high, and possibly nutrients are thus shunted to this tissue for storage ([111](#)).

Insulin Receptor and Postreceptor Defects. The first step in the action of insulin on the cell is the binding of the hormone to a specific receptor on the outer plasma membrane (see also [Chapter 37](#) and [Chapter 44](#)). This process then initiates a series of “postreceptor” biochemical events such as glucose and amino acid transport, stimulation of protein synthesis, activation of certain enzymes, inhibition of others, stimulation of certain gene transcription, and inhibition of others ([112](#)). Generally, when high levels of insulin prevail in the blood, low levels of insulin receptors are present. This self-regulation of the membrane insulin receptor, so that high insulin levels cause a lowering of insulin receptor number, is called downregulation ([113](#)). It now seems clear that cells of insulin-sensitive tissues (e.g., fat and muscle) from obese humans present a decreased number of insulin receptors at the surface cell membrane ([114](#), [115](#)). Although part of the insulin resistance in obesity can be attributed to changes in insulin receptor number and/or receptor affinity for insulin, the tissues of obese animal models show intracellular postreceptor defects in glucose metabolism that account for the major part of insulin resistance.

In obese humans, the degree of insulin resistance is much greater than that predicted from the magnitude of the decrease of insulin receptors. Using the euglycemic glucose clamp technique, researchers can study in vivo insulin dose-response curves. The least hyperinsulinemic, least insulin-resistant patients show only a receptor defect, whereas the most hyperinsulinemic show the largest postreceptor defect. The nature of the postreceptor defect is being actively investigated. The b subunit of the receptor, which faces inward, when stimulated by insulin, expresses kinase activity toward its tyrosine residues ([116](#), [117](#)). This tyrosine phosphorylation is faulty, causing defective signaling within the cell. The postreceptor defect could also be due to an abnormality in the glucose transporter system within the affected cells. Because levels of glucose transporter protein and mRNA are normal in skeletal muscle cells of insulin-resistant persons, the defect may rest in the functional activity or insulin-mediated translocation of the transporters ([118](#)), although thus far this has not been satisfactorily documented (see also [Chapter 37](#)).

Significance of Hyperinsulinemia. Production of excessive quantities of insulin for a prolonged period may lead to pancreatic exhaustion in those who are genetically predisposed ([119](#)). Eventually, insulin response can decrease to the point of metabolic decompensation ([120](#)). Support for this position comes from data suggesting that the

duration of obesity rather than the degree is best correlated with carbohydrate intolerance in obese adults.

Hypertension

Blood pressure elevation is a common concomitant of obesity ([121](#), [122](#) and [123](#)). The causes of the association of obesity and hypertension are not clear. A relationship between weight gain and increased blood pressure is well documented ([124](#), [125](#)). In hypertensive patients, weight reduction reduces blood pressure ([126](#), [127](#) and [128](#)), and weight regain raises pressure. The fall in blood pressure with weight reduction is associated with decreased blood volume, cardiac output, and sympathetic activity ([129](#)).

The cardiac output and the peripheral vascular resistance are the most important determinants of the blood pressure. These, in turn, are affected by the total body sodium content and by neurohumoral factors. Data of Dahl et al. incriminated sodium loss rather than weight loss as the cause of lowered blood pressure with caloric restriction ([130](#)). Others, however, have reported that it is weight reduction that is important ([131](#)).

Insulin may play a role in the hypertension of obesity ([132](#)), because changes in the plasma insulin concentration can affect sodium transport in the human kidney ([133](#)). Insulin reduces sodium excretion independent of changes in plasma glucose. This effect can be noted without concurrent changes in filtered load of glucose, glomerular filtration rate, renal blood flow, and plasma aldosterone levels ([134](#)). Natriuresis occurs during fasting or hypocaloric diets, when insulin levels fall, and antinatriuresis occurs with refeeding, when insulin levels rise again ([135](#)). The hyperinsulinemia of obesity may raise the blood pressure by increasing renal sodium absorption, which in turn expands the extracellular fluid volume, raising cardiac output, peripheral resistance, and blood pressure ([132](#)). Whether catecholamines play a role in the hypertension of obesity is unclear, although Landsberg and Young reported decreased sympathetic nervous system activity during weight loss diets and an increase during refeeding ([136](#)).

The distribution of fat in the body may have an important effect on blood pressure risk, as it does in diabetes, with central fat or upper body fat being more likely to raise blood pressure than the lower body fat of the gluteal and thigh region ([103](#), [137](#) and [138](#)). The reasons for this tendency are not clear, although it is now known that insulin resistance is associated with hypertension ([139](#)) and may actually be important in the etiology ([140](#)).

Respiratory Problems

As an individual becomes more obese, the muscular work required for ventilation increases. If movement of the chest wall is limited enough, CO₂ retention occurs, which can lead to lethargy and somnolence. CO₂ narcosis can also lead to periods of apnea that usually occur during sleep and exacerbate the problem of CO₂ retention ([141](#)). In addition, polycythemia may occur, which can enhance thrombosis. In severe cases of respiratory disease, pulmonary hypertension, cardiac enlargement, and congestive

heart failure may develop.

Gallbladder Disease

The risk for gallbladder disease rises as obesity increases and is greater for women than for men ([142](#), [143](#), [144](#), [145](#) and [146](#)). An increased body fat reservoir is associated with certain conditions that predispose individuals to gallstone formation. There is a supersaturation of the cholesterol in bile ([147](#), [148](#)) and increased biliary cholesterol excretion ([149](#)). Hypomotility of the gallbladder also occurs, allowing pooling and nucleation of stones ([150](#)). As a result, cholesterol stone formation is enhanced ([151](#)).

Arthritis

The clinical impression is that the incidence of osteoarthritis of the weight-bearing joints is higher in obese than in lean persons and that this condition tends to become worse with higher weight ([152](#)). No good prevalence studies are available, however.

Gout

The cause for the rise in uric acid levels with increasing weight is unclear. The effect is more common in men than women; thus, body fat distribution may play a role. Usually, this uric acid elevation is asymptomatic, but the occurrence of gouty attacks is higher in obese than in lean individuals, particularly when overweight reaches 30% above ideal.

Cancer

Obesity has been implicated as a risk factor in development of certain cancers. In a large prospective study, mortality ratios for cancer in persons who were more than 40% overweight were 1.33 for men and 1.55 for women ([153](#)). In men, the higher mortality was for colorectal and prostate cancer, and in women, for endometrial, gallbladder, cervical, ovarian, and breast cancers ([153](#)). Cancer of the endometrium has been particularly implicated ([154](#), [155](#) and [156](#)). Cancer of the gall bladder also increases with increasing obesity. It is possible that this association is related to endocrine abnormalities, and increased conversion of estrone to androstenedione in adipose tissue has been implicated. In addition, obesity is correlated with increasing estrogenicity of cervical smears ([157](#)). Although such increased estrogen activity could cause the increased risk of breast cancer reported in postmenopausal women ([158](#), [159](#), [160](#) and [161](#)), no proof of this effect is available. The increased cancer risk may be related to a dietary component rather than the obesity per se.

GENETICS AND ENVIRONMENT

Genetics

In the last few years, a great deal has been learned about the genetics of animal models

of obesity, and this has lent strength to the proposition that human obesity is to a large extent genetically determined. The *ob/ob* mouse was the first rodent model of obesity whose genetic defect was clarified, and the gene for the *ob* protein, leptin, was cloned (162). Two different mutations were identified in the *ob* gene of the *ob/ob* mouse, either of which produced a deficient, truncated, inactive leptin or no leptin at all. If *ob/ob* animals are injected with normal leptin, food intake drops, thermogenesis increases, and weight decreases (163, 164 and 165). The leptin gene is primarily expressed in fat cells. As fat cells enlarge, they secrete more leptin. Thus, this hormone appears to be a signal of fat surfeit that communicates with the central nervous system to decrease food intake and enhance thermogenesis. The receptor for leptin has also been cloned (166).

The *db/db* mouse has a defective leptin receptor (167). This mouse has high circulating levels of leptin (168) and does not respond to injections of leptin (164). The *fa/fa* rat, like the *db/db* mouse, has a defective receptor that does not respond to high levels of normal leptin (169).

The yellow agouti mouse, which develops obesity, has a defective gene that produces an abnormal 108–amino acid protein, which in turn antagonizes the melanocortin-4 receptor (MC4-R) in the hypothalamus (170). One possible effect of losing MC4-R activity is a disturbance of hypothalamic signaling. This could, for instance, stimulate release of either neuropeptide Y or galanin, both of which stimulate food intake.

Other models of obesity are the *tub/tub* mouse, which has a defective phosphodiesterase, and the *fat/fat* mouse, which has a defective carboxypeptidase E, preventing appropriate conversion of a large number of prohormones to the active hormones. The exact mechanisms by which these defects cause obesity require further investigation. These animal models and their genetic defects are shown in Table 87.6.

Rodent Obesity Mutations ^a	Gene	Inheritance	Chromosome Location	Human Syntenic Region
Mouse				
yellow	<i>Ay</i>	AD	2	20q11
diabetes	<i>db</i>	AR	4	1p31
fat	<i>fat</i>	AR	8	716c
obese	<i>ob</i>	AR	6	7q31
tubby	<i>tub</i>	AR	7	11p15
Rat				
fatty	<i>fa</i> <i>fa^h</i>	AR	5	1p31

^aMouse and rat obesity mutations are indicated as well as their mode of inheritance (AR, autosomal recessive; AD, autosomal dominant), chromosome location, and corresponding syntenic chromosomal regions in the human genome.

Table 87.6 Molecular Genetics—Molecular Biologic Techniques

Identification and cloning of the genes for these animal models have generated great interest in the genetics of human obesity. The relationship of these one-gene defects in

animal models of obesity to human obesity is not clear. However, very recently, two obese persons, an adult and a child, have been found to be leptin deficient (171). These are the first descriptions of one-gene defects in humans. In general, obese humans demonstrate high circulating levels of leptin (172, 173) and normal leptin receptors (174). Thus, if a defect is present in obese persons with regard to leptin, it must be beyond the leptin receptor in a postreceptor signaling process. Neuropeptide Y has been suggested as the possible substance not adequately suppressed by leptin (175) (see also Chapter 37 and Chapter 40). Whether this will be borne out requires further investigation. Clinical trials of leptin in humans are under way but have not yet been completed, so the effect of leptin injection on body weight is not yet known.

Environmental Influences

The role of inherited factors in the origin of obesity is not well defined. Whereas clear genetic effects exist, they are modified by environmental and behavioral factors. Twin studies have been pursued to try to determine the relative importance of genetic inheritance and environmental influences in obesity. The weights of identical twins raised in separate homes have been reported to be similar (176), suggesting that heredity contributes significantly to weight. Although Newman et al. showed a greater difference in twins raised apart than in twins raised together (implicating environment), they also found that fraternal twins raised apart showed a greater weight difference than did identical twins, suggesting a strong genetic component (177). Studies of twins by Stunkard et al. reinforce the importance of heredity (178, 179). Using a model of path analysis, Bouchard studied BMI and reported a total transmissible variance across generations of about 35% but a genetic effect of only 5% (180). The response to overfeeding in a group of pairs of identical twins has been studied. The intrapair resemblance was high, and the resemblance between pairs varied much more (181). Thus, the genotype seems important with regard to weight gain during overfeeding. The heritability of body fat distribution, particularly of central or visceral fat, has also been studied (166). The abdominal depot is also determined partly by genotype (182).

The Ten-State Nutrition Study suggests that environmental factors may be most important in the obesity found in families. Skinfold thicknesses were compared in 429 adoptive parent-child pairs and in 198 genetically unrelated siblings. In addition, 6372 pairs of biologic parent-child pairs and 3713 biologic pairs of siblings were measured. No difference was found between the correlations for biologic sibling pairs and those of genetically unrelated siblings (183). In addition, the correlations in skinfolds between parents and children were high (184). When parents were classified as lean, medium, or obese and various mother-father combinations (lean-lean, lean-obese, obese-lean, obese-obese) were examined, the children were fatter as the parents increased in fatness. This latter finding, however, does not prove a genetic risk; food may be more plentiful in households with fatter parents and result in fatter children.

Studying adoptive parent-child pairs, Withers could find no evidence that the correlation of fatness between a parent and an adopted child differed from that between a parent and a biologic child (185). However, Biron et al. (186) studied 374 families with one or more adopted children and found no correlation in weight between adopted children and their adoptive parents and siblings. Common environment seems to have less influence

as children grow older. Rao et al., studying 1068 families in Brazil, found that the influence of shared family environment on weight could account for only 18% of the variance (187). Thus, the relative importance of genetics and environment on weight remains unclear.

PATHOGENESIS

Endocrinopathy in Obesity

Although obesity is popularly ascribed to glandular troubles, endocrinopathy is actually a rare cause of obesity. Overactivity of the adrenal gland, leading to Cushing's syndrome, causes central obesity. Why adipocytes located at the center of the body are stimulated to multiply and fill in this condition while those at the extremities are not is unclear. The central obesity is associated with hypertension and diabetes.

In severe hypothyroidism, some increased adipose mass may occur, but most of the increased weight is water. Few obese patients suffer from hypothyroidism.

Hypogonadism is sometimes associated with mild obesity, although the reason is not clear. Women with polycystic ovarian syndrome (PCOS) are generally overweight. Although the origin of this syndrome is unclear, investigators have documented that the ovaries are the major source of androgens in PCOS (188). Not only are excess androgens produced, but in obesity, sex hormone-binding globulin is decreased (189), so less androgen is bound. These women have significant insulin resistance (188). The relationship between increased androgens and insulin resistance is not clear.

A hypothalamic lesion caused by tumor, infection, or, rarely, trauma may lead to obesity (190). This is secondary to damage to nerve fibers coursing through the ventromedial area that are important in food intake regulation.

In children, obesity may be seen with certain congenital syndromes, but its cause is unknown. The syndromes include Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, adiposogenital dystrophy (Fröhlich's syndrome), Bongiovanni-Eisenmenger syndrome, and pseudohypoparathyroidism.

Whereas the cause of obesity is seldom a hormonal abnormality, obesity may lead to abnormal hormone levels (191). Owing to the development of insulin resistance, insulin levels in the blood rise, as discussed above. Triiodothyronine (T_3) rises in conditions of high caloric intake with adequate carbohydrate (though not to abnormal levels). Thyroxine levels are normal. Urinary excretion of free cortisol and hydroxycorticoids, sometimes elevated in obesity, is probably related to increased cortisol turnover. These changes are related to the higher lean body mass in the obese. Blood cortisol levels are usually in the normal range in obesity, and diurnal patterns are generally normal. Growth hormone levels are in the low-normal range. Stimulatory tests with arginine, insulin hypoglycemia, or L-dopa demonstrate a poor growth hormone response, which reverts toward normal with weight loss.

Food Intake

Food intake regulation, while investigated for many years, is still very incompletely understood. There are clear internal and external controllers, which interrelate in a very complex manner. It has long been postulated that signals from the periphery are monitored by hypothalamic centers and create a feedback loop for body weight regulation ([192](#), [193](#)). Whether these signals relate to weight, fat, lean body mass, or some other marker has been the object of much debate. After food intake, satiety signals have been divided into preabsorptive and postabsorptive. Preabsorptive signals are probably responsible for cessation of eating after a single meal. Many preabsorptive signals of satiety have been proposed, and highest in rank are the gut peptides ([194](#)). The most documented of these is cholecystikinin ([195](#)). Others are bombesin, glucagon, and glucagon-like peptide 1. These hormones are released from the gut and pancreas after eating. How they signal the brain is not clear, but some may do so through the afferent branch of the vagus nerve.

Longer-range signals of satiety may be related to fat burden. Leptin is an example of such a signal. While its exact mechanism of action is unclear, secretion of this hormone from fat cells increases as fat cell size increases, and the leptin in some fashion signals the brain to decrease food intake and increase thermogenesis. Other long-range signals may monitor other aspects of body composition.

The central nervous system network that turns food intake on and off is very complicated (see [Chapter 40](#)). Neuropeptide Y is a powerful stimulator of eating, galanin also stimulates but is more macronutrient specific, while corticotropin-releasing factor and cholecystikinin inhibit ([196](#), [197](#), [198](#), [199](#) and [200](#)). Dopaminergic, noradrenergic, and serotonergic neurotransmission is also involved. How all these substances and others work in concert to create a coherent regulatory pattern is unknown.

Thermogenesis

Obese individuals have been described as using energy calories more “efficiently” than lean subjects. They have been characterized as requiring fewer calories per unit of lean body mass. If they take in the same number of calories as a lean subject, more of the calories are available as extra energy to be deposited as fat. Whether this phenomenon is important is unsettled. The expenditure of energy takes three forms: basal metabolic rate (BMR), activity, and the thermic effect of food.

Basal Metabolic Rate

The BMR is that energy required for the basic maintenance of the cells of the body and body temperature. In most sedentary adults, the BMR makes up about 60 to 70% of total energy expenditure ([201](#)). Fat-free mass, fat mass, sex, and age explain about 80% of the variance in BMR ([202](#)). Because the metabolic rate is defined primarily by the cell mass of the body, it is reasonable to express it in terms of the lean body mass (LBM). The contribution of the LBM to the BMR is much greater per kilogram than that

of body fat (203, 204). The correlation of BMR with LBM explains why men with a higher LBM have higher metabolic rates than women and why metabolic rates decrease with age. The high metabolic rate of children can be ascribed to the energy cost of growth (205, 206).

However, metabolic rates differ in individuals matched for age, sex, and LBM (207). These differences can be as high as 30%. As a result, at a given fixed intake per kilogram of LBM, one individual may gain weight while another does not. Thus, different people maintain weight on different caloric intakes.

The BMR of obese persons is higher than that of lean individuals (208, 209). Since obese people have a higher LBM than lean people, this finding is not surprising. The obese often have a lower BMR than lean individuals if it is expressed per kilogram of body weight. This finding is reasonable because per unit of weight, they have relatively less metabolizing cell mass. If one expresses BMR as total energy expended per unit time, the obese expend more calories than lean people. Individuals with a low relative metabolic rate are at risk for gaining weight and becoming obese (210, 211 and 212). Further studies are necessary to confirm this interesting phenomenon that suggests one mechanism by which individuals may be gaining weight. Moreover, a high 24-hour respiratory quotient (an index of carbohydrate/fat oxidation) has been shown to predict weight gain (213), and insulin resistance has predicted a low rate of weight gain (214).

Thermic Effect of Food

The rise of metabolic rate above basal level after eating has been called the thermic effect of food (TEF). About 10% of absorbed nutrients are lost as heat, which is created in intermediary metabolism of substrates, in the use of ATP, and in formation of ATP from reduced coenzymes by oxidative phosphorylation.

Although some studies suggest that obese people have a lower TEF than lean people (215, 216 and 217), others report no difference (218, 219 and 220). Insulin may be required for a full TEF effect (221). Insulin deficiency and/or resistance leads to defective glucose oxidation and impaired thermogenesis (222). Thus, whether obese individuals show impaired or delayed TEF depends on their insulin sensitivity or insulin response (223). The TEF seems to be diminished in the obese as a function of insulin resistance (222, 223). Although an independent effect of obesity has also been described (224), the decreased TEF in obese subjects seems to be secondary to obesity rather than primary (225). Thus, an impaired TEF is unlikely to play a role in the development of obesity. In addition, even in those studies showing a decreased TEF, if TEF is added to the elevated BMR all obese persons manifest, the total energy expenditure (BMR plus TEF) is higher than that of lean persons.

Thermogenesis and Overfeeding

Neumann suggested 90 years ago that when a lean individual overate, the excess calories were dissipated as heat (luxus consumption) and normal weight was maintained (226). Garrow, investigating further, summarized the results of 15 studies in which lean and obese subjects were overfed (227). Most show fairly conclusive

evidence that significant overfeeding (>2000 extra calories per day) of lean subjects for at least 10 days leads to some energy wastage. However, the four studies that evaluated obese subjects showed no evidence of luxury consumption. Thus, it is possible that the lean people are more adept at burning off excess ingested energy than are the obese. Even in lean people, however, caloric wastage has only been documented with caloric intake that is much higher than usual.

The suggestion of a deficient ability to increase thermogenesis with overingestion in obese humans is attractive because it has been documented in genetically obese rodents (228). Increased thermogenesis results from activation of an uncoupling protein (UCP-1), which allows ATP to be converted to ADP with the release of energy. UCP-1 is present in brown adipose tissue, but it is doubtful whether enough brown fat is available in adult humans to produce such excess heat. The extrapolation of small animal data to man is not valid at this time. However, recently, two uncoupling proteins (UCP-2 and UCP-3) have been discovered. UCP-2 is expressed in many tissues (228a, 228b), while UCP-3 is expressed preferentially in skeletal muscle and brown and white human adipose tissue (228c, 228d). The significance of UCP-2 in human obesity remains to be determined.

Does exercise potentiate TEF? Again, the data are contradictory. Some studies support this theory (229, 230), others do not (231, 232). Overfeeding did not potentiate the effect of exercise in two studies (233, 234), and even in studies that suggest a potentiating effect of exercise on TEF, the effect is small (235, 236). If a difference exists between lean and obese individuals, it is smaller still.

In summary, experimental evidence at present does not suggest that lean and obese individuals differ in wasteful energy production to any stimulant. There are two exceptions. First, it is probable that with great overfeeding (2000 kcal or more above the usual intake) for a long period of time (10 days or more), some wasteful energy production occurs, which may be greater in the lean than the obese person. Second, it is possible that obese patients with insulin resistance or insulin deficiency, having a defective glucose disposal system, have a depressed TEF.

FAT CELLS

Fat Cell Size and Number

Fat cells, or adipocytes, are distributed throughout the body. They form an elastic energy reservoir that can expand and contract to accommodate the energy balance of the organism. The depot can expand in two ways: by increasing the size of the fat cells or by increasing their number. Although fat cell size is generally tightly regulated between 0.3 and 0.9 μg , the number is more expandable, averaging from as low as 2×10^{10} to as high as 16×10^{10} (237). Thus, enormous flexibility exists for expansion of the adipose reservoir.

Fat cells develop from fat cell precursors called preadipocytes. It is unclear what stimulatory signal activates the preadipocyte to differentiate into an adipocyte and begin

to accumulate lipid, although insulin and cortisol are required. Adipocytes gradually increase in size if energy balance continues to be positive, until a cell size of about 1.0 μg is reached. At this point, adipocytes appear unable to enlarge further. If positive energy balance persists, adipocyte proliferation is triggered, and cell number begins to rise. Because the cell number is virtually unlimited, the adipose reservoir can reach huge dimensions if caloric intake remains high.

Key time periods of adipose cell proliferation have been a controversial subject. It was initially reported that rat fat cell numbers increased in the preweaning phase (238) and not in the postweaning phase (239). However, others have since shown that rat fat cells can proliferate in the postweaning period (240, 241 and 242). Although data in humans are more sparse, evidence indicates an increase in fat cell size in the initial year of life, with a subsequent rise in fat cell number (243) such that fat cell number increases fivefold between 1 and 22 years of age.

In humans, fat cell number may continue to increase as long as nutritional excess occurs; thus, excess storage energy is accommodated. Once fat cells are formed, however, it seems to be difficult to dedifferentiate them. The number seems to remain fixed even if weight is lost (244), although some decrease in number with weight loss has been reported. The net effect of weight loss is then to bring fat cell size down toward normal and eventually, if enough weight is lost, to below normal.

If infants attain maximum fat cell size at 1 year of age and then create additional fat reserves by increasing fat cell number, the child overfed on a long-term basis will develop an excess number of fat cells (hyperplasia). This condition is well documented. However, the hyperplastic child is not destined inevitably to become a hyperplastic adult. Obesity at age 2 or 3 does not necessarily predict obesity at age 21. Even though hyperplastic children have more fat cells than their lean contemporaries, they have fewer than lean adults. Thus, they may “outgrow” their obesity by maintaining their greater number of fat cells, which, if kept constant, may gradually approach normality. (See also [Chapter 63](#).)

Obesity can thus be classified as either hypertrophic or both hypertrophic and hyperplastic. Obese patients are not hyperplastic without being hypertrophic unless they have lost weight by dieting or illness. This classification may have prognostic importance in treatment. Hypertrophic obese patients have been reported to maintain weight loss better than hyperplastic ones (245). This possibility requires further investigation.

Fat Cells As Endocrine Organs

It has become clear in recent years that the adipocyte is not the passive receptacle of lipid that was once thought. It secretes a number of active substances that have an impact on physiologic function elsewhere in the body (246). Fat cells increase leptin secretion when they enlarge and decrease it when they are depleted. Leptin levels increase with satiation and plummet with fasting and starvation. How this secretory process is controlled is presently unknown and the preoccupation of many laboratories.

Another substance secreted by the adipocyte is tumor necrosis factor alpha (TNF- α). TNF- α has been postulated to decrease insulin sensitivity and may be important in the insulin resistance associated with obesity ([247](#), [248](#)). Adipocytes from obese animals and humans have greatly increased TNF- α expression ([248](#)). Also secreted from the adipocyte are angiotensin-1 and adipsin, a serine protease that is on the alternative complement pathway ([249](#)). Prothrombin activator inhibitor-1 (PAI-1) has also been described as being released by fat cells ([250](#), [251](#)).

Thus, the adipocyte possesses the machinery to communicate with other cells in the body and influence physiology at distant sites. For example, recent information suggests that leptin may be involved in sexual maturation and reproductive function ([252](#)).

Lipoprotein Lipase

Adipose tissue lipoprotein lipase (LPL) is an enzyme that determines the rate of uptake by fat cells of circulating plasma triglyceride. It originates in adipocytes and muscle cells and is secreted to the capillary endothelium where it acts on circulating VLDL triglyceride. Activated LPL enhances breakdown of triglycerides to glycerol phosphate and FFAs; the smaller molecular weight substances can enter adipose cells, be reesterified, and be stored as triglyceride (see also [31](#)) (see also [Chapter 74](#)).

Adipose tissue LPL activity is elevated in human obesity ([83](#), [253](#)). When adipose LPL is expressed per cell, it correlates significantly with fat cell size and with percentage of desirable weight ([83](#), [253](#), [254](#)). This correlation is not true of postheparin LPL, muscle LPL, or hepatic lipase ([253](#)). Racial differences also seem to exist in LPL. For example, Pima Indians, a group renowned for their high prevalence of obesity, have lower levels than obese Caucasians ([254](#)).

Obese individuals could have elevated LPL as a primary defect that enhances their ability to “pull” triglyceride into cells, or obesity could develop from some other cause and the enhanced LPL activity could be secondary to the enlarged fat cells. LPL activity rises further with weight loss and returns to lower (though elevated) values with weight regain ([255](#), [256](#)). The further elevation of LPL with any weight drop tends to enhance lipid clearance, to raise stored triglyceride levels, and to restore the obese state ([84](#), [85](#)).

After stabilized significant weight reduction, the elevated adipose tissue LPL activity drops ([253](#), [257](#)), whereas other tissues lipases are not affected ([253](#)). In addition, with refeeding, LPL activity rapidly rises above previous baseline levels ([257](#)). Thus, this change may enhance the capacity to store the circulating triglycerides that result from increased food intake, thus contributing to efficient weight regain by a refeeding obese patient who was previously on a hypocaloric regimen.

Weight Regain

Some 80 to 85% of patients who lose significant amounts of weight regain it ([258](#)). This

dismal record is not readily explained, but a few hypotheses bear mentioning.

The first is that a reducing obese patient has decreased energy requirements. Patients on a reducing diet experience a 15 to 20% drop in metabolic rate (259, 260). As a result, it is more difficult for them to lose weight on the same hypocaloric diet in the second month than in the first, and in the third than the second (259). This reduced metabolic rate also may make it easier to regain weight on returning to a more normal diet. After a fast or a hypocaloric diet, refeeding is associated with a supranormal tissue response to nutrients. This response is characterized by a “repletion reaction” that includes generalized increased substrate utilization with adaptive hyperlipogenesis in adipose tissue and liver. In adipose tissue, this hyperlipogenesis is characterized by marked production of triglyceride and CO₂ from glucose (261, 262). The rapid transfer of glucose into the tissues, enhanced by increased insulin levels plus greater tissue insulin sensitivity, may increase lipogenesis and lower blood glucose levels, which may enhance hunger and stimulate greater food intake (262).

Rats demonstrate increased efficiency after fasting. Animals fasted for 4 days and then refed could maintain their new lower weight (90% of baseline) on 60% of the original daily calories (263). In addition, fasted rats refed their original daily caloric intake could regain their lost weight without overeating. These reports suggest that during the refeeding period, animals can use the same number of calories more efficiently (264).

Evidence suggesting a similar phenomenon is beginning to emerge from human studies. In morbidly obese patients whose weight was significantly reduced (from an average 152 to 100 kg), 7-day energy intake requirements to maintain weight dropped from 1432 to 1021 kcal/m²/day (265). The figure of 1021 kcal/m²/day was significantly lower than the 1341 kcal/m²/day found in normal lean individuals weighing a mean of 63 kg. Because this weight loss was recent, a second metabolic study was executed with reduced obese patients who had maintained their weight loss for 4 to 6 years. These women also showed requirements averaging 1031 kcal/m²/day to maintain their weight.

More recently, obese subjects were studied whose weight fell 10% from baseline and was maintained there for some weeks. Total energy expenditure was reduced by a mean of 6 kcal/kg fat-free mass and 8 kcal/kg weight/day. It is interesting that the reduction in resting energy expenditure was appropriate for the loss of lean body mass. The primary cause of reduced caloric expenditure was reduced nonresting energy expenditure; that is, individuals required fewer calories to carry out similar activity patterns (266). Others have reported similar data.

This finding suggests that at least some reduced obese individuals have lowered caloric requirements that may persist for years and that if caloric intake is increased above 1000 kcal/m²/day, weight regain will occur. This theory may help to explain the poor record in maintaining weight loss after dieting.

Adipose tissue mass may be regulated by an ability of the organism to sense the filling of adipose cells with triglyceride. That is, weight regain in a refeeding animal seems to continue until fat cells have returned to their original size. Some investigators have

suggested that in this way adipose tissue exerts a regulatory function on energy intake and energy balance (257). It is clear that Leptin works in this way (163, 164 and 165). This process could explain why reduced obese patients have such difficulty staying on hypocaloric diets after they have dropped to a certain weight. At that point, their fat cells are at the lower limits of normal size. To drop weight further, these cells would need to become abnormally small. If hyperplastic obese persons do succeed in lowering their weight to the extent that fat cell size is below normal, they will be unable to remain at that weight, regain will occur, and fat cells will be filled to at least a “normal” size (268). The role of the fat cell in energy regulation is intriguing, and more investigative studies in this area are necessary.

THERAPY FOR OBESITY

Dietary Management

Many strategies for losing weight have been tried over the years because, as a rule, losing weight and keeping it off are extremely difficult. This is particularly true for individuals who are 25% or more overweight.

Impaired Absorption

Impairment of intestinal absorption of ingested calories is one suggested strategy. Fiber has been particularly touted in this regard, although little evidence exists that fiber significantly affects total intestinal absorption (269). Nondigestible fat substitutes have been developed. For example, sucrose polyester can be used in the diet as a replacement for fat. Whether the gastrointestinal side effects of fat malabsorption will be acceptable is presently unclear, as is the effectiveness of the substance.

Unbalanced Low-Calorie Diets

All unbalanced low-calorie diets have a marked imbalance of macronutrients that can also cause an imbalance of micronutrients. They emphasize particular food groups (carbohydrate, protein, or fat) and prohibit or deemphasize others. Their focused nature makes them easier for individuals to follow, which makes them popular.

They can be divided into different types. The ketogenic diets are high-protein, high-fat, low-carbohydrate diets. Carbohydrate generally makes up less than 20% of the calories. Proponents suggest that ketosis causes appetite suppression, but the effectiveness of ketone in inhibiting food intake has not been effectively demonstrated. Such diets tend to be low in vitamin C, and calcium loss can be enhanced. The high uric acid production may be dangerous for those predisposed to gout. These diets have a high cholesterol content, dangerous for people with hypercholesterolemia (270). They often cause nausea, hypotension, and fatigue (270).

The aforementioned diets have been modified to be high protein (40–45%), low fat (30–35%), and low carbohydrate (20–25%). These diets tend to be lower in calories because of limitation of fat, a high-calorie item. They are still ketogenic, with the same

side effects of nausea, hypotension, and fatigue. They tend to be high in saturated fats and cholesterol and low in vitamins A, C, and thiamin and iron. The amount of cholesterol may be triple that in a regular diet ([271](#)).

A radically different type of diet is high in carbohydrate, low in protein (35 g/day), and low in fat (as low as 10%) ([272](#)). The emphasis is on fruits, vegetables, breads, and cereals. No table fats, oil, or dairy products except skim milk are allowed. Often these diets prohibit sugar. If taken faithfully, such diets may be low in salt, iron, essential fatty acids, and fat-soluble vitamins. Most commonly used today are diets relatively low in fat (20–30% of calories) that are also hypocaloric and have adequate protein. Such diets have successfully induced weight loss ([273](#), [274](#) and [275](#)).

Some physicians have proposed total fasting as a way of losing weight ([276](#), [277](#)). Advocates have used it intermittently in treating obese type 2 diabetics. The problem with a total fast is that not only fat, but also much lean body mass, is lost ([278](#)). Lean body mass is difficult to regain, particularly in older individuals. In addition, the induced diuresis can result in significant mineral losses.

Protein-Supplemented Modified Fasts (PSMF)

Because of the deficiencies of total fasting, regimens called protein-supplemented modified fasts (PSMFs) have become popular ([279](#)). These severely limited diets of 400 to 700 calories generate rapid weight loss. The protein is given in the form of either formula or natural foods such as lean meat, fowl, or fish. These diets have been given for extensive periods of time, although the consensus is that it is dangerous to use them for longer than 16 weeks ([280](#)). Patients lose 1.5 to 2.3 kg/week on these diets. The protein that the patients take needs to be of high biologic quality to help prevent the loss of body protein that occurs during a standard fast ([279](#)).

Nitrogen Loss. In a fasting subject, nitrogen excretion is initially high (11–23 g/day) ([281](#)). Nitrogen loss decreases steeply in the first few days to a nadir of obligate nitrogen excretion ([282](#)). With total fasting, a cumulative nitrogen loss of 154 g of nitrogen or 963 g of protein occurs after 15 days ([283](#)). Simply adding 100 g of carbohydrate daily decreases nitrogen loss by 40% ([284](#)). Administering 55 g of high-quality protein daily causes negative nitrogen balance for the first 10 days, but many patients achieve balance at about 20 days ([285](#)). These low-caloric diets were given large-scale trials by three groups ([286](#), [287](#) and [288](#)). All required vitamin and mineral supplements daily as well as essential fatty acids ([287](#)). They reported little morbidity. Vertes et al., with 1200 outpatient years of experience, had four deaths, which they describe as fewer than expected for the population treated ([289](#)).

It has been hypothesized that these diets spare protein by decreasing the insulin level and enhancing ketonemia ([290](#)). The ketonemia in turn inhibits release of amino acids from muscle ([291](#)). Little experimental evidence supports this hypothesis, because insulin levels are not absolute determinants of protein sparing ([292](#), [293](#)).

Morbidity and Mortality with PSMF. With the popularization of these PSMF diets, numerous commercial preparations of liquid protein have become available for

over-the-counter purchase. Fifty-eight deaths were associated with the use of these formulas in the 1970s (294). Although the reason for these deaths is unclear, 17 of them were investigated (295, 296). Patients seemed to develop refractory ventricular arrhythmias. Whether this condition was secondary to myocardial protein atrophy, myocarditis, potassium deficiency, or other mineral losses is unclear (295, 297, 298). These deaths have been attributed to poor-quality protein in the commercial-formula diets. The proteins eaten in a regular diet, such as dairy products, meat, fish, poultry, and grain and cereal products, provide about 87% of the calcium, 80% of the phosphorus, 60% of the magnesium, 74% of the iron, 80% of the zinc, 57% of the copper, 80% of the manganese, and 100% of the selenium in a usual diet. Many of the poor-quality hydrolyzed protein diets did not adequately replace these minerals and others. The more recent formula preparations have used high-quality protein (casein or soy protein), have replaced micronutrients adequately, and have not led to untoward events (299).

Morbidity also occurs with these diets. Orthostatic hypotension may result from the sodium diuresis and volume depletion that occur (300). This condition is probably secondary to the natriuretic effect of hyperketonemia (301) and the impaired norepinephrine secretion associated with it (300). Other symptoms and signs include dehydration, cold intolerance, fatigue, dry skin, hair loss, and menstrual irregularities. Cholecystitis, pancreatitis, and peroneal nerve palsy have occasionally been reported.

Although nitrogen balance is better with PSMF than with starvation, there is little evidence that PSMF is better than a mixed diet. Comparison of an 800-kcal mixed diet, an 800-kcal all-protein ketogenic diet, and starvation in obese subjects showed that starvation gives the most negative nitrogen balance, while the mixed and the all-protein diet are not much different and result in less nitrogen loss (302). Over a 10-day period, 2.8 kg of weight is lost with a mixed diet and 4.7 kg with the ketogenic diet, but all the extra weight lost with the ketogenic diet is water. Longer 60-day studies show no difference in nitrogen balance between a mixed diet and a ketogenic diet (303).

Balanced Hypocaloric Diets

In view of the aforementioned risks and problems of unbalanced diets and the prolonged periods of time that restricted diets must be followed, a well-balanced mixed diet seems a sensible approach. Diets in the 1100- to 1200-kcal range can include appropriate macro- and microelements, vitamins, and protein (304). They can be followed for months without specific supplements. The nutrients most likely to be deficient are iron, folacin, vitamin B₆, and zinc (304). In such a diet, the percentage of protein is raised, so at least 240 calories or about 60 g/day are from protein. The protein should be of high quality and should make up about 25% of calories. At least 20% of the rest of the dietary calories should be carbohydrate and at least 20% fat. In this way, fat-soluble vitamins and essential fatty acids will be available from fat, and fiber and antiketogenic effect from carbohydrate. Diets of 800 to 1100 kcal must be supplemented with vitamins and minerals. In general, the caloric deficit should not exceed 500 to 1000 kcal/day, and total calories should not be below 800 kcal unless the individual is under tight medical surveillance.

A balanced diet for micronutrients and vitamins should contain food items from the following foods: (a) meat, fish, poultry, and meat substitutes; (b) milk and milk products; (c) cereals and cereal products; and (d) vegetables and fruits. The nutrients obtained are (a) protein, fat, niacin, iron, and thiamin; (b) vitamins A and D, calcium, magnesium, and zinc; (c) carbohydrates, fat, phosphorus, magnesium, zinc, and copper; and (d) carbohydrate, vitamins A and C, iron, and magnesium ([304](#)).

Because obese individuals need to be on a diet for a long time, the diet *must* be acceptable. It must fit the individual's tastes and habits and be flexible enough to allow eating both inside and outside the home.

Exercise

The therapeutic use of exercise to reverse obesity has been widely hailed. As mentioned above, body weight is determined by a balance between energy intake and energy expenditure. If energy expenditure can be increased by incremental physical activity and energy intake is kept constant, weight will drop. A number of points must be emphasized. First, a significant amount of physical effort is required to expend a significant number of calories. Calorie charts for expenditure usually list the total caloric expenditure for a given period of time. However, an individual who is not doing the activity does not expend zero calories but something above basal levels (sitting, standing). For example, an obese woman exercising on a treadmill at 4 mph expends about 7.0 kcal/min, or 210 calories if she continues this exercise for 30 min. Sitting in a chair, such a woman expends about 1.3 kcal/min, or 39 kcal over 30 min. Thus, her exercise-induced expenditure would not be 210 kcal but 210 minus 39, or 171 kcal. Therefore, in looking at expenditure tables, one must always subtract between 1 and 1.5 kcal/min for the resting or sitting metabolic expenditure that would occur anyway.

The second point that must be clarified is the purported prolonged elevation of oxygen consumption for long periods after exercise. Such a sustained effect of exercise lasting for 7 to 48 hours has been described, but two reviews of the literature concluded that no sustained increase could be demonstrated after exercise ([305](#), [306](#)). Studies support a lack of a sustained effect using exercise levels that are realistic for individuals on weight-control programs ([307](#), [308](#), [309](#) and [310](#)). Because little appreciable caloric loss occurs beyond that generated by the exercise period itself, claims for sustained effects of exercise on resting metabolic rate in weight control programs are unwarranted.

The third point relates to the effect of exercise on food intake. Although it has been generally suggested that exercise inhibits food intake, this phenomenon has not been documented. In lean individuals, exercise generally leads to increased energy intake and maintenance of body weight ([311](#)). This tendency is true with both mild (~400 kcal/day) and moderate (~775 kcal/day) exercise ([312](#)). Obese individuals may respond to exercise by defending weight to the same extent as lean persons.

Most studies of the effect of exercise on obese subjects only measured weight or body fat; they did not measure food intake. As mentioned above, if expenditure is increased and food intake remains stable, weight loss will be commensurate with the increased

expenditure. Such a result has been described (313). Other studies, however, have documented amounts of weight loss that suggest curtailed food intake (314, 315). Some studies show no effect of exercise on weight at all (316). Two metabolic ward studies over long periods of time, 19-day (307) or 57-day (308) intervals, suggest that obese women tend to fix on an intake and remain at that intake even if the amount of activity is changed. Intake changes seemed more related to dietary characteristics than to level of exercise (316). Prospective epidemiologic studies show a lower risk for overweight in more physically active persons (317). With regard to weight loss, one review describes a modestly greater effect of diet and exercise over diet alone (318). A beneficial effect of exercise is best documented in the weight maintenance phase, predicting greater success (319).

Although exercise does not magically sustain an enhanced metabolic rate or inhibit food intake, every calorie expended can help in the battle to use significantly more calories than are ingested. Moreover, exercise helps to maintain weight loss while allowing less stringent diets a more acceptable regimen to many patients.

Pharmacologic Treatment

The most widely used drugs for weight control are appetite suppressants; others attack food intake and metabolism at other sites, such as digestion, absorption, lipid synthesis, or thermogenesis. The anorectic agents, which suppress appetite, are considered first.

The first was amphetamine. Amphetamine, a *b*-phenethylamine, seems to induce anorexia via brain catecholamines, specifically norepinephrine and dopamine, although the relative importance of each in man is not yet clear. It causes not only anorexia, but also many other effects including central stimulation, mood enhancement, cardiovascular excitation, and a selective effect on certain neural transmitters, especially catecholamines. Some of these effects can lead to abuse (320). In addition, in a few patients, discontinuing the drug seems to be associated with onset of depression. Six anorectic agents that been shown to induce dependence have been most commonly used: diethylpropion, mazindol, *d,l*-fenfluramine, *d*-fenfluramine, phentermine, and phenylpropanolamine.

Diethylpropion seems to have little effect on sleep, and addiction has not been a problem. It is closest in structure to amphetamine, being modified by addition of a keto group on the *b* carbon and of ethyl groups on the amine terminal. Mazindol is thought to prolong the action of norepinephrine and also stimulates the central nervous system (321). It is a tricyclic compound with a long plasma half-life (33–55 hours). Fenfluramine has an ethyl group on the amine terminal and a CF₃ on the phenyl ring. Its action is mediated through a central serotonergic system. It has no central stimulant effect (322). Phentermine resin has methyl groups substituted on the carbon. It seems to be as effective as amphetamine, with lower stimulatory properties; however, dry mouth, tachycardia, and increased blood pressure often occur. Phenylpropanolamine, a derivative of amphetamine, has an extra hydroxyl group. It is available over the counter and as a result is widely used. Its effect is generally modest (323, 324).

Although we cannot yet classify obesity in terms of etiology, it probably has differing

causes. The drugs available also differ. Thus, it is not surprising that the response differs from person to person. These drugs may be a useful adjunct for the treatment of obesity in some patients. The widespread belief in some medical circles that all appetite-suppressant drugs are useless and that tolerance quickly develops is not necessarily true. In addition, although side effects are common with excess dosage, they do not necessarily occur at recommended dosages. An anorectic agent can be helpful in some people. However, the drug can only be effective if appropriate dosage is given and blood levels are adequate. It is also wise to individualize use to a patient's dietary habits. One would not administer a relatively short-acting drug in the morning if a patient eats no breakfast and is an evening and night eater. Recently, the suggestion has been put forward that long-term drug therapy for obesity should be considered (325). Certain experimental studies have reported moderate success with long-term therapy using *d,l*-fenfluramine (326), sibutramine (327), and a combination of phentermine and fenfluramine (328).

Recently, the drugs *d,l*-fenfluramine and fenfluramine have been withdrawn from the market by their manufacturer. The reason for this was development of heart valve lesions with the use of these agents (328a). The lesions, primarily in the aortic and mitral valve, consist of thickening of the valve, similar to what occurs with carcinoid syndrome. The result is development of aortic and mitral regurgitation. Twenty-seven persons required valve replacement, with three deaths reported (328b). The incidence of this side effect is not clear, but the Food and Drug Administration (FDA) has suggested that it may be as high as 30% (328b). On the basis of these side effects as well as the already known increased incidence of pulmonary hypertension (328c, 328d), these two drugs have been withdrawn from the market.

In 1998, a new drug, sibutramine, was approved by the FDA for long-term use. It is a norepinephrine and serotonin reuptake inhibitor. In clinical trials, it produces about the same degree of weight loss as the fenfluramines (327a). A side effect of this drug is possible elevation of heart rate and blood pressure, so patients need to be monitored carefully (328a).

Another pharmacologic agent, orlistat, inhibits dietary lipid absorption by decreasing intestinal lipase activity. Clinical trials suggest an effect on weight loss comparable to that of the drugs described above (329). The safety profile of this drug seems high, although some fat-soluble vitamin levels may drop slightly.

There is an effort to develop thermogenic agents, but no satisfactory drug is available to date. Thyroid preparations, digitalis, or human chorionic gonadotrophin have no place in the treatment of obesity. Diuretics are rarely necessary and certainly should never be used in combination with low-calorie diets. Bulking agents such as methylcellulose and other fibers have been touted as aids in weight loss, but no evidence of this is available. They do not cause malabsorption and have not been shown to decrease food intake (330).

In summary, though drugs may be helpful in some individuals at some periods in weight loss and weight maintenance, they do not hold first rank in any therapeutic program.

Psychotherapy

The psychologic treatment of obesity has not enjoyed much success. Although a few optimistic reports have stated the effect of psychoanalysis in producing weight loss (331, 332), particularly in adolescents (331), therapeutic failure is the common result. Many obese patients may have emotional problems, but these vary. Some have anxiety, some are depressed, but some have no evident psychiatric problems at all, except for overeating and/or underactivity (333). No particular personality type is obese.

Although some investigators have suggested that obesity may be protective for underlying neurotic behavior, this possibility has not been confirmed by patients undergoing surgical treatment of obesity. Some psychiatrists predicted that morbidly obese individuals would develop other addictive tendencies or overt neurotic or psychotic traits as weight loss occurred. This has not happened. Patients either have had no psychiatric change or have improved; few have deteriorated (334).

A distortion of body image does seem to exist in a minority of obese patients, with overestimation of body size (333). In a study of morbidly obese subjects whose weight was reduced enough to have significant changes in body size, the distortion of body image persisted, particularly in those obese from childhood (335). Some psychiatrists have even reported evidence of low anxiety and depression in obese individuals (336), and epidemiologic evidence suggests that they have a lower incidence of suicide than the general population. Because no evidence indicates that all or even most obese subjects are neurotic, health professionals must individually evaluate each patient.

Some persons who wish to lose weight are binge eaters. If they have true bulimia nervosa with vomiting, laxative use, and electrolyte changes, this condition should be addressed by a psychiatrically trained professional. If an obese person engages in binge eating without purging, it seems wise to direct therapy to the binge eating before attempting weight loss (337).

Behavior Modification

Because of the poor record in the treatment of obesity by classic psychoanalysis and psychotherapy, behavior modification has gained favor. Behavior modification programs grew out of the hypothesis that the obese overeat because they are stimulus bound and environmental food-relevant cues control eating rather than any psychogenic neurotic states (338). This "externality theory" suggested that external environmental stimuli overrode whatever internal hunger or satiety cues generally caused lean individuals to initiate or stop eating (339). This theory differentiating obese from lean is now questioned because others have not been able to duplicate these differences in the two groups (340). Nevertheless, the theory won wide recognition and stimulated interest in behavior modification programs to control food intake by diminishing the number of external cues that led to overeating (341).

The first step in a behavior modification program is identifying the eating and activity

patterns of an individual. Careful diaries are kept in which patients record not only when and what was eaten, but where, with whom, how (sitting, standing, walking), as well as their feelings and hunger. In addition to the diary of food-related behavior, a diary of all activity-related behavior is kept, including when, with whom, where, and feelings at the time. Food management behavior must also be itemized, including buying, storing, preparing, serving, and cleaning up food. These diaries are analyzed so that possible environmental (e.g., television) or emotional (e.g., depression) clues to overeating may be recognized and controlled. Once these cues have been identified, then techniques are invoked to try to control or evade them. Environmental stimuli to eating are controlled. Food shopping habits, visual cues, food preparation habits, and food storage habits are changed.

Techniques to control the act of eating are also imposed. These include always eating in the dining room, sitting, concentrating on eating (no reading or watching television), eating more slowly, taking more and smaller bites, putting utensils down between bites, not skipping meals, not taking snacks, changing high-calorie foods for low-calorie ones, and eating at prescribed times only. Besides these efforts to diminish environmental cues, new discriminative stimuli are introduced to develop new eating patterns. These include distinctive sites for eating, new and smaller plates, and eating with others as often as possible. Finally, behavior modification programs try to change the consequences of eating. A reward system is introduced for changing behavior. The rewards are generally immediate and may be monetary or social feedback. Family, friends, group members, and group leaders can all contribute.

Mahoney outlined the assumptions of the behavior modification movement ([342](#)):

1. Obesity is a learning disorder created by, and amenable to, principles of conditioning
2. Obesity is a simple disorder resulting from excess calorie intake
3. The obese individual is an overeater
4. Obese persons are more sensitive to food stimuli than are nonobese individuals
5. Important differences exist in the "eating style" of obese and nonobese persons
6. Training an obese person to behave like a nonobese one will result in weight loss

Many, if not all, of these assumptions are now considered untrue; thus many of the strategies for weight loss in behavioral modification programs were founded on false assumptions. Though the theoretical background may be incorrect, the strategy developed is effective. This argument is probably valid. Stunkard reviewed 30 controlled trials and found that behavioral treatment was more successful in producing weight loss than a variety of other treatments ([343](#)). Behavior modification programs seemed to be more successful than group psychotherapy, nutritional education, and relaxation training. That success is not universal, however; some patients do well and others poorly. To date, it has not been possible to identify the characteristics that determine success.

Although some weight has been lost, it has not been impressive. Jeffrey et al. reviewed 21 studies and found a mean weight loss of 11.5 lb ([344](#)). This amount, although a loss, is not clinically of much importance. In addition, not many persons have lost weight after

termination of the program (345), and maintenance of weight loss in the long term has been poor (346).

In summary, it is difficult to be certain at this point whether behavioral treatment is better, and if so, how much better, than other forms of treatment. Well-controlled follow-up studies suggest that the same problem of failure to maintain weight loss that is true of other weight-control programs is true of behavior modification programs.

Surgical Treatment

The refractoriness of many patients with morbid obesity to diet, psychotherapy, behavior modification, drugs, and exercise programs has led to physician pessimism about the likelihood of long-term therapeutic success. As a result, surgical treatment has been attempted, based on one of two principles: (a) a short bowel is created to produce malabsorption of ingested calories and (b) a small stomach is created to prevent much caloric intake at any one time.

Short Bowel Procedure

Many variations of the jejunioileal bypass procedure existed (347), depending on how much jejunum and how much ileum was bypassed. The earliest procedure connected 12 to 15 in. of jejunum to 4 to 8 in. of ileum. Connections were end to end or end to side. The bypass loop was either left to drain in situ (end to side) or was reconnected to drain into the ascending or transverse colon (end to end). Various-sized segments were left in continuity (14–4 in., 10–10 in., 14–8 in.). Weight loss did generally occur, although it was variable, and few patients lost only a small amount of weight. The bypass procedure created malabsorption of both exogenous nutrients and endogenous gastrointestinal secretions. Complications made this procedure unacceptable (347), including hypokalemia, hypocalcemia, vitamin B deficiency, hepatic toxicity, renal calculi, and polyarthritis. There were also operative risks, including pulmonary embolus, pneumonia, wound infections, wound dehiscence, and phlebitis. Because of all these problems, the procedure was discontinued.

Gastric Surgery. The gastric bypass operation was first described by Mason and Ito in 1967 (348). In this operation, the stomach was transected (or stapled) to create a small upper pouch (30–50 mL) that was anastomosed to a loop of jejunum. The opening between pouch and jejunum was 9 to 11 mm in diameter. This operation made a blind loop of much of the stomach, the duodenum, and the proximal jejunum.

More commonly now, a modification of this operation, the gastroplasty, is done. The stomach is stapled across, creating a small 50- to 60-mL reservoir on top and a small 1-cm outlet to the rest of the stomach on the lesser, middle, or greater curvature. Another recent procedure is the vertical banded gastroplasty (349). In this procedure, a 20- to 30-mL stomach pouch is made by two longitudinal staple lines. In addition, the pouch can be wrapped with Teflon mesh to prevent pouch distention and stoma widening.

These operations have been associated with considerably less morbidity than the intestinal operations (350, 350a). The problems are generally postoperative and include anastomotic leaks, transient gastrojejunostomy obstruction, and intraabdominal abscess. Wound infection, dehiscence, pulmonary embolism, and atelectasis can also occur. Subsequent to these early problems, late morbidity depends greatly on patient education and compliance. Vomiting is frequent if the speed or amount of eating is too great. Late complications consist primarily of revisions caused by suture-line disruption or channel size problems. If chronic vomiting persists, esophagitis, hypokalemia, and malnutrition with dehydration can occur. The success rate with gastroplasty has been variable, depending greatly on the surgeon. It is difficult to construct a stoma small enough to inhibit too-rapid transit from the small reservoir to the large, yet not small enough to cause obstructive symptoms. Mason and Ito reported a 36-kg average weight loss in 3 years, but others have not done as well (348). In addition, patients can ensure failure by consuming high-caloric-density liquid or semisolid food that can easily pass through the small stoma.

Lipectomy. Lipectomy is not a treatment for obesity. It is surgical removal of adipose tissue for cosmetic purposes. Not enough fat can be removed to make a real impact on obesity, and it should not be performed for this reason. Lipectomy may be used to treat localized unsightly adiposity. A recent modification of this procedure is suction lipectomy. Long-term results of this procedure are unavailable.

WEIGHT CYCLING

In recent years, data have suggested that weight cycling (i.e., gaining and losing weight several times) may be detrimental. Although some studies have suggested increased morbidity and mortality (351, 352), others have not borne this out (353, 354).

Selected Reading

The formation of blood cells (hematopoiesis) is sited in the bone marrow cavity (medulla) of virtually all bones in the newborn, but in adults, active blood formation is confined to the central skeleton (skull, vertebral column, ribs, and pelvis) and upper ends of the humerus and femur. All hematopoietic cells arise from a very small population of self-renewing stem cells, and no more than 5% of these are dividing at any one time (1). Stem cells are too few in number to be seen or, indeed, recognized in marrow aspirates but react with a monoclonal antibody designated CD 34. Stem cells,

under the influence of a range of growth factors, give rise to red blood cells, white blood cells including neutrophil, eosinophil, and basophil polymorphonuclear leukocytes, monocytes, lymphocytes, and platelets.

The nutritional requirements for hematopoiesis are no different from those of any other tissue. However, turnover of blood cells is normally greater than that of other tissues in the body, and availability of three nutrients can become limiting: iron, cobalamin (cbl, vitamin B₁₂), and pteroylglutamic acid, (folic acid, or folate). Iron is required as the oxygen carrier in the hemoglobin molecule in erythrocytes, and cbl and folate are essential in the synthesis of three of the four nucleotides of DNA required for the doubling of the DNA content of the cell before mitosis. Lack of other nutrients only rarely causes anemia; these include vitamin A, vitamin B₆, riboflavin, ascorbic acid, vitamin E, and copper.

A vegetarian diet usually supplies adequate amounts of iron, but its availability is low unless food of animal origin or ascorbate are also present. Furthermore, a vegetarian diet contains no cbl other than that arising from bacterial contamination. However, such diets usually have adequate amounts of folate (see [Chapter 106](#)).

ANEMIA AND ITS CLINICAL CONSEQUENCES

Impairment of normal red cell production results in a fall in the hemoglobin concentration, red cell count, and packed cell volume below the levels shown in [Table 88.1](#). Those living at an altitude of 4000 feet or more have higher blood values. There are no racial differences. The fall in blood values in turn leads to a reduction in the oxygen-carrying capacity of the blood and impairment of oxygen delivery to tissues. The effects of anemia are due not only to impaired oxygen delivery but also to the compensatory mechanisms that develop.

	Females	Males
Red cell count (10 ⁶ /mm ³)	4.0	4.5
Hemoglobin (g/dL)	12.5	13.5
Packed cell volume (%)	37	40

Table 88.1 Values in a Blood Count below Which Anemia Is Present

The compensatory mechanisms are of three kinds. There is an increase in the level of 2,3-diphosphoglycerate in anemic red blood cells, which leads to increased binding of this compound to deoxyhemoglobin and so reduces its affinity for oxygen. As a result, a greater proportion of the oxygen on hemoglobin can be released to tissues. A second adjustment to anemia is speeding circulation of blood by increasing cardiac output; this becomes clinically obvious when the hemoglobin concentration falls below 7 g/dL. Finally, the decline in oxygenation of the kidneys results in increased production of the erythropoietic hormone, erythropoietin, which leads to increased blood production and extension of hematopoiesis into fatty bone marrow. In chronic anemia, these compensatory mechanisms allow the patient to continue relatively normal activity, so that the severity of anemia often appears out of keeping with the paucity of symptoms.

Most patients with significant anemia are tired and tire easily after exertion. They are pale, most evident on inspection of mucous membranes. Palpitations (awareness of the heart beat), tinnitus (ringing or whistling noise in the ears or head), headache, irritability, dizziness, and weakness may be present. Patients are short of breath and have a rapid heart beat and pulse and visible arterial pulsation. There are often systolic heart murmurs on cardiac auscultation that disappear when the anemia has been corrected. In older people, cardiac pain (angina) and cardiac failure may develop, the latter characterized by swelling of the feet, enlarged liver, and pulmonary edema.

A sore mouth and tongue is often present in iron, cbl, or folate deficiencies. In the latter two deficiencies, impaired squamous cell renewal in mouth and tongue can be blamed, and a high iron requirement may also explain these findings in iron deficiency. There may be cracks at the angles of the mouth termed *angular stomatitis* ([Fig. 88.1](#)). Other findings in particular deficiencies are dealt with below in this chapter.

Figure 88.1. Angular stomatitis and a smooth shiny tongue in iron deficiency anemia.

IRON

Basic aspects are dealt with in detail in [Chapter 10](#). Since most of the iron in the body is in red blood cells, blood loss is the major cause of iron deficiency. Major sites of blood loss are the gastrointestinal tract in both sexes and menstrual blood loss in women. Intestinal malabsorption of iron and increased iron requirements for growth or that are not met from the diet in pregnancy are other causes of iron deficiency. This account is concerned with nutritional factors involved in producing a negative iron balance and iron deficiency. Frequently nutritional factors and blood loss coexist; most importantly, poor iron availability from a vegetarian diet in large numbers of people may coexist with hookworm infestation of the small gut, which produces considerable blood loss.

Physiologic Considerations

In addition to hemoglobin iron (1600–2400 mg in an adult), iron is present in myoglobin (300 mg) and various heme and many nonheme enzymes (150 mg) including cytochromes concerned with oxidative reactions producing energy. Reserve (storage) iron linked to ferritin and hemosiderin is present in liver, spleen, and marrow. An adult man has some 500 to 1000 mg of storage iron, and older men even more. Iron stores in women seldom reach 500 mg. Indeed, when iron requirements are high, as in growing children, menstruating women and in pregnancy, iron stores are more usually absent or low. Disappearance of iron stores precedes development of overt anemia, but by itself, absence of iron stores does not produce symptoms. Iron stores are assessed by the serum ferritin level (the higher the level, the greater the iron store) and by the amount of stainable iron in aspirated bone marrow fragments or liver biopsy specimens.

Adult iron turnover is some 22 mg of iron each day: 20 to 21 mg coming from recycled iron recovered from effete red blood cells and only about 1 mg in men and 2 mg in women from absorption of dietary iron. The latter constitute iron requirements and arise from iron loss as a result of desquamation of epithelial cells and by iron lost in menstruation. Children require additional iron for growth, and pregnancy increases iron requirements substantially. Iron losses have been assessed as follows.

In adult males, iron losses have been measured at 0.9 mg/24 h or 14 $\mu\text{g}/\text{kg}/24\text{ h}$ (2). Extrapolation of data from males indicates a basal iron loss of 0.8 mg/24 h for a 55-kg woman. Median menstrual blood loss in healthy women is between 25 and 30 mL per cycle. Averaged over the entire menstrual cycle, the daily iron loss is 0.5 mg/24 h. A quarter of women lose more than 0.8 mg/24 h, 10% more than 1.3 mg/24 h, and 5% more than 1.6 mg/24 h. When basal iron losses are added, the daily iron requirement in 5% of women exceeds 2.4 mg/24 h. Oral contraceptives reduce menstrual loss by about half, whereas intrauterine devices double the loss.

Pregnant women require iron to replace basal iron losses (220 mg iron during pregnancy going to term), to expand their red cell mass (500 mg), and to provide for the placenta and fetus. The full-term fetus has about 290 mg of iron, and placenta about 25 mg. Thus the total additional iron requirement in pregnancy is about 1000 mg. The increased requirement starts in the second trimester; the daily iron requirement increases from 0.8 mg in the first trimester to 4.4 mg in the second and to 6.3 mg daily in the third. In the latter two-thirds of pregnancy, iron needs cannot be satisfied from

dietary iron alone. Unless one believes that at least 500 mg of iron is available as iron stores present before pregnancy, iron supplements need to be given. There is further iron loss due to bleeding during delivery. During pregnancy, iron loss from menstruation ceases, and during the puerperium, reduction of the red cell mass makes the iron in these surplus red cells available. Following delivery, several months elapse before menstruation is restored in a lactating woman. There is, however, a daily loss of 0.3 mg in breast milk. The mean iron requirement during 6 months of lactation is 1.1 mg daily.

A normal newborn has about 75 mg of iron per kilogram, of which two-thirds is in hemoglobin. The physiologic decrease in red cell mass in the first 2 months of life returns some iron to stores. Absorption of dietary iron becomes significant only at 4 to 6 months of life, when initial iron stores have become considerably depleted. Premature (low-birth-weight) infants have much reduced iron stores and need dietary iron at a much earlier age than full-term infants. In childhood, additional iron is required for the expanding red cell mass and for growth. (See [Table 88.2](#) for FAO-WHO recommendations and [Table 88.3](#) for U.S. RDA.)

Age (Years)	Mean Body Weight (kg)	Growth Requirement (mg/24 h)	Basal Losses (mg/24 h)	Total Requirement (mg/24 h)

Table 88.3 Recommended Daily Dietary Allowances (U.S. 1989)

Absorption and Availability of Dietary Iron

There are two forms of dietary iron, heme iron and nonheme iron.

Heme Iron

Heme provides 10 to 15% of food iron taken in a mixed diet. The heme is present in hemoglobin and myoglobin of animal foods. Between 20 and 30% of heme iron is absorbed, and its absorption is largely independent of the overall composition of the diet. Heme iron may meet about one-quarter of iron requirements in those eating a diet of high meat content. In the enterocyte, the iron is split from the tetrapyrrol portion of the heme.

Nonheme Iron

Nonheme iron is present in cereals, pulses (seeds of leguminous plants), fruits, vegetables, and dairy produce. It provides 85 to 90% of dietary iron in a mixed diet and is the only source of iron in a largely vegetarian diet. The mixture of foods in a diet contains factors that either promote or inhibit iron absorption, and thus, the amount of iron absorbed may vary considerably.

Absorption of food iron is inhibited by phytates, polyphenols (3) including tannins present in tea, certain proteins, and certain dietary fibers. Inhibitors act by strongly binding ionic iron. Phytates are salts of inositol hexaphosphates, and about 90% arise from dietary cereals. Even small amounts of phytates have a strong inhibitory effect on iron absorption. Bran has a high phytate content as does high-extraction-rate flour. Fiber-rich foods have abundant phytates. A high dietary iron content does not counteract the inhibitory effect of fiber. Polyphenols are widely present in plants and some bind iron, particularly those in tea, coffee, and cocoa. They are also present in vegetables such as spinach and in some herbs and spices. Calcium as a salt or in milk and cheese interferes with both heme and nonheme iron absorption (4).

Absorption of food iron is enhanced by the presence of meat, poultry, seafood, and ascorbic acid. Ascorbic acid, as such or derived from fruit and vegetables, is a potent enhancer of iron absorption, probably by reducing ferric to ferrous iron. Iron can probably only be absorbed in its ferrous form. Apart from their effect as a reducing agent, iron-ascorbate complexes are absorbed as such. Other weak organic acids such as citric acid may also enhance absorption of nonheme iron. Why meat, fish, and other seafood enhance absorption of nonheme iron is not clear.

Apart from the composition of the diet, the amount of iron absorbed is affected by the

subject's iron status. Substantial iron stores decrease iron absorption, particularly of nonheme iron, and conversely, iron deficiency is accompanied by an increase in iron absorption to a maximum of 4 mg/24 h. This, however, is still short of the daily iron requirement in the latter months of pregnancy.

Total Dietary Iron Intake

Daily iron intake per capita in 137 countries ranged from 14.4 to 20.2 mg (2). Animal produce was a major contributor of iron in only 23 of these countries. This iron intake should be enough to meet a requirement of 1 to 2 mg daily, but it often does not do so because of the low availability of the iron in these diets. A comparison of the diet and iron status of 50 vegetarians and 50 matched subjects on mixed diets showed that the vegetarians consumed 16.8 mg iron daily compared with 14.6 mg from the mixed diet, but those on a mixed diet had larger iron stores. Serum ferritin levels in vegetarians were 36.6 ng/mL, compared with 105.4 ng/mL in those on a mixed diet (6).

Diets provide iron of low, intermediate, or high bioavailability (2). The data refer to iron absorption by individuals with no iron stores but with normal iron transport. A low-iron-bioavailability diet (iron absorption about 5%) is a monotonous diet of cereals, roots, and/or tubers and negligible amounts of meat, fish, or foods likely to contain ascorbate. These foods often contain inhibitors to iron absorption present in maize, beans, whole wheat flour, and sorghum and are largely consumed in lower socioeconomic groups in developing countries. Diets consisting largely of cereals may allow only 1 to 2% of the iron to be absorbed. This diet does not meet the needs of menstruating or pregnant women but may suffice under other circumstances.

Intermediate-iron-bioavailability diets (iron absorption about 10%) consist mainly of cereals, roots and/or tubers, some food supplying ascorbate, and minimal food of animal origin. A low bioavailability diet can be changed into one of intermediate bioavailability by increased intake of meat, fish, or ascorbate. A high bioavailability diet can be changed to one of intermediate iron availability by simultaneous consumption of tea or coffee, which contain inhibitors to iron absorption. This diet may meet the needs of some menstruating women but not the needs of pregnant women.

A high-iron-bioavailability diet (iron absorption about 15%) is a mixed diet with good quantities of meat, poultry, fish, and foods of high ascorbate content. It is typical of the diet in industrialized countries. It is adequate for menstruating women but without substantial iron stores will not meet the needs in many pregnancies.

Human breast milk contains about 0.5 mg iron per liter. The bioavailability is high; 50% of this iron is absorbed. This contrasts with cow's milk formulas or unfortified cow's milk, in which only 10 to 20% of the iron is available for absorption. Cow's milk formulas are usually fortified with iron to supply 6 to 12 mg/L. Breast milk supplies sufficient iron to full-term infants to meet their needs for the first 4 to 5 months of life. Weaning foods often consist of cereals with iron of low bioavailability. Thus many have iron and ascorbate added, and they are a major source of iron in the first year or two of life. The 1989 U.S. RDA for iron is shown in [Table 88.3](#). See also Appendix [Table II-A-2](#), [Table II-A-2-a-2](#), [Table II-A-2-a-3](#), [Table II-A-2-b-1](#), [Table II-A-2-b-2](#), [Table II-A-2-b-3](#), [Table](#)

Prevalence of Iron Deficiency

Conservative estimates indicate that at least 700 million individuals worldwide have overt iron deficiency anemia. Major factors contributing to widespread iron deficiency include diets low in available iron, intestinal blood loss where hookworm infestation is prevalent, and demands for iron that cannot be met during pregnancy and growth. In African countries, millet, sorghum, or maize is the staple food, and in many parts of Asia, it is rice. Anemia is present in 36% of the population in developing countries and in about 8% of the population of developed countries. It is the most prevalent nutritional deficiency in the world. The frequency of iron deficiency in the U.S. is shown in [Table 88.4](#).

Age (Years)	Males	Females
1-2	92	92
3-10	61	61
11-14	35-121	61
15-44	About 20	25-142
45-74	About 20	61

Table 88.4 Incidence of Iron Deficiency (%) in the United States Assessed by the National Health and Nutrition Examination Study

In clinical practice, iron deficiency is equated with blood loss, except in pregnancy and early childhood, when unmet demands for iron are the main factors. This is the proper clinical approach, since bleeding lesions in the gut, benign or malignant, and menorrhagia in women are generally amenable to intervention. A mixed diet is expected to supply enough iron when there is a normal iron requirement.

Clinical practice in communities that are largely vegetarian brings home the fact that

purely nutritional factors are of great importance. A study of megaloblastic anemia in an affluent Hindu community of strict lifelong vegetarians generally taking only cow's milk as the only form of animal food, showed that two-thirds of 138 patients had overt iron deficiency, 53 women and 38 men. Stainable iron stores in bone marrow were absent in 70%. There was no abnormal blood loss (14).

Signs and Symptoms in Iron Deficiency Anemia

There may be no clinical complaints, and evidence of iron deficiency may come to light as the result of a blood count. Most patients, however, have symptoms of anemia (described above). In addition, they may have complaints attributable to iron deficiency directly. These include difficulty in swallowing and a sensation of a lump in the throat. They may have a sensation of pins and needles (paresthesia) in hands and feet. Some have a sore mouth and tongue, which may be aggravated by hot drinks or spicy food. There may be angular stomatitis (Fig. 88.1) and possibly reversible gastric atrophy. Pica (eating of materials such as ice, clay, paper, dirt, etc.) occurs, particularly in children. Obsessive eating of ice (pagophagia) may be specific to iron deficiency and disappears within 1 to 2 weeks of iron treatment. Eating of ice was noted in 8.1% of 553 African American women with iron deficiency in pregnancy (5).

Examination reveals pallor, pale blue sclera, and nails that break easily and may be misshapen and even spoon shaped (koilonychia). Heart and pulse rate may be rapid, and in severely anemic patients of longstanding, the spleen may be enlarged, and the edge palpable under the left costal margin. Radiography may show a web in the oesophagus (postcricoid web) and atrophic gastritis. Less well established are observations indicating impaired work performance and muscle function, possibly due to an effect of iron lack on enzymes.

There is impairment of both cell-mediated (T-lymphocyte) immunity and neutrophil killing of phagocytosed bacteria by white blood cells from iron-deficient patients. Ingested organisms are killed by production of active oxygen species, including free hydroxyl radicals; this is termed the *respiratory burst*. Iron-containing enzymes including NADPH oxidase and cytochrome B are involved in generation of the active oxygen. Iron treatment, particularly with parenteral iron, can precipitate latent infection such as pyelonephritis and activate latent malaria. Indeed, patients from areas where malaria is endemic should be given iron therapy with antimalarial prophylaxis.

Impaired mental development was found when hemoglobin levels were below 10 g/dL at 5 years of age (7), manifested in lower scores in mental and motor function, although results became normal when tests were repeated after iron therapy. The children showed reduced attention and poor learning performance. The iron content of parts of the brain is comparable to that of liver and continues to increase until the third decade of life. Iron uptake in the central nervous system (CNS) is effected by a transferrin system comparable to that in the bone marrow.

In pregnancy, iron deficiency is accompanied by increased maternal morbidity including premature labor and low-birth-weight infants (8).

Diagnosis of Iron Deficiency

A blood count shows a reduced hemoglobin level and hematocrit ([Table 88.1](#)) and a fall in the size of the red blood cells to below 80 fL (femtoliters). Smaller red cells contain less hemoglobin, so that the mean corpuscular hemoglobin (MCH) is below 27 pg (picograms). In early anemia, the stained blood film often shows the smaller red cells to be fully hemoglobinized, but as the hemoglobin falls, hypochromia is visible. In severe anemia, the red cell appears as a thin pink ring ([Fig. 88.2](#)). The nuclei of the neutrophil polymorphs tend to have an increased number of lobes.

Figure 88.2. Peripheral blood film from a patient with severe iron deficiency anemia.

The serum iron level falls below the normal range of 11 to 28 $\mu\text{mol/L}$, and the serum iron-binding capacity rises above the normal range of 47 to 70 $\mu\text{mol/L}$. Transferrin saturation falls below the normal range of 16 to 60%. At these low iron levels, there is poor release of iron to normoblasts. Serum ferritin is below 11 $\mu\text{g/L}$, and stainable iron is largely absent from bone marrow particles.

Differential diagnosis

Apart from iron deficiency, small red blood cells are found in only a few situations, and these must be differentiated from iron deficiency. The newborn has larger red blood cells than adults, but they are soon replaced by cells that are substantially smaller than adult red blood cells. Not until the midteens does the mean MCV reach adult levels. Diagnosis of iron deficiency in children requires confirmation by serum iron and serum ferritin levels.

Thalassemia syndromes are accompanied by small red cells. Suspicion that the diagnosis is thalassemia trait rather than iron deficiency is suggested by a relatively high red cell count exceeding 5.5 to 6 million/ μL . In uncomplicated thalassemia trait, serum iron

and ferritin levels are normal, and the hb a₂ level in red cells is raised in b-thalassemia trait.

Anemia of chronic disorders may resemble iron deficiency, both having small red blood cells and a low serum iron level, but the serum iron-binding capacity is normal or low in the anemia of chronic disorders, whereas in iron deficiency it is raised. However, serum ferritin levels are normal in the anemia of chronic disorders even when there is accompanying iron deficiency. Similarly serum ferritin levels remain normal when iron deficiency is accompanied by liver disease.

Copper deficiency may be accompanied by a microcytic anemia that is unresponsive to iron therapy.

Nutritional deficiency, as a factor in producing iron deficiency, may be suspected from a careful assessment of the diet. A diet likely to be deficient in available iron is a strictly vegetarian one from which foods of animal origin are excluded. At the same time, exclusion of blood loss is essential. A good clinical history often provides a clue to gastric or gut problems, medication with aspirin or nonsteroidal analgesics, and menstrual blood loss. Fecal blood loss is often intermittent, and repeated tests for occult blood loss are needed. Where hookworm is endemic, hookworm ova will be present in fecal samples.

Iron Deficiency in Pregnancy

Pregnancy is accompanied by important changes in plasma and red cell volume that affect the hemoglobin concentration. The plasma volume expands by about 1000 mL, and the red cell volume by about 300 mL. The greater expansion of plasma volume results in dilution of red cells. The mean hemoglobin falls from 13.5 g/dL in nonpregnant women to 12.5 and 12.0 g/dL at 15 and 30 weeks of pregnancy, respectively. Thereafter there is some hemoconcentration, with a rise in hemoglobin to a mean of 12.8 g/dL at 38 weeks. At 30 weeks gestation, hemoglobin in iron-replete women ranges from 10.0 to 14.5 g/dL. At the same time, there are physiologic changes in the size of the red cells. These increase in size from a mean of 85 fL to 89 fL, but in some women the increase can reach 20 fL, so that the MCV is 105 fL. This is not influenced by folate supplements but is diminished or absent if the subject also has iron deficiency and/or b-thalassemia trait.

An extra 1000 mg of iron must be found in the second and third trimester to meet the needs of a normal singleton pregnancy. This has to be set against the total body iron present in an adult woman of 2500 mg with a normal iron absorption of 1 to 2 mg/day, increasing to 4 mg/day in the third trimester. It is unusual for sufficient iron stores to be present to meet such demands, and this amount is more than can be absorbed from a good diet. Serum iron and ferritin levels both fall steadily throughout pregnancy. In a study of over 2000 women not given any iron during pregnancy, not only did the hemoglobin level remain low to term, but even 1 year after childbirth, the mean hemoglobin of the group was still below the level present in the first blood sample taken in early pregnancy (9). Iron deficiency in pregnancy is due to increased demands for iron that cannot be met from stores and diet. It is coupled with poor nutrition insofar as a

poor iron intake prevents formation of adequate iron stores and fails to provide sufficient iron to meet immediate needs.

The diagnosis of iron deficiency in pregnancy is the same as in other situations. It is found in about one-third or more of pregnant women who do not receive an iron supplement from early pregnancy. A hemoglobin level below 10 g/dL is low. During the last 30 years, a combined iron and folic acid tablet has been given in pregnancy in most developed countries and proved so successful in removing anemia as a significant problem in pregnancy that a generation of midwives and obstetricians are in practice in affluent societies who see little anemia in their antenatal practice, and many advocate treatment only when anemia is diagnosed. It may be that better diet and widespread use of a contraceptive pill have improved the iron status of women, but it is unlikely to have changed the balance so greatly that women now have sufficient iron in pregnancy. A recent study comparing iron and placebo in pregnancy in Dublin showed the expected fall in hemoglobin in the placebo group; the mean hemoglobin level at term in the supplemented group was 13.6 g/dL, compared with 11.9 in the placebo group (10).

There is also some resistance to iron medication in pregnancy due to side effects experienced by some, including abdominal cramps and constipation. Much of the blame for this can be laid on the drug companies who want their pills to have at least as much iron as is supplied by their competitors, and this amount is 200 to 300 mg/day ferrous sulfate or its equivalent. The more iron, the greater are the side effects. As little as 30 mg ferrous sulfate once daily is fully adequate (11). Doses under 30 mg have not been tested but may well be enough.

Infants, Children, and Adolescents

In utero iron stores are built up in the fetus in the last few weeks of pregnancy. Premature birth curtails transfer of iron from mother to child, and premature infants need iron supplements at an earlier age than normal infants. Thereafter, rapid growth with expansion of the red cell mass increases iron needs, and if diet fails to supply enough iron, iron deficiency appears.

Fortification and Treatment

Fortification of food such as flour to improve intake of iron has not been successful. Addition of metallic iron was not beneficial because the iron remained insoluble and unavailable. Addition of soluble iron made the bread unpalatable. Addition of iron to individual foods such as cereals has been more successful, and iron is widely added to prepared infant foods. At present in the U.S., 4.4 mg iron is added per 100 g flour.

Iron deficiency is treated by soluble iron salts, of which ferrous sulfate, generally as a 200-mg tablet three times a day, is the most widely used. Many other preparations are available. They should be taken apart from meals, and ascorbate as in orange juice enhances iron absorption. Response to the iron is shown by clinical benefit and a rise in hemoglobin level of about 1 g/week. To build up iron stores, treatment should continue for about 6 months. Side effects include abdominal discomfort and constipation and are

dealt with by reducing the dose. Symptoms usually disappear after about 10 days.

COBALAMIN

Cbl is a pink, water-soluble vitamin. The main part of the molecule is similar in structure to heme but with cobalt replacing iron in the center of the pyrrole ring. Cbl is required for the integrity of blood formation, maintenance of the nervous system, and normal function of folate. The source of cbl is bacterial synthesis. Cbl is present in all diets containing food of animal origin and is totally absent in strictly vegetarian diets except as a result of bacterial activity or contamination from animal sources. Fruit bats obtain cbl by inadvertent consumption of insects on fruit. Bats on a diet of washed clean fruit die of cbl neuropathy in 9 months. In man, nutritional cbl deficiency occurs only in strict vegetarians.

Physiologic Considerations

A full account of the basic aspects of cbl is set out in [Chapter 27](#). Cbl is present in meat, poultry, fish and other seafood, and dairy products. In the U.S., meat, poultry, and fish supply 74.8% of dietary cbl, dairy products 19.7%, eggs 3.7%, and other foods 1.8% ([12](#)). Liver is a rich source (see Appendix [Table IV-A-23-a](#)). Cbl is stable, resists cooking, and is only destroyed in very alkaline conditions when the pH exceeds 12. In food, cbl is present as a coenzyme linked to protein in methionine synthase and in methylmalonyl-CoA mutase. Small amounts are present on transport proteins termed *transcobalamins*. There is no free dietary cbl.

Availability and Absorption of Cobalamin

Most cbl present in food is available for absorption, although there are reports of cbl in egg being less well absorbed. That from meat or liver is as well absorbed as aqueous cbl ([13b](#)). It has been proposed but not proven that failure to separate cbl from binding proteins in the gut is a cause of cbl malabsorption. If so, it is not a known cause of cbl deficiency producing anemia in man ([13a](#)).

There is a limit to the amount of cbl that is absorbed from a single dose or meal, probably because of saturation of cbl-intrinsic factor-binding sites in the small gut. This amount is about 1.0 to 1.5 μg ([13](#)). A second dose of cbl given 4 to 6 hours after the first is absorbed normally, so if three adequate meals are taken daily in a mixed diet, at least 4.5 μg of cbl can be absorbed. Daily food intake in men taking a mixed diet containing 70 g protein and 2400 kcal supplied 5.2 μg cbl, and one with 53 g protein and 1400 kcal in women had 5.6 μg cbl. The daily intake ranged from 0.4 to 85.5 μg , being heavily influenced by consumption of liver or other rich sources ([13b](#)). A vegetarian diet supplies between 0.25 and 0.5 μg cbl daily, derived from bacterial activity in the food, from water, and from animal products such as milk.

Cobalamin Requirement

Diets supplying 0.5 μg cbl or less daily are associated with a high proportion of subjects

having abnormally low serum cbl levels. Among Hindu vegetarians, more than half the population have low serum cbl levels (14). Patients with megaloblastic anemia due to nutritional cbl deficiency have similar cbl intakes. Such a cbl intake is clearly not adequate; an adequate cbl intake is one that maintains the serum cbl at the level found in those on mixed diets. This intake is probably nearer 1 to 2 µg/day cbl, the usual RDA in most countries (Table 88.3). Cbl is one of the nutrients for which the dietary sources in a mixed diet exceed the requirement. The total body pool of cbl in adults taking a mixed diet ranges from 2.5 to 5 mg. With a daily requirement of 1.0 µg, such cbl stores should suffice for 2500 days or more.

Cobalamin-Folate Metabolism: The Formate-Starvation Hypothesis

The biochemical pathways requiring cbl are discussed in Chapter 27. The methyl-folate trap was proposed to explain how cbl interacted with folate, but the few studies that tested this hypothesis failed to support it (15). More recently, considerable evidence has pointed to a failure in the supply of formate needed for folate-mediated carbon unit transfers in cbl deficiency. This has been termed the *formate starvation hypothesis*.

The role of folate in transferring single carbon units including formate (-CHO) in the synthesis of a variety of compounds was noted 50 years ago. Some forms of formate could be used by cbl-deficient preparations, but others could not. Formate that was available to cbl-deficient tissue was termed *active formate*. Twenty-five years ago, two studies found increased formate in the urine of cbl-deficient rats.

The observation that the anesthetic gas nitrous oxide (N₂O) destroyed reduced cbl provided an easy way to produce experimental cbl deficiency. Continuous N₂O administration in man leads to fatal megaloblastic anemia, and intermittent inhalation, to cbl neuropathy. The cbl-requiring enzyme regenerating methionine from homocysteine, methionine synthase, was inactivated in all species and in all tissues by N₂O. All folate-mediated pathways were impaired including those in which cbl had no direct role.

Folate given to cbl-deficient animals was not converted into the active coenzyme unless the folate had a formate group as part of the molecule. This and many similar studies suggested that cbl was concerned with formation of "active formate" needed to convert folate (actually tetrahydrofolate) into N¹⁰-formyltetrahydrofolate. The enzyme producing formylfolate was induced in cbl deficiency, indicating a lack of formylfolate. With impaired formate utilization in cbl deficiency, formate accumulated in tissues including blood, liver, and brain, and hence was lost into the urine. Two compounds bypassed the effect of cbl deficiency in a large variety of systems including synthesis of thymidine and cbl deficiency in man; these were N⁵-formylfolate (folic acid or citrovorum factor) and methionine. Formyltetrahydrofolate simply provided active formate; methionine did as well.

The pathway by which methionine bypassed cbl deficiency was via S-adenosyl-methionine and its utilization in polyamine synthesis when the methionine gave up three of its carbons. The methionine residue, methylthioribose, is regenerated into a new molecule of methionine using carbons from ribose to replace the missing

carbons used for the synthesis of polyamine. This reaction leaves behind a surplus carbon as formate (71). Using ^{14}C -methylthioribose incubated with bone marrow cells, it was shown that the residual labeled formate was used as a single carbon unit to provide carbons 2 and 8 of the purine nucleus and did so equally well in both normal and cbl-deficient bone marrow cells (72). Thus a major role for cbl and methionine is to make active formate available to the folate coenzyme (16).

The same defect likely underlies cbl neuropathy despite the wide variety of problems that have been described in relation to products of methionine metabolism (Chapter 26, Chapter 27 and Chapter 34). The reason for this view is that the fruit bat with fatal and histologically proven cbl neuropathy does not manifest any of these abnormalities of methionine metabolism, other than loss of methionine synthase activity, in the nervous system (17). However, the brain does accumulate formate in cbl deficiency, implying a defect of formate metabolism.

Prevalence of Nutritional Cobalamin Deficiency

As cbl is absent from the plant kingdom, cbl deficiency can occur with time in any strict vegetarian. This is the case with millions of subjects such as Hindu Indians. The mean serum cbl level among vegetarian Indian medical students was 121 pg/mL, compared with a mean level of 366 pg/mL in those taking a mixed diet. In London, 1000 consecutive samples from Indians who were largely vegetarian showed a mean serum cbl level of 198 pg/mL, compared with 334 pg/mL in an age-matched Caucasian group taking a mixed diet (18). The cbl level was low in 54% of the Indian subjects. A lower incidence of low cbl levels is encountered in Western subjects adopting a vegetarian diet. In Australia, an analysis of 3846 samples sent for cbl and red cell folate assay found 335 (8.7%) to be abnormal, and 20 of these patients appeared to have nutritional cbl deficiency (19).

Signs and Symptoms in Cobalamin Deficiency

Vast numbers of subjects who have nutritional cbl deficiency and a low serum cbl level as a result are well and appear to have no clinical problems. Thus among a community of 15,000 Hindu Indians, largely vegetarian, of whom 54% had low serum cbl levels, only 10 patients per year with cbl-deficient megaloblastic anemia were seen in one local hospital (14). Most are just in balance, with low cbl stores and a low cbl intake. Not infrequently, patients come to notice because macrocytosis has been found in a blood count, and such patients may have few complaints, though almost invariably, they feel better after cbl therapy. Most patients present with tiredness, lack of energy, shortness of breath, tingling in hands and feet, and a sore mouth and tongue.

A series of 95 patients with nutritional megaloblastic anemia, all Indian vegetarians, were seen over 14 years. There were 52 women and 43 men, and their ages ranged from 13 to 80 years (14). They complained of tiredness (33%), shortness of breath (25%), loss of appetite (23%), weight loss (22%), generalized aches (19%) generally due to calcium and vitamin D deficiency, vomiting (19%), paresthesia (11%), change in skin pigmentation (8%), sore mouth (7%), diarrhea (6%), headache (5%), and infertility (5%). In 6%, macrocytosis in a blood count was the first indication of clinical cbl

deficiency. All these patients had a megaloblastic bone marrow, and all had low serum cbl levels.

Examination showed pallor, a smooth tongue in some ([Fig 88.3](#) and [Fig 88.4](#)), and yellowish sclera in 13%. Indian patients may show increased pigmentation about the nails, and one patient with severe anemia showed splenomegaly. This 19-year-old male also had lost hair pigmentation and had gray hair; hair grown after the start of oral cbl therapy was jet black ([Fig. 88.5](#)).

Figure 88.3. Red “beefy” tongue in a 23-year-old male with cobalamin deficiency. For 1 year he complained that spicy food and, in particular, whiskey, produced a painful mouth and tongue.

Figure 88.4. Same patient as in [Figure 88.3](#) about 2 weeks after the start of cobalamin treatment. The tongue is normal in appearance, and the unpleasant symptoms after whiskey had disappeared.

Figure 88.5. Scalp hair of a 19-year-old Indian with nutritional cobalamin deficiency and a severe megaloblastic anemia. On presentation his hair was a dingy grey color. This picture was taken about 2 months after the start of oral cobalamin, 5 μ g/day. Cobalamin restored the normal pigment to the hair, which now grew jet black.

Neuropathy, if present, may manifest as symmetric tingling sensations in fingers and/or toes. There may be spastic movements, stiffness, and weakness. Difficulty with micturition includes hesitancy, a poor urinary stream, and even retention. Constipation and postural hypotension may be due to an effect on the autonomic nervous system. Irritability, memory disturbance, mild depression, and even hallucinations may occur. Visual impairment is uncommon. Loss of vibration sense, appreciation of passive movement, and a positive Romberg's sign may be present. There may be exaggerated reflexes and an extensor plantar, but others have a flaccid paralysis. Muscles may be wasted. Abnormal nerve conduction is found on electrophysiologic testing in 25% of patients.

In severe anemia, there is a fast pulse rate and low blood pressure. A soft systolic murmur may be present. Patients with severe anemia may be in cardiac failure with distended neck veins, swollen ankles, and cardiac enlargement.

Laboratory Findings

The diagnosis of cbl deficiency cannot be made on clinical grounds alone; it must be established by appropriate tests in the laboratory. Of these tests, a blood count and serum cbl level are the most helpful.

Blood Count. It is extremely rare to have clinically significant cbl deficiency without changes in the blood, and the vast majority of patients have large red cells shown by a raised MCV. Some patients may have a second blood disorder that produces small red cells; this is either a- or b-thalassemia trait or iron deficiency. In such a case the two diseases cancel each other out in so far as red cell size is concerned, and the MCV is usually normal; despite the normal MCV, the blood film is very abnormal, with bizarre red cell fragments. Cbl therapy restores the smaller red cells that characterize

thalassemia trait. Thalassemia trait is present in 5% or more of those of African or Asian stock.

Macrocytosis is the earliest change in the blood in cbl deficiency ([Fig. 88.6](#)) and, as the anemia becomes more severe, is followed by neutropenia and thrombocytopenia. The nucleus of the neutrophilic polymorphonuclear leukocyte tends to become hypersegmented ([Fig. 88.7](#)). With more severe anemia, variation in red cell size and shape appears. There are many causes of a raised MCV other than cbl deficiency; these include folate deficiency, alcoholism, hypothyroidism, young red blood cells, and medicinal drugs.

Figure 88.6. Early macrocytic anemia. The red blood cells are large compared with those in the strip on the *right*, which is a normal blood film.

Figure 88.7. A blood film from a patient with cobalamin deficiency showing a strikingly hypersegmented neutrophil polymorphonuclear leukocyte. The red blood cells show variation in size (anisocytosis) and are generally larger than normal (macrocytosis).

Bone Marrow. The blood changes are caused by abnormal blood formation in the marrow, and these changes, termed *megaloblastic*, are easily recognized with properly fixed and stained marrow preparations, even if the hemoglobin level is still 16 g/dL ([Fig. 88.8](#)). There is nothing particularly subtle about this as some have claimed. It has become very unfashionable to carry out marrow examination merely to establish megaloblastosis, and as a result, undue weight is being placed on other accompanying and newer laboratory tests that have not been well explored. When the blood count, blood film, and clinical picture all strongly suggest a megaloblastic anemia, marrow examination can be omitted, and one can await the results of serum cbl and red cell folate estimations.

Figure 88.8. Bone marrow film from a patient with severe megaloblastic anemia. The cells with finely stippled nuclei and gray cytoplasm are red cell precursors called megaloblasts.

Serum Cobalamin Level. The serum cobalamin level is the most important single test needed for the diagnosis of cbl deficiency because it is always low, provided the patient has normal cbl-binding proteins. There are no exceptions to this rule! Nevertheless, recently it has been claimed that cbl deficiency, particularly with neuropathy, occurs in elderly patients with a normal blood count and a normal serum cbl level. These patients have an elevated level of methylmalonic (MMA) in serum and are said to respond to cbl therapy. A raised level of MMA is present in a large majority of patients with cbl-deficient megaloblastic anemia but also in subjects with normal cbl levels who do not have megaloblastic anemia ([13a](#)). The test, as currently performed, lacks specificity. It is far more likely that the correct diagnosis in the patients with neuropathy and a normal serum cbl level is something other than cbl deficiency, such as osteoarthritis, and such patients have osteophytes pressing on nerve fibers. As the nerve stretches to accommodate the pressure of the osteophyte, the neuropathy is relieved, and the cure is attributed to cbl therapy. A normal serum cbl level excludes a diagnosis of cbl deficiency. The normal level of serum cbl is 170 to 800 pg/mL, and levels below 170 are

low. But there are other causes of low serum cbl that must always be considered.

Cbl assays are difficult to do well consistently, and at one time or another, most laboratories run into problems. It is not unusual for an assay to give too low a result and, less often, one that is too high. Rigid quality control procedures are essential to detect any problems in the test. These apply to isotope dilution methods with purified intrinsic factor as well as microbiologic assay methods. If there is any doubt a repeat assay in another laboratory is desirable. It is also wise to withhold treatment with cbl until such matters have been settled.

Some 30% of subjects with simple atrophic gastritis have a low serum cbl level and may even have cbl malabsorption, but the blood is and remains normal. At least 10% of the elderly have severe atrophic gastritis. Large numbers of strict vegetarians have low serum cbl levels but are hematologically normal. In these groups the low serum cbl level probably mirrors low cbl stores, with intake just balancing requirement. It is from these groups that patients with cbl-deficient megaloblastic anemia arise. About 5% of normal pregnant women have low serum cbl levels and are not cbl deficient. This is due to preferential transfer of absorbed cbl to the placenta and fetus in late pregnancy at the expense of maintaining the plasma level. About one-third of patients who have a megaloblastic anemia that is due to folate deficiency (and not to cbl deficiency) also have a low serum cbl level. The reason is not understood, and the serum cbl rises (often quite dramatically) into the normal range within a few days of folic acid treatment.

Not uncommonly, no explanation can be found for a low serum cbl level in a person who is otherwise normal. One report concerned 196 consecutive serum samples with cbl levels all below 170 pg/mL; 55% had a raised level of MMA and/or homocysteine and were accepted as being from patients with true cbl or folate deficiency, but 45% had no other abnormality. In a few such patients, liver biopsy has confirmed normal stores of cbl. Thus a low cbl level in the absence of the appropriate blood and bone marrow changes and in the absence of appropriate neuropathy is not likely to indicate clinically significant cbl deficiency (20). Such patients do not require treatment.

Methylmalonic Acid (MMA). MMA is formed from propionic acid and amino acids such as valine and isoleucine. MMA is converted to succinic acid by methylmalonyl-CoA mutase, which requires cbl as a coenzyme. MMA accumulates in cbl deficiency. Urinary excretion of MMA after an oral dose of 10 g valine was found to be abnormal in 74% of patients with proven cbl deficiency and a megaloblastic anemia; there were no abnormal results in 22 patients with folate-deficient megaloblastic anemia. The excretion of MMA returned to normal 3 to 5 days after cbl treatment. False-positive results were obtained when the assay was conducted by colorimetric methods (21). Although urinary excretion of MMA after stressing the pathway with a precursor such as valine is not applied widely, it may reflect the activity of this pathway more accurately than the newer serum MMA assay.

Recently, MMA has been assayed in serum. An increased MMA level in serum is found in a high proportion of patients with cbl deficiency, generally upward of 86% (22). More than 10% of subjects with normal serum cbl levels, such as elderly subjects in the Framingham population (23), 51 elderly European subjects (24), children on macrobiotic

diets (25), alcoholics with folate deficiency (26), and patients with thyroid disease (27) have a raised serum MMA. One-third of sera from pregnant women had raised levels of MMA irrespective of the serum cbl level (60). The normal serum cbl level in these groups makes it unlikely that the raised MMA is due to significant cbl deficiency (13a).

The raised MMA levels with normal cbl levels were used to imply, generally with no additional evidence, that the serum cbl level was misleading and insensitive as a marker of cbl deficiency. This overlooks a half century of experience with the serum cbl level that has stood the test of time. It ignores enormous efforts made to detect cbl deficiency in the elderly and other possibly susceptible groups such as those with psychiatric and neurologic problems; these have failed to find missed examples of cbl deficiency. The largest discrepancy occurs in the elderly.

Data from claims to Medicare in the U.S. in 1991 indicate that in a 5% sample comprising 1.8 million persons, 18,068 made a claim relating to cbl deficiency. This is 1% of this population largely over 65 years of age. On the other hand, measurement of MMA levels in 548 elderly subjects in Framingham showed raised levels in 82 (15%) (23). The MMA level suggests a frequency of cbl deficiency 15-fold higher than the probably true incidence of pernicious anemia, the usual cause of cbl deficiency in the elderly.

It seems that more study is needed in relation to the precise significance of raised MMA serum levels. Megaloblastic anemia and cbl neuropathy are due to impaired methionine synthase; a raised MMA level is due to change in function of methylmalonyl-CoA mutase. Changes in activity of these two enzymes do not run in parallel; hence the different set of results when tests for these enzymes are used to assess cbl deficiency.

Serum Homocysteine (Hcy). Hcy is usually raised in most patients with megaloblastic anemia due to either cbl or folate deficiency and thus does not help differentiate between these two situations. There are other reasons for a raised Hcy level (see [Chapter 34](#) and [Chapter 61](#)), so the test is of limited usefulness (19).

Deoxyuridine Suppression Test. The deoxyuridine suppression test is carried out with a suspension of bone marrow cells and measures the synthesis of thymidine, which is impaired in both cbl and folate deficiency. In the test, deoxyuridine, the precursor of thymidine, is added to bone marrow cells. Most of the thymidine needed by the bone marrow cells will be met by synthesis from deoxyuridine (the synthetic pathway). Thereafter tritium-labeled thymidine is added and any requirement not met by synthesis from deoxyuridine is met by uptake of thymidine (salvage pathway). DNA is extracted, and thymidine uptake is measured. Normally less than 10% of thymidine is taken up. A 100% value is obtained by incubating bone marrow cells with thymidine alone. In cbl- or folate-deficient marrows, more than 10% of the thymidine is taken up. The deoxyuridine is held to have suppressed thymidine uptake.

In cbl deficiency, the defect is partially corrected by adding cbl to the system. Folate (as such or as 5-formyltetrahydrofolate) produces complete correction in both cbl and folate deficiency. This is a specific way of diagnosing these deficiencies, and results confirm the great value of serum cbl assays. The test becomes abnormal within a few hours of

inactivating cbl by inhaling N₂O and returns to normal within a few hours of reversing the effect of cbl deficiency with folinic acid (16). However, some technicians have difficulty in carrying out this test properly. This may be indicated by failure to get a result of less than 10% uptake of labeled thymidine with normal marrow and, secondly, by a failure to get complete correction when folinic acid is added to the system.

A recent report found that among 50 patients with low serum cbl levels but normal or "limited megaloblastic" marrow change, 19 had a deoxyuridine suppression test result suggesting cbl deficiency, but only 10 had a raised MMA level (70). One-quarter of elderly patients selected on the basis of a low serum cbl level or a low red cell folate level had an abnormal deoxyuridine suppression test result, suggesting that the test may provide early evidence of transition to megaloblastic hematopoiesis (68).

The Hematologic Response. The response to treatment provides further evidence for the diagnosis of cbl deficiency, provided the response is optimal. In cbl deficiency, an injection of cbl is followed by a most gratifying clinical response with a remarkable feeling of well-being within 1 to 2 days and a dramatic return of appetite, etc.

There is a rise in reticulocytes (young red blood cells), which reach a peak 5 to 7 days after the start of treatment, and there is a rise in hemoglobin and red cells, which exceed 3 million/ μ l by the third week. Minor responses do not provide evidence of deficiency, since they are not uncommon after a host of interventions, including administration of substances given as part of diagnostic tests such as histidine and others such as glycine, choline, thymidine, pyrimidine, and even antibiotics and DNA (22, 28).

In the case of nutritional cbl deficiency, it is often desirable to treat with oral cbl; the response is far more subdued but in time restores a normal blood picture. Response to 5 μ g cbl daily by mouth is proof of nutritional cbl deficiency.

Folate Estimations. If the patient has megaloblastic anemia, the usual alternate diagnosis to cbl deficiency is folate deficiency. Serum folate has little diagnostic value but can be marginally raised in a small proportion of patients with cbl deficiency. The red cell folate level is more useful. A normal value (145 to 450 ng/mL packed red cells) generally excludes folate deficiency other than in pregnancy, but a reduced value is almost always present in folate deficiency and is also present in about half of patients with cbl deficiency.

Cobalamin Absorption Tests. Other than nutritional cbl deficiency, all the conditions producing cbl deficiency share a failure in the intestinal absorption of cbl. The usual cbl absorption test, such as the Schilling test, involves giving the patient an injection of 1000 μ g of cbl. This constitutes complete treatment and means that the chance of obtaining positive evidence for the diagnosis of nutritional cbl deficiency by demonstrating a response to 5 μ g cbl once daily by mouth, is lost. If the absorption of cbl is normal and the patient responds hematologically following the injection of cbl, then the likely diagnosis remains nutritional cbl deficiency, provided that the patient is a strict longstanding vegetarian. If there is malabsorption of cbl, the most likely diagnosis is pernicious anemia or another disorder producing cbl deficiency. Such disorders include

gastric surgery, abnormal small gut flora due to blind intestinal loops, strictures, diverticula, gut resections, and Crohn's disease. Disorders of the wall of the small gut producing cbl malabsorption include gluten sensitivity, tropical sprue, ileal bypass or resection, radiation damage, and drugs including alcohol. Five of 95 patients with nutritional cbl deficiency were found to have transient cbl malabsorption that disappeared after a few months of cbl therapy (14), and one-third had steatorrhea and xylose malabsorption. These latter findings also disappeared with cbl therapy.

Diagnosis

Diagnosis of nutritional cbl deficiency depends on establishing cbl deficiency in a person whose diet largely lacks all sources of cbl and in excluding cbl deficiency due to cbl malabsorption as in pernicious anemia, small intestinal bacterial overgrowth, and intestinal resection. Consumption of milk and occasional eggs and cheese will not supply enough cbl. Finding antibodies to intrinsic factor makes it likely that the diagnosis is pernicious anemia. In the study of Indian vegetarians, 95 patients had nutritional cbl deficiency, but another 20 had pernicious anemia, and only 4 had folate-deficient megaloblastic anemia, associated with excess alcohol in 2 and pregnancy in the other 2 (14). Restoration of a normal blood picture with 5 µg/day cbl by mouth prove that the diagnosis is nutritional cbl deficiency, since those with cbl malabsorption will not absorb sufficient cbl from this dose to restore normal hematopoiesis.

Cobalamin and Infection

Recurrent infections were found in a 6-year-old boy with an inherited abnormality of cbl transport (transcobalamin II deficiency) and consequent severe cbl deficiency. They were caused largely by the inability of this patient to produce antibodies; he could not generate a lymphoid response following contact with a foreign antigen until he was given regular cbl therapy (29).

Cbl-deficient neutrophils have an impaired respiratory burst, which prevents normal killing of phagocytosed bacteria. All patients with cbl deficiency and a red cell count below 2.0 million/µL gave an abnormal result when tested for neutrophil killing of phagocytosed bacteria, including several with nutritional cbl deficiency. Patients with folate deficiency were normal, other than those who were alcoholics. Phagocytosis was normal. The abnormal tests returned to normal 10 to 17 days after cbl treatment. This is the time required to produce a new post-cbl population of neutrophils in the bone marrow and have them reach the blood and tissues (30).

There is a high incidence of tuberculosis in the Indian community in the U.K. A survey of tuberculosis notification in the U.K. showed that if the incidence of tuberculosis in Caucasians was given a value of 1, in Asiatic Indians it was 38, in Africans from the Caribbean it was 3, and in Africans it was 13. Tuberculosis is known to be more common in new immigrant communities, but the Indian community in the U.K. is relatively prosperous. It was wondered whether the impaired neutrophil and presumably impaired macrophage killing of ingested bacteria in cbl deficiency could have a role in increasing susceptibility to tuberculosis. Furthermore, one of the components of the cell wall of *Mycobacterium tuberculosis* is mycocerosic acid, and MMA is an obligatory

substrate for its synthesis. MMA accumulates in cbl-deficient tissues. To test whether cbl deficiency had a role in producing the high susceptibility to tuberculosis a dietary questionnaire was sent to over 2400 Indian subjects whose names were obtained from lists of patients registered with doctors in the Harrow area of London. At the same time, permission was sought to look at the clinical records of the patients for history of tuberculosis. A positive response was obtained from 1187 subjects. Tuberculosis had been diagnosed in 13.3% of vegetarians and 4.8% of those on mixed diets. This difference was highly significant (18).

Nutritional Cobalamin Deficiency in Infancy

Cbl stores are transferred to the fetus in the last 2 months of pregnancy. Cbl levels in cord blood (373 pg/mL) are significantly higher than those in maternal blood at term (240 pg/mL). Low cbl stores in the mother, whether due to a longstanding vegetarian diet or to undetected pernicious anemia, is accompanied by inadequate cbl transfer in utero. Furthermore, the cbl level in breast milk is the same as that in maternal serum, and if this is low, the infant will not receive enough cbl. Most severely cbl-deficient women are infertile, but some do conceive and may have a relatively uncomplicated pregnancy. A significant number of infants with megaloblastic anemia and even neuropathy due to nutritional cbl deficiency have been reported, and even irreversible mental impairment has ensued.

Almost all such infants develop normally for the first 4 months of life. Thereafter they decline and are usually seen clinically between 6 to 14 months of age. The infants become irritable and lethargic, decline solid food, and are weak. They stop smiling, do not support their heads, and do not turn over. They have marked hypotonia and some choreoathetoid movements of upper limbs or constant wringing of hands. Their eyes do not fix or follow objects. They may even be in coma. Some have abnormal pigment on the back of their hands and about the nails. There is developmental delay, anemia (sometimes very severe), and usually enlarged liver and spleen. The blood is macrocytic, and marrow is megaloblastic. The serum cbl level is low, as is that of the mother. Response to cbl is excellent, and provided the delay in diagnosis has not been too long, recovery is complete and rapid (31, 32).

Treatment of Cobalamin Deficiency

With the exception of nutritional cbl deficiency, all patients with cbl deficiency have cbl malabsorption. Thus treatment must be given by intramuscular injection of large doses of cbl, usually 1000 µg every 2 months. Large doses of cbl can be given by mouth when, even in PA, about 1% is absorbed by passive diffusion. This must be taken daily to achieve an adequate intake of at least 1 µg/day. It is not recommended.

Patients who have nutritional cbl deficiency can absorb cbl normally and should be treated with oral cbl taken once daily. The preparation often has up to 50 µg cbl per tablet. This has to continue as long as they maintain a largely cbl-free vegetarian diet. Addition of cbl to cereals is widely practiced and is an important source of cbl in a vegetarian diet.

FOLATE

Folates are a group of labile compounds required for transfer of single-carbon units in a variety of biochemical pathways including synthesis of three of the four nucleotides of DNA. They are discussed in [Chapter 26](#).

Physiologic Considerations

All foods contain folates. They are all reduced (i.e., they are tetrahydrofolates); most have five to six glutamic acids (i.e., they are folatepolyglutamates), two-thirds carry a methyl group, a quarter a formyl group, and 9% are without an additional single-carbon unit. Endogenous enzymes called conjugases, present in foods and tissues, remove all glutamate residues but one, and the reduced state of the pteridine moiety renders the folate very susceptible to oxidation, even by atmospheric oxygen. This is aided by exposure to UV light and by warmth. The oxidized molecule tends to be split into separate pteridine and *p*-aminobenzoate portions, so the folate is destroyed.

Intestinal Absorption

Folates are absorbed in the upper gut. Enzymes on the brush border as well as in the lysosome of the intestinal cell remove all glutamate residues but one, and in the enterocyte, the folate monoglutamate is converted into 5-methyltetrahydrofolate, which enters the portal circulation. Studies with tritium-labeled folates and a fecal excretion method in which the tritium of the unabsorbed folate was converted to tritium-labeled water showed almost complete absorption of reduced folate monoglutamates and some 79% absorption of oxidized pharmacologic pteroylglutamic acid. Precise data on the absorption of reduced folate polyglutamates are not available, but most believe some 70% are absorbed.

Folate Intake

Data on dietary folate are relatively imprecise because of the instability of natural folates, the large number of folate analogues present, and the difficulties in carrying out reliable microbiologic folate assays in complex material. A tired lettuce purchased days ago may have half the folate shown in food tables; one just collected from the vegetable patch may have twice the content. The folate content of foods is given in Appendix [Table II-A-23](#), [Table II-A-23-b](#) and [Table II-A-23-c](#). Assays of duplicate food collections are probably better than data derived from food tables. A Swedish study using duplicate food collection among the elderly, found a 24-h folate intake for men of 361 μg and for women, 129 μg ([33](#)). A Canadian diet supplied 205 $\mu\text{g}/24$ h for men and 149 μg for women ([34](#)). In the U.S., 24-h folate intakes have been reported from 152 to 250 μg , and in the U.K., the daily intake assessed over 3 years was between 210 and 213 μg . The recommended daily allowance is generally agreed to be 3.1 μg folate per kg body weight per day ([Table 88.3](#)). This is about 200 μg folate daily for a 65-kg male and 170 μg for a 55-kg female. Total body content of folate in man is about 10 to 15 mg.

Both mixed and vegetarian diets supply ample folate, but poor cooking practices can reduce the folate content considerably. Reducing substances such as ascorbate protect natural folates from oxidation and degradation. Much of the folate is lost by boiling in large volumes of water, but steaming has an equal effect. The loss is between 80 and 95%. Frying foods in an open pan results in loss of 50 to 95%. Dietary intake has been assessed on cooked foods.

Prevalence of Nutritional Folate Deficiency

Surveys of red cell folate levels in populations taking apparently adequate amounts of folate show low levels in 8% of the population. The frequency of low red cell folates in the NHANES II study in the U.S. is shown in [Table 88.5](#). (See also Appendix [Table A-2-a-1](#), [Table A-2-a-2](#), [Table A-2-a-3](#), [Table A-2-b-1](#), [Table A-2-b-2](#), [Table A-2-b-3](#), [Table A-2-b-4](#), [Table A-2-b-5](#), [Table A-2-b-6](#), [Table A-2-c-1](#), [Table A-2-c-2](#), [Table A-2-c-3](#), [Table A-2-c-4](#), [Table A-2-c-5](#), [Table II-A-3-a](#), [Table II-A-3-b](#), [Table II-A-4-b](#), [Table II-A-4-c](#), [Table II-A-4-d](#), [Table II-A-4-e-1](#), [Table II-A-4-e-2](#), [Table II-A-4-f](#), [Table II-A-5-a](#), [Table II-A-5-b](#), [Table II-A-5-c](#), [Table II-A-5-d](#), [Table II-A-6](#), [Table II-A-7-a](#), [Table II-A-7-c](#), [Table II-A-7-a](#), [Table II-A-7-d-1](#), [Table II-A-7-d-2](#), [Table II-A-7-d-3](#), [Table II-A-7-d-4](#), [Table II-A-7-d-5](#), [Table II-A-7-d-6](#), [Table II-A-8-a-1](#), [Table II-A-8-a-2-a](#), [Table II-A-8-a-2-b](#), [Table II-A-8-a-2-c](#), [Table II-A-8-a-3](#), [Table II-A-8-b-2](#), [Table II-A-8-b-2-a](#), [Table II-A-8-b-3](#) and [Table II-A-8-b-4](#) for various national and international standards.) The frequency of low results is 8% in adult males, but 13% in women between the ages of 20 and 44 years. Surveys among the elderly based on 14 reports found a frequency of low red cell folate of 8.7% in persons living at home and 18% in those living in institutions ([35](#)). However, liver folate concentrations measured in samples collected at autopsy in Canada found only two low folate values among 560 samples ([34](#)). Perhaps the liver samples should have the last word, as clinical nutritional folate deficiency in adults without other complications is rare in Western society. More commonly, inadequate folate intake accompanies other problems such as alcoholism, pregnancy, chronic hemolytic states, or medication with anticonvulsant drugs. Nutritional folate deficiency, however, remains common in Third World countries, although documentation is poor. In Africa, between one-quarter and one-third of adults have low red cell folate levels ([36](#)).

Age (Years)	Males		Females	
	Number Examined	% Low	Number Examined	% Low
0.5-9	243	2	201	2
10-19	178	5	173	8
20-44	299	8	389	13
45-74	503	8	439	4

Table 88.5 Frequency of Red Cell Folate Levels below 140 ng/mL in the U.S. Assessed by the National Health and Nutrition Examination Study (1988)

The frequency of megaloblastic anemia in pregnancy is an excellent guide to the folate status of women in the population. The additional amount of folate required in a singleton pregnancy is approximately the same everywhere, and the ability to meet the additional requirement depends on folate stores on entering pregnancy and on the dietary folate intake. The best test is the presence of megaloblastic changes in the marrow, since concurrent iron deficiency makes it difficult to assess changes in peripheral blood. Such data are available from around the world and are shown in [Table 88.6 \(37\)](#). One-quarter of women in Western countries show changes of folate deficiency that largely disappear when a folate supplement is given during pregnancy, and this frequency rises to 60% in south India. Thus dietary folate intake in the West does not meet the requirements of pregnancy, and this is demonstrable hematologically in a quarter of such women and well over half the women in Third World countries.

From Chanarin I. *The megaloblastic anemias*. 2nd ed. Oxford: Blackwell, 1979.

Table 88.6 Frequency of Megaloblastic Marrow Changes in Pregnancy Near Term

Red cell folate levels underestimate the frequency of folate deficiency in pregnancy because folate is put into the red cell in the marrow at the time of formation of the red blood cell and remains locked there for about 110 days, which is the life span of the red blood cell. Lowering red cell folate levels requires replacing existing red blood cells by new cells of lower folate content. Maximum folate requirement corresponds to the time of greatest fetal growth in late pregnancy; at this time there is a markedly negative folate balance with a falling red cell level, but in about a third of women with megaloblastic marrows, the level has not yet fallen below the conventional normal range when full term is reached. Birth of the baby restores more normal folate needs. In Nigeria, 85% of

all primigravidae have low red cell folate levels (38).

Apart from pregnancy, folate deficiency can be a problem among premature infants and among the elderly.

Signs and Symptoms in Folate Deficiency

The signs and symptoms in folate deficiency are the same as those described under cbl deficiency, since the ultimate defect is a failure of folate function in both cbl and folate deficiency. The exception is that neuropathy is extremely rare in folate deficiency.

Laboratory Findings

Blood and Bone Marrow. The changes that characterize megaloblastic hematopoiesis are identical in either cbl or folate deficiency and are described above under cbl.

Serum Cobalamin. A normal serum cbl level, for all practical purposes, in a patient with normal cbl serum binders (assessed by the uptake of labeled cbl by an aliquot of serum) and a megaloblastic blood film and/or marrow excludes a diagnosis of cbl deficiency and indicates that the deficiency is of folate. However, one-third of patients with folate-deficient megaloblastic anemia have a low serum cbl level that rises to normal within days of treatment with folic acid alone (39). The clinical circumstances may help in deciding which is the more likely diagnosis. Pregnancy, alcoholism, anticonvulsant drugs, and bulky stools may favor folate deficiency; neuropathy, a vegetarian diet, and other autoimmune disorders such as thyroid disease may favor cbl deficiency. Diagnosis thus depends on the final clinical and laboratory situation. If in doubt, it is best to start treatment with cbl and if there is no response switch to folate. Folate-deficient patients do not respond to cbl, but both deficiencies can respond to folate.

Serum Folate. Serum folate levels are of little diagnostic help as they are often low in ill patients with no folate problem.

Red Cell Folate. As indicated, red cell folate level is the best test for folate deficiency. The normal range is 145 to 450 ng/mL packed red cells. Unfortunately, commercial kits used in folate assays are designed for serum assays, and poor results for red cell assays are common.

Methylmalonic Acid and Homocysteine. Some 12% of folate-deficient patients, mostly alcoholics, have a raised serum MMA level (26) as do many other apparently healthy subjects (13a). This is not the case with MMA excretion in the urine after oral valine, which remains normal. A normal serum MMA in a patient with megaloblastic anemia favors a diagnosis of folate deficiency but by no means excludes cbl deficiency. As the serum homocysteine level can be elevated in both folate and cbl deficiency, the result is of no help.

Deoxyuridine Suppression Test. The deoxyuridine suppression test is abnormal in

virtually all patients with megaloblastic anemia, and full correction of the defect in thymidine synthesis by addition of N5-formyltetrahydrofolate (folinic acid) but no correction with cbl confirms a diagnosis of folate deficiency.

Hematologic Response. A hematologic response to 200 µg/day of folate generally confirms a diagnosis of folate deficiency. This can only be done in patients who are sufficiently anemic to show a suitable response. Failure to respond to cbl providing that there are no interfering factors such as an intercurrent disorder or infection, favors a diagnosis of folate deficiency, confirmed by a response to folate.

Diagnosis of Folate Deficiency

In the absence of blood changes, subclinical folate deficiency is diagnosed by a low red cell folate level. When blood changes indicating a megaloblastic form of hematopoiesis are present, folate deficiency is diagnosed by excluding cbl deficiency by a normal serum cbl level and a normal serum MMA level, bearing in mind the limitations in the interpretation of these test results. Positive evidence is a low red cell folate level and a raised serum homocysteine level. No hematologic response to cbl, given orally if nutritional cbl deficiency is suspected or by injection if cbl malabsorption is more likely, favors folate deficiency and is confirmed by a full response to folate therapy.

Clinical Situations

Prematurity

Folate is actively transferred to the fetus in the last weeks of pregnancy. Assay of paired maternal and cord blood samples for serum and red cell folate showed values of 3.2 and 149 ng/mL for the mother and 17.1 and 325 for the fetus (40). Premature birth reduces fetal folate stores, with reduction of red cell folate levels averaging 270 ng/mL in samples from infants of 25 to 37 weeks gestation, compared with 340 ng/mL in infants at term. Red cell folate levels reach their nadir at 7 to 10 weeks postnatally in premature infants and at 11 to 12 weeks in full-term infants. After this time, the infant depends on dietary sources for folate.

Stored or frozen human milk shows a fall in folate content from about 45 µg/L to 30 µg/L at 4 weeks, to 25 µg at 8 weeks, and 19 µg at 12 weeks. Pasteurization of milk destroys the ascorbate, and reheating such a sample causes a fall of folate from 54 to 10 µg/L. Powdered milk is usually supplemented with folate.

Clinically the neonate fails to gain weight, and the anemia, if due to folate deficiency, does not respond to oral iron, which is the more usual cause. It does respond to oral folate.

Growth

Poor dietary folate intake, particularly when the folate requirement is increased (e.g., in children with sickle cell anemia and with the increased requirement for normal growth),

can delay growth and the onset of menstruation in girls. This was shown dramatically in Nigeria, where folate therapy in women over the age of 20 was followed by growth spurts and the onset of normal menses ([41](#)).

Goat's Milk Anemia

Goat's milk has very low levels of both folate and cbl: 6 µg/L of folate in goat's milk (vs. 52 in human milk) and 0.1 µg/L cbl in goat's milk (vs. 4 µg in human milk). The kid grazes within days of birth and does not depend on maternal sources for either folate or cbl. Human infants reared on goat's milk develop a folate-deficient megaloblastic anemia at 3 to 5 months of age. If goat's milk must be used, a folate supplement is necessary ([13b](#)).

Neural Tube Defects (NTD)

NTDs arise from a failure of the neural tube to close completely at about the fourth week of embryonic life. The disorders include anencephaly (in which most of the brain and skull are absent), encephalocele (in which brain protrudes through a defect in the skull), and spina bifida (in which the spinal canal is not closed). The more severe defects are not compatible with life, and severer forms of spina bifida lead to very severe handicaps with paralysis of legs and bladder. The prevalence is about 4 per 1000 births, and most of these are diagnosed by raised α -fetoprotein levels in maternal blood and amniotic fluid and an ultrasound scan. Most such pregnancies are terminated, and defects present at birth now number about 0.3/1000 births.

In 1991, randomized, double-blind trials confirmed earlier evidence that supplemental folate given at conception and in the early weeks of pregnancy, reduced the frequency of NTDs by about 70% ([42](#), [43](#), [44](#) and [45](#)). The daily folate supplement given varied from 0.36 to 5.0 mg. On the whole, the data did not suggest that affected women had conventional folate deficiency, although there were indications of an association with poor diet. Study of women who had two episodes of NTD showed no evidence of a reduced folate intake ([46](#)), and usually red cell folate levels were normal. Thus the reason for a localized folate deficiency that led to a failure to close the neural tube is not clear. Possibly, in some women, vascularization of the placental site is inadequate in the early weeks and prevents folate access; raising the blood folate level significantly by increasing oral folate intake facilitates diffusion or active transfer of folate to the embryo. Other factors that produce NTDs include chromosomal abnormalities and maternal obesity ([46a](#)) and are not likely to be influenced by folate. A suggestion of a defective enzyme, methylene-tetrahydrofolate reductase, was not confirmed because the frequency of the defect was similar in controls and in mothers who had a pregnancy complicated by NTD ([46b](#)).

Whatever the explanation for the beneficial effect of folate, it is now imperative to increase dietary folate in very early pregnancy, indeed, at a time when many women will not know that they are pregnant. As there is a risk of a second NTD in a subsequent pregnancy, women who have already had a pregnancy complicated by an NTD can be advised to take supplemental folate if they plan a further pregnancy. But half of all pregnancies are unplanned. Many authorities have issued advice on taking folate-rich

food and on getting folate supplements, which has been largely unheeded by most women (47). It seems inescapable that the only way to increase dietary folate in very early pregnancy to all at risk is folate fortification of food such as flour. This will increase the folate intake of the population at large from about 0.2 mg/day to somewhere in the region of 0.5 to 1.0 mg/day. What are possible disadvantages of such a policy?

When folate became available after 1947, it was used by some to treat all megaloblastic anemias, including those that involved primarily cbl deficiency. It soon became clear that a high proportion of patients who needed cbl responded well initially to folate but, after several months, relapsed with damage to the nervous system and, ultimately, return of megaloblastic anemia. Generally the picture was restored by treatment with cbl, but some retained permanent neurologic damage (48). The plot thickened when it was realized that folates present in multivitamin preparations purchased without medical prescription could also produce a response in the blood in undiagnosed cbl deficiency but allow cbl neuropathy to develop. Although in the U.S. the amount of folate in the multivitamin preparation was not permitted to exceed 0.4 mg/day, many persons took the view that if one pill was good for you, up to six a day was even better. Folate restored normality to the blood pictures of those with undiagnosed cbl deficiency, which made it difficult for the clinician to suspect that the symptoms and signs were due to cbl deficiency with normal blood. Those at risk are usually patients with, as yet, undiagnosed pernicious anemia, which has a frequency of about 1.0% above the age of 60.

In the early 1950s, assays for serum cbl became widely available. A low serum cbl level was always present in cbl deficiency, and the test became mandatory when faced with a neuropathy that could be due to cbl deficiency. Since the early 1960s, reports of cbl deficiency concealed by folate therapy have been few, and it must be concluded that cbl deficiency is being properly diagnosed, despite the fact that 40% of North American adults take regular multivitamin supplements that include folate, sometimes in amounts that should prevent NTDs. It has been estimated that about one-third of American women take enough folate to prevent NTDs (49).

Proposals have been made to fortify flour so that the total folate intake should not exceed 1.0 mg/day. Such proposals are now being implemented in the U.S.

Pregnancy

The increased folate requirement in pregnancy arises from its role in increasing the mother's red cell mass, formation of the placenta, growth of the uterus and the fetus, and, finally, providing folate to be transferred to the fetus in the last few weeks before term (40). An increased folate requirement is evidenced at the 20th week of pregnancy by the more rapid clearance from the blood to tissues of a small injected dose of folate (50). Folate requirement increases throughout pregnancy and is maximal near term.

At the same time there is increased urinary loss of folate in pregnancy because of a lower renal threshold. Folate in the urine in pregnancy averages 14 µg/day, versus 4.2 µg/day in nonpregnant women and 3.5 µg/day in the puerperium. In some women, the urinary loss in pregnancy exceeds 50 µg/day (51). Claims of excessive folate catabolism

in pregnancy await confirmation (52). The increased folate requirement, which has been assessed at 100 µg/day (53, 54) has to be met from the diet and from whatever folate stores are available.

In the U.S., 13% of women of childbearing age have a low red cell folate level (Table 88.5), and thus it is not surprising that 16% of women in New York had low red cell folate levels at their first visit to an antenatal clinic (55). Similar figures have been noted elsewhere, and in Nigeria, the frequency of a reduced red cell folate level at the first visit was 31%.

The red cell folate level generally falls throughout pregnancy, and in a London study, mean red cell folate levels at 12, 24, and 36 weeks and in the puerperium were 317, 302, 288, and 252 ng/mL packed red cells (54). This indicates a negative folate balance in pregnancy, but in Denmark and Australia, folate levels were maintained during pregnancy, implying a more adequate folate intake. Generally one-quarter to one-third of women have abnormally low folate blood levels at term, which corresponds to the frequency with which megaloblastic marrow changes have been found at term (Table 88.6). The serum folate level also falls during pregnancy, and at presentation, 30 weeks, 35 weeks, and puerperium, mean serum folate levels were 6.6, 5.2, 4.5, and 3.7 ng/mL. In part this is due to expansion of the plasma volume. Low levels are found in 15 to 54% of women.

Iron deficiency is the major cause of anemia in pregnancy, and folate deficiency comes next. The frequency of significant folate deficiency is related to the efforts made in its detection. Overt megaloblastic anemia is easily recognized, but more often it is concealed by accompanying iron deficiency; if there is no response to iron, marrow examination is the only certain way to make the diagnosis. Short of that, it can be suspected in a stained blood film by the presence of macrocytes in a microcytic red cell population, although responding iron deficiency can be similar, and hypersegmented neutrophils can be common to both deficiencies. The high frequency of megaloblastic anemia seen on bone marrow examination is shown in Table 88.6. Examination of the blood film will raise suspicion of megaloblastic anemia in only about 2% of women in late pregnancy.

Diagnosis is usually made in the last few weeks of pregnancy, and in about half of patients, in the puerperium. Megaloblastic anemia is 10 times more frequent in twin pregnancies, is more common in multigravidae, and has a seasonal incidence, with the highest frequency following the time of year when fresh vegetables are least available. In pregnancy, it is always due to folate deficiency. Women who get a megaloblastic anemia in pregnancy enter pregnancy with the lowest folate stores as assessed by the red cell folate level at presentation (54). Iron deficiency occurs in the same women who become folate deficient and implies a dietary deficiency of both nutrients (11).

Although a variety of consequences have been attributed to folate deficiency in pregnancy, only one has been established beyond doubt: prematurity and low-birth-weight infants. Pregnancy outcome in South Africa was compared in groups of well-nourished women taking a mixed diet and groups whose staple diet was boiled maize (corn). There were three supplements to each of 50 to 60 women, iron alone, iron

and folate, or iron, cbl, and folate, and these were taken once daily. The supplements did not affect either birth weights or duration of gestation in the well-nourished group. In the group with maize as the main dietary item 19 of 63 women taking only iron had low-birth-weight babies weighing less than 2270 g, which fell to 4 of 65 in women taking iron and folate. The mean birth weight increased from 2466 g to 2798 g in those given iron and folate. Addition of cbl made no difference (56). Folate increased gestation by 1 week and increased placental weight from 456 g to 517 g (57). These findings have been widely confirmed, and only in well-nourished, affluent societies did folate supplements make no difference.

A folate supplement of 100 µg/day throughout pregnancy caused a rise in red cell folate levels during the first half of pregnancy, and thereafter the red cell folate did not change (54). There was a marked fall in the number of patients with megaloblastic marrows in the folate-supplemented group, but it was not abolished because not all the volunteers took their tablets. Since dietary folate intake in pregnancy can vary from less than 60 to over 200 µg/day, the daily folate supplement given in a single tablet with 30 mg ferrous sulfate needs to be no less than 200 µg folate to meet the needs of all pregnant women. The RDA for folate in pregnancy in the U.S. is 400 µg/day. Treatment of megaloblastic anemia in pregnancy is 5 mg folic acid given once or twice daily and continued for 4 weeks after delivery.

Lactation

Most patients with megaloblastic anemia in pregnancy are diagnosed in the puerperium. With delivery, folate requirements decline, and undiagnosed megaloblastosis will remit with dietary folate. This must be the case with most of the 25% of women who have a megaloblastic marrow at this time and who never come to clinical notice in the usual course of events. But in some, dietary folate is insufficient, and lactation poses a persistent increase in folate requirement. Human milk after the 2nd month of lactation contains 25 µg/L of folate; with secretion of 700 mL, this involves a loss of about 20 µg/day of folate. Milk contains an avid folate-binding protein, and small doses of folate given to the mother appear in the milk without any measurable rise in the maternal serum level (58). In Third World countries, megaloblastic anemia is more often diagnosed 2 to 18 months after birth than during pregnancy (59). The RDA during the first 6 months of lactation is 280 µg/day of folate, and in the second 6 months, 260 µg (Table 88.3). Treatment of megaloblastic anemia found during lactation is 5 mg of oral folic acid once daily.

The Elderly

The elderly are another group reported to be vulnerable to nutritional folate deficiency. In Western society, poverty and a very poor diet has been associated with clinical folate deficiency. Institutionalized elderly persons are more vulnerable than those living in their own homes. A survey of 17 studies on red cell folate levels in the elderly found that the incidence of low levels ranged from zero to 42.9% of subjects (69). The variation probably represents variation in assay technique rather than real differences in the samples tested. Very few of these subjects had anemia, and there was no obvious benefit from folate treatment. Diagnosis of significant folate deficiency must be based on

a blood count and the additional tests set out above, but it is not common today except where there is general malnutrition.

Folate and Alcohol

There is a strong association between excessive alcohol consumption, folate deficiency, and megaloblastic anemia, and not infrequently, alcohol abuse turns out to be the explanation for an otherwise puzzling anemia. Alcohol has a direct toxic effect on hematopoietic cells in the bone marrow and perhaps on cells in the peripheral blood as well; it promotes excessive iron absorption, and patients who substitute alcohol for food can develop nutritional folate deficiency. The direct toxic effect is most obvious in those on a high alcohol intake and is best seen in the bone marrow, where there is megaloblastosis, vacuolation of red and white cell precursors, and ringed sideroblasts, that is, red cell precursors with iron granules forming a ring around the nucleus. These changes disappear within 10 days of alcohol withdrawal.

The peripheral blood in alcoholics may show a mixture of hypochromic and normochromic red cells, called a dimorphic blood picture, or just macrocytosis present in over 80% of alcoholics taking more than 80 g ethanol daily. The first diagnosis in a patient with a normal hemoglobin level and large red blood cells is alcohol abuse. Indeed, routine health screens carried out on the employees of a large U.S. insurance company showed that almost all the employees with large red blood cells and a normal hemoglobin level were taking excessive amounts of alcohol. The changes in the peripheral blood, although resulting from a direct toxic effect of alcohol on the marrow, take up to 100 days to disappear, related more to the survival of red cells in the circulation than to events in the marrow.

Folate deficiency occurs in those who substitute alcohol for food; they show low serum, red cell, and liver folate levels (61). It is seen in spirit drinkers rather than beer drinkers, since beer is a good source of folate. It occurs in one-third of alcoholics. They give a history of not taking an adequate meal during the day.

There is no good evidence that alcohol has a direct effect on folate metabolic pathways. Evidence does indicate that alcohol produces transient malabsorption of a variety of nutrients, including cbl and folate, but there is enhanced absorption of iron, leading to iron overload. This situation has been reproduced in alcoholic, folate-deficient rabbits but not in rabbits just given alcohol (62).

Diagnosis of folate deficiency in alcoholics, which is nutritional folate deficiency, is the same as that described above in this section.

Fortification and Treatment

The addition of folate to food is of importance in the prevention of NTDs. Furthermore, raised plasma levels of homocysteine may predispose for blood vessel damage and heart disease, and the homocysteine level is reduced by folate (73). New regulations in the U.S. indicate that flour must be enriched with 0.15 mg folate per 100 g flour, milled

rice by 0.154 mg folate per 100 g, alimentary paste should contain 0.198 to 0.265 mg folate per 100 g, and enriched bread, 0.96 mg folate per 100 g bread.

Treatment of folate deficiency is by oral folate; tablets containing 5 mg are the usual dose given once or twice daily for 4 to 6 weeks. In sickle cell anemia and in chronic myelofibrosis there is a high folate requirement, and one 5-mg folate tablet is given daily for life. In pregnancy, a combined iron and folate supplement is strongly recommended.

LESS COMMON NUTRITIONAL DEFICIENCIES AFFECTING THE BLOOD

Ascorbic Acid (Vitamin C)

A full account of ascorbic acid is given in [Chapter 29](#). Ascorbic acid and folate are both heat-labile water-soluble vitamins, and they occur in the same kind of foods. A diet deficient in one is likely to be deficient in the other. Ascorbate in food protects folate from oxidative destruction. A large proportion of patients with clinical scurvy have megaloblastic hematopoiesis or even frank megaloblastic anemia. Most of these patients respond only to ascorbate, but some may respond to folate ([63](#)). The relationship is likely to be a nutritional deficiency of both these substances in the same individual. There is no good evidence for a biochemical relationship other than the protective effect of ascorbate as a reducing agent preventing oxidation of labile tetrahydrofolate analogues, which occurs in an in vitro situation.

A cow's milk diet in monkeys led to development of severe ascorbate deficiency followed by a severely megaloblastic bone marrow about 2 weeks later ([64](#)). The liver had very low levels of both ascorbate and folate. As little as 1 mg ascorbate daily produced a response in both the scurvy and in the megaloblastic anemia, with accumulation of folate in the liver. Addition of folate alone to the diet precipitated clinical scurvy. The authors concluded that there was an increased folate requirement in scurvy, but they did not find a role for ascorbate in normal folate metabolism.

Pyridoxine

Pyridoxine metabolism is dealt with in [Chapter 24](#). Pyridoxine-responsive anemias are not uncommon and are associated with pyridoxine antagonists such as cycloserine and pyrazinamide used to treat tuberculosis and with a group of anemias called sideroblastic anemias in which iron accumulates in erythroblasts as a ring around the nucleus. The accumulation of iron granules linked to mitochondria accompanies a failure of hemoglobin formation so that the cytoplasm of the erythroblast is pale and, if this cell matures, will give rise to an iron-deficient red cell. Apart from pyridoxine antagonists, sideroblastic anemia occurs as a preleukemic refractory anemia in older people or as sex-linked hereditary anemia in males. Folate deficiency is common, so there is a megaloblastic overlay.

All these disorders are suspected by examination of the stained blood film, which shows a mixture of iron-deficient (hypochromic) and normochromic red blood cells, also called

a dimorphic blood picture. A dimorphic blood film is also present after a blood transfusion to an iron-deficient patient or after iron treatment in iron deficiency. The pyridoxine responsiveness is not due to nutritional deficiency but to a biochemical problem with pyridoxine metabolism, and high doses of pyridoxine in excess of 100 mg/day are needed for a response. Folate-deficient patients respond to folate in small doses (65).

Protein-Energy Deficiency (Kwashiorkor)

Children with protein malnutrition as recorded in Third World countries almost invariably have other problems, including infection and lack of other nutrients. Anemia is common and may be normocytic and normochromic. Hemoglobin levels may be below 8 g/dL, and the blood film may show anisocytosis. Some show evidence of scurvy, and slow hematologic responses follow repletion with protein. Marrows are often megaloblastic, and low blood folate levels are not infrequent. In some, megaloblastosis due to folate deficiency becomes evident only after protein repletion has been started. Blood changes have been reviewed (66).

Vitamin E Deficiency

Vitamin E deficiency is discussed in [Chapter 19](#). α -Tocopherol serves as an antioxidant. Deficiency of vitamin E is rare but does occur in premature infants at about 4 to 6 weeks of age. There is anemia not responding to iron and recognizable from the appearance of the blood film, which shows contracted red blood cells and polychromasia. Polychromatic red cells are new red cells or reticulocytes; when increased under these circumstances, they indicate a response to increased red cell destruction (a hemolytic anemia), presumably due to loss of the protective effect of vitamin E. The hemolytic anemia is accompanied by a raised platelet count and edema of the dorsum of the feet and pretibial area. These symptoms and signs disappear with vitamin E treatment. It has been suggested that the anemia may be related to a diet rich in polyunsaturated fatty acids. A mild hemolytic anemia responding to vitamin E may also occur in cystic fibrosis.

Riboflavin

Riboflavin is discussed in [Chapter 22](#). Experimental deficiency in volunteers was accompanied by anemia only affecting the red blood cells. Clinically, anemia due to riboflavin deficiency is rare, and is said to accompany alcohol abuse when a smooth, cherry-red tongue is a feature. The author encountered anemia responding well to riboflavin in a young woman with anorexia nervosa, with a hemoglobin level of 6 g/dL and a cherry-red tongue.

Copper

Copper deficiency has been described in malnourished children and in patients on parenteral nutrition. It is dealt with in [Chapter 12](#). Copper is required in a number of enzymes; it is carried in plasma bound to a protein termed *ceruloplasmin*. The level is

low in copper deficiency. Anemia and neutropenia rarely occur in copper deficiency and are said to be similar to those in iron deficiency but unresponsive to iron. An undoubted example of a macrocytic anemia responding to copper has been documented (67).

Conversion factors to SI units: iron, 1 mg = 0.18 mmol, 1 µg = 0.18 µmol; ferritin, 1 ng = 3.51 nmol; hemoglobin, 1 g = 0.62 mmol; cobalamin, 1 ng = 7.4 pmol, 1 µg = 0.75 nmol; folate, 1 ng = 2.27 nmol, 1 µg = 2.27 µmol, 1 mg = 2.27 mmol.

KIDNEY FUNCTION

The kidney has three primary functions: excretory, endocrine, and metabolic. All three functions may be impaired in renal disease and may affect the patient's nutritional status and management. When injury, necrosis, and scarring of the renal parenchyma cause a loss of renal function, the amount of substances filtered by the kidney falls. However, many aspects of renal function undergo changes that preserve homeostasis and minimize the derangements in plasma and tissue concentrations of substances normally excreted by the kidney. Prominent among these adaptations is nephron hypertrophy and an increase in blood flow and glomerular filtration rate in those nephrons that are still functional.

Many organic compounds accumulate in renal failure (1); most are products of amino acid and protein metabolism. Quantitatively, the most prominent are urea, creatinine, other guanidine compounds, and uric acid (Fig. 89.1). Some of these compounds are considered toxic in high concentrations. Low protein intake reduces accumulation of

many of these substances. Eventually, renal failure may become so severe that the aforementioned adaptive mechanisms can no longer maintain homeostasis, even with special dietary therapy that restricts intake of fluid, electrolytes, and protein. Accumulation of these compounds, the endocrine and metabolic disturbances, and the clinical signs and symptoms that result from renal failure are referred to as uremia. If this condition is not treated by hemodialysis, peritoneal dialysis, or renal transplantation, death will supervene.

Figure 89.1. Relationship between the plasma urea nitrogen (*PUN*) and GFR as indicated by urea clearance in Sprague-Dawley rats with chronic renal insufficiency and sham-operated controls. Chronic renal failure was produced by ligation of two-thirds to three-fourths of the arterial supply to the left kidney and contralateral nephrectomy. (From Kopple JD. Nutrition and the kidney. In: Alfin-Slater RB, Kritchevsky D, eds. Human nutrition: a comprehensive treatise, vol 4. New York: Plenum Publishing, 1979;409–57, with permission.)

Excretion and regulation of body water, minerals, and organic compounds are clearly the most important functions of the kidney. Without renal excretory function, patients rarely live longer than 4 to 5 weeks and often less than 10 days, particularly if they are hypercatabolic. In contrast, anephric patients can be kept alive for years with intermittent hemodialysis or peritoneal dialysis, even though endocrine and metabolic functions of the kidney are not replaced.

The kidney elaborates hormones with diverse metabolic effects, including 1,25-dihydroxycholecalciferol, erythropoietin, renin, and kallikreins. These effects have been the subject of many excellent and comprehensive reviews (2, 3, 4 and 5). The kidney plays an essential role in vitamin D metabolism (4) (see Chapter 18). Vitamin D₃ (cholecalciferol) is hydroxylated in the liver to form 25-hydroxy cholecalciferol. This compound is then converted in the kidney to 1,25-dihydroxycholecalciferol (1,25-dihydroxyvitamin D). The actions of 1,25-dihydroxyvitamin D are discussed in Chapter 18. In renal failure, impaired synthesis of 1,25-dihydroxyvitamin D contributes to a vitamin D–deficient state associated with impaired intestinal calcium absorption,

hyperparathyroidism, resistance to the actions of parathyroid hormone on bone, and development of renal osteodystrophy.

Erythropoietin is a glycoprotein that stimulates erythropoiesis in bone marrow ([5](#), [6](#)). The anemia of chronic renal failure is primarily caused by impaired erythropoiesis. Decreased red cell formation is mainly due to reduced erythropoietin production in the diseased kidneys, although compounds that accumulate in renal failure may also suppress erythropoiesis. A mild hemolysis often contributes to the anemia. Certain kidney diseases such as kidney cysts or tumors occasionally increase erythropoietin synthesis, which enhances erythropoiesis and leads to elevated hemoglobin and hematocrit levels. Recombinant DNA-synthesized human erythropoietin is commonly used to increase blood hemoglobin levels in nondialyzed patients with advanced renal failure and those undergoing maintenance dialysis ([7](#)).

Renin stimulates conversion of angiotensin I to angiotensin II, a potent vasoconstrictive agent that raises blood pressure and also may stimulate collagen formation and cell proliferation in the kidney and probably other tissues. Renal renin secretion is stimulated by renal ischemia (e.g., in renal artery stenosis) and sometimes other renal diseases; increased plasma renin levels can cause hypertension. Renal disease and particularly renal failure also may engender hypertension by other mechanisms, including retention of sodium chloride and water.

INTERRELATIONSHIPS BETWEEN NUTRIENTS AND KIDNEY FUNCTION

Kidney function both regulates, and is influenced by, the body's pools and concentrations of water, minerals, and many other nutrients and their metabolites. The reader is referred elsewhere in this text for a discussion of water, sodium, potassium, and acid-base physiology ([Chapter 6](#)) and calcium and phosphorus ([Chapter 8](#)), magnesium ([Chapter 9](#)) and trace element ([Chapter 10](#), [Chapter 11](#), [Chapter 12](#), [Chapter 13](#), [Chapter 14](#) and [Chapter 15](#)) metabolism.

Effects of Malnutrition on the Kidney

Malnutrition can have important, but usually reversible, effects on renal function. In humans, malnutrition decreases the glomerular filtration rate (GFR) ([8](#), [9](#)) as well as the capacity to concentrate and acidify urine ([9](#), [10](#) and [11](#)). If nutritional intake improves, these functions may normalize. GFR falls reversibly in obese subjects placed on weight-reduction diets that contain no protein or calories but provide water, vitamins, and small quantities of minerals. This phenomenon is at least partly due to a reduction in extracellular body water, circulating blood volume, and renal blood flow. Increased salt and water intake rapidly reverses this condition. The low or absent protein intake also contributes to the lower renal blood flow and GFR ([8](#), [9](#)).

Ichikawa et al. investigated the mechanisms responsible for the reduction in GFR with protein malnutrition ([12](#)). They found that in rats pair-fed a low-protein (6%) diet as compared with an isocaloric high-protein (40%) diet, the GFR was almost 35% lower.

Increased resistance was evident in the arterioles leading into (afferent) and out of (efferent) the glomerulus. The glomerular capillary plasma flow rate was about 25% lower, and the glomerular capillary ultrafiltration coefficient was almost 50% lower. Glomerular transcapillary hydraulic pressure differences were similar in the two groups. A reduction in insulin-like growth factor-I (IGF-I) levels may contribute to these changes (13, 14).

Malnourished individuals often have lower specific gravity in random urine specimens and increased daily urine volumes. Impaired concentrating ability probably contributes to the nocturia that may occur in malnutrition. The inability of the malnourished patient to concentrate urine normally appears to be due to low protein intake and consequent low rate of urea synthesis (10). Urea is critical for normal urinary concentration. Some urea filtered by the glomerulus is reabsorbed in the renal tubule and accumulates in the interstitium of the renal medulla where it attracts water from the collecting duct by osmotic pressure. Loss of water from the collecting duct lumen concentrates the urine. When protein intake is low, urea synthesis falls, and serum urea nitrogen (SUN) decreases; less urea is filtered by the glomerulus and reabsorbed into the renal medulla. Thus, medullary hypertonicity falls, and there is less tendency for water to move from the distal tubule and collecting duct to the medulla; hence maximum renal concentrating ability is reduced. Ingestion of urea or more protein by malnourished subjects or those who eat low protein diets improves renal concentrating ability (10). The capacity to dilute urine is normal in malnutrition.

Malnourished subjects are more likely to develop acidosis after an acid load (11). Urinary phosphate and ammonia are primary carriers of acid in the urine. Hydrogen ion secretion into the lumen of the distal nephron lowers the pH of tubular fluid and converts HPO_4^{2-} to H_2PO_4^- and ammonia to NH_4^+ . In individuals who have a low phosphorus intake, phosphate filtered in the kidney is largely reabsorbed, which conserves body phosphate pools; less phosphorus is excreted in the urine, however, which reduces the capacity of the kidney to excrete acid. Infusion of phosphate improves urinary excretion of titratable acid in malnourished patients (11). In malnutrition, renal production and excretion of ammonium are also reduced, both under basal conditions and after an acid load (11).

During prolonged starvation, the kidney may account for up to 45% of endogenous glucose production, although part of this percent increase in glucose synthesis is due to a fall in total body glucose production (15). In extended starvation, net renal extraction of lactate, pyruvate, amino acids, and glycerol also occurs (15). The carbon skeleton in these compounds is almost completely converted into glucose. During prolonged starvation, free fatty acids and β -hydroxybutyrate are also extracted by the kidney, and acetoacetate is released (15).

Acute starvation and other conditions associated with increased catabolism of nucleic acids, purines, and amino acids, such as may occur with chemotherapy of leukemias and certain other tumors, can markedly increase uric acid production. Hyperuricemia can lead to deposition of uric acid sludge in the kidney and lower urinary tract and may cause acute renal failure. Treatment consists of allopurinol (which inhibits synthesis of uric acid), maintaining good hydration and large urine flow, and alkalinizing the urine to

increase the solubility of uric acid (16).

Effects of Protein and Amino Acid Intake on Renal Function

Protein intake appears to engender both an immediate and a longer-term increase in renal blood flow and GFR in humans. A transient increase in renal blood flow and GFR of about 20 to 28% occurs following ingestion of a protein or amino acid load (17, 18). The rise occurs about 2 hours after the meal and generally lasts about 1 hour. Renal blood flow and GFR increase more quickly and also transiently following an intravenous infusion of a mixture of essential and nonessential amino acids (19) or a 30-minute infusion of arginine hydrochloride (20).

The mechanisms responsible for the rise in renal blood flow and GFR following intake of protein or amino acids are not well delineated. Data concerning potential hormonal causes are either negative, inconclusive, or conflicting (21). Cytokines, paracrines, and other intrinsic renal processes, such as enhanced renal tubular amino acid and sodium reabsorption and altered tubuloglomerular feedback, have been proposed (21). Infusion of somatostatin blocks the rise induced by an amino acid infusion, indicating that peptide hormones may mediate the amino acid and protein enhancement of renal blood flow and GFR (19).

An infusion of glucagon that raises blood glucagon levels to those observed after an amino acid load is reported to increase renal blood flow and GFR (22). Hence glucagon may play a role in the amino acid- or protein-induced increase in renal blood flow and GFR. However, in some studies, the amount of glucagon necessary to increase renal blood flow and GFR exceeded that which occurs after a meat meal (23) or after ingestion or infusion of amino acids (18, 24). Moreover, infusing glucagon directly into the renal artery in dogs (25) and humans (24) does not increase renal blood flow or GFR, although infusion into the portal vein does. Acromegalic patients have an abnormally high GFR (26). An injection of growth hormone into normal humans increases renal blood flow and GFR after several hours (27). IGF-I appears to mediate the growth hormone-induced rise in renal hemodynamics (13, 28).

Most patients with renal insufficiency also demonstrate a protein- or amino acid-induced rise in renal blood flow and GFR (17, 21). This increase has been called the *renal functional reserve*. Some investigators have suggested that the maximum renal blood flow and GFR after a protein or amino acid load in patients with renal disease (compared with normal subjects) better estimates the magnitude of renal damage and scarring than the basal levels of these hemodynamic parameters. This has not been confirmed, because the maximum renal blood flow and GFR following a protein load appear to vary, depending on the individual's previous daily protein intake. The changes in renal blood flow and GFR in patients with diabetes mellitus given protein or amino acids are quite variable in different studies (22).

EFFECT OF NUTRITIONAL INTAKE ON THE RATE OF PROGRESSION OF RENAL FAILURE

Mechanisms of Progression

Physicians have known for many decades that patients with chronic renal disease who have sustained a substantial loss of GFR often continue to lose renal function inexorably until they develop terminal renal failure (29, 30 and 31). Although the rate of progression of renal failure varies greatly among patients, in many individuals, the decline in kidney function is linear (29, 30 and 31). The percentage of patients with renal insufficiency who progress to renal failure is not known, but it seems likely that renal failure will continue to progress in most patients who lose 50% or more of GFR. Renal failure may progress because of the underlying renal disease or because of superimposition of other diseases that may contribute to renal injury such as hypertension, adverse effects of nephrotoxic medicines (e.g., antibiotics or radiocontrast material), obstruction, kidney infection, hypercalcemia, or hyperuricemia. However, continued progression is not rare even after the initial cause of the renal disease seems to have disappeared and when no superimposed illnesses are present (32, 33, 34 and 35). For example, renal failure may progress in patients after relief of urinary tract obstruction, control of hypertension, discontinuance of nephrotoxic medications, or partial recovery from acute renal failure.

Studies of animal and in vitro models of chronic renal disease or renal failure have led to the following observations. There is a rather common physiologic and biochemical response to chronic loss of renal function that is largely independent of the underlying type of kidney disease. When enough functioning nephrons are lost to cause renal insufficiency, the remaining individual functioning nephrons show a rise in glomerular plasma flow and GFR, and both glomeruli and tubules increase in size (i.e., nephron hypertrophy) (36, 37). The capillary blood flow of the remaining glomeruli increases as does the blood pressure gradient across the capillary wall (37, 38). In addition, the chemical, electrical, and pore-size barriers to movement of plasma proteins across the glomerulus and into the renal tubule are impaired (39, 40). Migration of leukocytes and monocytes, platelet aggregation, collagen deposition, cellular proliferation, and other inflammatory and scarifying changes may occur to a greater or lesser degree and may cause progressive renal damage. Many of these changes, some of which could be considered adaptive physiologic responses, are believed to promote further renal injury and lead to progressive renal failure.

Current thinking regarding potential causes of progressive renal failure is summarized in [Table 89.1](#). Most of these processes have been investigated only in animal models, and a role in human renal disease is inferred. Many of these mechanisms appear susceptible to amelioration or reversal by nutritional therapy ([Table 89.1](#)); for example, protein-restricted diets reduce renal blood flow, GFR, and proteinuria in humans with renal disease (21).

Continued activity of the underlying renal disease
 Systemic hypertension^a
 High-protein diet^b
 High-phosphorus diet^b
 High-cholesterol or -cholesterol diet^b
 High calcium-phosphorus product in serum^b
 Vitamin D overdose causing hypercalcemia^b
 High serum oxalate levels (can be enhanced by high ascorbic acid intake)^b
 Hyperuricemia
 Acidosis
 Nephrotoxic medicines (e.g., radiocontrast material, aminoglycoside antibiotics)
 Intraglomerular capillary pressure and capillary blood flow
 Intraglomerular transcapillary hydraulic pressure
 Glomerular and tubular hypertrophy
 Lipoprotein and lipid deposition in glomerulus
 Deposition of other proteins in glomerulus
 Inflammatory response in kidney with release of cytokines and molecules
 Platelet aggregation in kidney
 Calcium phosphate or calcium oxalate deposition in the kidney
 Release of growth factors in kidney
 Increased mesangial matrix production
 Enhanced renal tubular generation of ammonia leading to compensatory activation
 Increased generation of reactive oxygen metabolites in remaining functional nephrons
 Load, maximum toxicity

^aEvidence that many of these factors may cause progressive renal failure is derived from animal models or in vitro systems.
^bThese causes of progressive renal failure may act through one or more of the mechanisms listed in the lower half of this table.

Table 89.1 Potential Causes and Mechanisms of Progressive Renal Failure^a

Experimental Evidence for Effects of Nutritional Intake on Progression of Chronic Renal Failure

Dietary protein restriction has been used for many decades to minimize uremic toxicity (41). In the first half of the 20th century, research in rats also indicated that protein restriction could retard progression of renal failure (42, 43 and 44). The experimental design of these studies as well as observations in humans concerning the effects of dietary protein restriction on progression of renal disease were not well controlled, and the results were inconsistent.

In the 1970s and 1980s, studies in both rats and humans indicated that dietary control can retard progression of renal failure in a variety of renal diseases. In rats, several models of renal insufficiency were studied. These included surgical removal of the upper and lower poles of one kidney or ligation of about two-thirds to three-quarters of the arteries to one kidney; in both models, contralateral nephrectomy was performed. In some cases, experimental glomerulonephritis was created (45, 46, 47, 48 and 49). In these animal models, diets low in protein and/or phosphorus retarded or prevented progression of renal failure (45, 46, 47, 48 and 49). In addition, a diet low or high in certain fats may retard progressive renal damage (50, 51, 52 and 53). Moreover, administration of prostaglandins may affect the progression of chronic renal disease in animals (54, 55 and 56).

Proteins

In experimental animals with renal disease, a high-protein diet stimulates an increase in GFR, glomerular capillary blood flow, blood pressure gradients across the glomerular capillary wall, and enlargement of individual nephrons, whereas a low-protein diet blunts or prevents this response (37). Moreover, normal rats with renal injury who are fed a high-protein diet develop renal failure, and when such animals are fed a low-protein diet, the progression of renal failure is retarded or arrested (43, 44, 48). A current theory postulates that a high-protein intake, by increasing both glomerular capillary blood flow

and trans capillary glomerular hydraulic pressure, causes progressive renal injury to the basement membrane (filtering wall) of the glomerulus. These alterations, in turn, increase capillary permeability, enhance movement of large molecules across the glomerular basement membrane, and cause deposition of these compounds in the mesangium, mesangial expansion, an inflammatory response in the glomerulus, scarring, and glomerulosclerosis (38, 57, 58).

High-protein diets may also promote renal insufficiency by other mechanisms: (a) induction of nephron hypertrophy with activation of growth factors that stimulate cell hypertrophy, proliferation, and scarring in the glomerulus; (b) enhanced oxidation rates in the nephron with increased generation of reactive oxygen species (59); (c) an acid load that stimulates renal ammonium production and activation of complement C (60); (d) increased generation of urea, which itself may cause hypertrophy of segments of the renal tubule (61); and (e) generation of angiotensin II and other hormones (61a, 61b). A low-protein diet retards or stops progressive renal damage by preventing or reducing these phenomena. Diets providing soya protein, a vegetable protein, rather than casein, an animal protein, may be more effective in retarding progression of kidney failure in rats with remnant kidneys (62).

Diabetic rats with moderate hyperglycemia develop renal hypertrophy and increased hemodynamics (63), and similar abnormalities appear to occur in the intact kidney of humans with diabetes mellitus. Early in the course of diabetes mellitus, patients develop increased renal blood flow, increased GFR, and large kidneys (64). Ultimately, in a large proportion of these individuals, glomerulosclerosis occurs and renal failure supervenes (65, 66). In the early stages of diabetes, strict blood glucose control may reverse these phenomena.

Phosphorus and Calcium

As previously indicated, a low phosphorus intake independent of protein intake seems to retard progression of renal failure (45, 67, 68). The mechanism of action of the low phosphorus intake is unclear. One theory is that a low phosphorus intake decreases deposition of calcium phosphate in kidney tissue, which may cause further renal damage (67, 68). Indeed, in renal tissue obtained by biopsy or autopsy, a direct correlation exists between the calcium content and the serum creatinine concentration (69). Moreover, in rats with chronic renal insufficiency, administration of the calcium-channel blocker verapamil retards the rate of progression of renal failure, compared with treatment with an antihypertensive agent that does not impede intracellular movement of calcium (70). In general, the calcium concentration of renal tissue is higher in those parts of the kidney with more severe renal histopathologic changes.

Lipids and Lipoproteins

Many animal studies suggest a pathogenic role of dietary fat intake and hyperlipoproteinemia. Rats, rabbits, and guinea pigs fed a high-cholesterol diet developed hypercholesterolemia and progressive glomerulosclerosis and renal failure (50, 71, 72). The lipid composition of renal cortical tissue is altered, and both mesangial

cellularity and matrix formation increase (71). Glomerular capillary pressure rises, even though systemic blood pressure is not very elevated, which suggests a role for glomerular hypertension in the loss of renal function in the dietary cholesterol or hypercholesterolemia model of renal insufficiency. Cholesterol-induced renal injury is much greater when cholesterol-supplemented rats have other underlying renal diseases. Drugs that lower serum lipoprotein levels may also ameliorate glomerular injury in rats (73).

Mesangial cells and monocytes have receptors for certain lipoproteins (74). Monocytes may ingest low-density lipoprotein (LDL) cholesterol and other lipoproteins. These compounds, once incorporated, may initiate a series of biochemical and physiologic processes that are pathologic. For example, monocytes from hypercholesterolemic animals have greater adherence to endothelial cells and migrate to the subendothelial spaces more effectively than normal monocytes (75). Activated macrophages produce more reactive oxygen species. Moreover, rats made hypercholesterolemic by high-cholesterol diets show evidence of increased glomerular arteriole contractility, probably by oxidized lipoprotein activation of thromboxane (76). Hypercholesterolemia may also alter the metabolism of certain fatty acids, including arachidonic and linoleic acid.

In addition to a number of growth factors (see above), many other compounds may affect renal physiology and progression of renal failure (5), including angiotensin and various eicosanoids. Angiotensin not only causes vasoconstriction but also alters glomerular permeability and may stimulate mesangial cell proliferation. The essential fatty acid linoleic acid can be metabolized in the kidney to several families of eicosanoids, including prostaglandins. Prostaglandins have far-reaching effects on blood flow and blood pressure inside the glomerulus, the propensity for platelets to clot in the glomerulus, and the inflammatory process. Certain eicosanoids have antagonistic effects; some increase glomerular blood flow and pressure and may impair platelet clotting, whereas others do the opposite and may also stimulate an inflammatory response. In renal insufficiency, elaboration of certain eicosanoids and other cytokines increases in the kidney (53, 77), and they appear important in the complex adaptive processes the nephron exhibits as kidney function deteriorates (78, 79). In various animal models of chronic renal disease, feeding or infusions of linoleic acid, vasodilatory prostaglandins, or injections of thromboxane or leukotriene B₄ may retard progression of renal failure in rats (54, 55 and 56, 80, 81). In rats with Heymann nephritis, dietary protein itself reduces eicosanoid synthesis (82). Hence the beneficial effects of dietary protein restriction may be partly due to its effects on eicosanoid production.

Medicines

Although results of the above studies in animals indicate an important role for dietary restriction of protein and phosphorus and reduction or increase of certain fats in controlling progressive renal failure, evidence indicates that certain medicines may be able to substitute for or add to these benefits. Angiotensin-converting enzyme inhibitors (which decrease blood pressure by inhibiting the enzyme that catalyzes conversion of angiotensin I to angiotensin II) also lower glomerular capillary blood flow and blood pressure gradients across the glomerular capillary wall in rats with renal insufficiency

(83). They also appear to retard progressive renal failure in these animals (83, 84) and reduce urinary protein excretion in patients with kidney disease (85). These medicines also reduce or abolish microalbuminuria in diabetic patients and retard the rate of progression of renal failure in patients with type I and type II diabetes mellitus and nephropathy and in nondiabetic patients with renal disease (86, 87). Another class of antihypertensive medicines, calcium-channel blockers, may also inhibit progressive renal failure in animals (88, 89). Evidence also strongly suggests that blood pressure control, by itself, retards progressive renal failure (88, 90).

Medicines that bind phosphorus in the intestinal tract enhance the effectiveness of dietary phosphorus restriction in reducing progression of renal failure in animals (45, 68). These drugs are of particular value as an adjunct to dietary phosphorus restriction, because it is difficult to lower dietary phosphorus intake to necessary levels without making diets highly restrictive and unpalatable, which limits adherence.

Human Studies on the Effect of Dietary Therapy on Progression of Chronic Renal Failure

To what extent do the animal data apply to patients? From the mid-1970s to the present, virtually all dietary studies in humans with renal insufficiency have indicated that low intake of dietary protein and phosphorus is effective in retarding the rate of progression of renal failure (91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101 and 102). Some evidence indicates that low protein and phosphorus intakes may act separately to slow progressive renal failure (67).

Earlier studies of this question in humans generally suffered from one or more major defects in experimental design, including small sample size, inadequate or absent control groups, poor documentation of the patients' actual intake, and imprecise methods of measuring renal function. More-recent clinical trials have used more effective research protocols. These latter studies have generally compared a low-protein, low-phosphorus diet providing either about 0.40 to 0.60 g protein/kg body weight per day or about 0.28 g protein/kg/day supplemented with essential amino acids or ketoacids with either a more liberal diet containing approximately 1.0 g protein/kg/day and more phosphorus or an ad libitum diet.

The very low protein diet providing about 0.28 g/kg/day (e.g., about 16–25 g protein/day) is supplemented with 10 to 20 g per day of the nine essential amino acids or of mixtures of several essential amino acids, several nonessential amino acids, and ketoacid or hydroxyacid analogues of other essential amino acids (91, 93, 94, 95 and 96, 98, 101). The ketoacid or hydroxyacid analogue is structurally identical to its corresponding essential amino acid, except that the amino (NH₂) group attached to the second (α) carbon of the amino acid is replaced by a keto group or hydroxy group, respectively.

The ketoacid and hydroxyacid analogues can be transaminated in the body to the respective amino acids, although a proportion of the analogues are degraded rather than transaminated. Because the ketoacids and hydroxyacids lack the nitrogen-containing amino group on the α carbon, these compounds provide the patient

with a lower nitrogen load. As they are degraded in the body, they should generate fewer waste products to accumulate in renal failure. Ketoacid analogues of the branched chain amino acids, especially of leucine, may be particularly likely to promote protein anabolism, possibly by decreasing protein degradation (103, 104). Hence it is possible, but not yet demonstrated, that these ketoacids may play a beneficial role in maintaining protein mass in patients with renal failure.

The largest and most intensive examination of whether dietary control will retard the rate of progression of renal disease was the Modification of Diet in Renal Disease (MDRD) Study funded by the National Institutes of Health (101, 102). This project investigated, in an intention-to-treat analysis, the effects of three levels of dietary protein and phosphorus intakes and two blood pressure management goals on the progression of chronic renal disease. A total of 840 adults with various types of renal disease (excluding insulin-dependent diabetes mellitus) were divided into two study groups according to their GFRs.

In study A, 585 patients with a GFR, measured by ^{131}I -iothalamate clearances, of 25 to 55 mL/1.73 m²/min were examined. Patients were randomly assigned to either a usual-protein, usual-phosphorus diet (protein, 1.3 g/kg standard body weight per day; phosphorus, 16 to 20 mg/kg/day) or a low-protein, low-phosphorus diet (protein, 0.58 g/kg/day; phosphorus, 5–10 mg/kg/day) and also to either a moderate or strict blood pressure goal (mean arterial blood pressure, 107 mm Hg [113 mm Hg for those 61 years of age or older] or 92 mm Hg [98 mm Hg for those 61 years of age or older]). Study B included 255 patients with a baseline GFR of 13 to 24 mL/1.73m²/min. Patients were randomly assigned to the low-protein, low-phosphorus diet or to a very low protein, very low phosphorus diet (protein, 0.28 g/kg/day; phosphorus, 4–9 mg/kg/day) with a ketoacid–amino acid supplement (0.28 g/kg/day). They were also randomly assigned to either the moderate or strict blood pressure control groups, as in study A. Adherence to the dietary protein prescription in the different diet groups was good.

In study A, those prescribed the low-protein diet had significantly faster declines in GFR during the first 4 months than those assigned to the usual protein diet. Thereafter, the rate of decline of the GFR in the low-protein, low-phosphorus group was significantly slower than that in the group fed the usual-protein, usual-phosphorus diet. Over the entire treatment period, the overall rate of progression of renal failure in the two diet groups did not differ. However, the initial greater fall in GFR in the patients prescribed the low-protein diet probably reflects a hemodynamic response to the reduced protein intake rather than more rapid progression of the parenchymal renal disease. This might in fact be beneficial, reflecting reduced intrarenal hyperfiltration and intrarenal hypertension. If this explanation is correct— and it is not proven that it is correct— the slower rate of disease progression after the first 4 months of dietary treatment is consistent with a beneficial effect of this intervention in renal disease. In study B, the very low protein group had a marginally slower decline of GFR than the low-protein group; the average rate of decline did not differ significantly between the two groups ($P = .07$).

In a secondary analysis of study B in which the decrease in GFR was correlated with the actual quantity of protein ingested, progression of renal failure was the same with

ingestion of the low protein diet as with the very low protein diet supplemented with ketoacids and amino acids (102). However, if the two diet groups were analyzed together and the protein intake of the latter diet was considered to be the sum of the protein and ketoacid–amino acid supplement ingested, a significantly lower rate of decline in GFR was found in the patients who actually ingested the lower-protein diets (102). These findings suggest that a lower total protein intake, but not the ketoacid–amino acid preparation itself, retarded the rate of progression of renal failure.

The MDRD study did not compare the very low protein ketoacid/amino acid supplemented diet with the usual protein intake. Moreover, the lack of significant effect of the low-protein diet on progression of renal failure might possibly reflect the rather short mean duration of treatment in the MDRD study, 2.2 years. Indeed, if the trend toward slower progression of renal failure in the low-protein-diet groups that was present at the termination of the MDRD study had persisted during a longer follow-up period, statistically significant slower progression would have been observed with the 0.60 g/kg protein diet in study A and the very low protein, ketoacid–amino acid supplemented diet in study B. The response to low-protein diets may possibly be similar to the experience with the Diabetes Control and Complications Trial (DCCT) comparing intensive and more-conventional serum glucose control (105). After 2 years of study, there was no trend toward less microalbuminuria in the more rigorously controlled glucose group; however, when the study was terminated after a mean of 6.5 years, a much lower incidence of microalbuminuria was found in these latter patients.

Two other factors may have reduced the differences in the rate of progression between the diet groups. Many patients assigned to each diet in the MDRD study showed no progression of kidney disease. Also, a disproportionately large number of patients had adult polycystic kidney disease, which may be less responsive to dietary therapy.

Two recent meta-analyses each evaluated several clinical trials of the effects of low-protein and (in some studies) low-phosphorus diets on the rate of progression of kidney failure (106, 107). The two metaanalyses evaluated a somewhat different series of clinical trials, and only one included the MDRD trial (107). Both metaanalyses concluded that low-protein diets retard the rate of progression of renal failure. One of these studies also analyzed the results of five prospective clinical trials of the effects of such diets on progression of renal failure in patients with insulin-dependent diabetes mellitus (107). This metaanalysis indicated that low-protein diets also retard progression in these individuals. However, the results were much less definitive because many fewer patients were analyzed; two of the trials had no randomized, concurrent control group; and the key endpoints were less definitive.

Vegetarian diets providing soy protein may retard progression of chronic renal failure more effectively than diets of similar protein content that contain animal protein (62, 108, 109). The mechanism of such an effect is not known, but it may be related to the total content and different composition of fats in the vegetarian diet. The latter diet is reported to improve the serum lipid profile in patients with chronic renal disease and the nephrotic syndrome (109, 110).

An interesting ancillary question concerning these studies of the effects of diet on

progression of renal failure is whether diet may promote or retard development of renal failure in individuals with no underlying renal disease. As indicated above, very high cholesterol diets may cause renal failure in animals. Rats without renal disease or with only one kidney that are allowed to eat ad libitum or are fed high-protein diets throughout life have a higher incidence of renal disease in old age ([111](#), [112](#), [113](#) and [114](#)). In normal humans, after about the fourth decade of life, renal function falls progressively with age ([115](#)); possibly high-protein diets play a role in this phenomenon. As indicated above, in healthy young men and women, high-protein intake increases renal blood flow and GFR ([21](#)). Moreover, similarities exist between the type of scarring that occurs in normal aging human kidneys as compared with kidneys of rats fed high-protein diets. Adults with congenital absence, developmental failure, or surgical removal of one kidney during childhood have a slightly higher incidence of spontaneous glomerular scarring in the remaining kidney ([116](#)). The cause of this phenomenon is not known. It is possible, but by no means established, that the typical protein intake of Americans, which is considerably higher than the recommended dietary allowances (RDAs) for dietary protein ([117](#)), may increase glomerular capillary blood flow and hydraulic pressure and cause progressive renal injury.

NUTRITIONAL ALTERATIONS IN THE NEPHROTIC SYNDROME

The nephrotic syndrome is a kidney disorder characterized by loss of large quantities of protein in the urine (3.0 g/day), low serum albumin concentrations, high serum levels of cholesterol and other fats, and accumulation of excess body water to form edema ([118](#)). This condition is caused by diseases that affect the glomerulus and increase glomerular permeability to protein. Because they have large urinary protein losses and their appetite is frequently poor, patients with the nephrotic syndrome often develop protein malnutrition and debility. Certain vitamins and most trace elements are protein bound in plasma, and these patients are therefore also at risk for developing deficiencies of these nutrients. Vitamin D deficiency has been reported in patients with the nephrotic syndrome ([118](#), [119](#)). Malnutrition may occur in nephrotic patients even when they do not have advanced kidney failure. For a given type of renal disease, heavy proteinuria is associated with more-rapid progression of renal failure, possibly because of incorporation of proteins into the glomerular mesangium, which may cause sclerosis or inflammatory responses ([120](#)). Many growth factors and other bioactive substances are also bound to proteins filtered by the leaky glomerulus in patients with the nephrotic syndrome. It is postulated that some of these bioactive compounds may promote progressive renal damage ([121](#)).

Studies indicate that both protein-restricted diets and angiotensin-converting enzyme inhibitors reduce proteinuria in nephrotic patients without decreasing serum albumin levels or albumin pools ([122](#), [123](#), [124](#) and [125](#)). Treat-ing nephrotic syndrome patients with both an angiotensin-converting enzyme inhibitor, which may decrease proteinuria, and a higher-protein diet, to increase protein synthesis, has been suggested as the most effective way to maintain a more normal albumin mass in these individuals ([122](#), [123](#), [124](#) and [125](#)). This has been demonstrated in one study in nephrotic rats but has not yet been well tested in nephrotic patients ([125](#)).

NUTRITIONAL AND METABOLIC CONSEQUENCES OF CHRONIC

RENAL FAILURE

Chronic renal failure causes pervasive nutritional and metabolic disorders that may affect virtually every organ system. These abnormalities are reviewed briefly below.

Clinical, Nutritional, and Metabolic Disorders

Patients with chronic renal failure develop azotemia and uremia. Azotemia refers to accumulation of nitrogenous metabolites in the blood. Uremia is the combination of azotemia with the clinical signs and symptoms of advanced renal failure. Chronic advanced renal failure is a complex disorder caused by marked reduction in the excretory, endocrine, and metabolic functions of the kidney.

The many symptoms of uremia include weakness, a feeling of ill health, insomnia, fatigue, loss of appetite, nausea, vomiting, diarrhea, itching, muscle cramps, hiccups, twitching or jerking of the extremities, fasciculations, tremors, emotional irritability, and decreased mental concentration and comprehension. A characteristic fetid breath is often present. The sodium and water disturbances associated with renal failure include retention leading to congestive heart failure and hypertension or, if excessive sodium depletion occurs, reduction in extracellular fluid volume and a fall in blood pressure.

Altered serum concentrations of other electrolytes and acidosis can occur and can have profound and life-threatening effects on the physiologic processes and metabolism of the body ([Fig. 89.1](#)). Abnormalities in water and electrolyte balance and acidosis are caused by impaired ability of the failing kidney to regulate the content of water, salts, and acids in the body. Most of these clinical and metabolic disorders can be controlled or prevented with dietary therapy or dialysis. Untreated uremia can lead to lethargy, loss of consciousness, coma, convulsions, and death.

Chronic advanced renal failure causes pervasive alterations in the absorption, excretion, and metabolism of many nutrients. These disorders include accumulation of chemical products of protein metabolism ([1](#)); decreased ability of the kidney either to excrete a large sodium load or to conserve sodium rigorously when dietary sodium is restricted ([126](#)); impaired renal ability to excrete water, potassium, calcium, magnesium, phosphorus, trace elements, acids, and other compounds; a tendency to retain phosphorus ([126a](#), [127](#), [128](#)); decreased intestinal absorption of calcium ([127](#)) and possibly iron ([128](#)); and a high risk for developing certain vitamin deficiencies, particularly of vitamin B₆, vitamin C, folic acid, and the most potent known form of vitamin D, 1,25-dihydroxycholecalciferol ([127](#), [129](#)). The patient with chronic renal failure is also likely to accumulate certain potentially toxic chemicals such as aluminum that normally are ingested in small amounts and excreted in the urine ([128](#)).

Uremia is also a polyendocrinopathy, and many of its metabolic and clinical manifestations are caused by the endocrine disorders. A number of hormone concentrations are elevated in renal failure, particularly those of the peptide hormones, because of the impaired ability of the kidney to degrade peptides. These substances include parathyroid hormone, glucagon, insulin, growth hormone, prolactin, luteinizing

hormone, often follicle-stimulating hormone (FSH), and gastrin ([127](#), [130](#), [131](#), [132](#), [133](#), [134](#), [135](#), [136](#), [137](#) and [138](#)). Increased secretion of some hormones, such as parathyroid hormone and insulin, may contribute to elevated plasma levels. Chronically uremic patients have altered thyroid hormone levels that are similar to those in the euthyroid sick syndrome, but hypothyroidism is not common ([139](#)). Of the hormones elaborated by the kidney, plasma erythropoietin and 1,25-dihydroxycholecalciferol are reduced ([4](#), [5](#), [6](#) and [7](#), [127](#)), and plasma renin activity may be increased, normal, or decreased. Serum IGF-I (somatomedin C) levels, measured by radioreceptor assay or radioimmunoassay, are usually reported to be normal in renal failure, but there is resistance to the activity of IGF-I ([140](#), [141](#)). Sensitivity to the actions of glucagon increases; this is reversed by hemodialysis, but hyperglucagonemia persists ([131](#)). Resistance to the peripheral action of insulin occurs ([142](#)). These effects on insulin and glucagon contribute to the mild glucose intolerance usually present in chronic renal failure ([132](#)). Impaired actions of hormones in uremia may be due to circulating inhibitors in serum, downregulation of receptor number, or postreceptor defects in the signal transduction system. Cytosolic calcium participates in certain cell signaling systems. Elevated basal cytosolic calcium, induced by hyperparathyroidism, appears to be one of the postreceptor signal transduction disorders induced by chronic renal failure ([143](#)).

The ability of the failing kidney to synthesize or to metabolize many compounds, including amino acids, is impaired. In chronic renal insufficiency, the kidney displays reduced catabolism of glutamine, impaired synthesis of alanine, and decreased conversion of glycine to serine ([144](#), [145](#)). Many products of metabolism accumulate in renal failure; the majority are derived from amino acids and proteins ([146](#)). Most of these compounds accumulate because of decreased excretion, although in some instances enhanced synthesis or impaired degradation by the diseased kidney or other organs plays a role. Abnormal metabolism in the gastrointestinal tract and probably the liver also contributes to increased levels of certain metabolites in renal failure ([147](#)).

Quantitatively, the most important end product of nitrogen metabolism is urea ([146](#)). In a clinically stable patient with chronic renal failure who eats at least 40 g of protein daily, the net quantity of urea produced each day contains an amount of nitrogen equal to about 80 to 90% of the daily nitrogen intake. Guanidines are the next most abundant end product of nitrogen metabolism; these compounds include creatinine, creatine, and guanidinosuccinic acid ([1](#), [146](#)). The “middle molecules” are a class of compounds midway in size between the small, readily dialyzable substances that accumulate in renal failure and small proteins. Most middle molecules are considered to have molecular weights of approximately 300 to 2500 and contain amino acids. Levels of some middle-molecule compounds increase in uremic sera ([1](#), [146](#)). Despite decades of study, the compounds that cause uremic toxicity are not well defined; probably, many compounds contribute to this toxicity. Prime suspects as uremic toxins include urea, guanidine compounds, phenolic acids, middle molecules, and some of the hormones elevated in uremic plasma, especially parathyroid hormone and possibly glucagon ([1](#), [131](#), [143](#), [146](#), [148](#), [149](#)).

Altered gastrointestinal function may affect nitrogen metabolism in uremic patients. The gastrointestinal tract metabolizes urea, uric acid, creatinine, and choline and synthesizes (or releases from larger molecules) dimethylamine, trimethylamine,

ammonia, sarcosine, methylamine, and methylguanidine (146). Gut metabolism or synthesis of many of these compounds increases in chronic renal failure, possibly because of increased numbers of intestinal bacteria (147).

Some of the metabolic alterations in uremia are adaptive homeostatic responses that both benefit and harm the patient (148). Hyperparathyroidism is an example. As the kidneys fail, impaired excretion of phosphorus leads to phosphorus retention. Concomitantly, the diseased and scarred renal parenchyma is less able to convert 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (127). Low plasma concentrations of 1,25-dihydroxycholecalciferol lead to an increase in parathyroid hormone secretion. In addition, deficiency of 1,25-dihydroxycholecalciferol both impairs intestinal calcium absorption and causes resistance to the actions of parathyroid hormone in bone. These alterations also promote hypocalcemia, low serum levels of both calcium and 1,25-dihydroxycholecalciferol, and lead to development of hyperparathyroidism. Elevated serum parathyroid hormone reduces renal tubular reabsorption of phosphorus (enhancing urine phosphorus excretion), lowers serum phosphorus, promotes renal synthesis of 1,25-dihydroxycholecalciferol, mobilizes calcium from bone, and increases intestinal calcium absorption (although intestinal calcium absorption usually remains low or, in mild renal insufficiency, normal). The benefits derived from these homeostatic actions are that more normal concentrations of plasma phosphorus and calcium are maintained. The “trade-off” is development of hyperparathyroidism (148, 149). Parathyroid hormone has been implicated as a pervasive uremic toxin that adversely affects many organs and tissues and contributes to the uremic syndrome (149).

With the institution of dietary therapy or treatment with hemodialysis or peritoneal dialysis, blood levels of many metabolic products that accumulate in uremic plasma decrease, and the patient may experience clinical improvement. Maintenance hemodialysis or peritoneal dialysis enables patients to live for many years with essentially no renal function. Despite such improvement, however, many clinical and metabolic disorders may persist or even progress. These include (a) a type IV hyperlipidemia and other disorders of lipid metabolism, (150, 151); (b) a high incidence of cardiovascular disease (152); (c) osteodystrophy with disordered bone architecture, osteoporosis, or osteomalacia (aluminum toxicity often contributes to the osteomalacia) (127, 153); (d) anemia (5, 6 and 7); (e) impaired immune function and decreased resistance to infection; (f) mildly impaired peripheral and central nervous system function; (g) muscle weakness and atrophy; (h) frequent occurrence of viral hepatitis (154); (i) sexual impotence and infertility; (j) generalized wasting and malnutrition (155, 156, 157, 158, 159, 160, 161, 162 and 163); (k) a general feeling of ill health or emotional depression; and (l) poor rehabilitation (164). Most of these complications can be aggravated by poor nutritional intake or improved with good nutrition.

Anemia, usually primarily due to impaired erythropoiesis caused by erythropoietin deficiency, can be treated effectively with this hormone (7). To reduce the risks and cost of therapy, usually enough erythropoietin is given to raise the hematocrit to only 33 to 36%. When kidney failure is a complication of an underlying systemic disease, such as diabetes mellitus, hypertension, or lupus erythematosus, other manifestations of the underlying disease may also adversely affect the patient and may progress. All the above problems do not seriously affect every patient, and many patients with chronic

uremia or who undergo dialysis lead full and productive lives.

The above considerations indicate that intestinal absorption, excretion, and/or metabolism of virtually every nutrient may be altered in chronic renal failure. In addition, decreased intake of food and excessive intake of certain minerals (e.g., aluminum from ingestion of aluminum phosphate binders) may alter nutritional status. Medicinal therapy may also adversely affect nutrient metabolism in renal failure. For example, anticonvulsant medicines may cause deficiencies of vitamin D and folic acid; hydralazine, isoniazid, and other medicines may cause vitamin B₆ deficiency (165). The many altered nutritional requirements and tolerances that occur in chronic renal failure are a challenge for the dietary therapy of such patients.

Wasting Syndrome

The patient with chronic renal failure frequently shows evidence of wasting or protein-energy malnutrition (Table 89.2) (155, 156, 157, 158, 159, 160, 161, 162 and 163, 166). Evidence includes decreased relative body weight (i.e., the patient's body weight divided by the median weight of normal people of the same age, height, sex, and skeletal frame size), skinfold thickness (an estimate of total body fat), arm muscle mass, and total body nitrogen and potassium; low growth rates in children; decreased serum concentrations of many proteins including albumin, transferrin, and certain complement proteins; and low muscle alkali-soluble protein. The plasma amino acid pattern, which is pathognomonic for renal failure, also resembles that found in malnutrition. The findings of malnutrition are sometimes observed in nondialyzed patients with chronic renal failure but are more prevalent in patients undergoing maintenance hemodialysis or chronic peritoneal dialysis. Not every dialysis patient shows evidence of these disorders; however, virtually every survey of maintenance dialysis patients indicates that as a group, these patients show evidence of malnutrition (155, 156, 157, 158, 159, 160, 161, 162 and 163, 166). Malnutrition is mild to moderate in most malnourished chronic dialysis patients; about 6 to 8% of dialysis patients have evidence of severe wasting. In addition to protein-energy malnutrition, patients with chronic renal failure are at higher risk for malnutrition of iron, zinc, and certain vitamins, including vitamin B₆, vitamin C, folic acid, 1,25-dihydroxycholecalciferol and possibly carnitine (167, 168, 169, 170, 171 and 172).

Anthropometry, Body Composition, and Isotope Dilution Studies*	Biochemistry*
Decreased	Decreased
Body weight	Serum
Height (children)	Total protein
Growth (children)	Albumin
Body fat (skinfold thickness)	Transferrin
Fat-free solids	Prealbumin
Intracellular water	Cr
Muscle mass (midarm muscle circumference)	Cr Activator
Total body potassium (nondialyzed patients)	Cholinesterase
Total body nitrogen (CPD patients)	Plasma
Total albumin mass, synthesis, and catabolism (valine pools (nondialyzed patients))	Leucine
	Isoleucine
	Total tryptophan
	Valine
	Tyrosine
	Valine:glycine ratio
	Essential:nonessential ratio
	Muscle
	Alkali-soluble protein
	RNA:DNA ratio
	Valine
	Tyrosine
	Normal to increased
	Plasma glycine

*Patients with chronic renal failure may have normal values for these parameters, but statistical comparisons indicate that the values are often abnormal in these individuals.

Table 89.2 Evidence for Protein-Energy Malnutrition in Patients with Advanced Chronic Renal Failure

There are many causes of protein-energy malnutrition in chronic renal failure (158). First, dietary intake is often inadequate, particularly for energy requirements (156, 157, 173, 174, 175, 176 and 177). The low dietary intake is mainly due to anorexia, caused by uremic toxicity, the debilitating effects of acute or chronic illness, and depression. The effects of acute superimposed illness on the patient's ability to eat or to accept tube feeding also reduce nutrient intake. In addition, the dietary prescription in renal failure, which is low in protein and other nutrients and may be difficult to prepare or unpalatable, can lead to low nutrient intake.

Second, patients with renal failure have a high incidence of superimposed catabolic illnesses (178, 179 and 180). Third, the dialysis procedure itself may induce wasting. Hemodialysis and peritoneal dialysis remove free amino acids, peptides or bound amino acids (181, 182, 183 and 184), water-soluble vitamins (129), proteins (with peritoneal dialysis and, rarely, with hemodialysis) (182, 185), glucose (during hemodialysis with glucose-free dialysate) (186), and probably other bioactive compounds. Hemodialysis also increases net protein breakdown, especially by activating the complement cascade system and inducing release of catabolic cytokines (187, 188). This catabolic stress is particularly likely when bioincompatible dialyzer membranes are used (187, 188) and can be mitigated with use of dialyzers made from more biocompatible materials (188, 188a). Fourth, patients with renal failure sustain blood loss. Because blood is a rich source of protein, this loss might contribute to protein depletion. Blood loss results from frequent sampling for laboratory testing, occult gastrointestinal bleeding (common in renal failure), and sequestration of blood in the hemodialyzer and blood tubing (189).

Other possible but unestablished causes of wasting include (a) altered endocrine activity, particularly resistance to insulin (142) and IGF-I (140, 141), hyperglucagonemia (131), hyperparathyroidism (127, 143, 148, 149), and deficiency of 1,25-dihydroxycholecalciferol (127); (b) endogenous uremic toxins (c); exogenous uremic toxins, such as aluminum; and (d) loss of metabolic functions of the kidney. Because the kidney synthesizes or degrades many biologically valuable compounds, including amino acids (144, 145), loss of these activities in kidney failure could possibly disrupt the body's metabolism and promote wasting.

Several investigators have shown an inverse relationship between dietary protein consumption (as determined by the patient's urea nitrogen appearance [UNA] or average SUN level) and morbidity and mortality (166, 190, 191 and 192). Moreover, a striking inverse relationship exists between the serum albumin level and the mortality rate in these patients (166). These studies were not prospective with randomized assignment to different nutritional intakes, and it is likely that the patients' underlying illnesses contributed to both their high mortality and the low protein intake or serum albumin. Nonetheless, the data are consistent with the thesis that poor nutrient intake

and malnutrition adversely affect prognosis in patients receiving maintenance hemodialysis or peritoneal dialysis.

DIETARY MANAGEMENT OF CHRONIC RENAL DISEASE AND CHRONIC RENAL FAILURE

A recommended plan for nutrient intake is given in [Table 89.3](#) for patients with chronic renal failure who are not undergoing dialysis therapy as well as for patients undergoing maintenance hemodialysis or chronic peritoneal dialysis. This approach to dietary management of these patients is explained below.

Table 89.3 Recommended Nutrient Intake for Nondialyzed Patients with Chronic Renal Failure and Patients Undergoing Maintenance Hemodialysis or Peritoneal Dialysis

General Principles of Dietary Therapy

The widespread metabolic and nutritional disorders, frequent occurrence of protein-energy malnutrition, and evidence that diet may retard the progression of renal failure indicate that nutritional management is critical to the treatment of chronic renal failure. The three goals of dietary therapy are (a) to maintain good nutritional status, (b) to prevent or to minimize uremic toxicity and the metabolic derangements of renal failure, and (c) to retard or to stop the rate of progression of renal failure.

Adherence to specialized diets is difficult and stressful for most patients and their families. Generally, patients must make a major change in their behavior patterns and forsake many of their traditional sources of daily pleasure. They must procure special foods, prepare special recipes, usually forgo or severely limit intake of many favorite foods, and often eat foods that are not desirable. Demands are made on the time, effort, and emotional support of family or close associates. Thus, it is incumbent on the physician not to prescribe radical changes in dietary intake without a clear indication that they may benefit the patient. To ensure successful dietary therapy, patients with

renal failure must undergo extensive training in the principles of nutritional therapy and the design and preparation of diets and receive continuous encouragement regarding dietary adherence. They must receive repeated retraining with regard to their nutritional therapy. When nutritional intake is not carefully monitored, patients tend to adhere poorly to dietary prescriptions and may eat too little of certain nutrients rather than too much.

A team approach to dietary management may improve adherence to the special diet. The team should include the physician, dietitian, close family members, nursing staff, and (where available) psychiatrists or social workers. A problem-oriented approach to dietary compliance can be very effective (193). Diet plans should be tailored to the patient's tastes, and at each visit, the physician should monitor dietary intake and discuss the results with the patient.

The physician must strongly support the dietitian's efforts to train and counsel the patient and to obtain dietary compliance. Generally, the patient's spouse or other close relatives or friends should work closely with the patient to provide moral support and assist with acquisition and preparation of food. To promote adherence to the diet, the entire medical team should assume an energetic, positive, and sympathetic approach. Research indicates that these techniques enable many patients to attain acceptable dietary compliance (193).

Patients with advanced renal failure are at particular risk for inadequate energy intake. Because the prescribed diets are often marginally low in some nutrients (e.g., protein) and high in others (e.g., calcium) and malnutrition is frequent, the adequacy of the diet and the patient's nutritional status must be monitored periodically. Dietary intake should be assessed by interviews, dietary diaries, and measurement of UNA and nutritional status evaluated by anthropometry, biochemical measurements, bone radiography, and other parameters (194) (see Table 89.2). The dietitian is often best qualified to perform nutritional evaluation. In general, to maintain good dietary compliance and to monitor fluid and electrolyte disorders and clinical and nutritional status, patients with advanced renal failure should be seen monthly by the physician and the dietitian. Patients with slowly progressive mild-or-moderate renal insufficiency, under some circumstances may see the physician less frequently but may still need to see the dietitian monthly to promote adherence to the diet.

Evidence suggests that chronically uremic patients are at greatest risk for protein energy malnutrition when the GFR falls below 5 mL/min and when the patient is beginning maintenance dialysis therapy (158, 175, 195, 196). Moreover, the nutritional status of patients at the onset of chronic dialysis treatment appears to be a good predictor of nutritional status 1 to 2 years later (158, 197). Hence, particular effort should be made to prevent malnutrition as the patient approaches the time when dialysis should be instituted and during the first few weeks of chronic dialysis therapy. This effort should be directed toward maintaining good nutritional intake, rapidly instituting therapy for supervening illnesses, and maintaining good nutritional intake during such illnesses.

Urea Nitrogen Appearance and the Serum Urea Nitrogen:Serum Creatinine Ratio

Control of protein intake is pivotal to nutritional management of patients with acute or chronic renal failure. Hence one must accurately monitor nitrogen intake. Fortunately, this is possible for most patients. Those who are in nitrogen balance should have a total nitrogen output equal to nitrogen intake minus about 0.5 g nitrogen per day for unmeasured losses from growth of skin, hair, and nails and from sweat, respiration, flatus, and blood drawing (198). For clinical purposes, a slightly positive or negative balance does not substantially alter the use of the nitrogen output to estimate intake. If patients are in very positive or negative balance (e.g., from pregnancy or severe infection), nitrogen output may not reflect intake. However, it is usually readily apparent to the clinician whether the patient is in very positive or negative balance and whether the nitrogen output will reflect intake.

Measurement of total nitrogen output is too laborious and expensive to be widely applied for clinical uses. However, because urea is the major nitrogenous product of protein and amino acid degradation, the UNA can be used to estimate total nitrogen output and hence nitrogen intake (199, 200 and 201). UNA refers to the amount of urea that appears or accumulates in body fluids and all output, such as urine, dialysate, and fistula drainage. The term *urea nitrogen appearance* (UNA) is used rather than urea production or generation because some urea is degraded in the gastrointestinal tract; the ammonia released from urea is largely transported to the liver and converted back to urea (202, 203). Thus, the enterohepatic urea cycle has little effect on urea or total nitrogen economy, and this cycle can be ignored without compromising the ability of the UNA to estimate total nitrogen output or intake accurately. Moreover, urea recycling cannot be measured without costly and time-consuming isotope studies.

UNA is calculated as follows:

Equation 1:

$$\begin{aligned} \text{UNA} = & \text{urinary urea nitrogen} \\ & + \text{dialysate urea nitrogen} \\ & + \text{change in body urea nitrogen} \end{aligned}$$

where all values are in grams per day.

Equation 2:

$$\begin{aligned} \text{Change in body urea nitrogen (g/day)} = & \\ & (\text{SUN}_f - \text{SUN}_i \text{ g/L/day}) \times \text{BW}_i \text{ (kg)} \times (0.60 \text{ L/kg}) \\ & + (\text{BW}_f - \text{BW}_i \text{ kg/day}) \times \text{SUN}_f \text{ (g/L)} \times (1.0 \text{ L/kg}) \end{aligned}$$

where *i* and *f* are the initial and final values for the period of measurement, SUN is

serum urea nitrogen (grams per liter), BW is body weight (kilograms), 0.60 is an estimate of the fraction of body weight that is water, and 1.0 is the fractional distribution of urea in the weight that is gained or lost (i.e., 100%).

The estimated proportion of body weight that is water may be higher in patients who are edematous or lean and lower in individuals who are obese or very young. Changes in body weight during the 1- to 3-day period of UNA measurement are assumed to be due entirely to changes in body water. In patients undergoing hemodialysis, the urea concentration in dialysate is low and difficult to measure accurately, and UNA can be calculated during the interdialytic interval and then normalized to 24 hours. Because many patients undergoing dialysis have little or no urinary excretion, the equation for calculating their UNA during the interdialytic interval often can be simplified to Equation 2.

In our metabolic studies, the relationship between UNA and total nitrogen appearance (output) in chronically uremic patients not undergoing dialysis is as follows ([201](#)):

Equation 3:

$$\text{Total nitrogen appearance} = 1.19 \text{ UNA} + 1.27$$

where all values are in grams per day. If the individual is more or less in neutral nitrogen balance, the UNA also correlates closely with nitrogen intake. Equation 4 describes our observed relationships between UNA and dietary nitrogen intake in clinically stable, nondialyzed, chronically uremic patients in neutral protein balance.

Equation 4:

$$\text{Dietary nitrogen intake} = 1.20 \text{ UNA} + 1.74$$

where all values are in grams per day. Multiplying Equation 3 by 6.25 converts total nitrogen output to net protein degradation (grams per day), that is, the difference between the absolute rates of protein degradation and protein synthesis in the study. Multiplying Equation 4 by 6.25 converts dietary nitrogen intake to dietary protein intake (grams per day). When both nitrogen intake and UNA are known, nitrogen balance can be estimated from the difference between nitrogen intake and nitrogen output estimated from the UNA.

If the patient is markedly anabolic (e.g., as in pregnancy, particularly in its later stages), Equation 4 will underestimate nitrogen intake. For patients who have large protein losses, such as from nephrotic syndrome or peritoneal dialysis, or who are acidemic and have sufficient kidney function to excrete large quantities of ammonia, equations 3 and 4 will underestimate both nitrogen output and nitrogen intake. In most circumstances, however, these conditions are not present, and the UNA provides a powerful tool for monitoring nitrogen output and intake or estimating balance. Maroni et al. and other researchers have described similar techniques for monitoring these parameters ([199](#),

[200](#)).

The relationships between the UNA, total nitrogen output, and dietary nitrogen intake in patients undergoing continuous ambulatory peritoneal dialysis are shown in Equations 5 and 6 ([201](#)). Other researchers have described similar equations ([204](#)). Since protein losses in peritoneal dialysate are variable, some equations have an independent term for the daily protein losses in peritoneal dialysate. As indicated above, multiplying these terms by 6.25 converts the equations to net protein output (grams per day) or, in clinically stable patients who are in approximately neutral protein balance, to dietary protein intake (grams per day).

Equation 5:

$$\text{Total nitrogen output (g/day)} = 0.94 \text{ UNA} + 5.54$$

Equation 6:

$$\text{Dietary nitrogen intake (g/day)} = 0.97 \text{ UNA} + 6.80$$

The UNA (also called G_u) in hemodialysis patients can be calculated by urea kinetic modeling ([199](#), [205](#)). This technique essentially involves pre- and postdialysis SUNs and body weights, the urea clearance characteristics of the dialysis, and the blood flow, dialysate flow, and duration of dialysis therapy. The relationships between UNA, net protein degradation, and dietary nitrogen intake in maintenance hemodialysis patients have been described in other studies. A critique of the precision and reproducibility of these calculations is presented elsewhere ([201](#), [205](#)).

The SUN:serum creatinine ratio also correlates closely with dietary protein or amino acid intake in chronically uremic patients who are not undergoing dialysis treatment ([206](#)). This relationship can be used to estimate the recent daily intake of such patients. Although this ratio is not as precise as the UNA and is influenced by certain clinical factors, it is easy and inexpensive to measure.

Dietary Prescription

For purposes of nutritional prescription, the body weights in this chapter refer to the standard (normal) body weights from the NHANES data ([207](#)). An exception is individuals who are obese (e.g., more than 115% of standard body weight) or very underweight (e.g., less than 90% of standard body weight). For these patients, the adjusted actual body weight (aBW) may be used for the body weight term ([207a](#)). The adjusted aBW appears to be gaining in popularity but has not yet been validated by experimental data. The aBW, modified from the American Dietetic Association report ([207a](#)), is calculated as follows:

$$\text{Adjusted aBW} = \text{standard (normal) BW} + ([\text{edema-free aBW} - \text{standard (normal) BW}] \times$$

0.25)

Protein, Amino Acid, and Ketoacid Intake

GFR above 70 mL/1.73 m²/min. Virtually no data exist concerning the optimal dietary protein and phosphorus intakes for patients with chronic renal disease and mildly impaired renal function. As more information becomes available, dietary guidelines doubtless will change. At present, we do not routinely restrict protein for patients with a GFR above 70 mL/1.73 m²/min, except perhaps to 0.80 to 1.0 g/L/day, unless renal function is continuing to decline. In the latter case, the patient is treated as indicated in the next paragraph.

GFR of 25 to 70 mL/1.73 m²/min. The studies, including the metaanalyses (see above), indicating that low-protein, low-phosphorus diets may retard progression of renal failure are sufficiently convincing to warrant offering patients dietary therapy. Currently, our policy is to discuss with the patient the evidence that such diets retard progression and to indicate that the data justify restricting dietary protein. If the patient agrees to dietary therapy, a diet is offered providing 0.55 to 0.60 g protein/kg/day, of which at least 35 g/kg/day is high-biologic-value protein to ensure sufficient intake of the essential amino acids. This quantity of protein should maintain neutral or positive nitrogen balance, and for many patients, it should not be excessively burdensome.

GFR below 25 mL/1.73 m²/min without Dialysis. When GFR falls below 25 mL/1.73 m², the potential advantages of a low-protein, low-phosphorus diet become more compelling. First, at this degree of renal insufficiency, potentially toxic products of nitrogen metabolism begin to accumulate in larger quantities. The low-protein diet will generate fewer potentially toxic nitrogenous metabolites. Second, because the low-protein diet generally contains less phosphorus and potassium, intake of these minerals can be reduced more readily with this diet (see later sections on recommended [phosphorus](#) and [potassium](#) intakes). Third, some patients with chronic renal insufficiency eat too little protein rather than too much. Specific training and encouragement to follow a prescribed diet may increase the likelihood that the patient will not ingest too little protein. The dietary prescription should include 0.60 g of protein/kg/day with at least 0.35 g/kg/day of high-biologic-value protein ([Table 89.3](#)). This diet will generally maintain neutral or positive nitrogen balance as long as energy intake is not deficient and should generate a low UNA ([200](#), [201](#), [208](#), [209](#)). The protein content of this diet should be increased by 1.0 g of high-biologic-value protein daily for each gram of protein excreted in the urine each day.

Because of the lack of definitive evidence in large-scale clinical trials that the ketoacid–amino acid supplemented, very low protein diets retard progression of renal failure, these supplements are not currently available in the United States. Some researchers consider this unfortunate because smaller-scale studies suggest that these compounds are very effective in slowing progression ([98](#), [210](#)). There is insufficient research experience to evaluate the potential for essential amino acid–supplemented, very low protein diets to retard progression, and these diets are therefore not currently

recommended for this purpose.

When the GFR falls below 5 mL/1.73 m²/min, there is inconclusive evidence that patients fare as well with low-nitrogen diets as with regular dialysis and higher protein intake. Because patients with these low GFR levels may be at high risk for malnutrition ([158](#), [175](#), [195](#)), it is recommended that maintenance dialysis treatment or renal transplantation be inaugurated at this time.

Nephrotic Syndrome. Formerly, it was recommended that patients with the nephrotic syndrome be prescribed high-protein diets to prevent protein malnutrition ([211](#)). Current evidence that a high-protein intake may accelerate progression of renal failure has caused a rethinking of the dietary protein prescription for nephrotic patients. Moreover, low-protein diets (e.g., 0.80 g/kg/day) may decrease urinary protein excretion and may maintain or actually slightly increase serum albumin levels ([123](#), [124](#), [212](#)). A vegetarian, soy-based, low-protein diet may decrease proteinuria and serum lipid levels in nephrotic patients ([108](#), [109](#) and [110](#)). Until more information is available, it is recommended that patients with the nephrotic syndrome be prescribed a diet containing about 0.70 g protein/kg/day and an additional 1.0 g/day of high-biologic-value protein for each gram of urinary protein lost each day above 5.0 g/day. The angiotensin-converting enzyme inhibitors may reduce proteinuria ([122](#)) and thus should be given preference in treating hypertension in these patients. Patients with the nephrotic syndrome should be given multivitamins, including vitamin D supplements, and must be monitored closely for depletion of protein and protein-bound nutrients, including vitamin D analogues and trace elements.

Maintenance Dialysis Therapy. Although few studies of dietary protein requirements have been conducted in patients undergoing maintenance hemodialysis ([213](#), [214](#) and [215](#)), it seems clear that these patients have greater protein needs because of the removal of amino acids and peptides by dialysis procedures ([181](#), [182](#) and [183](#)) and possibly because of other metabolic disorders that occur with end-stage renal disease, such as catabolic stimulus of hemodialysis ([188](#), [188a](#), [214](#)). On the basis of available evidence from nitrogen balance studies and clinical monitoring of outpatients, it is recommended that patients undergoing maintenance hemodialysis receive 1.0 to 1.2 g protein/kg/day ([Table 89.3](#)). Because many maintenance hemodialysis patients have evidence of protein malnutrition, a protein intake of 1.2 g/kg/day is preferable for most individuals. Patients undergoing chronic daily peritoneal dialysis (CPD) lose about 9 g of protein per day into dialysate as well as a small amount of peptides and about 2.5 to 4.0 g/day of amino acids ([184](#), [185](#)). Nitrogen balance studies suggest that CPD patients should, in general, be prescribed 1.2 to 1.3 g protein/kg/day ([216](#)). Protein-depleted patients undergoing CPD may be prescribed up to 1.5 g protein/kg/day ([216](#)).

At least 50% of the daily protein intake of all patients undergoing maintenance dialysis should be of high biologic value. Some physicians suggest that maintenance hemodialysis or CPD patients may maintain their body protein mass with lower dietary protein intake (e.g., about 0.9 g/kg/day). The above recommendations, although based upon relatively small numbers of studies, are designed to maintain good protein nutrition for the great majority of maintenance dialysis patients. Hence, although some patients may maintain good protein nutrition with lower daily protein intake, there is no

demonstrated method for identifying these individuals. Because there is a high incidence of protein malnutrition in these patients ([154](#), [155](#), [156](#), [157](#), [158](#), [159](#), [160](#), [161](#), [162](#) and [163](#), [166](#), [191](#), [192](#)), we suggest that the higher protein intakes recommended in this chapter should be prescribed.

Energy

Studies in nondialyzed chronically uremic patients and in those undergoing maintenance hemodialysis indicate that energy expenditure is normal or nearly normal when patients are lying in bed or sitting, following ingestion of a standard meal, and during defined exercise ([217](#), [218](#), [219](#) and [220](#)). Nitrogen balance studies in nondialyzed chronically uremic patients ingesting diets providing 0.55 to 0.60 g protein/kg/day and 15, 25, 35, or 45 kcal/kg/day indicate that the energy intake necessary to ensure neutral or positive nitrogen balance is approximately 35 kcal/kg/ ([217](#)). Similar findings were obtained in nitrogen balance studies of maintenance hemodialysis patients who were ingesting 1.1 g protein/kg/day and 25, 35, or 45 kcal/kg/day ([221](#)). However, virtually every survey of energy intake in nondialyzed chronically uremic patients and in patients undergoing maintenance hemodialysis or CPD indicates that on average, the dietary intake is below this level and usually substantially below 30 kcal/kg/day ([157](#), [177](#), [222](#), [223](#) and [224](#)). In nondialyzed patients with advanced renal failure and in patients undergoing hemodialysis, decreased body fat is one of the more prominent alterations in nutritional status, which supports the contention that these patients require more energy than they usually ingest ([157](#), [160](#), [163](#), [224](#)). In contrast, CPD patients not uncommonly gain fat, probably because of additional energy intake from peritoneal absorption of glucose from dialysate.

We currently recommend that nondialyzed chronically uremic patients and patients undergoing maintenance hemodialysis or CPD ingest at least 35 kcal/kg/day. Obese patients with an edema-free body weight more than 120% of desirable body weight may be treated with lower calorie intakes. Some patients, particularly those with mild renal insufficiency and young or middle-aged women, may become obese on this energy intake or may refuse to ingest the recommended calories out of fear of obesity. These individuals may require a lower energy prescription.

Many commercially available high-calorie foodstuffs are low in protein, phosphorus, sodium, and potassium. A nephrology dietitian can recommend these foodstuffs as well as other low-protein, high-calorie foods that can be prepared easily at home.

Lipids and Obesity

Nondialyzed chronically uremic patients and patients undergoing maintenance hemodialysis and CPD have a high incidence of type IV hyperlipoproteinemia with increased serum triglyceride levels, elevated serum LDL and very LDL (VLDL) levels, and a low serum high-density-lipoprotein (HDL) cholesterol level ([150](#), [225](#), [226](#), [227](#), [228](#) and [229](#)). Serum lipoprotein (a) [Lp(a)] is frequently elevated ([228](#), [229](#)), and serum VLDL cholesterol and total cholesterol may also be increased in CPD patients. In chronic renal failure, a number of serum apolipoproteins and apolipoprotein fragments

are increased and the composition of apolipoproteins may be altered (229).

One cause of hypertriglyceridemia is impaired clearance of triglyceride-rich LDL and VLDL from blood. In addition, because diets for patients with renal failure are usually restricted in protein, sodium, potassium, and water, it may be difficult to provide sufficient energy without resorting to a large intake of purified sugars, which may increase triglyceride production. Activities of plasma and hepatic lipoprotein lipase and lecithin cholesterol acyltransferase (LCAT) are decreased (230). Moreover, carnitine actions may sometimes be impaired (231, 232).

Patients with the nephrotic syndrome have hypercholesterolemia. Elevated serum cholesterol is caused by increased hepatic synthesis of lipoproteins and cholesterol and reduced LDL-receptor activity, which plays an important role in clearance of intermediate-density lipoproteins (IDL). These changes are stimulated by hypoalbuminemia. Decreased activity of lipoprotein lipase contributes to the elevated serum triglyceride levels. Serum triglycerides, phospholipids, and apoproteins B, C-II, C-III, and E are increased, whereas apoproteins A-I and A-II are normal (233). Plasma lipoprotein(a) [Lp(2)] is elevated (234). Both serum LDL and VLDL may be increased. There is elevated plasma cholesterol ester transfer protein (CETP) and decreased catabolism of LDL apolipoprotein, at least by the more typical receptor pathway.

Renal transplant recipients may have type IIb hyperlipidemia with high serum total cholesterol. Types II-a and IV hyperlipidemia also often occur after kidney transplantation, particularly if renal failure persists (235, 236 and 237). Medicinal therapy (glucocorticoids, cyclosporine A, diuretics, antihypertensives), renal failure, fasting hyperinsulinemia, and obesity, which occurs frequently after renal transplantation, all may add to the high incidence of serum lipid disorders in renal transplant patients. Because these abnormalities may contribute to the high incidence of atherosclerosis and cardiovascular disease in patients with chronic renal failure, those undergoing maintenance dialysis, and those receiving renal transplants, attention has been directed toward reducing serum cholesterol and triglycerides and increasing HDL cholesterol.

Serum triglycerides may be lowered by a diet in which the carbohydrate content is reduced to about 35% of total calories, the fat content is increased to about 55% of total calories, and the polyunsaturated:saturated fatty acid ratio is raised to about 1.5:1.0 (Table 89.3) (238, 239). However, evidence suggesting that high cholesterol and fat intakes increase the risk of atherosclerotic vascular disease argues against using such diets, particularly because hypertriglyceridemia is not a strong risk factor for atherosclerotic vascular disease. Several investigators have reported that serum triglycerides may be decreased if dialysis patients take L-carnitine, which is often low in their plasma and possibly muscle (see below) (231, 232); other investigators have not confirmed this effect (240, 241). Fibric acids (e.g., gemfibrozil) also lower serum triglyceride levels in uremic patients, but owing to the altered pharmacokinetics of this drug in renal failure, the risk of developing myopathy or other toxicities is high (242). w-3 Fatty acids, such as eicosapentanoic acid and docosahexanoic acid, which are found in fish oil, lower serum triglyceride and total cholesterol levels as well as phospholipids and may be tried (243). Fish oil also decreases platelet aggregation and exerts

antiinflammatory effects (243). Some evidence suggests that w-3 fatty acids or fish oil may retard progression of chronic renal failure, particularly when it is caused by IgA nephropathy (244). Ingestion of activated charcoal may lower serum cholesterol and triglycerides in chronically uremic rats (245).

At present, we recommend a dietary plan based upon the National Cholesterol Education Program (NCEP) for patients with chronic renal failure, patients with the nephrotic syndrome, and renal transplant recipients (see Chapter 75). This diet provides (246) no more than 30% of total calories from fat: up to 10% of total calories from polyunsaturated fatty acids, 10–15% of calories from monounsaturated fatty acids, less than 10% of calories from saturated fatty acids, and a cholesterol content of 300 mg/day or less. We treat hypertriglyceridemia by dietary modification when serum triglyceride levels are approximately 400 mg/dL or above. Dietary fat intake is not increased above 40% of total calories and as much as possible of the carbohydrate should be complex carbohydrates. The patient's energy intake should be monitored with this diet to ensure that it does not fall.

If serum triglyceride levels are substantially elevated, serum carnitine should be measured. If serum carnitine is low, 0.5 to 1.0 g/day orally may be given to nondialyzed patients with chronic renal failure and to patients undergoing maintenance dialysis. Alternatively, patients undergoing hemodialysis may be given L-carnitine, 1.5 g orally or intravenously, at the end of each dialysis. Fish oil supplements may be tried for severe hypertriglyceridemia (247). Hypercholesterolemia is most effectively treated by giving hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (248) (see Chapter 75).

No established treatment exists for low serum concentrations of HDL in uremic patients, although a small amount of alcohol (e.g., one glass of red wine per day) and exercise may increase levels (249). As indicated above, while hemodialysis patients rarely gain substantial amounts of body fat, patients undergoing CPD commonly gain excessive body fat, probably because of the additional 400 to 700 kcal they receive from glucose absorbed from dialysate.

There are virtually no long-term data on the effects of dietary fat and carbohydrate intake, obesity, or changing serum lipid levels on the clinical course of patients with specific renal diseases, the nephrotic syndrome, renal failure, or renal transplantation. The recommendations given here are largely derived from data obtained from populations without renal disease, recognizing that patients with renal disease or renal failure have a high incidence of abnormal serum lipid and lipoprotein levels and atherosclerotic vascular disease, and from studies in animals with renal disease that indicate that high lipid intake or elevated lipoprotein levels may accelerate progression of renal failure, as discussed above.

Carnitine

Carnitine is an essential nutrient that is both synthesized in the body and ingested. Carnitine facilitates transfer of long-chain (>10 carbon) fatty acids into mitochondria and probably other cellular structures (250). Since fatty acids are the major fuel source for

skeletal and myocardial muscle at rest and during mild-to-moderate exercise, this process is considered necessary for normal skeletal muscle and myocardial function. (See [Chapter 31](#).)

Patients with chronic renal failure have low free carnitine and increased acylcarnitines (fatty acid/carnitine compounds) in serum ([240](#), [241](#)). In skeletal muscle, some but not all studies describe low free carnitine and increased acylcarnitines ([251](#), [252](#)). As a result of these observations, it was postulated that patients with chronic renal failure had carnitine deficiency, presumably caused by decreased synthesis and intake and increased losses from dialysis ([240](#), [241](#)). More recently, it has been suggested that carnitine actions may be impaired in chronic renal failure, possibly because of interference by the increased concentration of acylcarnitines.

Clinical studies in patients with chronic renal failure suggest that carnitine may improve physical exercise capacity, reduce dialysis-related symptoms of skeletal muscle cramps and hypotension, improve overall sense of well-being, increase blood hemoglobin levels, reduce cardiac arrhythmias, and improve cardiac function ([253](#), [254](#), [255](#), [256](#) and [257](#)). Some studies indicate that carnitine will lower serum triglyceride levels; other studies have not confirmed this ([240](#), [241](#)). Many nephrologists are unconvinced by this research, in part because of the suboptimal experimental design of many of these studies and also because many of the reported benefits are not easy to quantify. New clinical trials of carnitine therapy should help determine more definitively the therapeutic potential of carnitine for patients with chronic renal failure. L-Carnitine appears to be a safe drug.

Until more-definitive information is available, we consider using L-carnitine for patients who satisfy both of the following criteria: (a) disabling or very bothersome skeletal muscle weakness or cardiomyopathy, skeletal muscle cramps or hypotension during hemodialysis treatment, severe malaise, or anemia refractory to erythropoietin therapy for no apparent reason and (b) these disorders do not respond to standard treatments. The patient is given a 3- to 6-month trial of L-carnitine (9 months for refractory anemia). If the symptoms do not improve by the end of the treatment period, carnitine therapy is discontinued. L-Carnitine may be administered orally, intravenously, or in dialysate. Oral L-carnitine is less expensive, but intestinal absorption is somewhat unpredictable in nonuremic individuals and has not been examined well in patients with chronic renal failure. The optimal dose of carnitine is not defined. Carnitine may be infused intravenously, 10 to 20 mg/kg, at the end of each hemodialysis, three times weekly, or given orally, about 0.50 g/day ([253](#), [256](#)).

Carbohydrates

The patient should be encouraged to eat complex rather than purified carbohydrates to reduce triglyceride synthesis and (where pertinent) to improve glucose tolerance.

Fiber

Studies in the normal population suggest that high dietary fiber intake may reduce the incidence of constipation, irritable bowel syndrome, diverticulitis, and neoplasia of the

colon (258). Fiber may improve glucose tolerance in diabetic patients including those with chronic renal failure (259). Soluble fiber, which is soluble in the intestinal lumen but is not absorbed, includes pectins, certain gums, and psyllium. Supplemental soluble dietary fiber may also reduce plasma total cholesterol and LDL cholesterol levels in hypercholesterolemic men (260) and may decrease serum fasting triglyceride levels in hypertriglyceridemic patients with diabetes mellitus (261). A high dietary fiber intake also may reduce the SUN by decreasing colonic bacterial ammonia generation and enhancing fecal nitrogen excretion (262). High-fiber intake may promote fecal losses of trace elements. Foods high in fiber are often high in potassium, phosphorus, and low-quality protein. Thus, caution must be exercised when prescribing high-fiber diets to patients with renal failure. Because patients with renal failure may benefit from fiber intake, we currently encourage them to eat 20 to 25 g of total fiber daily.

Phosphorus

In patients with chronic renal failure, a high dietary phosphorus intake can lead to a high plasma phosphorus and calcium phosphorus product, with increased risk of calcium phosphate deposition in soft tissues (127). Moreover, hyperphosphatemia, by lowering serum calcium levels, provides a strong stimulus to development of hyperparathyroidism. As discussed above, both animal and human studies suggest that low phosphorus intake may reduce progression of chronic renal failure (45, 67, 69).

The optimal dietary phosphorus intake for patients with renal insufficiency has not been established. For the nondialyzed patient, one approach is to attempt to maintain normal renal tubular reabsorption of phosphorus to prevent elevated serum parathyroid hormone levels. This approach would require an extremely low phosphorus intake, lower than can usually be obtained with the combination of a low-phosphorus diet and phosphate binders, unless ketoacid- or essential amino acid-supplemented very low protein diets are used and the GFR is above 15 mL/min (Table 89.3). At least, in both nondialyzed and dialyzed patients, the morning fasting serum phosphorus concentrations should always be maintained at normal or possibly slightly elevated levels (e.g., about 5.0 mg/dL). Because a rough correlation exists between the protein and phosphorus content of the diet, it is easier to restrict phosphorus if protein intake is reduced.

For nondialyzed patients with a GFR below 25 mL/1.73 m²/min who are prescribed 0.55 to 0.60 g/day of protein, phosphorus intake generally is decreased to about 5 to 10 mg/kg/day. This may make the diet more burdensome, particularly at lower phosphorus intakes. This level of dietary phosphorus restriction usually does not maintain serum phosphorus levels within normal limits in patients with a GFR below about 15 mL/min, even with reduced renal tubular reabsorption of phosphorus. Hence phosphate binders are also used. Traditionally, the two most commonly used phosphate binders have been aluminum carbonate and aluminum hydroxide. Usually, two to four 500-mg capsules taken three to four times daily are needed. Higher doses may be used if necessary. Evidence that aluminum-induced osteomalacia, anemia, and possibly dementia could result from intake of aluminum phosphate binders has made many nephrologists reluctant to use them (262a, 263).

Several alkaline calcium salts are often used to bind phosphate: calcium carbonate, calcium acetate, and calcium citrate. Calcium acetate may be slightly more potent than calcium carbonate at binding phosphate in the intestinal tract, whereas calcium citrate appears to be the least effective binder (264, 265, 266 and 267). Calcium acetate may be more likely to induce gastrointestinal discomfort (267). Patients should not ingest calcium citrate if they are also taking aluminum, because the citrate anion may complex with aluminum and enhance its intestinal absorption (264). The calcium salts are taken in divided doses with meals and should not be given unless the serum phosphorus level is normal or nearly normal, to avoid precipitation of calcium phosphate in soft tissues. Thus, hyperphosphatemic patients may be treated with an aluminum binder of phosphate until serum phosphorus falls to normal and then be placed on calcium carbonate or calcium acetate. Concern exists that calcium binder doses providing more than about 2.0 g of elemental calcium daily may cause excessive accumulation of calcium in soft tissues.

For patients with a GFR between 25 and 70 mL/1.73 m²/min or with a higher GFR and progressive loss of renal function, 7 to 12 mg of phosphorus/kg/day may be prescribed with the 0.55 to 0.60 g of protein/kg/day diet. Even this level of reduction in phosphorus intake is difficult for many patients to accept, and lower phosphorus intakes make the diet too restrictive for virtually all patients. These individuals generally are not given phosphate binders unless serum phosphorus levels are above normal. The recommended phosphorus intake for patients undergoing maintenance hemodialysis or CPD is about 17 mg/kg/day or less. This higher upper limit was chosen because dialysis patients, with their greater protein intakes, cannot readily ingest less phosphorus without making the diet too restrictive. Patients undergoing maintenance dialysis usually require phosphate binders as well as this dietary phosphorus restriction to prevent hyperphosphatemia.

At present, no lower safe limit for the serum phosphorus level in renal failure has been defined. Experience suggests that if fasting serum phosphorus is maintained above the lower limit of normal, patients will not develop manifestations of phosphate depletion. More work is necessary to test the validity of this perception.

Calcium

Patients with chronic renal failure, including those undergoing maintenance dialysis therapy, usually have an increased dietary calcium requirement because they have both vitamin D deficiency and resistance to the actions of vitamin D. These disorders, which lead to impaired intestinal calcium absorption, are compounded by the low calcium content of diets for uremic patients. A 40-g protein, low-phosphorus diet, for example, generally provides only about 300 to 400 mg of calcium daily. Dietary calcium intake is low because many foods high in calcium are high in phosphorus (e.g., dairy products) and are thus restricted for uremic patients.

Nondialyzed chronically uremic patients usually require 1200 to 1600 mg of calcium daily for neutral or positive calcium balance (268). The current recommendation is to provide a total daily calcium intake (diet plus supplement) of 1400 to 1600 mg. Thus,

low-protein diets need to be supplemented with 1000 to 1400 mg of elemental calcium daily. Supplemental calcium should not be given unless the serum phosphorus concentration is normal or only slightly elevated (e.g., 2.5 to about 5.5 mg/dL), to prevent calcium phosphate deposition in soft tissues. In addition, frequent monitoring of serum calcium is important because hypercalcemia may develop, particularly if serum phosphorus should fall to low-normal or low levels. This is especially likely to occur if the patient also has hyperparathyroidism, a common complication of chronic renal failure (127). Patients undergoing maintenance hemodialysis or peritoneal dialysis may require 1.0 g/day of supplemental oral calcium even though there is net calcium uptake from dialysate. The supplemental calcium should be taken in two or three divided doses each day.

Calcium comprises 40% of calcium carbonate, 25% of calcium acetate, 21% of calcium citrate, and 9% of calcium gluconate. Treatment with vitamin D analogues may decrease the daily calcium requirement by enhancing intestinal calcium absorption. To reduce the total daily calcium load to the dialysis patient who is taking calcium binders of phosphate, the calcium content of dialysate is often reduced. Currently, this is easier to arrange with chronic peritoneal dialysis than with maintenance hemodialysis.

As indicated above, the use of calcium binders of phosphate often results in a daily calcium intake that exceeds these levels. It is not known whether these large intakes of calcium cause hazardous calcium deposits in skeletal or soft tissues. A syndrome called aplastic or hypoplastic bone disease has been described in chronic dialysis patients (127, 269, 270 and 271). It is characterized by relatively low serum parathyroid hormone concentrations, decreased bone osteoblasts, and marked reduction in bone turnover. The syndrome can be caused by aluminum toxicity but also occurs in the absence of such toxicity (127, 269, 270). Treatment with large doses of calcium binders of phosphate with consequent suppression of parathyroid hormone has been postulated to cause this disorder (127, 269, 271).

Magnesium

In chronic renal failure, there is net absorption of approximately 50% of ingested magnesium from the intestinal tract (net absorption is the difference between dietary intake and fecal excretion) (268). The absorbed magnesium is excreted primarily by the kidney. Hence, in renal failure, hypermagnesemia may occur (272). Because the restricted diets of uremic patients are low in magnesium (usually about 100 to 300 mg/day for a 40-g protein diet), their serum magnesium levels are usually normal or only slightly elevated unless the patient ingests substances with high magnesium content, such as magnesium-containing antacids and laxatives (268, 272). Nondialyzed chronically uremic patients require about 200 mg/day of magnesium to maintain neutral balance (268). The optimal dietary magnesium allowance for the chronic dialysis patient is not well defined and is influenced by the level of magnesium in the dialysate; at current dialysate magnesium concentrations, the optimal magnesium allowance is probably about 200–250 mg/day.

Sodium and Water

Sodium is freely filterable by the glomerulus. In the normal kidney, the renal tubules reabsorb well over 99% of the filtered sodium. As renal insufficiency progresses, both glomerular filtration and fractional reabsorption of sodium fall progressively. Thus, many patients with renal failure can maintain sodium balance with a normal salt intake. Normally, only about 1 to 3 meq/day of sodium are excreted in the feces, and in the nonsweating individual, only a few milliequivalents of sodium are lost daily through the skin. Despite an adaptive reduction in renal tubular reabsorption of sodium when end-stage renal disease supervenes, patients may be unable to excrete the quantity of sodium ingested, and they may develop edema, hypertension, or congestive heart failure. This syndrome is particularly likely to occur when the GFR is below 4 to 10 mL/min. When renal insufficiency is complicated by congestive heart failure, the nephrotic syndrome, or advanced liver disease, the propensity for sodium retention is increased. With decreased ability to excrete sodium, restriction of sodium and water intake and the use of diuretic medications may be necessary. In renal failure, hypertension often is more easily controlled with sodium restriction and may be accentuated with increased sodium intake, possibly because of expansion of the extracellular fluid volume (273).

In addition, nondialyzed patients with chronic renal failure are often unable to conserve sodium normally (126, 126a). A low sodium intake may not be sufficient to replace urinary and extrarenal sodium losses, and the patient may develop sodium depletion, decreased extracellular fluid volume, blood volume, and renal blood flow, and a further reduction in GFR. Volume depletion may be difficult to recognize. An unexplained weight loss or decrease in blood pressure may signal this condition. Nondialyzed patients with chronic renal failure who do not have evidence for fluid overload, hypertension, or heart failure may be cautiously given a greater sodium intake to determine whether their GFR can be improved slightly by extracellular volume expansion.

In general, when sodium balance is well controlled, thirst will regulate water balance adequately. However, when the GFR falls below 2 to 5 mL/min, there is a particular risk of overhydration. In diabetics, hyperglycemia may also increase thirst and enhance positive water balance. For patients with far-advanced renal failure whose total body water is at the desired level (as indicated by normal or near-normal blood pressure, absence of edema, and normal serum sodium), urine volume may be a good guide to water intake. The daily water intake should equal the urine output plus approximately 500 mL to replace insensible losses.

In most nondialyzed patients with advanced renal failure, a daily intake of 1000 to 3000 mg (40–130 meq) of sodium and 1500 to 3000 mL of fluid will maintain sodium and water balance. The requirement for sodium and water varies markedly, and each patient must be managed individually. Patients undergoing maintenance hemodialysis or peritoneal dialysis usually become oliguric or anuric after several weeks to 1 or 2 years of treatment. For hemodialysis patients, sodium and total fluid intake generally should be restricted to 1000 to 1500 mg/day and 700 to 1500 mL/day, respectively. Patients undergoing CPD usually tolerate a greater sodium and water intake because salt and water can be easily removed each day by using hypertonic dialysate, which increases

the flow of water from the body into the peritoneal cavity where it can be drained. Maintaining a large dietary sodium and water intake allows the quantity of fluid removed from the CPD patient and, hence, the daily dialysate volume to be increased. This increase may be advantageous because the daily clearance of small molecules with CPD is directly related to the volume of dialysate outflow. In nondialyzed chronically uremic patients or in those undergoing maintenance dialysis who are not anuric and who gain excessive sodium or water despite attempts at dietary restriction, a potent loop diuretic, such as furosemide or bumetanide, may be tried to increase urinary sodium and water excretion.

Potassium

Normally, the kidney provides the major route for potassium excretion. In renal failure, potassium retention may occur and may lead quickly to fatal hyperkalemia. Two factors act to mitigate this process in renal failure. First, as long as urine output remains at approximately 1000 mL/day or above, tubular secretion of potassium in the remaining functioning nephrons tends to be increased, and thus renal potassium clearance does not fall as markedly as the GFR. Second, fecal excretion of potassium is increased owing to enhanced intestinal secretion (208). Thus, patients with chronic renal failure usually do not become hyperkalemic unless there is (a) excessive intake of potassium; (b) acidosis, oliguria, or hypoaldosteronism (e.g., secondary to decreased renin secretion by the diseased kidney or renal tubular resistance to the actions of aldosterone); or (c) catabolic stress. Patients with chronic renal failure and those undergoing maintenance hemodialysis, in general, should receive no more than 70 meq of potassium daily. Some patients, particularly those with less-advanced chronic renal failure, may tolerate higher potassium intakes; they may be identified by liberalizing their dietary potassium and carefully monitoring serum potassium levels.

Trace Elements

Several factors tend to either increase or decrease the body burden of certain trace elements in renal failure patients (274, 275 and 276). Many trace elements are excreted primarily in the urine and may accumulate with renal failure (275, 277). Elements such as iron, zinc, and copper, which are protein bound, may be lost in excessive quantities when there are large urinary protein losses, as in the nephrotic syndrome (277). The effect of the altered dietary intake of the uremic patient on body pools of trace elements is unknown (276). Since many trace elements bind avidly to serum proteins, when present even in small quantities in dialysate, they may be taken up into blood and cause toxicity. Therefore, dialysate should be routinely purified of trace elements prior to use. In certain circumstances, therapeutic doses of trace elements might be administered through dialysis, as has been done for zinc (278). Assessing the trace element pools in renal failure patients is difficult because the serum binding-protein concentrations or affinities for trace elements may be altered, and red cell levels of trace elements may not reflect concentrations in other tissues.

Dietary requirements for trace elements have not been well defined in uremic patients (Table 89.3). Trace element supplementation should be undertaken cautiously, because impaired urinary excretion of trace elements increases the risk of overdosage. Oral iron

supplements are often given to patients who are iron deficient or patients who have a propensity to develop iron deficiency (e.g., individuals who frequently have marginal or low serum iron, reduced percentage saturation of the iron-binding capacity, or decreased ferritin levels). Iron requirements increase when erythropoietin therapy is started and hemoglobin synthesis rises. Ferrous sulfate, 300 mg up to three times per day, one-half hour after meals, may be used. Some patients develop anorexia, nausea, constipation, or abdominal pain with ferrous sulfate and may tolerate other iron compounds better, such as ferrous fumarate, gluconate, or lactate. Patients who are intolerant of oral iron supplements or who have iron deficiency that does not respond to oral iron therapy may be treated with intramuscular or intravenous iron. Recent data indicate that higher serum iron concentrations may reduce the dose of erythropoietin necessary to maintain a given blood hemoglobin level.

The zinc content of most tissues is normal in renal failure (276), although serum and hair zinc may be low and red cell zinc is increased (275, 278, 279 and 280). In nondialyzed chronically uremic patients, the fractional urinary excretion of zinc is increased; however, since the GFR is reduced, total urinary excretion of zinc may be normal or reduced (274). Fecal zinc is increased (279), and a dietary zinc intake above the RDA (117) may be necessary to maintain normal body zinc pools. Further studies are needed to confirm this. Some reports indicate that dysgeusia, poor food intake, and impaired sexual function, which are common problems of uremic patients, may be improved by giving patients zinc supplements (278, 279, 281, 282); however, other studies have not confirmed this (283).

As indicated above, in nondialyzed chronically uremic patients and in those receiving maintenance dialysis, an increased body burden of aluminum has been implicated as a cause of a progressive dementia syndrome (particularly in hemodialysis patients), osteomalacia, weakness of the muscles of the proximal limbs, and anemia (127, 262a, 263, 269, 270). Although contamination of dialysate with aluminum previously was the major source of aluminum toxicity in many dialysis centers, current methods of water treatment have removed virtually all aluminum from dialysate. At present, ingestion of aluminum binders of phosphate is probably the major cause of the excess body burden of aluminum (262a, 263). Consequently, many nephrologists now use aluminum binders more sparingly and rely more upon low-phosphorus diets and nonaluminum phosphate binders, particularly calcium carbonate or acetate, to control serum phosphorus levels (264, 265, 266 and 267). Aluminum toxicity may be treated by reducing aluminum intake and by intravenous infusions of desferrioxamine, a chelator of aluminum (284). This chelator can be removed from the body by hemodialysis or peritoneal dialysis. Since desferrioxamine may predispose to serious infections, nephrologists tend to use this medicine infrequently.

Vitamins

Chronically uremic patients are prone to deficiencies of water-soluble vitamins unless supplements are given (129). Vitamin deficiencies occur for the following reasons. First, vitamin intake is often low because of anorexia and poor food intake and also because many foods that are high in water-soluble vitamins are often restricted owing to the elevated potassium content. The typical diet for nondialyzed chronic renal failure and

maintenance dialysis patients is frequently below the RDAs for certain water-soluble vitamins (117). Second, the metabolism of certain water-soluble vitamins tends to be altered in chronic renal failure (285, 286). Third, many medicines interfere with intestinal absorption, metabolism, or actions of vitamins (165, 187). Vitamin B₆, vitamin C, and folic acid are the water-soluble vitamins most likely to be deficient in nondialyzed patients with chronic renal failure and in maintenance dialysis patients. Vitamin B₁₂ deficiency is uncommon in uremia because the daily requirement is small (2 µg/day for normal nonpregnant, nonlactating adults) (117), the body can store relatively large quantities of this vitamin, and vitamin B₁₂ is protein bound in plasma and, hence, is poorly dialyzed.

Many of the studies that indicated a need for routine multivitamin supplementation in nondialyzed patients with chronic renal failure or those undergoing maintenance dialysis were carried out in the 1960s and early 1970s, when the incidence of poor nutritional intake of these patients may have been greater than it is today (288). Indeed, some more-recent studies suggest that many maintenance hemodialysis patients may subsist for months with no vitamin supplementation without developing deficiencies of water-soluble vitamins (289). However, these studies have not demonstrated that without vitamin supplements, a small but substantial proportion of patients will not develop water-soluble vitamin deficiencies, particularly after one or more years of dialysis treatment. Because water-soluble vitamin deficiencies are caused by several different mechanisms in these patients and because the water-soluble vitamin supplements are safe, it would seem prudent to continue to use them routinely until these issues are more completely resolved.

Daily supplements for most vitamins are not well defined in renal failure (129). Evidence indicates that in addition to vitamin intake from foods, the following daily supplements of vitamins will prevent or correct vitamin deficiency (Table 89.3): pyridoxine hydrochloride, 5 mg in nondialyzed patients and 10 mg in maintenance hemodialysis or peritoneal dialysis patients (290); folic acid, 1 mg; and the RDA for normal individuals for the other water-soluble vitamins (117). Patients with renal failure probably require less than 1.0 mg of folic acid daily; however, since this vitamin is safe and some evidence suggests that there may be competitive interference with its actions (285, 288), it may be advisable to prescribe this dose of folic acid until more definitive studies of the requirements are carried out. A supplement of only 60 mg/day of vitamin C is advised because ascorbic acid can be metabolized to oxalate. Large doses of ascorbic acid have been associated with increased plasma oxalate levels in renal failure patients (291, 292). Oxalate is highly insoluble, and there is concern that high plasma oxalate concentrations may lead to precipitation in soft tissues. Moreover, in the nondialyzed patient with chronic renal insufficiency, oxalate deposition in the kidney might further impair renal function.

Because serum retinol-binding protein and vitamin A are elevated in uremia (293), routine use of supplemental vitamin A is not recommended, particularly since even relatively small doses of vitamin A (i.e., 7500–15000 IU/day) may cause bone toxicity (294). Additional vitamin E and K are probably not necessary. However, patients who receive antibiotics for extended periods and who do not ingest foods containing vitamin

K may need vitamin K supplements (295).

Although in renal failure many of the beneficial effects of 1,25-dihydroxycholecalciferol can be reproduced by administration of other vitamin D analogues such as dihydrotachysterol, cholecalciferol, or 25-hydroxycholecalciferol, 1,25-dihydroxycholecalciferol is the most potent agent (127). Because it is given in smaller doses and has a shorter half-life, there is little storage of this compound. Hence, it may be a safer agent to use. The high potency of 1,25-dihydroxycholecalciferol, however, increases the risk of hypercalcemia and hyperphosphatemia (127).

Treatment with oral 1,25-dihydroxycholecalciferol increases intestinal calcium and phosphorus absorption, raises serum calcium, lowers serum parathyroid hormone, decreases serum alkaline phosphatase activity, reduces bone resorption, decreases endosteal fibrosis, and often improves osteomalacia (127). Therapy with 1,25-dihydroxycholecalciferol or other active vitamin D analogues is indicated for hyperparathyroidism, osteitis fibrosa, mixed osteomalacia, and severe hypocalcemia. Some chronically uremic patients with vitamin D deficiency develop a myopathy, primarily of the proximal limb muscles, and may present with severe weakness. Strength may improve with vitamin D therapy. 1,25-Dihydroxycholecalciferol has many immunologic effects in vitro (296, 296a); whether treatment of patients with renal failure with this substance improves their immune function is not known. Uremic children require vitamin D analogues to promote growth.

It has been argued that because of the high incidence of vitamin D deficiency in patients with advanced chronic renal failure and patients undergoing maintenance hemodialysis and the pervasive benefits of vitamin D, 1,25-dihydroxycholecalciferol or other active vitamin D analogues should be used rather routinely in these patients unless there are specific contraindications to its use (e.g., hypercalcemia, severe hyperphosphatemia).

Treatment with 1,25-dihydroxycholecalciferol usually is started at 0.25 to 0.50 $\mu\text{g}/\text{day}$. The serum calcium concentration must be monitored carefully, and if it is low and does not rise by more than 0.5 mg/dL with any particular dosage, the dose may be increased by 0.25 to 0.50 $\mu\text{g}/\text{day}$ every 4 to 6 weeks. Hypercalcemia is treated by temporary withdrawal of 1,25-dihydroxycholecalciferol. Ultimately, the best criterion for effective treatment with 1,25-dihydroxycholecalciferol is improved bone anatomy as determined by bone histology, radiographs, and densitometry. Improved muscle function or abolition of severe hypocalcemia also may indicate appropriate dosage of 1,25-dihydroxycholecalciferol. With time, the requirement for 1,25-dihydroxycholecalciferol and tolerance for this vitamin may decrease, and the maintenance dosage may have to be reduced. This change may occur after there has been sufficient bone healing so that the skeleton no longer serves as a sink for calcium and phosphorus. 1,25-Dihydroxycholecalciferol should not be started unless serum calcium is not elevated, serum phosphorus is not more than slightly increased, and the calcium-phosphorus product is below 45. Serum calcium and phosphorus should be monitored during therapy to ensure that the concentrations are normal.

In patients receiving maintenance hemodialysis or CPD, intravenous or oral boluses of 1,25-dihydroxycholecalciferol, given about 3 times weekly, are more effective than

routine daily doses of the oral preparation in suppressing secretion and serum levels of parathyroid hormone and ameliorating osteitis fibrosa (297, 298). Intravenous or oral 1,25-dihydroxycholecalciferol boluses may exert a greater effect because less of the dose may be taken up by the small intestine, where it promotes calcium absorption and hypercalcemia. Thus, greater amounts of 1,25-dihydroxycholecalciferol can be administered safely. Hence, with this treatment, higher blood concentrations of the vitamin can be obtained, and the parathyroid glands may be suppressed more readily.

Acidosis

Metabolic acidosis occurs frequently in nondialyzed patients with chronic renal failure because the ability of the kidney to excrete acidic metabolites is impaired. In earlier stages of chronic renal failure, metabolic acidosis can also be caused by excessive renal loss of bicarbonate. The rate of acid production is probably normal or below normal in stable chronically uremic patients. Acidosis is reported to cause bone reabsorption, net protein degradation (299, 300), and symptoms of lethargy and weakness.

Ingestion of low-nitrogen diets may prevent or reduce the severity of acidosis by decreasing the endogenous generation of acidic products of protein metabolism. Alkali supplements are usually effective in preventing or treating the acidosis of chronic renal failure. Calcium carbonate, 5 g/day, may correct mild acidosis, provide needed calcium, and reduce intestinal phosphate absorption. For more severe acidosis, sodium bicarbonate or citrate may be administered orally or intravenously. If the nondialyzed chronically uremic patient is not oliguric and is not likely to develop edema, sodium is usually readily excreted when administered as sodium bicarbonate or citrate.

Alkali therapy should probably be initiated if the arterial pH is below 7.35 or the serum bicarbonate is less than 20–22 meq/L. Before alkali therapy is implemented, it must be ascertained that the low serum bicarbonate is not a compensatory response to chronic respiratory alkalosis. If acidosis is severe and not controlled by the foregoing measures, hemodialysis or peritoneal dialysis may be used.

Prioritizing Dietary Goals

The number and magnitude of dietary modifications for chronically uremic patients are so great that if they are all presented to the patient at one time, demoralization and noncompliance are likely. Hence, we often list goals for dietary treatment according to priority. Control of protein, phosphorus, sodium, energy, potassium, calcium, and magnesium intake generally is emphasized. Unless the patient has a lipid disorder that carries a high risk of atherosclerotic disease, recommendations concerning the types and amounts of carbohydrates and fats ingested are usually given lower priorities. Also, a high dietary fiber intake is given lower priority.

NUTRITIONAL THERAPY IN ACUTE RENAL FAILURE

Metabolic Derangements

Acute renal failure is characterized by sudden reduction or cessation in GFR. The most common causes of acute renal failure include shock, severe infection, trauma, medicines, obstruction, and certain types of glomerulonephritis. In most instances, patients who survive the underlying diseases recover from the acute renal failure. Patients who sustain acute renal failure are likely to develop fluid and electrolyte disorders, uremic toxicity, and wasting. These disorders are particularly likely when the patient is both oliguric and hypercatabolic, which are common complications of acute renal failure.

Patients with acute renal failure, particularly those with underlying catabolic illnesses, frequently undergo metabolic changes that promote degradation of protein and amino acids and consumption of fuel substrates. Energy expenditure is often increased (301). In vitro studies with rat muscle tissue indicate that protein degradation is enhanced and protein synthesis is reduced (302, 303). In addition, hepatic gluconeogenesis increases. If livers from these animals are perfused or incubated with amino acids, the elevated hepatic glucose and urea production is further enhanced (304). The metabolic changes promoting catabolism are not uncommonly severe in patients with acute renal failure, and these individuals may be among the sickest and most metabolically deranged patients in the hospital. As a result of these metabolic derangements, these patients often cannot use protein, amino acids, and energy substrates efficiently. Hence, it may be difficult to maintain and improve the nutritional status of these patients by enteral or parenteral nutrition (305, 306 and 307).

General Nutritional Principles

Because available data concerning optimal nutritional therapy for patients with acute renal failure are both limited and conflicting, it is not possible to strongly justify any treatment plan for such patients. The following therapeutic approach is based upon our analysis of the literature and personal experience.

Fluid and mineral balance should be carefully monitored in patients with acute renal failure to prevent overhydration or electrolyte disorders. Water intake, in general, should equal output from urine and all other measured sources (e.g., nasogastric aspirate, fistula drainage) plus 400 mL/day. This regimen takes into account the contributions of endogenous water production from metabolism and the insensible water losses (primarily respiration and skin losses) to water balance. In general, if the patient is catabolic, weight should be allowed to decrease by 0.2 to 0.5 kg/day to avoid excessive fluid accumulation. Sodium, potassium, phosphorus, and magnesium intake should be restricted to prevent accumulation of these minerals. Energy and, if feasible, protein intake should satisfy the patient's nutritional requirements, which may exceed normal. By controlling the water and electrolyte intake and lowering the UNA, one may be able to reduce the need for dialysis treatments.

The patient's desirable nutrient intake depends upon the nutritional status, catabolic rate, residual GFR, and clinical indications for initiating dialysis therapy. For example, if

a patient is wasted, one might be more inclined to give a surfeit of nutrients and to provide dialysis as needed. A patient with acute renal failure who has a high residual GFR also may receive larger quantities of nutrients, because there is less risk of developing fluid and electrolyte disorders or accumulating potentially toxic metabolites. On the other hand, for a patient who has little or no urine flow and who is not very catabolic or uremic, intake of small quantities of water, minerals, and amino acids may reduce the need for dialysis; this approach may be particularly beneficial if it is anticipated that the patient will not tolerate dialysis well. Similarly, a patient who is starting to recover from acute renal failure may be given this latter treatment to avoid dialysis for a few days until renal function becomes adequate. In these latter patients, high-calorie diets providing small amounts of essential amino acids or ketoacids with little or no protein may be used for short periods.

Whenever feasible, patients with acute renal failure should receive oral nutrition. If the patient will not eat adequately, use of liquid formula diets, elemental diets, and tube or enterostomy feeding should be considered. Often parenteral nutrition is the only technique that will provide adequate nutrient intake ([Table 89.4](#)).

Table 89.4 Typical Composition of Solutions for Total Parenteral Nutrition in Patients with Acute Renal Failure^a

Specific Nutrient Intakes

Protein and Amino Acid Intake

The quantity of nitrogen and the composition of the amino acid formulations that are administered enterally or parenterally to patients with acute renal failure are the subject of controversy. Abel and associates carried out a series of studies suggesting that parenteral nutrition benefitted patients with acute renal failure ([308](#), [309](#) and [310](#)). The patients were infused with solutions containing hypertonic D-glucose and 12 to 30 g/day of essential amino acids but no nonessential amino acids. The authors reported that the SUN and serum potassium, phosphorus, and magnesium often stabilized or decreased,

and dialysis therapy sometimes could be postponed or avoided. In a prospective, randomized, double-blind study, these investigators compared infusion of hypertonic glucose and essential amino acids with an isocaloric infusion of hypertonic glucose that contained no amino acids (310). Patients receiving glucose and essential amino acids had significantly greater survival until renal function recovered; hospital survival was slightly but not significantly increased. In retrospective studies with nonconcurrent controls, parenteral nutrition that provided essential and nonessential amino acids appeared to improve morbidity and mortality, particularly in patients who had more complicated clinical courses (311, 312).

Leonard et al. reported that parenteral nutrition with hypertonic glucose and about 21 g/day of essential amino acids had no advantages over isocaloric infusions with glucose alone with regard to SUN levels, nitrogen balance, or survival in patients with acute renal failure (313). Feinstein et al. carried out a randomized, prospective, double-blind study of individuals with acute renal failure who could not eat adequately (305). Thirty patients were treated with one of three isocaloric parenteral nutrition formulations: hypertonic glucose with no amino acids, hypertonic glucose with 21 g/day of essential amino acids, or hypertonic glucose with 21 g/day each of essential and nonessential amino acids. The mean duration of study was 9.2 days per patient. The metabolic balance data indicated that many of these patients were severely catabolic with net rates of protein degradation as high as 240 g/day (determined by the difference between nitrogen intake and UNA). UNA tended to be lower with the essential amino acid regimen. Neither nitrogen balance nor mortality rates were significantly different with any of the three infusion regimens, but each tended to be less adverse with the essential amino acid intake.

It has been argued that more than 40 g/day of a mixture of essential and nonessential amino acids may be more effective at improving nitrogen balance. Feinstein et al. tested this hypothesis in a randomized prospective trial (306). Patients received total parenteral nutrition (TPN) providing 21 g/day of essential amino acids or TPN with essential and nonessential amino acids provided in a 1.0:1.0 ratio. With the latter treatment, attempts were made to infuse a quantity of nitrogen equal to the UNA. Thirteen patients with acute renal failure were randomly assigned to one of the two treatments. The results indicated that although the nitrogen intake was five times greater with the latter regimen, nitrogen balance, determined from the difference between intake and UNA, was not different. The UNA fell significantly only in the patients receiving essential amino acids, and it tended to rise in the other group.

These data suggest that high-calorie solutions providing about 21 g/day of essential amino acids may be used more effectively than isocaloric preparations containing larger quantities of essential and nonessential amino acids (e.g., 40–70 g/day) provided in an essential:nonessential ratio of 1.0:1.0 (307). Essential amino acid solutions seem to reduce the UNA and total nitrogen output more than those solutions with essential and nonessential amino acids. Consequently, nitrogen balance seems to be no more negative with the former preparations, but accumulation of nitrogenous metabolites is lower. Studies in clinically stable patients with chronic renal failure also indicate that diets providing small amounts of essential amino acids as the sole nitrogen source maintain nitrogen balance more effectively than diets providing similar quantities of protein (314). It would be of interest to examine the response to a TPN regimen that

provides greater quantities of essential and nonessential amino acids but with a larger proportion of essential amino acids.

The data from rat studies are also inconclusive. Toback and associates induced acute renal failure in rats by injecting mercuric chloride (315, 316). The rats infused with glucose and a mixture of essential and nonessential amino acids had greater regeneration of renal cortical cells, as determined by ¹⁴C-choline incorporation into phospholipids, than rats that were infused with glucose alone. Amino acids promoted intracellular protein synthesis as determined by ¹⁴C-leucine uptake (317). The maximum serum creatinine concentration also was lower in the rats infused with glucose and amino acids, suggesting that these nutrients enhanced recovery of renal function. However, Oken et al. were unable to show a consistent benefit of glucose and essential amino acids or glucose and essential and nonessential amino acids over glucose alone on the rate or incidence of recovery of renal function or survival in rats with acute renal failure (318).

These conflicting observations probably result from the following factors: (a) the clinical course of patients with acute renal failure is so complex and variable that it would be necessary to study large numbers of patients to show statistically significant benefits of nutritional therapy if such benefits exist; (b) many of these studies were retrospective or not randomly controlled and thus may contain unintentional biases; (c) the optimal composition of nutrients in the TPN solutions has not been defined, and the use of suboptimal formulations may reduce the clinical benefits of nutritional therapy; and (d) catabolic patients or rats with acute renal failure may need both good nutrition and metabolic intervention to suppress catabolic processes and to promote anabolism, and providing nutrients without metabolic intervention may not benefit nutritional status or clinical outcome, particularly in the first days after onset of acute renal failure.

It is pertinent that the prospective studies of parenteral nutrition in patients with acute renal failure compared different regimens of nutritional therapy; that is, infusion of high-calorie solutions containing amino acids versus isocaloric infusions without amino acids and administration of isocaloric solutions with essential amino acids versus those with essential and nonessential amino acids (305, 306, 310, 313). No prospective, randomized study has compared the clinical course of patients receiving nutritional therapy with that of patients receiving no nutritional support.

Our current policy for amino acid or protein intake in patients with acute renal failure is as follows (Table 89.4): Patients may be prescribed a low enteral or intravenous nitrogen intake if there is a low UNA (i.e., 4–5 g N/day), if they have no evidence of severe protein malnutrition, if they are anticipated to recover renal function within the next 1 or 2 weeks, and if there is an indication to avoid dialysis therapy (307). Under these conditions, we may prescribe 0.3 to 0.5 g/kg/day of primarily high-quality protein or essential amino acids, preferably with arginine. We do not give more than 0.4 g/kg/day of essential amino acids as the sole nitrogen source because larger quantities of the nine essential amino acids may cause serious amino acid imbalances (307, 319). Diets providing 0.10 to 0.30 g/kg/day of miscellaneous protein and 10 to 20 g/day of essential amino acids or ketoacids may also be used in patients who can eat. These regimens should minimize the rate of accumulation of nitrogenous metabolites and,

unless the patient is severely catabolic, will usually maintain neutral or only mildly negative nitrogen balance. Hence, the need for dialysis therapy may be minimized or avoided. Patients with substantial residual renal function (e.g., GFR of 5–10 mL/min) who are not very catabolic may be treated as nondialyzed patients with chronic renal failure. They would receive 0.55 to 0.60 g protein or amino acids/kg body weight daily.

For patients who are more catabolic and have a higher UNA (>5 g N/day), are severely wasted, or are undergoing regular dialysis therapy and either have or are anticipated to have acute renal failure for more than 2 weeks, we are inclined to prescribe a higher protein or amino acid intake, up to 1.0 to 1.2 g/kg/day. If tolerated, 1.2 g protein or amino acids/kg/day is preferable. In comparison to small quantities of essential amino acids, these larger nitrogen intakes may improve nitrogen balance, particularly after the first 1 or 2 weeks of dialysis treatments. However, the UNA almost invariably rises, and the increased azotemia and, in those patients receiving TPN, the larger volumes of fluid necessary to provide this amount of amino acids may increase the need for dialysis.

If acute renal failure persists for more than 2 to 3 weeks, patients undergoing regular dialysis treatment are treated as maintenance dialysis patients, with about 1.0 to 1.2 g/kg/day of protein or amino acids for hemodialysis patients or 1.2 to 1.3 g/kg/day for peritoneal dialysis patients.

Other Maneuvers to Improve Protein Balance and Clinical Outcome

Continuous arteriovenous hemofiltration (CAVH), CAVH with concurrent hemodialysis (CAVHD), continuous venovenous hemofiltration (CVVH), and CVVH with concurrent hemodialysis using low dialysate flow rates (CVVHD) are used increasingly for management of very ill patients with acute renal failure or other causes of fluid or nitrogen intolerance (e.g., severe liver or congestive heart failure). With CAVH, catheters are placed into a large artery and vein, such as the femoral artery and vein (320). The blood flows through a small filtering apparatus where some of the plasma water is filtered; the remaining blood is returned to the vein. CVVH/CVVHD are often preferred to CAVH or CAVHD because these procedures reduce the risks of complications caused by arterial catheter placement.

The following are among the advantages to this treatment (for simplicity, CVVH or CVVHD also refers to continuous arteriovenous hemofiltration with or without dialysis): (a) Large quantities of water, electrolytes, and metabolic products may be removed each day; (b) because the rate of removal of water and electrolytes is slow, CVVH/CVVHD is less likely to cause or worsen hypotension or induce other adverse physiologic changes (e.g., cardiac arrhythmias); (c) the high daily clearances of water and small molecules, including metabolic waste products, allow safer administration of large amounts of amino acids and other nutrients to the patient. Physicians frequently combine parenteral nutrition therapy with CVVH/CVVHD to provide intravenous nutrition while simultaneously controlling the water and salt balance and removing the metabolic products that accumulate in renal failure.

When CVVH/CVVHD is not used, patients with acute renal failure who receive parenteral nutrition may require treatment with a hemodialyzer as often as every day

rather than three times weekly the usual treatment for clinically stable patients receiving maintenance hemodialysis. With CVVH, and particularly CVVHD, standard hemodialysis treatments are usually needed less frequently and often can be avoided altogether. Indeed, CVVH/CVVHD often allows patients with acute renal failure to receive the amount of infused nutrients normally given to hypercatabolic, critically ill patients who do not have fluid, electrolyte, or nitrogen intolerance (i.e., patients who do not have renal, liver or heart failure). For patients receiving CVVHD, we often prescribe 1.5 to 2.5 g/kg/day of mixtures of essential and nonessential amino acids intravenously or similar amounts of protein given enterally. Amino acid losses with CVVH/CVVHD are generally about 4 to 7 g/day and are slightly higher when patients are receiving amino acid infusions than when they are not ([321](#), [322](#)).

Some investigators have proposed adding amino acids and additional glucose to the dialysate of patients undergoing CAPD or maintenance hemodialysis ([323](#), [324](#)). The nutrients diffuse into the body during dialysis. At present, these techniques may provide supplemental nutrition but cannot be used for total nutritional support.

Because the metabolic status of patients with acute renal failure often facilitates catabolism of protein, amino acids, and other energy substrates ([302](#), [303](#), [304](#), [305](#), [306](#) and [307](#), [313](#)), there may be advantages to administering agents that promote anabolic processes or reduce catabolic pathways. As mentioned above, nitrogen intake appears to be used more efficiently if a greater proportion of the administered amino acids is essential amino acids ([305](#), [307](#), [314](#)). This hypothesis has not yet been tested clinically. In addition, studies in catabolic patients without renal failure suggest that intravenous infusions in which a large proportion of the amino acids are branched-chain amino acids (i.e., isoleucine, leucine, and valine) may have a specific anabolic effect ([325](#), [326](#)). Not all studies confirm these findings. Ketoacid analogues of the branched-chain amino acids also promote anabolism, both when studied in in vitro preparations and when given to nonuremic individuals who are not hypercatabolic ([103](#), [104](#)). Intravenous infusion of the salt complex of α -ketoglutarate and ornithine in postoperative patients receiving TPN is reported to reduce UNA and to increase nitrogen balance ([327](#)). Severely stressed patients without renal failure display a rapid fall in intracellular muscle glutamine ([328](#)), and administration of glutamine improves protein balance in these patients ([328](#), [329](#)). Arginine has also been reported to increase nitrogen balance ([330](#)).

Anabolic steroidal compounds, many of which are androgenic and resemble testosterone, have been used in patients with acute renal failure ([331](#), [332](#)). These agents can reduce UNA and improve nitrogen balance and are reported to decrease the need for dialysis treatments. In vitro studies of skeletal muscle from rats with acute renal failure indicate that insulin may increase synthesis and reduce degradation of protein ([303](#)). Studies in catabolic patients who do not have renal failure indicate that insulin may decrease the UNA ([333](#), [334](#)). Recombinant DNA-synthesized human growth hormone has been used to improve nitrogen balance in postoperative, acutely stressed patients without renal failure, and the results are encouraging ([335](#), [336](#)). This hormone has also improved nitrogen balance in stable, malnourished patients undergoing maintenance hemodialysis ([337](#)). However, individuals acutely stressed from infection or physical trauma or who receive low quantities of nutrients sometimes become refractory to growth hormone, possibly because of downregulation of growth hormone

receptors with reduced ability to express IGF-I (338).

These findings suggest that recombinant human IGF-I (rhIGF-I) therapy may be more beneficial than growth hormone treatment for hypercatabolic patients with acute renal failure. Indeed, studies in rats with ischemic- or toxin-induced acute renal failure indicate that rhIGF-I may enhance recovery of renal function (339, 340). However, a recent study suggests that rhIGF-I therapy does not enhance the rate of recovery of renal function, reduce the need for dialysis treatment, or improve survival in sick intensive care unit patients with acute renal failure (341). Because IGF-I appears to stimulate growth of dedifferentiated cells, neither growth hormone nor rhIGF-I should be given to patients with active malignancy.

Several other growth factors (epidermal growth factor [342], hepatocyte growth factor [343]), hormones (thyroxin [344], atrial natriuretic peptide [345]), or adenine nucleotides (346) are reported to enhance recovery of renal function in experimental animals or in preliminary studies in humans. None of these agents has yet been shown to improve renal function in well-controlled clinical trials in humans with acute renal failure.

Energy

Several lines of evidence suggest that patients with acute renal failure may benefit from a high energy intake. Because patients with acute renal failure are frequently in negative energy and nitrogen balance (301, 305, 306, 313), some investigators contend that greater energy intake may reduce protein wasting. Moreover, unlike nonuremic acutely ill patients who may receive large quantities of amino acids, patients with acute renal failure are usually given relatively small amounts of amino acids because of their excretory impairment. It is possible, although not proven, that higher energy intake may improve the utilization of low nitrogen intake. In two studies of patients with acute renal failure who were not randomized for energy intake, those who died were found to have a higher energy expenditure and more-negative energy balance (301) or lower energy intake (301, 305) than those who survived. As a result of these findings, we usually administer about 30 to 40 kcal/kg standard (normal) weight/day (Table 89.4) (207, 347), except in patients who are obese (e.g., above about 125% standard body weight) or very underweight (207a).

The higher intakes (40 kcal/kg/day) are used for patients who have a higher UNA, who are severely ill, and who are less obese. For example, if nitrogen balance, estimated from the difference between the patient's nitrogen intake and the nitrogen output calculated from the UNA, is negative, we try to provide an energy intake close to 40 kcal/kg/day. Alternatively, the patient's energy needs may be estimated by multiplying the Harris-Benedict equation (348) or the newer World Health Organization equations (349) for calculating the daily energy requirements of normal individuals by a stress factor to adjust for the patient's illness (350, 351) and by 1.25. The 1.25 is included to provide a surfeit of energy to promote anabolism or to diminish the rate of catabolism of the patient; the benefit of using this term has not been clearly demonstrated. Energy expenditure, measured by indirect calorimetry, can also be multiplied by 1.25 to estimate the daily energy requirement.

These energy intakes exceed those currently recommended for severely stressed patients without renal failure. However, because nitrogen intolerance limits the amount of amino acids or protein that can be given to the patient with renal failure and higher energy intake tends to reduce protein and amino acid degradation, the patient with renal failure may benefit from a larger energy load. Unfortunately, prospective studies to test this hypothesis are not available.

Larger energy intakes are not used because there appears to be little nutritional advantage to administering more calories to catabolic patients. Indeed, because high energy intakes generate more carbon dioxide from infused carbohydrate and fat, they can promote hypercapnia if pulmonary function is impaired (352). Carbon dioxide retention is particularly likely to occur with very high carbohydrate loads. In addition, high energy intakes may cause obesity and fatty liver (353), and they may increase the water load to the patient.

Because most patients with acute renal failure do not tolerate large water intakes, glucose is usually administered in a 70% solution. The glucose and amino acid solutions are mixed, so that amino acids and energy are provided simultaneously (Table 89.4). Patients receiving TPN for more than 5 days should receive lipid emulsions. Patients require about 25 g/day of a lipid emulsion to prevent essential fatty acid deficiency. Some investigators have recommended giving up 30 to 40% of calories as lipid emulsions to provide sufficient fatty acids to organs that normally use lipids as their main energy source and to approximate the normal American dietary intake more closely. However, some researchers have reported that infusions of large amounts of fat emulsions (e.g., 50 g over 8 to 12 hours) may impair the function of the reticuloendothelial system (354) and have questioned whether infusion of lipid emulsions might lower host resistance. A prudent approach may be to infuse lipid emulsions over at least 12 hours, if not 24 hours, to prevent marked increases in plasma lipids. For patients who are septic or at high risk of severe sepsis, probably no more than 10 to 20% of total calories should be provided from fat. For patients who are not septic and not at high risk of infection, about 20 to 30% of calories may be given as lipid emulsions.

Intravenous lipid emulsions are available in 10% (1.1 kcal/mL) and 20% (2.0 kcal/mL) solutions. Traditionally, lipid emulsions have been infused separately from the glucose and amino acid mixtures. With careful attention to aseptic control, the lipid emulsions may be mixed with glucose and amino acids; the mixtures should be infused shortly after preparation (355).

Minerals

A mineral prescription for parenteral nutrition in acute renal failure is shown in Table 89.4. Any recommended intake of minerals is tentative and must be adjusted according to the clinical status of the patient. If the serum concentration of an electrolyte is increased, it may be advisable to reduce the quantity infused or not administer it at the onset of parenteral nutrition. The patient must be monitored closely, because the hormonal and metabolic changes that often occur with initiation of parenteral nutrition

may cause a rapid drop in serum electrolytes, particularly in potassium and phosphorus. On the other hand, a low concentration of a mineral may indicate a need for greater than usual intake of that element. Again, metabolic changes and the impaired GFR can lead to a rapid rise in the serum concentrations during repletion.

Except for iron and zinc, trace elements are probably not necessary in parenteral nutrition solutions given to catabolic patients with acute renal failure unless this is the sole source of nutritional support for at least 2 to 3 weeks. Nutritional requirements for trace elements have not been established for uremic patients receiving TPN.

Vitamins

The vitamin requirements have not been well defined for patients with acute renal failure. Tentative recommendations for vitamin intake for patients receiving parenteral nutrition are shown in [Table 89.4](#). Much of the recommended intake is based on information obtained from studies in chronically uremic patients, normal individuals, or nonuremic acutely ill patients. Vitamin A is probably best avoided for the first several days of nutritional support, because serum vitamin A levels are elevated in chronic renal failure, and small doses of vitamin A have been reported to cause toxicity to chronically uremic patients ([293](#), [294](#)). After the first several days of nutritional therapy, a dose of vitamin A that is between one-half and the complete RDA ([117](#)) for normal individuals may be given daily.

Vitamin D is fat soluble, and vitamin stores should not become depleted during the few days to weeks that most patients with acute renal failure receive parenteral nutrition. However, turnover of its active analogue, 1,25-dihydroxycholecalciferol, is much faster. Hence, this analogue may be needed in patients with acute renal failure ([297](#)).

Although vitamin K is fat soluble, vitamin K deficiency has been reported in nonuremic patients who are not eating and are receiving antibiotics ([295](#)). Vitamin K therefore should be given routinely to patients receiving parenteral nutrition ([Table 89.4](#)). Ten milligrams per day of pyridoxine hydrochloride (8.2 mg/day of pyridoxine) is recommended because studies in clinically stable or sick patients undergoing maintenance hemodialysis indicate that this quantity may be necessary to prevent or correct vitamin B₆ deficiency ([290](#)). Patients should probably not receive more than 60 mg of ascorbic acid daily because of the risk of increased oxalate production ([291](#), [292](#)).

The nutrient intake of patients with acute renal failure must be carefully reevaluated each day and sometimes more frequently. This reevaluation is particularly important because these patients may undergo rapid changes in their clinical and metabolic condition.

Peripheral Parenteral Nutrition

Parenteral nutrition through a peripheral vein avoids the risks of inserting a catheter into the inferior vena cava. Because the osmolality of the infusate must be restricted to reduce the risk of thrombophlebitis, it is necessary to use a larger volume of fluid and/or

a lower intake of nutrients. Both approaches may have undesirable consequences for patients with acute renal failure. It has been argued that the financial cost of TPN administered through a peripheral vein is about the same as, or greater than, the cost of administration through a central vein because of the large quantities of isotonic lipid emulsions used to provide the energy needs when peripheral veins are used.

Peripheral partial parenteral nutrition may be advantageous for patients with acute renal failure who can ingest or be tube fed only part of their daily nutritional requirements. Peripheral infusions may enable these patients to receive adequate nutrition without resorting to TPN through a large-flow vein. In these patients, it is often most practical to infuse an 8.5 to 10% amino acid solution or a 20% lipid emulsion into a peripheral vein and to administer as much as possible of the other essential nutrients, including carbohydrates, through the enteral tract. This treatment is used uncommonly.

The peripheral vascular access used for hemodialysis can also be used for parenteral nutrition. Because there is high blood flow through the vascular access used for hemodialysis, hypertonic solutions can be used, and the water load to the patient can be reduced. This technique probably increases the risk of infection or thrombosis in the vascular access, however, and it should not be used except in an emergency or in patients who will need a hemodialysis access for extended periods.

Supplemental Intradialytic Parenteral Nutrition

Amino acids, glucose, and/or lipids may be infused as a nutritional supplement to patients with acute or chronic renal failure who eat poorly. Supplemental amino acids, glucose, and/or lipids can be infused conveniently during the hemodialysis procedure. Because most patients in need of nutritional supplements have decreased intake of both amino acids and energy, I infuse 40 to 42 g of essential and nonessential amino acids and 200 g of D-glucose (150 g of D-glucose if the hemodialysate contains glucose). This preparation is infused throughout the hemodialysis procedure at a constant rate into the blood leaving the dialyzer. This technique minimizes the normal fall in amino acid and glucose pools that results from dialysis of these nutrients. Most of the infused glucose and amino acids are retained; amino acid losses into dialysate increase by only about 4 to 5 g (181). Lipid infusions have been substituted for some of the infused glucose, but they are more expensive and possibly pose some risk of reducing host resistance to infection (354). Patients who have low serum phosphorus or potassium concentrations at the onset of dialysis treatment may require supplements of these electrolytes during the amino acid and glucose supplementation. To prevent reactive hypoglycemia, the infusion should not be stopped until the end of hemodialysis, and the patient should eat a carbohydrate source 20 to 30 minutes before the end of the infusion.

Whether intravenous supplements with amino acids, glucose, and/or lipids thrice weekly for about 3–4 hours during hemodialysis benefit maintenance hemodialysis patients who eat poorly is controversial. Two recent retrospective analyses suggest that intradialytic parenteral nutrition may reduce the mortality rate in malnourished patients undergoing maintenance hemodialysis (356, 357). One study indicated that this benefit was only observed when the serum albumin was 3.3 g/dL or lower (357). Intradialytic parenteral nutrition should only be used in patients who cannot increase their intake of foods or

take oral supplements. Intravenous supplements should be continued only if nutritional or clinical assessment indicates that they are beneficial.

Amino Acids That May Predispose to Acute Renal Failure

Several studies in rats suggest that amino acid or protein intake may increase the susceptibility to acute renal failure caused by ischemia or aminoglycoside nephrotoxicity (358, 359, 360 and 361). The nutrients seem to increase both the incidence and the severity of acute renal failure induced by these agents. Although some studies have demonstrated this effect with large doses of intravenous amino acids or dietary protein (358, 361), the quantities of amino acids and protein that might be prescribed for patients can also predispose to renal failure in animal studies (359, 360). D-Serine, DL-ethionine, and L-lysine appear to be particularly nephrotoxic (359, 361). It is not known whether amino acid or protein intake will predispose to renal failure in humans. If either one does, then patients who receive nephrotoxic medicines or who are at high risk for renal ischemia might benefit from low amino acid or protein intake for transient periods. On the other hand, in vitro studies also indicate that some amino acids, particularly L-glycine and L-alanine, may protect renal tubular cells from ischemic or nephrotoxic injury (362). Clearly, more research is needed in this area.

Future Direction for Nutritional Support

Several new techniques for improving nitrogen balance and host resistance could lead to major changes in nutritional support if the reported benefits are confirmed. The potential use of growth factors for patients with renal failure has been described previously (339, 340, 342, 343, 345). Arginine and glutamine supplements are reported to have specific effects on enhancing nitrogen balance (328, 329 and 330). In addition, evidence indicates that supplemental arginine (330, 363), nucleotides (364), and w-3 fatty acids (364) may improve parameters of immunologic function and host resistance. Peptides have been added to TPN solutions to increase the delivery of less soluble or less stable amino acids (e.g., tyrosine and glutamine) (329).

[Chapter References](#)

There has been increasing, although somewhat belated, appreciation of the important relationship between nutritional status and respiratory disease. During the past decade, a number of clinical investigations have appeared to support longstanding anecdotal impressions that nutritional compromise adversely affects the course of patients with diverse respiratory problems and that in some instances, improving nutritional support may complement other beneficial aspects of therapy. Progressively, basic science and clinical investigations are addressing the roles of nutrients in the genesis and modifications of pulmonary disease.

Cellular respiration is essential for normal function of all tissues. Food substrate is converted into usable energy by formation of high-energy phosphate bonds. Oxygen is required for efficient use of nutrients, and carbon dioxide is produced as a byproduct. The respiratory system is responsible for the uptake of oxygen and the elimination of carbon dioxide for the whole organism and can rapidly adjust these gas-exchange functions as necessary in response to dynamically changing metabolic needs. Such immediate adjustments are integrally related to overall substrate use. Moreover, compromise of nutritional status imposes major limits upon respiratory function in health and disease. This chapter provides an overview of the components of the respiratory system, their relationships to nutritional status, and how these interactions are altered by acute and chronic illnesses. In addition, we discuss the impact of nutrition on the epidemiology and pathogenesis of diverse pulmonary diseases and the challenges and potential benefits of nutritional modification in patients with these conditions.

THE RESPIRATORY SYSTEM

The respiratory system consists of (a) the lungs, including alveoli and blood vessels (where gas exchange occurs), the supporting structure, and the conducting airways; (b) the thoracic cage housing the lungs; (c) the respiratory muscles (the pump); (d) the central and peripheral nervous systems; and (e) the cellular constituents involved in host defense and the metabolic activity of the lungs ([Table 90.1](#)). Defects in any of these individual components can lead to clinical disease. The impact of nutritional state on development and progression of disease has only recently been investigated. Selected components of the respiratory system (central control of breathing, respiratory muscles, and the lung itself) are particularly affected by nutritional deficiency.

Central and peripheral nervous system
Control of breathing
Respiratory muscles
The "pump"
Thoracic Cage
Lungs
Conducting airways
Terminal respiratory unit and alveoli
Pulmonary vasculature
Supporting structures
Trafficking cells
Host defense cells

Table 90.1 The Respiratory System

Control of Breathing

Rhythmic automatic respiration arises from neural input originating in the pontomedullary portion of the brainstem and sets the resting breathing pattern. Abnormal respiratory patterns can reflect a specific anatomic problem at one of the brainstem loci of respiratory neurons. Input from the higher voluntary center, the cerebral cortex, can modify the rate, rhythm, and depth of respiration or interrupt the automaticity to permit voluntary patterns of respiration (e.g., breath holding, cough, tachypnea, bradypnea). Rapid adjustments in the pattern of breathing are required to adapt to the changing metabolic demands of the organism. Feedback from the periphery allows integration of peripheral needs of the organism with the central output. Such adjustments maintain the acid/base and respirable gas (oxygen and carbon dioxide) balance within a narrow range. Thus, while higher centers set the automaticity of the respiratory system, peripheral receptors modify this pattern to accommodate metabolic needs. These intricate relationships enable the respiratory system to

appropriately adjust bulk gas exchange.

The peripheral chemoreceptors (carotid and aortic bodies) respond to changes in the arterial partial pressure of oxygen (P_{aO_2}), arterial partial pressure of carbon dioxide (P_{aCO_2}) and arterial pH. Reduced P_{aO_2} and pH and elevated P_{aCO_2} result in increased chemoreceptor activity and respiratory stimulation. In humans, the carotid bodies are the dominant chemoreceptors (1). Central chemoreceptors located in the medulla respond to changes in cerebral spinal fluid pH (which reflects changes in the P_{aCO_2}), but not to changes in P_{aO_2} . Like the peripheral chemoreceptors, central chemoreceptors stimulate an increase in minute ventilation (the volume of gas inspired in a minute, V_e) (Table 90.2) in the presence of acidemia or hypercapnia but are slower to react to changes in the arterial blood.

Tidal volume (V_T): volume of gas moved during a single inspiration.
Minute ventilation (V_e): total amount of air moved in and out of the lungs in one minute: $V_e = V_T \times$ respiratory rate (RR) in breaths per minute
Dead-space ventilation: inspired gas that does not participate in gas exchange because it does not reach alveoli that are perfused
V_d/V_T : fraction of each tidal volume that is dead space
Alveolar minute ventilation (V_A): amount of inspired air able to participate in gas exchange; alveolar ventilation is the difference between total minute ventilation and dead-space ventilation. $V_A = RR \times V_T - RR \times V_d = RR \times V_T (1 - V_d/V_T)$
Forced vital capacity (FVC): the volume of gas that can be forcibly exhaled after a maximal inhalation
Forced expiratory volume in one second (FEV₁): the volume of air expired within the first second of a forced expiration
Cardiac output (CO): the volume of blood pumped by the heart in one minute; the product of stroke volume and heart rate
P_{aO_2}: partial pressure of oxygen in the arterial blood
P_{aCO_2}: partial pressure of carbon dioxide in the arterial blood
\dot{V}_{O_2}: oxygen consumption (mL/min)
\dot{V}_{CO_2}: carbon dioxide production (mL/min)

Table 90.2 Definitions of Respiratory Physiology Terms and Abbreviations

Other sensors are located in the lungs, upper airways, and respiratory muscles and influence breathing in diverse ways. For the most part, receptors in the lungs and upper airways respond to focal conformational changes and irritant stimuli. They are important in originating the cough reflex, coordinating the upper and lower airway caliber, controlling inspiration and expiration, and producing and secreting mucus. The role of the sensors in respiratory muscle is unclear, but they may contribute to the balance between agonist and antagonist muscle groups, posture, and the sensation of dyspnea. Final integration of afferent and efferent information takes place in the spinal cord, from which segmental motoneurons destined for the respiratory muscles carry the fully integrated message.

Respiratory Muscles

Normally, at rest, inspiration is active and expiration occurs passively with relaxation of the inspiratory muscles. With increased ventilatory demands, however, expiration may become an active process. Contraction of the inspiratory muscles leads to expansion of

the thoracic cage, resulting in negative intrathoracic pressure (Boyle's law)

$$PV = K$$

where P is the pressure of a gas, V is volume, and K is a constant). Airflow is initiated when a pressure gradient develops between the opening of the respiratory system, the mouth, which is at atmospheric pressure and the alveoli, in which pressures become subatmospheric with inspiration. Inspiratory flow ceases when these pressures attain equilibrium. Return of the thoracic cage to its resting position by relaxation of the inspiratory muscles reverses the pressure gradient and leads to exhalation.

The muscles of the respiratory “pump” are the diaphragm, the intercostal and accessory muscles, and the abdominal muscles. The diaphragm is the major inspiratory muscle and anatomically separates the thoracic cavity from the abdominal cavity. It is composed of striated skeletal muscle with a rich vascular supply and a central tendon. At rest, it is dome shaped. With each contraction, the diaphragm flattens and descends, raising the lower ribs in the zone of apposition. This increases both the vertical and anterior-posterior dimensions of the thoracic cage and causes a decrease in intrathoracic pressure ([Fig. 90.1](#)). Although this muscle contracts rhythmically during the lifetime, it does not have intrinsic automaticity like the smooth muscle of the heart. The chest wall and abdominal muscles may also assist with inspiration and forced exhalation.

Figure 90.1. The diaphragm. Contraction of the diaphragm causes downward descent of the dome of the diaphragm. Contraction of the fibers that insert on the ribs, causes the ribs to lift and rotate outward. Additionally, the descent of the diaphragm increases the intraabdominal pressure leading to lateral outward movement of the lower thoracic cage. The net result is expansion of the thoracic cavity in both the vertical and horizontal dimensions.

Like other skeletal muscle groups, the respiratory muscles are subject to fatigue from an imbalance between supply and demand. Roussos and Macklem defined muscle fatigue

as a reversible inability of a muscle to continue to generate prior attainable force (2), whereas respiratory muscle weakness is the chronic inability of the muscle to attain adequate force. Both respiratory muscle fatigue and weakness can result in failure of the muscles to produce sufficient force to support continuous gas exchange in and out of the lung. Clinically, hypercapnic respiratory failure and, subsequently, hypercapnic and hypoxemic respiratory failure result from the respiratory system's incapacity to meet metabolic demands. Respiratory muscle fatigue may be central (resulting from loss of appropriate central neural drive), transmissional (resulting from reversible impairment of neural impulses through the nerves or across the neuromuscular junction), or peripheral (due to primary failure of muscle performance). Nutritional deficiencies affect primarily central and peripheral muscle fatigue.

Both fatigue and weakness have obvious, important relationships to nutritional status. The diaphragm and other respiratory muscles are composed of type I and type II muscle fibers. Type I fibers are slow-twitch fibers that require a longer period of time after stimulation to reach peak tension, have high levels of oxidative enzymatic capacity which makes them more resistant to fatigue, and are recruited earlier than type II, fast-twitch fibers. Type II fibers have relatively higher levels of glycolytic enzymes and less oxidative enzymatic capacity. Type II muscle fibers can generate a greater peak force than the type I fibers but are more easily fatigued.

The differential effects of malnutrition upon these two fiber types has been well studied. Lewis et al. studied rats subjected to 6 weeks of undernutrition (reduction of body weight to 50% of expected body weight) and found a significant reduction in the cross-sectional area of both types of fibers in the animal's diaphragm, but the fast-twitch fibers were quantitatively more affected (3). Goldspink and Ward (4) and Oldfors et al. (5) reported greater atrophy of fast-twitch fibers than of slow-twitch fibers in animal skeletal muscle preparations with malnutrition and protein-deficient nutrition, respectively. The fast-twitch fibers containing less oxidative enzymatic capacity were more affected than those fast twitch fibers with greater amounts of oxidative enzymes. Sieck et al. found that fatigue resistance was actually improved in an in vitro nerve-muscle-strip preparation from diaphragms of nutritionally deprived rats (daily food access restricted to one-third of estimated daily consumption until body weight was approximately 50% of the controls), despite a significant reduction in the cross-sectional area of both fibers (6). Type II fibers were selectively more affected than type I fibers (6). No change was noted in the oxidative capacity of the muscle fibers (6). These authors felt that the increase in fatigue resistance was most likely related to selective atrophy of the more fatiguable type II fibers (6). These observations suggest that malnutrition would result clinically in diminished peak-pressure generation by the respiratory muscles, with little or no effect on endurance.

However, in physiologic terms, inspiratory muscle fatigue can be predicted by the length of time in each respiratory cycle that the muscles are in active contraction and the ratio of tension developed to peak tension. Bellemare and Grassino defined the product of the ratio of inspiratory time to the total respiratory cycle (T_i/T_{tot}) and the ratio of diaphragmatic pressure generation to peak pressure ($P_{di}/P_{di_{max}}$) as the tension time index (7)

$$TTdi = Pdi/Pdi_{max} \times Ti/T_{tot}$$

In both normal subjects and patients with chronic airflow obstruction, a TTdi above 0.15 is associated with electromyographic evidence of diaphragmatic fatigue (7, 8). Therefore, any mechanism that increases Pdi/Pdi_{max} , Ti/T_{tot} , or both can lead to respiratory muscle fatigue. If the peak pressure that can be generated is reduced, any given pressure produced during the inspiratory cycle represents a greater percentage of the reduced peak pressure than of a normal peak pressure. Thus, if malnutrition contributes to a decline in peak pressure, the pressure required for a normal tidal breath represents a larger proportion of the “lower” peak pressure and can result in inspiratory muscle fatigue. Even if adaptation then leads to a lower inspiratory pressure per breath, the tidal volume (V_t , resting inspiratory volume) would have to fall, assuming lung mechanics remain the same. Therefore, to maintain the same minute ventilation

$$V_e = V_t \times RR$$

where RR is the respiratory rate in breaths per minute, the respiratory rate would have to increase, which would shorten each respiratory cycle and, given a static inspiratory time, increase T_i/T_{tot} . Again, this could lead to respiratory muscle fatigue.

Although diseases that primarily affect the respiratory muscles are much less common than those affecting the lung itself, the respiratory muscles are important as a compensating mechanism. Despite major alterations in the lung parenchyma or communicating airways, adequate gas exchange at the alveolar capillary membrane may still occur as long as an increase in bulk air exchange can offset the deficiencies. In fibrotic lung diseases, the elastic load to respiratory muscles is increased, whereas in obstructive airways diseases, the resistive load is increased. If the respiratory muscles can overcome such increased loads without fatigue, even though the work of breathing is markedly increased, function may be preserved. Unfortunately, with advancing disease or increased demand (e.g., in exercise), the imposed loads exceed the compensatory limits of the respiratory muscles, ultimately compromising the patient's functional status.

Lungs

The lungs comprise the conducting airways, the gas-exchange organ (alveoli and pulmonary capillary bed), the supporting structural elements, the pulmonary and bronchial vasculature, and trafficking immune effector cells.

Tracheobronchial Tree

The conducting airways are a series of dichotomously branching structures extending from the proximal main airway (the trachea) to the periphery (alveoli). There are two major types; the bronchi or cartilaginous airways and the bronchioles, noncartilaginous or membranous airways. As the bronchioles further divide toward the periphery, they are subdivided into nonrespiratory and respiratory bronchioles. The latter contain alveoli

and participate in gas exchange as well as conduct the gas stream to more distal gas-exchange units (alveolar ducts and alveoli).

The airways not only conduct the gas to the alveoli but also further condition it (humidifying, warming, and filtering) through specialized bronchial epithelial cells and bronchial submucosal glands. The bronchial epithelium consists of ciliated columnar cells that sweep inhaled particles, by coordinated beating of the cilia, proximally for removal (“mucociliary elevator”). Other cell types include mucous and serous cells partially responsible for producing mucus that helps entrap particles for the ciliary elevator; basal and intermediate cells that migrate toward the surface to replace the luminal epithelial cells; argyrophil cells, which may have endocrine properties; and Clara cells found in the distal respiratory bronchioles, which may contribute to the luminal liquid lining (1). The submucosal bronchial glands contribute to the bronchial mucous layer and are most frequent in the medium-sized bronchi (1). In response to chronic irritation (e.g., chronic bronchitis), they can increase their output and size, thus narrowing the airway lumen.

Smooth muscle is found throughout the walls of the tracheobronchial tree. Muscle contraction imparts rigidity to the airways (1) and reduces the caliber of the airway lumen. Innervation is primarily through the parasympathetic and the nonadrenergic, noncholinergic nervous pathways, but receptors are present for other neurotransmitters. Gas flows through the tracheobronchial tree down a pressure gradient. Airflow is inversely related to the airway resistance, which in turn is inversely related to the fourth power of the radius of the tracheobronchial tube.

Terminal Respiratory Unit

The terminal respiratory unit consists of respiratory bronchioles, alveolar ducts, and alveoli. The total surface area of the alveoli in a normal human adult is estimated to be 140 m² (1). Gas exchange occurs at the alveolar-capillary membrane, which consists of the alveolar epithelium and capillary endothelium and their basement membranes, the tissue and cellular components of the contiguous interstitial space, and the surfactant lining (1). Surfactant, a complex phospholipid and protein mixture produced by the alveolar epithelium (type II pneumocyte), lines the alveolar airspace. Surfactant reduces the surface tension of the alveolus at the air interface, which decreases the tendency of the airway to collapse and thus maintains alveolar stability at low lung volumes.

Pulmonary Physiology

The ultimate purpose of the respiratory system is to facilitate transfer of O₂ from inspired gas to the bloodstream and CO₂ from blood to expirable gases. This exchange occurs at the alveolar-capillary interface. O₂-poor blood returns from the peripheral circulation to the right side of the heart where it is pumped through the pulmonary vasculature to the pulmonary capillaries. At the alveolar-capillary level, oxygen diffuses down a concentration gradient from the alveoli to the capillary blood. Most of the O₂ binds to and fully saturates hemoglobin in red blood cells; a small amount dissolves in the plasma. Simultaneously, CO₂ leaves the blood and enters the alveoli across a

concentration gradient in the opposite direction. Inspired air, at sea level, has a partial pressure of O₂ of 160 torr (1 torr = 1 mm Hg) and a partial pressure of CO₂ of 0 torr. After hydration and mixing with the resident gas in the alveoli the normal partial pressures of O₂ and CO₂ in the terminal respiratory units and alveoli are approximately 100 and 40 torr, respectively. The partial pressures of O₂ and CO₂ in the capillary blood entering the gas exchange area are 40 and 46 torr, respectively; therefore, the driving pressure for O₂ is normally 60 torr, and for CO₂, 6 torr. Equilibrium between alveolar gas and entering capillary blood is achieved within the first 0.25 seconds of the total capillary transit time of 0.75 seconds at rest (1).

Implied in this system is rapid replenishment of fresh gas to alveoli to match the arrival of desaturated, CO₂-loaded blood to the alveolar-capillary unit. As described above, inspired gas enters the lungs when negative intrathoracic pressure is generated by respiratory muscle contraction. However, not all of an inspired breath can participate in gas exchange. About 30% of each breath remains in the conducting airways, which conduct gas to the lung parenchyma but do not participate in gas exchange. These large non-gas-exchanging airways are collectively termed *the anatomic dead space*. Some inspired gas also reaches alveoli that are not perfused and hence cannot participate in gas exchange. This volume is the physiologic dead space. Together, the anatomic and physiologic dead space make up the total dead space. Minute alveolar ventilation (V_A) is the difference between total minute ventilation and total dead space ventilation, that is, the portion of the tidal volume that participates in gas exchange times the respiratory rate (Table 90.2). This can be regarded as the “effective” minute ventilation.

Impairment of the fresh supply of gas to match perfusion of alveoli limits efficient gas exchange. The gas supply can be impaired by obstructed airflow (increased airway resistance) or limited expansion of the lungs (decreased compliance). These obstacles lead to ventilation and perfusion mismatch. When perfused alveoli are not ventilated, deoxygenated blood from these areas mixes with oxygen-saturated blood, reducing total oxygen content. This results in arterial hypoxemia and represents shunt physiology. Ventilation/perfusion mismatches ranging between the extremes of shunt and dead space ventilation have variable impact on overall gas exchange. Mechanical alterations increase the work of breathing, not only from the need to overcome increased airway resistance or decreased lung compliance, but also from the compensatory mechanisms (usually increased V_e) required to meet the continuing metabolic demands of the individual. Eventually, when metabolic demand exceeds respiratory reserve, gas exchange abnormalities appear.

In addition to its gas-exchange functions, the lung acts as a “filter” for blood and has extensive metabolic functions, including synthesis of surfactant, various proteins (both structural and enzymatic), and humoral substances (arachidonic acid metabolites, histamine, substance P, and vasoactive intestinal protein) and transformation of biochemical substances (1). Relatively little is known about the effects of altered nutrition in these areas.

In a broad sense, pulmonary diseases can be categorized on the basis of their primary

physiologic abnormalities as obstructive airflow diseases or restrictive diseases, and either can be acute or chronic (Fig. 90.2). With obstructive airflow disease, the primary problem is maintaining adequate V_A to match perfusion and allow adequate gas exchange in the setting of increased airflow resistance. The resulting ventilation/perfusion mismatch causes hypoxemia. CO_2 excretion is maintained initially by increased V_A ; but if the V_A cannot increase or decreases, CO_2 excretion falls and the $Paco_2$ rises. In disease processes marked by decreased lung compliance (e.g., pulmonary fibrosis or air-space filling diseases such as pneumonia and pulmonary edema), loss of functioning alveolar-capillary units with varying degrees of ventilation/perfusion mismatch leads to hypoxemia. Compensation again occurs, usually with an increased respiratory rate to replenish alveolar oxygen stores, but the V_t may fall because of the increased work to inflate stiffer lungs; a greater pressure must be generated to achieve a given change of lung volume. If the process progresses or the respiratory reserve is diminished (e.g., respiratory muscle fatigue), CO_2 elimination decreases and $Paco_2$ rises, leading to hypercapnic, hypoxemic respiratory failure.

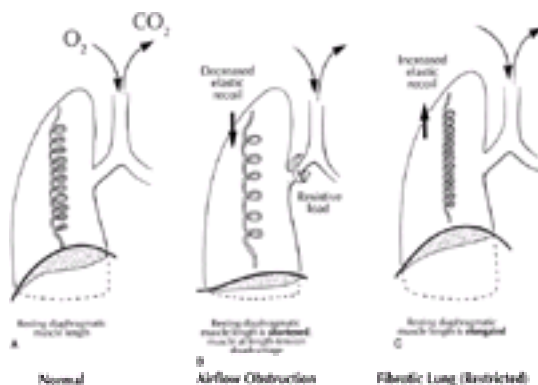

Figure 90.2. Normal (A), obstructive (B) and fibrotic (C) lungs. *Obstructive (B):* Airflow obstruction leads to an increased resistive load for the respiratory muscles to overcome. In emphysema, elastic recoil is lost because of destruction of multiple alveolar-capillary units. As expiratory flow is limited, the lungs become hyperinflated and flatten the normal curvature of the diaphragm. This places the diaphragm at a mechanical disadvantage by the shortened resting length of the diaphragm. The work of breathing is increased because of the increased resistive load and relative inefficiency of the respiratory muscles because of the shortened resting length. *Fibrotic (C):* Increased elastic recoil (decreased compliance of the lung) places an elastic load on the respiratory muscles and thus increases the work of breathing.

Arterial blood gas determinations at rest or with exertion can provide a guide to the efficiency of gas exchange. Pulmonary function tests that measure exhaled gas volumes and flow rates can identify abnormal lung compliance and airflow obstruction. The forced vital capacity (FVC), the volume of gas that can be forcibly exhaled after a

maximal inhalation, reflects total lung volume. The forced expiratory volume in 1 second (FEV₁), the volume of gas that is forcefully exhaled in 1 second, can be reduced in both obstructive and restrictive lung diseases. This value allows quantitative information about both total lung volume and airflow resistance, since it is a timed maneuver. In restrictive lung diseases, the FEV₁ and the FVC are proportionally reduced, resulting in a normal FEV₁:FVC ratio; in obstructive diseases, the FEV₁ is reduced, but the FVC remains normal, resulting in a decrease in the FEV₁:FVC ratio, the hallmark of clinically important airflow obstruction.

Pulmonary function testing objectively reveals the presence and severity of respiratory diseases and has important implications for nutritional research investigations. Objective changes in lung volumes, flow rates, and respiratory muscle strength are commonly assessed endpoints when examining the effects of dietary modifications. The relevance of respiratory muscle function and exercise performance status to dyspnea and limitations in daily function have made measures of maximal inspiratory pressure (MIP), maximal expiratory pressure (MEP), walking distance (12-min walk), or more-comprehensive exercise testing valuable in assessing effects of nutritional supplementation. Terms used in these common physiologic indicators of lung and respiratory muscle function are defined in [Table 90.2](#).

EFFECTS OF MALNUTRITION ON RESPIRATORY SYSTEM DEVELOPMENT, STRUCTURE, AND FUNCTION

Both laboratory investigations and clinical studies suggest that the major adverse effects of malnutrition upon the respiratory system are in respiratory muscle structure and function, ventilatory drive, and host immune defenses ([Table 90.3](#)). Appropriate nutritional support may reverse these effects. Malnutrition may affect adversely lung architecture, surfactant production, and reparative ability.

Established

Decreased respiratory muscle structure and function

Decreased ventilatory drive

Decreased pulmonary host immune defenses

Proposed

Altered lung architecture, especially in immature animals

Decreased ability to repair after injury

Decreased surfactant production

Table 90.3 Respiratory Complications of Malnutrition

Developmental Effects

Both animal and human studies suggest that undernutrition during development can profoundly alter the structure and function of various organs. Fetal malnutrition in rats and guinea pigs can result in pulmonary hypoplasia (9, 10). Protein deprivation in developing rats can diminish collagen and elastin synthesis and simulate a defect pathologically similar to emphysema (11). Manifestations of developmental nutritional insults depend upon when they occur. Investigations in animal models showed that early undernutrition leads to small but normally proportioned animals, whereas later insults result in lungs that are disproportionately small for body size (12). In humans, airway division to the level of the terminal bronchiole is completed by gestational week 16; between weeks 17 and 20, a tremendous growth of lung cells occurs (12). Various authors have described associations between low birth weight and subsequent decreases in pulmonary function (13, 14). FEV₁ (adjusted for age and height) is directly related to birth weight, and mortality rates from chronic airflow obstruction are inversely related to birth weight (14). Rona et al. examined relationships between birth weight, gestational age, respiratory symptoms, and lung function in an attempt to define the independent effects of prematurity and intrauterine growth retardation (15). They found that birth weight corrected for gestational age correlated with measures of lung function whereas prematurity did not. Symptoms of wheezing and cough, however, correlated with prematurity (15).

Effects on Respiratory Muscles

Studies based on animal models showed a linear correlation between diaphragm weight and body weight (16, 17). One investigation of the effects of a short-term fast in young rats leading to a 28% loss of body weight demonstrated a proportional loss in diaphragmatic weight (18). Similar correlation exists between body weight and diaphragm weight in normal humans (19) and persons with emphysema (20). Poorly nourished patients (body weights of 71 ± 6% of ideal body weight—based height and sex from Metropolitan Life Insurance tables) had diminished respiratory muscle strength, manifested by reductions in both MIP and MEP (21). The extent of muscle mass loss could not fully account for the disproportionately severe decline in respiratory muscle strength, and it was suggested that poor nutritional status could also result in possible myopathy of the remaining muscles (21). Although the effects of underlying disease (such as malignancy) cannot be excluded as contributing factors in this study, these observations suggest a clinical correlate to the anatomic findings.

Effect on Ventilatory Drive

Normal human subjects limited to a 500-kcal carbohydrate diet exhibit a decrease in both hypoxic ventilatory drive and metabolic rate (22), with significant correlation between the two (22). With refeeding, the hypoxic ventilatory response normalized (22). Normal male volunteers given only a daily infusion of 3 L of a 5% amino acid solution (550 kcal/day) for 10 days to maintain nitrogen balance had a lower hypoxic ventilatory drive than controls given a daily infusion of 3 L of 5% amino acid solution supplemented with 500 mL of 10% safflower oil emulsion (1100 kcal/day) (23). This suggests that a

minimum caloric intake is necessary to preserve the normal ventilatory drive in semistarvation (23). However, neither study demonstrated significant alteration in the hypercapnic response in semistarvation. Conversely, in normal volunteers, after an overnight fast, enteral protein feeding (1000 kcal of egg albumin) caused the normal ventilatory response slope to CO₂ to rise, but the CO₂ response was unaffected by a carbohydrate meal (1000 kcal of a glucose solution); both feedings increased both resting metabolism and the hypoxic ventilatory response (24).

Both low V_e and low mouth occlusion pressure occurred in response to hypercapnea in a patient with severe anorexia nervosa who weighed 46% of ideal body weight (25). Mouth occlusion pressure correlates with the intensity of phrenic nerve stimulation and reflects the output of the respiratory center. Taken together, these data suggest that both abnormalities of central control of breathing and muscle weakness contributed to the abnormal response to hypercapnea (25). Refeeding can completely reverse the abnormalities seen with anorexia nervosa (25, 26).

Effect on Host Defenses

Along with a general susceptibility to infections, malnourished (both protein- and calorie-deficient) individuals are likely to develop alterations in pulmonary defense mechanisms. In infant rats, protein-calorie malnutrition reduced T lymphocyte-dependent alveolar macrophage function, although neutrophil-dependent alveolar macrophage function was preserved (27). In adult rats, effects of malnutrition on alveolar macrophage function are conflicting. One study recovered a reduced number of alveolar macrophages by bronchoalveolar lavage but showed normal phagocytic function in protein-restricted adult rats (28). In another investigation, more-severe starvation resulted in reduction in both alveolar macrophage phagocytosis and microbial killing (29). Protein-calorie malnutrition did not inhibit macrophage adherence or bacterial killing but did change the profile of inflammatory mediators produced by alveolar macrophages (30). Gram-negative bacterial adherence and colonization of the lower respiratory mucosa correlates inversely with nutritional status in tracheostomized patients (31). In malnourished patients with chronic obstructive pulmonary disease (COPD), absolute lymphocyte counts and reactivity to common skin test antigens improved with refeeding and weight gain, suggesting a link between these parameters (32). Malnourished subjects exhibit decreased tidal volumes and number of sighs leading to alveolar collapse (atelectasis) and inadequate clearance of secretions, which in turn may predispose to pulmonary infection (33). Studies in animals also suggest that adequate nutrition may be important in maintaining normal lung repair and structure (34) and surfactant production, but the clinical relevance of these observations is unclear.

PROTOTYPIC DISEASES OF THE LUNGS: RELATIONSHIPS TO NUTRITIONAL STATUS

Diseases of the pulmonary system can be grouped into those that cause acute alterations in normal function and those that cause chronic changes. The potential benefits, hazards, and clinical priorities of nutritional care differ in these settings. In

acute lung injury, the general goal of nutritional support is to meet the expanded requirements of a hypercatabolic state to prevent protein breakdown. In chronic obstructive lung disease, emphasis is placed on maintaining respiratory muscle strength, mass, and function in an effort to optimize the patient's overall performance status and meet the demands of daily activities. In this section, we review acute respiratory failure and COPD as examples of the complex interactions of nutritional status and commonly encountered respiratory diseases.

Acute Lung Injury

Acute lung injury can result from a simple localized lung infection (pneumonia) or from a systemic process that leads to diffuse alveolar damage as seen with the acute respiratory distress syndrome (ARDS). Most acute respiratory illnesses are associated with the systemic symptoms of anorexia, fatigue, and malaise. When these are combined with cough and/or dyspnea, oral intake is generally poor. Patients with severe lung injury may require endotracheal intubation and mechanically assisted ventilation that precludes adequate oral intake. Acute lung injury often occurs in the setting of multisystem organ failure (MSOF) due to sepsis or trauma, conditions associated with a hypercatabolic state. The combination of decreased oral intake and increased metabolic demand can lead to negative nitrogen balance with decreased respiratory muscle strength because of protein catabolism, diminished ventilatory drive, and altered immune function (35). Nutritional support can potentially alleviate this imbalance between metabolic supply and demand.

Giner et al. prospectively evaluated the impact of malnutrition on outcome in an ICU population and found that patients who were malnourished at admission (defined by serum albumin levels and height:weight ratios) had a significantly higher incidence of complications and were less likely to be discharged from the hospital (36). Bartlett et al. showed that negative caloric balance postoperatively (measured by indirect calorimetry) correlated significantly with MSOF in 57 surgical patients (37). However, despite these correlations, optimal strategies for nutritional support have not been established.

Metabolic Requirements

The metabolic responses and requirements imposed by severe lung injury (e.g., ARDS) are similar to those associated with sepsis, trauma, major injury, or burns and differ from the normal fasting state. In ARDS, the degree of metabolic alteration depends more on the underlying insult than on the extent of lung injury because ARDS represents only the pulmonary response to an underlying local or distant injury. In the phase characterized by hypercatabolism, negative nitrogen balance generally occurs. Carbohydrate metabolism is altered; hyperglycemia results from increased glucose turnover because of relative insulin "resistance" with expanded hepatic gluconeogenesis and an excess of counterregulatory hormones (glucagon, epinephrine, and cortisol) (38). Fat oxidation appears to be preferred and may be the main caloric source in the stressed patient (39). However in shock states and MSOF, fat may be poorly used and may accumulate (38). Muscle proteolysis develops to maintain a steady glucose supply to the brain, leading to negative nitrogen balance (40). (See [Chapter 96](#).)

The best method of determining energy requirements in the critically ill patient is not yet established. Energy requirements can be measured at bedside by indirect calorimetry or estimated using the Harris-Benedict equation (Table 90.4). Oxygen consumption (Vo_2) can be used as an estimate of caloric use and can be calculated using the Fick equation

$$Vo_2 = CO \times (CaO_2 - CvO_2)$$

where CO is the cardiac output, CaO_2 is oxygen content of arterial blood and CvO_2 is the mixed venous content of blood. The disadvantages of this approach are the requirement for a pulmonary artery catheter to sample mixed venous blood, the need for a relatively stable patient, the inherent inaccuracies of using multiple measurements with their own standards of error to calculate a final product, and the intermittent timing of measurements. Despite these limitations, Liggett et al. found an excellent correlation ($r = 0.90$) between the calculated resting energy expenditure

$$REE = Vo_2 \times 4.86 \text{ kcal/L}$$

using the Fick method and the results of the gas-exchange method of calorimetry in 19 stable patients (41).

-
1. $EE = Vo_2 \times 4.7 \text{ kcal/l} \times 1440 \text{ min/day}$
or
 $EE = (3.9 \times VO_2 + 1.1 \times VCO_2) \times 1.44$
 2. Harris-Benedict equation
Females:
 $BEE = 655 + (43 \times wt \text{ (lb)}) + (43 \times ht \text{ (in)}) - (4.7 \times age)$
Males:
 $BEE = 65 + (6.2 \times wt \text{ (lb)}) + (12.7 \times ht \text{ (in)}) - (6.8 \times age)$
-

Table 90.4 Estimates of Energy Requirements

Alternatively, Vo_2 can be assessed by means of a metabolic cart (the gas-exchange method). This approach requires the technical ability to measure exhaled gases directly and is not universally available. Problems related to its use include availability, the need for skilled technicians trained to operate the analyzer, a leak-free system, a stable F_iO_2 (fraction of inspired oxygen), and expensive instrumentation. In addition, at the high F_iO_2 (≥ 0.80) often required in patients with severe hypoxemic respiratory failure, the assumptions made in the derivation of the Vo_2 by this method begin to fail (42).

Nevertheless, if it can be performed accurately, this approach can be used continuously and represents a more “direct” measurement. The Vo_2 (mL/min) obtained by either method is converted to kilocalories per day by simply using the caloric value of oxygen (4.69–5.05 kcal/L of O_2 consumed) based on a nonprotein respiratory quotient (RQ) (27) or by using the modified Weir equation if the Vco_2 (CO_2 production) is also known (42) (Table 90.4)

$$\text{Energy expenditure (EE)} = (3.9 \text{ Vo}_2 + 1.1 \text{ Vco}_2) \times 1.44$$

Another estimate of the resting energy requirement can be derived from standard regression formulas based on various population studies. The most common formula used is the Harris-Benedict equation (Table 90.4) (43). The regression equation was derived from studies on normal subjects at rest (43) and was not designed to address the stress and hypercatabolism seen in many disease states, especially those encountered in the critical care setting. Therefore, “stress factors” have been developed for certain commonly seen clinical scenarios. These range from 1.2 times the calculated REE for elective surgery (42) to 1.5 or more times the REE for burn patients (44). However, the correlation between the measured REE by indirect calorimetry and that predicted from the Harris-Benedict equation has been found to be only moderate in postoperative, hemodynamically stable, noncomatose but critically ill patients requiring mechanical ventilation (Fig. 90.3) (45). More recently, Liggett and Renfro have shown that in nonseptic mechanically ventilated medical ICU patients, the Harris-Benedict equation satisfactorily predicted the energy expenditure (EE) using the Fick method of determining Vo_2 without modification or stress factors (46). In patients with sepsis, the energy requirements were approximately 20% more than those predicted from the Harris-Benedict equation (46).

Figure 90.3. Distribution of the ratio of measured resting energy expenditure (REE) by indirect calorimetry to the predicted energy requirement using the Harris-Benedict equation in mechanically ventilated, postoperative, critically ill patients who were hemodynamically stable and noncomatose. Perfect correlation would have a value of 1.00. (From Weissman C, Kemper M, Askanazi J, et al. *Anesthesiology* 1986;64:673–9.)

Because there are potential inherent complications of both underfeeding and overfeeding, proper estimation of caloric requirements is particularly important in patients with acute lung injury. Overfeeding can lead to fluid overload, glucose intolerance, fatty infiltration of the liver (with either parenteral or enteral feedings), diarrhea (with enteral feedings), net lipogenesis increasing the V_e demand secondary to increases in the net VCO_2 (CO_2 production), and an increase in the baseline REE due to diet-induced thermogenesis (DIT). Underestimation of caloric needs can lead to underfeeding and negative nitrogen balance with muscle proteolysis. Clinical evidence suggests that malnutrition has detrimental effects on pulmonary mechanics by impairing ventilatory drive, respiratory muscle function, and normal lung defense mechanisms (35), thereby increasing the need for mechanical assistance. Nutritional supplementation may aid in weaning patients with respiratory failure from mechanical ventilation (47, 48).

Substrate Supplementation: Implications for Ventilatory Requirements

Nutritional supplementation can be in the form of protein, carbohydrate, or fat. The nutritional characteristics of these substrates are detailed in [Chapter 2](#), [Chapter 3](#) and [Chapter 4](#). This chapter discusses the relative merits of these substrates as they relate to pulmonary diseases.

Most patients with acute respiratory failure who require mechanical ventilation are in a hypercatabolic state and will break down their protein stores to meet immediate metabolic needs. In addition, glucose-dependent tissue (brain, red blood cells, and healing wounds) requirements are met through gluconeogenesis from amino acids if glucose supplies are limited (49). Inhibition of glucose neosynthesis with protein sparing can be accomplished in normal fasting patients by administration of 100 g of glucose/day. By contrast, injured or septic patients may require up to 600 g or more (50). Intravenous fat emulsions can also spare protein if administered with at least 500 kcal/day of carbohydrate calories (either glycerol or glucose) (51). Exogenous protein administration can also replace endogenous protein stores as a substrate for gluconeogenesis and limit proteolysis (51). Protein supplementation may increase oxygen consumption (thermic effect of protein) (52), V_e (52), and the ventilatory response to hypercarbia and hypoxemia (24). Clinically, a high-protein diet could result in increased dyspnea in patients with an already augmented respiratory drive and/or those with borderline respiratory reserve. Because of the integral role of protein in normal physiologic and cellular function (e.g., structural support, enzyme activity, transport, receptor activity, and messenger activity), protein sparing is essential to recovery from any insult.

The appropriate mix of substrate (protein, carbohydrate, or fat) delivered depends on the clinical state and the desired goals. In acute or chronic respiratory failure where respiratory reserve is limited, carbohydrates impose a greater demand on the respiratory system than the other substrates because more CO_2 is produced during its oxidation. For every molecule of glucose completely oxidized, six molecules of CO_2 are

produced, giving a respiratory quotient (RQ = molecule of O₂ used/molecule of CO₂ produced) of 1. On the other hand, the RQ of fat is 0.7 (less CO₂ produced for every molecule of O₂ consumed) and the RQ of protein is 0.8 (see [Chapter 5](#)). Therefore, more CO₂ is produced for the lung to eliminate in oxidizing carbohydrate than fat or protein ([Fig. 90.4](#)) (53). The partial pressure of arterial CO₂ is determined by the relationship

$$Paco_2 = K(Vco_2/V_A)$$

where *K* is a constant, *Vco₂* is CO₂ production, and *V_A* is alveolar minute ventilation

$$V_A = RR \times V_t(1 - V_d/V_t)$$

where *RR* is the respiratory rate, *V_t* is the tidal volume, and *V_c/V_t* is the fraction of wasted or dead space ventilation. Thus, if *VCO₂* increases, *V_A* must also increase to keep the *Paco₂* normal. Alveolar ventilation can be increased by increasing the respiratory rate or tidal volume, which in turn, increases the work of breathing. Reducing the physiologic dead space (that which is ventilated but not perfused) will also improve *V_A*, but such a reduction usually is not easily accomplished, because many patients with respiratory failure have an elevated dead space fraction because of their underlying pulmonary disease. If the patient has little or no respiratory reserve to meet the augmented ventilatory demand of increased CO₂ production, respiratory failure may be further exacerbated and complicate weaning from artificial ventilatory support.

Figure 90.4. Effects of increased carbohydrate intake on CO₂ production, O₂ consumption, and RQ in a normal subject. As the carbohydrate intake increases, CO₂ production and eventually O₂ consumption increase. (From Elwyn DH, Askanazi J, Kinney JM. *Acta Chir Scand* 1981;507(Suppl):209–19.)

Respiratory failure precipitated or aggravated by administration of high glucose loads to patients with compromised respiratory function has been reported (54, 55 and 56). In chronically nutritionally depleted patients and acutely ill patients with injury or infection, Askanazi et al. studied the effect of total parental nutrition (TPN) supplementation at 1.5 times their REEs, with up to 50% of the nonprotein calories as either glucose or fat emulsions (54). No one in the two groups required assisted ventilation or was noted to have respiratory impairment. In the chronically nutritionally depleted group, however, VCO_2 rose by 20% and V_A (mostly due to an increase in V_t) rose by 26% after conversion from a high fat to a high glucose source (54). In the acutely ill individuals, VCO_2 also rose significantly by 21% (54). Changes in V_e in the acutely ill were not characterized in this report, but in an earlier investigation of high glucose TPN (1.2–2.25 × REE), V_e increased by 71% in the hypermetabolic patients and by 121% in those with mild or moderate injury (56). Respiratory deterioration was not reported in either study. Heymsfield et al. showed that the VCO_2 difference between a high-fat and a high-carbohydrate infusion in stable medical patients with chronic illness was exaggerated once supplementation was increased from a maintenance rate to a replenishment rate (57). This may be explained by the amount of CO_2 liberated in production of triglyceride from glucose, which is 30 times the amount of CO_2 produced in converting dietary fat into triglyceride (57).

Micronutrients may also be important in maintaining normal hemostasis. In rats, deficiency of selenium, an essential cofactor of the antioxidant enzyme glutathione peroxidase, increases susceptibility to lung injury induced by exposure to high oxygen concentrations (58, 59). Production of oxygen free radicals in excess of antioxidants is thought to contribute to acute lung injury (see Chapter 14). The clinical role of selenium and other trace elements in preventing lung injury is currently being investigated. Most enteral formulas contain sufficient levels of micronutrients, and it is unclear whether supplementation above these levels is beneficial.

Timing and Route of Nutritional Support

The relationships between malnutrition and worse outcomes support use of nutritional support in the critically ill. Despite these data and the hypothetical benefits of nutritional support, at present there are no prospective, randomized, controlled investigations that clearly demonstrate the efficacy of nutritional supplementation in this population (60) (see also Chapter 98). The optimal timing, composition of substrate, and route of administration of nutritional supplementation have not yet been unequivocally established either in the critically ill, but they are probably patient specific and greatly influenced by baseline nutritional status and type of imposed stress. The route of supplemental feeding may be either parental or enteral. The indications, techniques, formulations, goals, and complications are presented in detail in Chapter 51 and Chapter 64 (infants and children) and Chapter 98, Chapter 100 and Chapter 101.

Enteral Feeding and Pulmonary Issues

Enteral feeding is most commonly accomplished through a nasogastric feeding tube or a small-caliber (10-Fr) nasoduodenal tube. Potential mechanical risks are associated with enteric feeding tubes, including misplacement in the tracheobronchial tree beyond cuffed endotracheal tubes, occasionally with perforation into the pleural space (61), underscoring the need to confirm proper placement before use. In addition, epistaxis, sinusitis, esophagitis, tracheoesophageal fistula, and ruptured esophageal varices can complicate the use of nasoenteral tubes (62). Substituting oroenteral tubes for nasoenteral tubes can limit development of some upper airway complications. Theoretically, enteral feeding into the duodenum should reduce the likelihood of aspiration by bypassing the problem of delayed emptying secondary to gastric paresis and adding the pylorus as a barrier to regurgitation. Zaloga found a 30% incidence of aspiration when feeding tubes were placed in the stomach, compared with no occurrences when tubes were confirmed to be in the duodenum (63). On the other hand, Strong et al. demonstrated that the site of tube placement did not affect the incidence of aspiration (64). Various duodenal feeding tubes designed to be inserted either through the nose or through the abdominal wall (via surgery or endoscopy) have been developed (see Chapter 100). Unfortunately, the diagnosis of aspiration pneumonia cannot always be made with certainty, nor is it clear what degree of aspiration is clinically important. Maintaining patients in a semirecumbent rather than supine position can significantly decrease pulmonary aspiration of gastric contents in patients receiving nasogastric feeding (65).

Parenteral Nutrition and Pulmonary Issues

Parenteral nutrition (PN) can be accomplished through a central vein (allowing more concentrated and hypertonic solutions) or peripherally, unless a large amount of lipids is infused. Peripheral parenteral nutrition requires a greater obligate fluid load to meet similar caloric needs compared to the central route (see Chapter 101). Because impaired fluid handling is common in patients with acute lung injury, limited fluid intake is generally preferred and may be associated with improved outcomes (66).

Access is obtained through percutaneous catheterization of one of the central veins, most commonly the subclavian and jugular veins. Technical difficulties with insertion can lead to ipsilateral pneumothorax, arterial puncture, thoracic duct disruption, catheter misdirection, catheter fracture, thrombosis, catheter or air embolism, infection at the local site with subsequent bloodstream seeding, and local bleeding and hematoma formation. Complications associated with insertion occur more frequently when such catheters are placed by less experienced individuals (67). Catheter-related thrombosis can be diminished by adding 6000 U of heparin per day in the PN solution (68). Since PN solutions are also good media for microorganisms, strict aseptic technique *must* be used, and line disruptions minimized. Restricting catheter use to alimentation decreases infectious complications (69). Prolonged PN generally requires multiple catheter replacements (with their attendant risk) or surgical placement of a more permanent catheter (usually Silastic) tunneled in the subcutaneous tissues into a central vein.

Special formulations are available for different clinical circumstances often associated with acute lung injury. As noted above, if ventilatory reserve is limited, the formula that

produces the least CO₂ during metabolism imposes the lowest demand on the ventilatory system and may facilitate weaning. Clearly, the net effects of multiple organ failure impose complex nutritional stresses (see [Chapter 96](#) and [Chapter 98](#)); other problems arise in managing renal failure (see [Chapter 89](#)) and liver failure (see [Chapter 94](#)).

Studies from several centers have shown altered lung function (decreased oxygen saturation and diffusing capacity of carbon dioxide) in both humans and animal models given lipid emulsions (70). These changes appear to be caused principally by an increase in ventilation/perfusion inequalities induced by lipid infusions (70), but their clinical relevance even in the severely compromised is unknown. The choice of lipid may affect which inflammatory eicosanoids are produced. Linoleic acid, an ω-6 essential fatty acid, is converted to arachidonic acid (AA), the precursor of many proinflammatory eicosanoids (both prostaglandins and leukotrienes) (71). On the other hand, linolenic acid, an ω-3 fatty acid, is converted into eicosapentanoic acid (EPA), which produces different eicosanoids with markedly different actions (71). The eicosanoids (prostaglandins and leukotrienes) produced from AA are thought to perpetuate the inflammation associated with acute lung injury much more than those derived from EPA do (see [Chapter 45](#).)

The quantity or composition of surfactant can be altered in acute lung injury. Some investigators have examined dietary fat supplementation as a way to enhance surfactant production. Baybutt et al. demonstrated that dietary supplementation with EPA, an ω-3 fatty acid, could increase the amount of whole-lung surfactant in a rat model but did not alter the amount of surfactant found in the alveolus (72). This study also demonstrated decreased AA content in the type II pneumocyte. Palombo et al. also demonstrated increased EPA in membrane phospholipids of lung tissue, alveolar macrophages, and surfactant after dietary supplementation with ω-3 fatty acids. (73). Although these data are intriguing, much still needs to be elucidated before a dietary fatty acid modification can be recommended to modulate inflammation in acute lung injury.

Chronic Lung Disease

Chronic lung disease is typically classified as either obstructive or restrictive, based upon the primary physiologic mechanism of ventilatory dysfunction. Obstructive pulmonary disease is a generic term encompassing asthma, emphysema, and chronic bronchitis. The hallmark of these diseases is airflow obstruction principally during expiration. Each of these diseases has unique characteristics, but there is overlap in the pathophysiologic and clinical manifestations. Asthma is defined as airflow obstruction that is at least partially reversible, which is caused by airway smooth muscle contraction, bronchial inflammation and edema, and bronchial gland hypertrophy with mucous plugging. Chronic bronchitis is a clinical syndrome manifested as cough, mucus hypersecretion, sputum production, and bronchial gland hypertrophy. Emphysema is a pathologic finding in which there is destruction of lung tissue, loss of the “tethering effect” (elastic recoil) of lung, and resultant dynamic collapse of unsupported airways. In most patients, emphysema and chronic bronchitis are caused by tobacco smoking and are collectively labeled chronic obstructive pulmonary disease (COPD). Obstructive lung

disease can result in hyperinflation and air trapping. Air trapping elevates the residual volume and causes flattening of the diaphragm (Fig. 90.1). The diaphragms are therefore placed at a mechanical disadvantage by being shortened in length prior to inspiratory contraction (the longer the precontractile fibers, the greater the tension that can be generated), and patients become limited during inspiration as well as expiration.

Restrictive lung diseases include infiltrative, fibrotic lung diseases and extrapulmonary conditions (e.g., musculoskeletal disease, obesity, neurologic disease) and are manifested by decreased total lung capacity, generally with preservation of expiratory flow rates. Restrictive lung disease causes decreased compliance of the lung, which increases the elastic load on the muscles and the work of breathing.

Most investigations of the interrelationships between nutrition and chronic pulmonary disease have focused on COPD, asthma, and cystic fibrosis. However, since most of these conditions also impose an inspiratory load on ventilatory mechanics, the management principles and interventions designed to improve respiratory muscle function in COPD are likely to prove helpful in these diseases as well. The other benefits of improved nutrition on lung function should also be advantageous in other specific lung diseases.

Role of Nutrition and Lifestyle in Development of Chronic Obstructive Pulmonary Disease

In 1984, COPD was the fifth leading cause of death in the United States (74). In the Tecumseh Community Health Study, the prevalence rate for obstructive airways disease, chronic bronchitis, or both was approximately 14% of adult men and 8% of the adult women (75).

Emphysema is thought to be due to an excess of proteases, causing destruction of the elastin and collagen matrix supporting the lung architecture. Tobacco smoking, overwhelmingly the most common cause of emphysema, causes an influx of neutrophils into the lung and a subsequent release of elastase and other proteases. Oxidants inhaled from tobacco smoke and released from activated inflammatory cells also play a role in the development of emphysema by impairing endogenous antiproteases.

There are several naturally occurring antioxidants (e.g., the enzymes superoxide dismutase and catalase and the peptide glutathione) present in lower respiratory tract to counteract inhaled oxidants. Ceruloplasmin, copper, methionine sulfoxide, retinols, and vitamins E and C may also protect against oxidant-induced destruction. The extent to which dietary supplementation with antioxidants might protect against environmentally encountered oxidants causing pulmonary disease is unknown. There are concerns about the use of the antioxidant *b*-carotene because of adverse findings. (See section on nutrition and lung cancers, below.) Interestingly, Massaro and Massaro reported reversal of elastase-induced emphysematous-like histologic changes in rats treated with all-*trans*-retinoic acid (75a).

Because only about 15 to 20% of cigarette smokers develop clinical evidence of COPD, several groups have evaluated the role diet may play in predisposing smokers to

developing this disease. Several investigators have demonstrated an inverse relationship between dietary antioxidant intake and level of pulmonary function ([76](#), [77](#), [78](#), [79](#) and [80](#)). It is, therefore, hypothesized that dietary antioxidants such as vitamin C and retinols may limit the destruction of lung tissue by proteases and protect against development of COPD. Recently, an analysis of a cohort of asbestos workers with a high rate of current or former cigarette smoking participating in the Carotene and Retinol Efficacy Trial (CARET), showed that b-carotene and retinol, based on serum levels, protect against the loss of ventilatory function in this group ([81](#)). These findings agreed with those from an earlier study ([80](#)) but differed from the baseline data in the Atherosclerosis Risk in Communities (ARIC) study ([82](#)).

Airway obstruction and wheezing have also been positively associated with dietary sodium:potassium ratios and negatively associated with serum niacin and zinc:copper ratios, independent of cigarette smoking ([79](#), [83](#), [84](#)). The clinical implications of these observations are not yet established.

Prostanoids from EPA have less inflammatory capabilities than those released from AA. The ARIC study investigators examined the relationships between dietary intake of w-3 fatty acids and development of COPD in 8960 current or former smokers and found a quantity-dependent inverse relationship between the two after controlling for confounding variables including tobacco use ([85](#)). Sharp et al. and Schwartz and Weiss demonstrated similar results in 6346 and 2526 subjects, respectively ([86](#), [87](#)). Prostanoids released from AA are also thought to contribute greatly to the pathophysiologic changes seen in asthma. Epidemiologic studies from the 1960s and 1970s demonstrated a low incidence of asthma in populations whose diets were rich in EPA ([88](#)). Various investigators have, therefore, hypothesized that dietary supplementation with EPA could potentially attenuate manifestations of asthma. Although in vitro changes in inflammatory cells were demonstrated after dietary supplementation, the effects upon clinical markers of disease varied ([89](#), [90](#)).

It has been hypothesized that vitamin C may be beneficial in treating atopic asthma, although the mechanism by which this may occur has not been fully elucidated. A metaanalysis of this subject by Bielory and Gandhi was inconclusive ([91](#)). Adding intravenous magnesium to inhaled b-agonist therapy during an acute asthma exacerbation improves pulmonary function acutely better than b-agonist therapy alone in children ([92](#)), but its efficacy in adults with asthma has not been clearly demonstrated ([93](#)).

Malnutrition in COPD. Nutritional depletion is exceedingly common in persons with COPD; various authors have shown an incidence of malnutrition from 20 to 60% ([94](#), [95](#), [96](#), [97](#), [98](#), [99](#), [100](#) and [101](#)). Furthermore, many series demonstrate that nutritional depletion is an indicator of poor prognosis in patients with COPD ([94](#), [102](#), [103](#), [104](#), [105](#) and [106](#)). A retrospective analysis of patients enrolled in the Intermittent Positive Pressure Breathing Trial found that individuals who were less than 90% of ideal body weight upon entry into the study had a greater overall 5-year mortality after normalization for the severity of their lung dysfunction ([94](#)) ([Fig. 90.5](#)). Low body mass index (BMI) has been identified as an independent predictor of mortality ([105](#), [106](#)), and BMI correlates with FEV₁, FEV₁:FVC ratio, and diffusion capacity ([100](#)). It is especially

important to recognize malnutrition as an independent risk factor because it may potentially be modified.

Figure 90.5. Survival curves for patients with COPD enrolled in the National Institutes of Health Intermittent Positive-Pressure Breathing Trial. **A.** Survival of patients with $FEV_1 > 47\%$ predicted by %IBW category; **B.** Survival of patients with $FEV_1 = 35\text{--}47\%$ predicted by %IBW category; **C.** Survival of patients with $FEV_1 < 35\%$ predicted by %IBW. (From Wilson DO, Rogers RM, Wright RC, et al. *Am Rev Respir Dis* 1989;139:1435–8.)

Mechanisms for this weight loss in patients with chronic lung disease have been summarized by Wilson et al. (34). Impaired gastrointestinal function, inadequate dietary intake (a potential adaptive mechanism to lower oxygen consumption to theoretically lower the work of breathing), altered pulmonary and cardiovascular hemodynamics limiting nutrient supply to other tissues, and a hypermetabolic state might all contribute to the malnutrition in these patients (34). Several investigators have shown that the measured REE in a large portion of stable patients with COPD, with and without weight loss, exceeds the REE calculated from the Harris-Benedict equation (95, 107, 108), although they do not seem to be hypercatabolic with preferential fat oxidation (107); some of these patients though may have been taking theophylline preparations that increase the REE in normal subjects (109). Donahoe et al. measured the oxygen cost of augmented ventilation with dead-space stimulation of ventilation in normal subjects and well-nourished and malnourished patients with COPD (108). Both groups of COPD patients had a higher oxygen cost of ventilation than the normal subjects, but the increase was greater in the malnourished group than in the well-nourished COPD patients (108). Patients with COPD had significantly increased energy expenditure for respiratory muscle activity (108). Although not quite analogous to ambulatory patients, Jounieaux and Mayeaux found a higher cost of breathing and lower somatic stores (arm muscle circumference and tricep skin fold) in emphysematous patients intubated for acute respiratory failure (110). Presumably, this elevation in energy requirements of the respiratory muscles for an increase in V_e can be extra-polated to the increases seen in

daily activities of normal life.

Higher energy consumption by the respiratory muscles to meet the demands of daily life could produce a hypermetabolic state (compared with normal subjects) and lead to progressive weight loss when output exceeded caloric intake. Wilson et al. concluded that increased daily energy expenditure led to weight loss in patients with chronic lung disease related to increased resistive load and decreased respiratory muscle efficiency (34). Most studies show that caloric intake is adequate or better than that predicted for REE or measured at rest (95, 97, 111, 112) in COPD patients. However, these studies do not satisfactorily address the caloric expenditure necessary for activity (95) or intercurrent illness and also tend to use nutritional inventory (i.e., patient recall) to assess caloric intake rather than direct measurement (111). Conversely, Schols et al. found that although COPD patients with and without weight loss had similar REEs, those with weight loss had an inadequate dietary intake in relation to their energy expenditure and failed to adapt to undernutrition (112a). Baaraends et al. noted that the total free-living energy expenditure as measured by doubly labeled water was significantly higher in eight patients with stable COPD admitted to a pulmonary rehabilitation center than in eight matched controls. The REEs in the two groups were not significantly different. This supports the belief that there is a higher metabolic demand for physical activity in COPD patients than in matched healthy subjects (112b).

Tumor necrosis factor- α , a cytokine that can induce cachexia in laboratory animals, is elevated in weight-losing patients with COPD without acute infections (113). Although no causal relationship has been demonstrated, it is hypothesized that this could contribute to malnutrition in these patients.

Nutritional Supplementation in COPD. Despite the theoretical and proven benefits of improved nutritional status, realizing these goals is challenging. Attempts to augment caloric intake over baseline may be difficult because of respiratory and gastrointestinal symptoms (e.g., anorexia, early satiety, dyspnea, fatigue, bloating, constipation, and dental problems) (114). Some of these symptoms (bloating, satiety, anorexia) may be related to flattening of the diaphragm with impingement on the abdominal cavity. In hypoxemic COPD patients, arterial oxygen desaturation during eating may increase baseline dyspnea, further limiting intake (115). This change has been related to altered ventilation-perfusion relationships caused by diminished lung volume accompanying abdominal distention and, less often, increased splanchnic blood flow. Smaller, more frequent meals may alleviate some of these problems.

Most studies addressing nutritional supplementation in COPD have used less than ideal body weight as an index of poor nutritional status and changes in respiratory muscle function as the outcome assessed. Other pulmonary function tests (spirometry, lung volumes) should not be expected to improve and do not; they are related to the underlying cause of airflow obstruction, which nutritional support would not be anticipated to change directly. There are inherent limitations in this approach. Less than ideal body weight is only one manifestation of malnourishment, but it is related to prognosis (94). Changes in respiratory muscle strength may not be a good surrogate marker for prognosis, may lack clinical or functional significance, and/or may not only

reflect nutritional deprivation or intervention.

The results of six efforts to improve the nutritional status of malnourished but clinically stable COPD patients are summarized in [Table 90.5](#). Four studies ([112](#), [116](#), [117](#) and [118](#)) noted significant weight gain that correlated with demonstrable improvement in respiratory muscle function. The other two studies showed an insignificant trend toward weight gain, but no improvement in respiratory muscle function, which might have been related to the shorter duration of nutritional supplementation ([119](#), [120](#)). The likelihood of improved respiratory muscle function may thus be linked to the amount of weight gain and, possibly, the severity of initial deficits. Further information is needed in this area.

Author (ref)	No. Fed	Study Type	RMS*	Weight Gain
Wilson et al. (112)	6	Inpatient 2 weeks	MIP improved Mean: 142%	Yes
Whittaker et al. (117)	6	Inpatient 2.3 weeks	MIP improved Mean: 119%	Yes
Lewis et al. (119)	10	Outpatient 8 weeks	MIP no change Mean: 89%	No
Knowles et al. (120)	25	Outpatient 8 weeks	MIP no change [†] Mean: 105-115%	No
Efthimiou et al. (116)	7	Outpatient 12 weeks	MIP improved Mean: 116%	Yes
Rogers et al. (118)	15	Inpatient 4 weeks	MIP improved Mean: 134%	Yes

*RMS, respiratory muscle strength; MIP, maximal inspiratory pressure; Mean, mean percentage of baseline after supplementation.

[†]No significant change in MIP between fed and control patients.

Table 90.5 Nutritional Intervention in Malnourished COPD Patients

Both Lewis et al. ([119](#)) and Knowles et al. ([120](#)) noted the difficulty these COPD patients experience in ingesting and maintaining sufficient caloric intake to gain weight. It has been hypothesized that diet-induced thermogenesis (DIT) and/or the increased energy expenditure required while eating may compromise the value of ingested nutrients and contribute to inadequate nutrition. In a cohort of 11 stable COPD patients with REEs 10% above those predicted, DIT did not differ significantly from that of controls ([121](#)). These investigators also found no significant difference in 24-h energy expenditure by 16 patients with stable COPD and 12 normal controls, despite an increased basal metabolic rate in those with COPD ([121](#)). However, COPD patients compensated for the increased basal metabolic rate by decreasing their spontaneous physical activity ([121](#)). Dore also found no difference in DIT between undernourished patients with COPD and normally nourished patients with COPD, although the REE was approximately 120% of the predicted BMR in both groups ([121a](#)). In contrast, Goldstein et al. demonstrated that malnourished COPD patients had a greater increase in resting oxygen consumption after a meal than malnourished patients without COPD ([122](#)).

Recently, investigators have supplemented the diets of patients during hospitalization for an acute exacerbation of COPD ([122a](#)). Supplemented patients were able to consume significantly more calories per kilogram than the control groups without

increased breathlessness. The FVC increased significantly more during treatment in the supplemented group than in the control group (122a). However, 6-min walking distance and overall feeling of well-being were the same, and both groups demonstrated negative nitrogen balance of similar magnitude, suggesting muscle wasting. All subjects, though, received systemic glucocorticoids, which may have contributed to the muscle wasting.

It is clear that low body weight is associated with a poorer prognosis in patients with COPD. It is much less clear that nutritional supplementation changes the outcome of these patients in a meaningful way. This is especially important in view of the difficulty in obtaining and maintaining weight gain and the cost of this intervention.

Roles of Hormone Administration. In a preliminary study, Suchner et al. found that administration of 60 µg/kg/day of growth hormone promoted positive nitrogen balance (123). Growth hormone supplementation has also been associated with weight gain and increased MIP (124). Rudman et al. gave biosynthetic growth hormone (30 µg/kg/day) to a group of healthy elderly males and noted a significant increase in lean body mass and a decrease in adipose tissue compared with a control group with similar caloric intake (25–30 kcal/kg) (125). Schols et al. compared the effects of nutritional supplementation, with or without anabolic steroids, with placebo in 217 patients with COPD enrolled in a rehabilitation program and found that nutritional support in combination with anabolic steroids increased fat-free body mass and MIP in subjects who were depleted at baseline (126). The use of trophic agents in malnourished patients is also discussed in [Chapter 96](#), [Chapter 98](#), [Chapter 101](#).

If body weight is an independent predictor of survival and nutritional support can improve and maintain body weight, one could hypothesize that optimizing nutritional support should improve survival. However, no long-term studies are available to substantiate that hypothesis.

Nutrient Composition and Administration. Since COPD patients have a limited ventilatory reserve, a high-carbohydrate diet that produces more CO₂ per mole of O₂ consumed for energy requirements might be expected to stress the respiratory system, whereas a high-fat diet would be expected to produce less CO₂ per mole of oxygen consumed and perhaps be beneficial. Angelillo et al. performed a randomized, double-blinded study of COPD patients with hypercarbia and found that a 5-day low-carbohydrate diet (28% carbohydrate calories, 55% fat calories) resulted in lower CO₂ production and arterial P_{aco}₂ than a 5-day high-carbohydrate diet (74% carbohydrate calories, 9.4% fat calories) (127). Kwan and Mir also noted that a low-carbohydrate diet benefited (reduced P_{aco}₂) COPD patients with hypercapnia (128). In addition, P_{ao}₂ and mouth pressure at 100 msec (a measure of respiratory center output) increased with carbohydrate restriction (128). A large carbohydrate load also reduced the 12-min walking distance in patients with COPD (129). Alternatively, Sue et al. found that altering dietary fat and carbohydrate proportions in normal subjects did not alter exercise gas exchange response or mean V_e during exercise (130).

Although the clinical significance is unclear, protein supplementation can increase

oxygen consumption (from its thermic effect) (52), increase V_e (52), and increase the ventilatory response to hypoxemia and hypercarbia (24) that may potentially result in dyspnea in respiratory limited patients.

Electrolyte deficiencies such as hypophosphatemia, hypokalemia, and hypocalcemia can also adversely affect respiratory muscle function (see Chapter 6, Chapter 8 and Chapter 9). Aubier et al. showed that phosphorus replacement improved diaphragmatic contractility in hypophosphatemic patients with acute respiratory failure (131). This observation is particularly relevant to patients with COPD who are placed on mechanical ventilation; intracellular shifts commonly occur in these individuals after correction of respiratory acidosis (132). Serum phosphorus levels may drop acutely in asthmatics after intensive bronchodilator therapy, which is probably related to intracellular shifts and parallels improvement in the arterial pH and $Paco_2$ (133, 134), but the clinical consequences of acute hypophosphatemia were not clear in these reports. Aubier et al. reported that lowering the serum calcium level acutely with a chelating agent (EDTA) can also reduce diaphragmatic maximal contraction (135). Restoring normal intracellular concentrations of these ions may account for acute improvements of respiratory muscle strength.

Cystic Fibrosis. Cystic fibrosis, physiologically resembles COPD, although a restrictive defect may also be present. In addition to lung involvement, the underlying defect in ion transport affects multiple organs. Pancreatic deficiency and resulting in malabsorption, glucose intolerance, intestinal obstruction, salt depletion, fatty liver, and gallbladder disease are common nonpulmonary complications of cystic fibrosis that increase the difficulty of maintaining an adequate nutritional status (see Chapter 69). Like patients with COPD, patients with cystic fibrosis have an REE about 20% higher than matched normals (136). However, as opposed to COPD, in which the oxygen cost of breathing is responsible for most, if not all, of the increase in baseline REE, only about 50% of the increase in REE is attributable to the oxygen cost of ventilation (136). Chronic infection and inflammation, increased sympathetic nervous activity, and (perhaps) increased energy expenditure at the cellular level as a consequence of the abnormal cystic fibrosis transmembrane conductance regulator (CFTR) may account for the other half of the increase in REE (136). Weight gain or loss correlates with the overall general health of the patient and is an important monitor and predictor of prognosis.

Although considerable advances have been made recently in delineating the genetic defect of cystic fibrosis, treatment is still largely supportive. A high-calorie, high-protein diet with supplemental pancreatic enzymes and multivitamin fortification is generally recommended to maintain weight. In a retrospective comparison between a traditional diet of low fat, high calorie, and an unrestricted diet of high fat and high energy with aggressive enzyme supplementation, there was improved survival from 21 years to 30 years in the latter group (137). Other studies have also shown that an aggressive approach to nutrition, even using enteral feedings, improves body weight and may even improve lung function (138). Caution is advised in providing dosages of pancreatic enzymes above 10,000 U/kg/day because of the reported association of higher dosages with fibrosing colonopathy in young patients (138a).

Role of Nutrition in Lung Cancer

Lung cancer is the leading cause of cancer deaths in both men and women. It is second in incidence only to prostate cancer in men and breast cancer in women. Over 80% of lung cancer cases can be attributed to tobacco abuse, principally cigarette smoking, with a direct relationship between the dose and duration of smoking and the incidence of this lethal disease. However, only approximately 10 to 20% of heavy smokers develop lung cancers. This has led to speculation that there may be a genetic predisposition to developing lung cancer and/or that other environmental factors may be involved. Studies with experimental cancers (both in vivo and in vitro) in animal models and case-control studies as well as cohort studies of dietary intake and serum levels have implicated dietary micronutrients (chemopreventive agents) in the development of malignancies (see [Chapter 81](#)).

Observations from epidemiologic studies have associated reduced intake and serum levels of carotenoids or retinoids with increased incidence of lung cancer and have led to several prospective studies. The first clinical randomized trial using retinoids in the prevention of secondary tumors in lung cancer patients began in 1985, at the National Cancer Institute in Milan ([139](#)). Patients with stage I (localized) disease were randomized to retinyl palmitate treatment (oral 300,000 IU daily for 12–24 months) or to a control group without treatment. There was significant improvement in the disease-free interval and the number of new malignancies related to tobacco use in the treatment group, but no improvement in overall survival. Subsequently, the Alpha-Tocopherol, Beta Carotene Cancer Prevention Group (ATBC), based in Finland, published results of a randomized, double-blind, placebo-controlled primary prevention trial consisting of 29,133 male smokers between the ages of 50 and 69 ([140](#)). Participants were randomized to one of four regimens: a-tocopherol (50 mg/day), b-carotene (20 mg/day), both a-tocopherol and b-carotene, or placebo. There was no significant reduction in the incidence of lung cancer among this group after 5 to 8 years of dietary supplementation with a-tocopherol or b-carotene. However, total mortality was 8% higher in participants who received b-carotene than in those who did not, primarily from increased mortality from lung cancer and ischemic heart disease. Two more-recent studies corroborate these findings. In a trial of b-carotene (30 mg) and vitamin A (25,000 IU) versus placebo in high-risk asbestos workers who were current or former smokers, the interventional group had a significantly higher relative risk (1.28) for lung cancer ([141](#)). A study of 22,000 male physicians taking b-carotene (50 mg) or placebo every other day for an average of 12 years found no difference in the rates of malignancy in general or in any specific type of malignancy ([142](#)). At this time, recommending dietary b-carotene supplementation for lung cancer chemoprevention does not appear warranted.

Other Clinical Considerations

In many commonly encountered clinical circumstances, compromised nutritional status may exacerbate or be worsened by respiratory illness. For example, protein malnutrition causing hypoalbuminemia alters the threshold for transudation of fluid into the lung and pleural space and results in pulmonary edema and pleural effusion formation. Both of

these can cause a restrictive ventilatory defect and increase the work of breathing.

Occasionally, a respiratory disease may impose particular nutritional demands. Patients who have a malignancy metastatic to the pleura may leak large amounts of protein into the pleural space. Repeated drainage of this fluid may lead to severe protein wasting. In patients who develop chylothorax, disruption of the thoracic duct (generally due to trauma, cancer, or surgical complication) may lead to massive loss of protein, fat, electrolytes, and lymphocytes in the pleural space. While it may be necessary to use parenteral alimentation to maintain nutrition, administration of oral medium-chain triglycerides has been effective because they are directly absorbed from the portal vein rather than transported through the thoracic duct ([143](#)).

The medications administered to patients with respiratory disease have their own implications for nutritional supplementation. Systemic corticosteroids, commonly used in the treatment of respiratory diseases, have many untoward effects including glucose intolerance, sodium retention, nitrogen loss, hyperphagia, and weight gain with resultant increased load imposed on respiratory muscles (see [Chapter 44](#), [Chapter 84](#), [Chapter 99](#)). Improper administration of inhaled corticosteroids may lead to oropharyngeal fungal overgrowth and local pain, resulting in reduced oral dietary intake. Theophylline, commonly administered to patients with obstructive lung disease, and a variety of antibiotics for superimposed infections (e.g., bronchitis, pneumonia) may induce nausea or diarrhea, with obvious implications for nutritional status. Patients receiving anticoagulants for deep vein thrombosis and pulmonary embolic disease require particular attention to factors interfering with vitamin K metabolism. Dietary suppressants including aminorex and fenfluramine (Redux) have been associated with development of primary pulmonary hypertension ([144](#)).

Although particular emphasis has been placed on the adverse effects of malnutrition and low body weight on respiratory function, obesity also has imposing and potentially lethal respiratory sequelae. A restrictive ventilatory defect may be caused not only by the direct effects of increased weight on the chest and elevation of the hemidiaphragm due to increased abdominal pressure but also by structural and functional impairments of the respiratory muscles. In extreme clinical manifestations of this problem, these mechanical changes interact with abnormalities of the respiratory center (decreased sensitivity to hypoxemia and hypercarbia) and culminate in the “obesity-hypoventilation syndrome.” Moreover, increased body weight is a major risk factor and clinical predictor for obstructive sleep apnea, a common and frequently unrecognized health hazard in the United States, associated with profound cardiovascular and functional sequelae. In patients with the spectrum of respiratory dysfunction related to obesity, weight loss is the primary measure for effectively improving the respiratory disease and its systemic consequences.

[Selected Readings](#)

Degenerative diseases of the retina represent a significant cause of visual loss to people from all over the world. For the most part, these conditions result in visual loss due to compromise of the rod and cone photoreceptor cells in the outer retina. The role of adequate nutrition (especially vitamins A and E) in maintaining normal photoreceptor cell function and viability is well known. It is now apparent that some patients with photoreceptor cell degeneration can benefit from nutritional intervention. This chapter focuses on diseases involving the photoreceptor cells that have yielded to treatment with nutritional supplementation and/or dietary modification.

RETINITIS PIGMENTOSA

Background

Night blindness was first recognized in Egypt more than 3400 years ago as described in a papyrus called *The Book of the Eyes* found during archeologic excavations in Thebes. The Egyptians recommended a nutritional treatment for night blindness, namely, eating liver, which is now recognized as a rich source of vitamin A. In 1851 the ophthalmoscope was invented, and it became possible to visualize the living retina and underlying retinal pigment epithelium for the first time. Ophthalmoscopic examination of

some night-blind individuals revealed a distinctive pattern of pigment around the peripheral retina, which led to the designation of their condition as retinitis pigmentosa (1).

Retinitis pigmentosa affects 50,000 to 100,000 people in the United States and an estimated 1.5 million people worldwide. Affected patients usually report impaired dark adaptation, night blindness, and loss of midperipheral visual field in adolescence. As the condition progresses, they lose far peripheral visual field and eventually lose central vision as well. Some patients become blind as early as age 30, and most are legally blind by age 60, with a central visual field diameter less than 20°. In addition to the characteristic intraretinal pigment seen around the midperiphery, findings on ophthalmoscopy include attenuation of the retinal vessels and, in some cases, waxy pallor of the optic discs. Histopathologic examination of autopsy eyes with advanced-stage disease show that loss of vision is due to degeneration of both rod and cone photoreceptor cells (2).

Retinitis pigmentosa can be detected in early life by electroretinographic testing. Electroretinograms (ERGs) are recorded in response to flashes of light with a contact lens electrode placed on the topically anesthetized cornea; responses are amplified and displayed on an oscilloscope. Patients with the early stages of retinitis pigmentosa have ERGs that are reduced in amplitude and delayed in their temporal aspects (Fig. 91.1). ERG amplitudes become smaller as the disease progresses; patients are usually legally blind when their cone ERG amplitudes fall below 0.05 microvolts (μV) (normal, 50–100 μV). Abnormal ERGs have been detected in asymptomatic children in some cases a decade before diagnostic changes are seen on a routine ophthalmoscopic examination. Individuals, age 6 and older, with normal ERGs and a family history of retinitis pigmentosa have not been observed to develop a widespread form of retinitis pigmentosa at a later time (2).

Figure 91.1. ERG responses for a normal subject and four patients (ages 13, 14, 14, and 9) with retinitis pigmentosa. Stimulus onset is *vertical hatched lines* for columns 1 and 2 and *vertical shock artifacts* for column 3. Rod b-wave implicit times in column 1 and cone implicit times in column 3 are designated with *arrows*. Calibration symbol (*lower right corner*) signifies 50 msec horizontally and 100 μV vertically for all tracings. Under these test conditions, normal amplitudes are $\approx 100 \mu\text{V}$ (*left column*), $\approx 350 \mu\text{V}$ (*middle column*), and $\approx 50 \mu\text{V}$ (*right column*). Normal rod implicit time is ≈ 108 msec

and normal cone implicit time is £32 msec. (From Berson EL. Invest Ophthalmol Vis Sci 1993;34:1659–76, with permission.)

Retinitis pigmentosa can be inherited by an autosomal dominant, autosomal recessive, X-linked, digenic, or mitochondrial mode (2, 3 and 4). Substantial genetic heterogeneity has been observed in this condition, with over 20 chromosomal loci mapped (5, 6). Mutations have been identified in eight genes (4, 7, 8, 9, 10, 11, 12, 13 and 14) and undoubtedly more abnormal genes will be discovered. Four of these genes encode proteins in the rod phototransduction cascade—rhodopsin, the a- and b-subunits of rod cGMP phosphodiesterase, and the rod cGMP cation-gated channel protein a-subunit. Two of these genes encode proteins involved in maintaining photoreceptor outer segment disc structure—peripherin/RDS and rod outer segment membrane protein 1 (ROM1). Mutations in the gene encoding myosin VIIa have been found in a form of autosomal recessive retinitis pigmentosa with associated profound congenital deafness (Usher syndrome, type I). Mutations have also been found in a GTPase regulator gene in a form of X-linked retinitis pigmentosa. Mutations in these eight genes account for about 20 to 25% of cases of retinitis pigmentosa in the United States. In the case of rhodopsin gene defects, patients with the same mutation display considerable variability in clinical expression at a given age, suggesting that some factor(s) other than the gene defect can affect the course of this condition (15, 16).

Treatment

While studying the course of the common forms of retinitis pigmentosa with the ERG from 1979 to 1983, it was observed that patients self-treating with a separate capsule of vitamin A or vitamin E appeared to be losing less ERG amplitude annually than those not taking these supplements. The relationship between vitamin A intake and ERG amplitude suggested that a total (i.e., diet plus supplement) intake of more than 15,000 IU of vitamin A or more than 200 IU of vitamin E or the combination was potentially therapeutic (17). These preliminary findings, as well as the known biologic roles of vitamin A and vitamin E in maintaining normal photoreceptor cell function and structure (18, 19, 20 and 21), prompted a randomized, controlled, double-masked trial with a 2 × 2 factorial design to determine whether vitamin A or vitamin E, alone or in combination, would halt or slow the progression of retinitis pigmentosa as monitored by the ERG. The main outcome variable was the 30-Hz cone-flicker ERG.

In broad outline, patients were evaluated twice over a 6-week interval prior to institution of vitamin supplementation. The screening visit was used to determine eligibility and the baseline visit to determine intervisit variability. The average of screening and baseline was used to provide pretreatment values. Patients were randomly assigned to one of four treatment groups: vitamin A, 15,000 IU/day, plus vitamin E, 3 IU/day (group A); vitamin A, 75 IU/day, plus vitamin E, 3 IU/day (group trace); vitamin A, 15,000 IU/day, plus vitamin E, 400 IU/day (group A+E); and vitamin A, 75 IU/day, plus vitamin E, 400 IU/day (group E). The procedure for randomization took into account the estimated dietary intake of vitamins A and E as well as the genetic type recorded at the screening

examination. ERGs were monitored annually. Visual field areas and visual acuities were also followed as additional measures of visual function.

Mean annual rates of decline of remaining ERG amplitude were slowest for the group taking 15,000 IU/day of vitamin A and fastest for the group taking 400 IU/day of vitamin E. These rates were observed among all randomized patients as well as among a subgroup of 354 patients with slightly higher initial ERG amplitudes who could be followed more reliably; this subgroup was designated the higher-amplitude cohort. Mean annual rates of decline of the remaining 30-Hz ERG amplitude among this cohort were as follows: group A, 8.3%; group trace, 10.0%; group A+E, 8.8%; and group E, 11.8%. Rates of decline for visual field area showed similar trends, although the differences were not statistically significant. No significant differences were observed among groups with respect to rates of decline of visual acuity. These results are summarized in [Table 91.1](#).

Test	All Randomized Patients				Higher-Amplitude Cohort			
	A	Trace	A+E	E	A	Trace	A+E	E
30 Hz ^a	6.1	7.1	6.3	7.9	8.3	10.0	8.8	11.8
0.5 Hz ^a	8.7	9.6	9.1	10.6	8.1	9.4	8.4	10.9
Field area ^a	5.6	5.9	6.2	6.3	6.3	7.2	7.3	7.8
Visual acuity ^b	1.1	0.9	0.7	0.9	0.8	0.8	0.7	0.7

Table 91.1 Mean Rates of Decline in Visual Function by Treatment Group

The mean declines in 30-Hz cone ERG from baseline for the higher-amplitude cohort by year are plotted in [Figure 91.2](#). The greatest separation among treatment groups occurred at years 5 and 6. Mean change analyses revealed that the two groups receiving 15,000 IU/day of vitamin A had, on average, significantly smaller declines from baseline than those not receiving this dose at years 1, 2, 5, and 6 ($P < .01$ in each of these years), while the two groups receiving vitamin E at 400 IU/day had, on average, significantly greater declines in retinal function than those not on this dose at years 1, 3, and 6 ($P < .03$ in each of these years).

Figure 91.2. Mean change from baseline over 6 years in 30-Hz ERG amplitude in the higher-amplitude cohort by treatment group (*top*), by vitamin A main effect (*center*); and by vitamin E main effect (*bottom*). Sample sizes for years 1 through 6 respectively were $n = 171, 167, 168, 164, 123,$ and 59 for patients receiving vitamin A, 15,000 IU/day, and $n = 178, 182, 172, 171, 125,$ and 64 for patients receiving vitamin A, 75 IU/day. Sample sizes for years 1 through 6 respectively were $n = 178, 177, 173, 168, 122,$ and 61 for the patients on vitamin E, 400 IU/day and $n = 171, 172, 167, 167, 126,$ and 62 for patients receiving vitamin E, 3 IU/day. (From Berson EL, Rosner B, Sandberg MA, et al. Arch Ophthalmol 1993;111:761–72, with permission of the American Medical Association, Chicago; copyright 1993, American Medical Association.)

The mean declines from baseline in 30-Hz cone ERG amplitude were related to the total vitamin A intake (i.e., diet plus supplement) irrespective of randomization assignment. The average decline in amplitude in the higher-amplitude cohort was greatest for those with a daily vitamin A intake below 2,428 IU, intermediate for those between 2,428 and 16,946, and least for those with an intake of 16,947 IU or more (Fig. 91.3); a significant difference was found among these subgroups. These data show that the optimal total intake of vitamin A was approximately 18,000 IU per day; that is, a supplement of 15,000 IU plus a regular diet of about 3,500 IU of vitamin A daily resulted in the smallest ERG decline. Intake above 18,380 IU provided no greater benefit. Doses of 25,000 IU or more over the long term are considered potentially toxic (22, 23 and 24).

Figure 91.3. Mean \pm SE decline from baseline in 30-Hz ERG amplitude by total vitamin A intake (diet plus capsules) irrespective of randomization assignment for all patients with retinitis pigmentosa in the higher-amplitude cohort. The mean decline was calculated as the mean of screening and baseline minus the mean of all follow-up visits by quintile of total vitamin A intake averaged over all visits. Sample sizes were 69, 72, 74, 65, and 74 for the lowest to highest quintiles of total vitamin A intake. *Vertical bars indicate SEs.* (From Berson EL, Rosner B, Sandberg MA, et al. Arch Ophthalmol 1993;111:761–72, with permission of the American Medical Association, Chicago; copyright 1993, American Medical Association.)

These data support the hypothesis that a 15,000-IU supplement of vitamin A taken daily will slow the progression of the common forms of retinitis pigmentosa as monitored by ERG testing. The findings also suggest that a 400-IU supplement of vitamin E taken daily may adversely affect the course of the common forms of this disease. With respect to rates of decline of remaining 30-Hz cone ERG amplitude, the beneficial effect of vitamin A was shown for all randomized patients at the $P = .01$ level and for the higher-amplitude cohort at the $P < .001$ level. The possible adverse effect of vitamin E was shown for the higher-amplitude cohort ($P = .04$) but not for all randomized patients (17).

Based on these ERG results, it is recommended that most adults with the common forms of retinitis pigmentosa take 15,000 IU of vitamin A daily under medical supervision and avoid high-dose supplements of vitamin E such as the 400 IU/day used in the trial. It is also recommended that patients continue on a regular diet without specifically selecting foods containing high levels of preformed vitamin A. As a precaution, patients should have a pretreatment assessment of fasting serum vitamin A and liver function and annual evaluations thereafter. Because of the potential for birth defects, women who are pregnant or planning to become pregnant should not take this dose of vitamin A. Since patients under age 18 were not included in this study, no formal recommendation can be made for such patients.

No toxic side effects attributable to this vitamin A supplement were observed over 4 to 6 years. Furthermore, no reported case of toxicity in adults in good general health on this dose has been reported. The palmitate form of vitamin A used in the trial is recommended for therapeutic use; other forms might be suitable, but some are probably not, for example β -carotene which is not predictably converted to vitamin A from one patient to another.

The precise mechanism by which vitamin A preserves retinal function in retinitis pigmentosa is not known. Vitamin A may provide some of its benefit through the rescue of remaining cones, thereby explaining how one supplement may help a group of patients with a variety of different rod-specific gene defects. Vitamin E may adversely affect this condition by reducing the amount of vitamin A reaching the eye; serum

vitamin A levels were observed to be significantly lower in patients on vitamin E ([17](#), [25](#)).

In this study, the rate of decline for the group taking 15,000 units of vitamin A daily was about 20% slower than the rate of decline for the trace group. Assuming that the rates of decline observed in this study are sustained over the long term, the estimated time to reach 0.05 μV (i.e., legal blindness) for an average patient with 1.3 μV who starts supplementation at age 32 would be age 70 for group A, 63 for group trace, 67 for group A+E, and 58 for group E. Thus, vitamin A supplementation would be expected to provide 7 additional years of useful vision for the average patient in this trial ([17](#)). A patient with twice the amplitude, or 2.6 μV , to 30-Hz white light who starts vitamin A at age 32 would reach 0.05 μV at age 78. Although not a cure, for some patients with retinitis pigmentosa and larger pretreatment ERGs, vitamin A supplementation may make the difference that allows them to retain some vision for their entire lives ([17](#), [26](#)).

BASSEN-KORNZWEIG SYNDROME

Background

In 1950, Bassen and Kornzweig described an 18-year-old girl, born of first cousins, who had a malabsorption syndrome, generalized retinal degeneration, a diffuse neuromuscular disease similar to Friedreich's ataxia, and a peculiar crenation of the red blood cells, now called acanthocytosis ([27](#), [28](#) and [29](#)). In 1958, low serum cholesterol was observed ([30](#)). Soon thereafter, an absence of low-density plasma lipoproteins or so-called b-lipoproteins was found, and the term *abetalipoproteinemia* was assigned to this recessively inherited disorder ([31](#), [32](#) and [33](#)) (see also [Chapter 70](#)). Other classes of lipoproteins have also been found to be abnormal ([34](#)).

Patients with the Bassen-Kornzweig syndrome can assimilate fat into the intestinal mucosa, but a defect exists in its removal from this site because of the lack of chylomicra. Intestinal biopsies have revealed normal-sized villi filled with lipid droplets that are essentially triglycerides. Mutations in the gene encoding a microsomal triglyceride-transfer protein have been found in patients with this condition ([35](#)). It appears that the liver and then the retina become depleted of vitamin A. Abnormal ERGs have been reported in a 15-month-old child ([36](#)) and a 6-year-old patient ([37](#)) in whom the fundi were still normal. The original patient described by Bassen and Kornzweig showed multiple white dots in the early stages, but by age 31, she developed multiple areas of pigment epithelial cell atrophy. In other patients, the typical intraretinal pigment associated with retinitis pigmentosa has been noted in the retinal periphery.

Treatment

Patients with this condition are treated with a low-fat diet and supplements of the fat-soluble vitamins A, E, and K. Vitamin A supplementation has been shown to restore elevated dark adaptation thresholds and reduced ERG responses to normal in two patients with the early stages ([Fig. 91.4](#)) ([38](#) and [39](#)). More-advanced patients have not responded, but in one instance, examination of the retina after the death of the patient revealed widespread loss of photoreceptor cells ([40](#)). Vitamin A therapy may not

maintain retinal function over the long term, as patients have been reported whose vitamin A levels were restored to normal without halting progression of retinal degeneration (41, 42). Since these patients have low serum vitamin E levels, supplementation with vitamin E in addition to vitamin A has been advocated with reported stabilization of retinal function (43, 44 and 45).

Figure 91.4. Full-field ERGs to a red (*top*) and a blue (*middle*) light, equal for rod vision, and a brighter white stimulus (*bottom*) from a patient with hereditary abetalipoproteinemia (dark adapted). Responses in the *left column* were obtained before vitamin A therapy, those in the *middle column* at 6 hours, and those on the *right*, 24 hours after vitamin A therapy. Two to three responses to the same stimulus are superimposed. *Arrows* indicate an exclusively cone response. The light stimulus begins with each trace. The calibration (*lower right*) signifies 0.06 mV vertically and 60 msec horizontally. (From Gouras P, Carr RE, Gunkel RD. Invest Ophthalmol Vis Sci 1971;10:784–93, with permission.)

Vitamin E supplementation has also been reported to be beneficial for patients with another rare recessively inherited form of ataxia associated with retinitis pigmentosa. These patients present with Friedreich-like ataxia, dysarthria, hyporeflexia, and decreased proprioceptive and vibratory sensation as well as markedly decreased serum vitamin E levels. They later can develop fundus changes of retinitis pigmentosa with abnormal ERGs. Molecular genetic analysis revealed a mutation in the α -tocopherol-transfer protein (α -TTP) gene (see also [Chapter 19](#)). Oral administration of vitamin E restored serum vitamin E levels to normal and appeared to halt or slow progression of the neurologic abnormalities and retinitis pigmentosa in three patients followed for 1, 4, and 10 years, respectively (46, 47).

REFSUM DISEASE

Background

Refsum disease is an inborn error of metabolism in which the patient accumulates

exogenous phytanic acid. Findings include a peripheral neuropathy, ataxia, an increase in cerebrospinal fluid protein with a normal cell count, and retinitis pigmentosa. Anosmia, neurogenic impairment of hearing, and cardiac abnormalities can be present. Additional signs include pupillary abnormalities, lens opacities, skeletal malformations, and skin changes sometimes resembling ichthyosis. The fundus can be granular around the periphery, with a subnormal ERG in early stages or show more typical retinitis pigmentosa, with a nondetectable ERG in more advanced stages.

In 1946, Refsum recognized the clinical association of seemingly unrelated findings (48). Klenk and Kahlke (49) demonstrated the biochemical abnormality in 1963, namely, storage in many tissues of 3,5,7,11-tetramethylhexadecanoic acid or phytanic acid. In 1966, affected patients were found to have a defect in the first step in phytanic acid oxidation—introduction of a hydroxyl group on the α -carbon of phytanic acid (Fig. 91.5) (50, 51). This loss of activity of phytanic acid α -hydroxylase has been detected in cultured skin fibroblasts of affected patients; carriers of this autosomal recessive disorder have a partial deficiency (52). The relationship between elevated serum phytanic acid and the manifestations of Refsum disease is still unclear. One proposal is that phytanic acid can replace long-chain fatty acids in phospholipids and triglycerides with consequent malfunction. Another hypothesis is that phytanic acid accumulates in the myelin lipid bilayer and disrupts the packing of myelin because of its branched methyl groups. In one autopsy specimen a large amount of fat-staining substance could be seen in the retinal pigment epithelium, which could presumably compromise the retinal pigment epithelial cells and eventually the photoreceptors (53).

Figure 91.5. Phytanic acid, its immediate precursors and metabolites and site of enzyme defect in Refsum disease (*Rd*). (From Eldjarn L, Stokke O, Try K. Biochemical aspects of Refsum's disease and principles for the dietary treatment. In: Vinken PJ, Bruyn GW, eds. Handbook of clinical neurology. Amsterdam: North-Holland, 1976;27: 528, with permission.)

Treatment

Phytanic acid is present primarily in dairy products, meat, and green leafy vegetables (54). Experiments in normal animals and man have shown that free phytol can be converted to phytanic acid in the body, but it is not clear whether the phytol bound to chlorophyll in green leafy vegetables is absorbed in the intestine. Therefore, until more is known, patients are advised to restrict not only milk products and animal fats (i.e., phytanic acid) but also green leafy vegetables containing phytol (55). Success in dietary treatment of Refsum disease depends on the patient receiving sufficient calories; if not, body weight becomes reduced and phytanic acid is released from tissue stores, resulting in increased serum phytanic acid levels that can exacerbate symptoms.

Refsum reported two patients whose serum phytanic acid levels were lowered to normal with subsequent improvement in motor nerve conduction velocity, some relief of ataxia, and return of the cerebrospinal fluid protein to normal (56). The retinitis pigmentosa and hearing impairment did not progress. One patient was followed for over 10 years and the other for many years. Other researchers have documented improvement in nerve conduction times and cerebrospinal fluid protein (57, 58 and 59) as well as the histologic appearance of peripheral nerve (60). The long-term effects of dietary modification on retinal function in Refsum disease continue to be studied. Plasma exchange complementing the dietary regimen has been reported to be helpful in the treatment of this disease (61, 62 and 63). Although the mechanism that links phytanic acid to the disease process remains to be defined, successful reversal of at least some of the abnormalities after dietary treatment supports the idea that the phytanic acid itself is responsible for some, if not all, of the clinical manifestations.

GYRATE ATROPHY OF THE CHOROID AND RETINA

Background

Gyrate atrophy of the choroid and retina is a chorioretinal degeneration with an autosomal recessive mode of inheritance (64, 65). Patients usually report night blindness and loss of peripheral vision between the ages of 10 and 20 years. Ocular findings include myopia, constricted visual fields, elevated dark adaptation thresholds, very small or nondetectable ERG responses, and chorioretinal atrophy distributed circumferentially around the peripheral fundus and sometimes near the optic disc. In addition to the ocular findings, abnormalities in electroencephalograms, muscle and hair morphology, and mitochondrial structure in the liver have been reported (66, 67, 68 and 69). Enlargement, coalescence, and posterior extension of areas of atrophy have been observed in young patients within 2 years (70). Patients develop cataracts and, if untreated, usually become virtually blind between the ages of 40 and 55 because of extensive chorioretinal atrophy (71).

Patients with gyrate atrophy have plasma ornithine concentrations 10 to 20 times normal (72, 73) due to a deficiency in ornithine-ketoacid-aminotransferase (OAT) activity (Fig. 91.6) (74, 75 and 76). Patients cannot convert ornithine to pyrroline-5-carboxylic acid (PCA), and this deficiency can be detected in extracts of cultured skin fibroblasts. Patients have virtually no OAT activity in contrast to normal subjects, while carrier parents have a partial deficiency. Cultured cells from some patients have shown

increased OAT activity when increasing concentrations of the cofactor for OAT, pyridoxal phosphate or vitamin B₆, are added to the media. Plasma lysine (77), glutamate, and glutamine (78), as well as serum and urine creatine (79) levels are reduced. More than 60 mutations have been discovered in the OAT gene on chromosome 10 in affected patients (80, 81 and 83).

Figure 91.6. Pathways of ornithine metabolism. (From Weleber RG, Kennaway GN, Buist NR. *Int Ophthalmol* 1981;4:23–32, with permission.)

Intravitreal injections of ornithine in the normal primate led to swelling and death of retinal pigment epithelial cells, with subsequent death of overlying photoreceptors (84). Moreover, the enzyme OAT is found in the normal pigment epithelium (85, 86), leading to the proposal that death of the pigment epithelial cells and then the photoreceptor cells results from elevated levels of ornithine combined with absence of OAT activity. Since arginine is a precursor of ornithine and since arginine (but not ornithine) is a constituent of food protein, it has been suggested that dietary restriction of protein and arginine would reduce plasma ornithine levels in these patients (87). OAT-deficient mice produced by gene targeting develop a retinal degeneration over several months that is amenable to treatment postweaning with an arginine-restricted diet (88, 89).

Treatment

The hyperornithinemia associated with gyrate atrophy has been lowered toward normal with low-protein, low-arginine diets in all patients so far studied (87, 90, 92 and 93) and with vitamin B₆ (300–500 mg/day) in some cases (70, 94, 95). However, extreme protein restriction (10–15 g/day) with substantial lowering of plasma ornithine, accomplished under supervision in the hospital, has been difficult to achieve at home; thus many patients have followed modified (20–35 g/day) protein restriction with slight rises in their plasma ornithine levels. Some investigators have reported improvements in visual acuity, visual fields, dark adaptation thresholds, and/or ERGs in patients with gyrate atrophy after initiating either the diet or vitamin B₆ (91, 93, 96 and 98); others have not

documented any significant improvement in visual function despite substantial reductions in plasma ornithine concentrations (92, 99). Improvement in muscle morphology following creatine supplementation was reported in several patients (100).

Kaiser-Kupfer and coworkers (101) reported results of severe arginine restriction of two pairs of siblings under 10 years of age who were followed for 5 to 7 years. Plasma ornithine levels were reduced to approximately the normal range (106 and 121 $\mu\text{mol/L}$) in one pair of siblings and reached twice the upper limit of normal (251 and 313 $\mu\text{mol/L}$) in the other pair. These younger siblings had significantly less atrophy than their elder siblings when they reached or approached the age at which their elders began the diet. Thus, there is evidence that a low-protein, low-arginine diet can slow progression of the chorioretinal degeneration, but only a small number of patients have been studied.

The goal of treatment is to maintain serum ornithine levels as close to normal as possible. Since some patients may respond to supplementation with pyridoxine (vitamin B₆), all patients are initially given a trial of this vitamin to determine to what extent, if any, it will lower plasma ornithine levels. Both pyridoxine-responsive and nonresponsive patients are then placed on a low-protein, low-arginine diet. Biochemical control is classified as good to excellent ($\leq 200 \mu\text{mol/L}$), fair (200–400 $\mu\text{mol/L}$), and poor ($>400 \mu\text{mol/L}$). In the management of children, expertise is required to be certain that growth and development remain normal while ornithine levels are lowered with a low-protein diet. An arginine-free essential amino acid mixture (e.g., Cyclinex-1 or -2 [Ross Laboratories], depending on the patient's age) is used to provide sufficient nitrogen and meet essential amino acid requirements. In adults, a low-protein diet is also likely to result in amino acid deficiency. Thus, adults should also be placed on an arginine-free essential amino acid mixture. Lysine supplementation may be necessary, depending on plasma levels. As a precaution, all patients are placed on a multivitamin preparation with minerals. In addition to a regular ocular examination, all patients on this treatment regimen should have their amino acid and protein levels monitored periodically (102).

SORSBY FUNDUS DYSTROPHY

Background

Sorsby fundus dystrophy is a rare autosomal dominant retinal degeneration in which patients report night blindness in young adulthood and then experience progressive loss of central vision in association with subretinal neovascularization and hemorrhage; in later stages, patients lose peripheral vision as well (103, 104, 105 and 106). The condition is caused by mutations in the tissue inhibitor of metalloproteinase-3 (TIMP3) gene on chromosome 22 (107). The exact pathogenesis of this condition remains to be defined, but it has been speculated that mutations lead to an abnormal lipid-containing deposit interposed between the photoreceptors and their blood supply in the choroid. This subretinal deposit, located within Bruch's membrane and present beneath the entire retina, appears to create a barrier to diffusion of nutrients to the photoreceptors.

Treatment

In a family with Sorsby fundus dystrophy, orally administered vitamin A in a dose of 50,000 IU/day reversed nightblindness within 1 week in early stages of the disease. Recovery of rod sensitivity in the macula followed recovery of rod sensitivity in the retinal periphery by several days, but once achieved, could not be maintained on a dose of 5,000 IU/day. Cone sensitivity in the central macula remained normal during the period of the study, while rod function varied ([108](#)).

The mechanism leading to a local deficiency of vitamin A in the retina in Sorsby fundus dystrophy is unknown. It has been suggested that the disturbance in the extracellular matrix caused by TIMP3 mutations may over decades impair storage of vitamin A in the retinal pigment epithelium and/or its transport to the photoreceptors. Photoreceptors deprived of vitamin A lose sensitivity to light and cannot regenerate functional visual pigment (i.e., opsin plus vitamin A) at a normal rate after exposure to light, resulting in slowed dark adaptation ([108](#)). Although supplementation with vitamin A has had short-term benefit for some patients with early stages of this condition, it remains to be determined whether vitamin A supplementation in doses considered safe for chronic administration (i.e., <25,000 IU/day) can be used to modify the course of this disease over the long term.

AGE-RELATED MACULAR DEGENERATION

Background

Age-related macular degeneration (AMD) is the leading cause of irreversible blindness in the United States among persons over age 50 ([109](#), [110](#)). The condition affects 1.7 million people in the United States and many millions worldwide ([109](#)). Patients develop moderate- to large-sized drusen (yellowish white spots) and a disturbance of the retinal pigment epithelium (RPE). Visual loss is related to atrophy of the RPE (dry form) or to a choroidal neovascular membrane (CNVM) that leads to hemorrhage, exudation, elevation of the macular retina, and scarring (wet form). There is no proven way to halt or slow progression in eyes with the dry form; and, despite the availability of laser photocoagulation, more than half of the eyes with a CNVM decline to a visual acuity below 20/200. Most patients who are legally blind as a result of AMD have the neovascular form of the disease ([111](#)).

Treatment

A high dietary intake of carotenoids has been associated with a lower risk for developing neovascular AMD. Those in the highest quintile of carotenoid intake had a 43% lower risk for developing an advanced stage of AMD than those in the lowest quintile. Lutein and zeaxanthin, primarily obtained from dark green leafy vegetables, were the carotenoids most strongly associated with a reduced risk for AMD. Several foods with a high content of carotenoids were inversely associated with AMD. Specifically, higher frequency intake of spinach or collard greens was associated with a substantially lower risk for AMD (P for trend <.001). Intake of preformed vitamin A (retinol) was not appreciably related to AMD. Moreover, neither vitamin E nor total vitamin C intake was

associated with a statistically significant reduced risk for AMD. Based on these results, Seddon et al. have recommended that patients with AMD increase their consumption of vegetables, particularly, dark green leafy vegetables rich in lutein and zeaxanthin (112). VandenLangenberg et al. reported that higher intake of fruits and vegetables and certain carotenoids may be associated with decreased risk of developing the early fundus changes of AMD (113). Sanders et al. found no consistent differences in plasma concentrations of vitamin E, retinol, or carotenoids or in the erythrocyte phospholipid composition in patients with AMD compared with concentrations in a control population matched with respect to age and sex (114). These observational studies are helpful in generating hypotheses but should not be interpreted as conclusive for showing cause and effect.

Some preliminary evidence suggests that supplementation with zinc may slow the course of AMD (115). It has also been hypothesized that antioxidants—b-carotene, vitamin C, and vitamin E—might have a protective effect on the membranes of photoreceptors that are rich in polyunsaturated fatty acids (116, 117 and 118). A randomized, controlled trial is in progress to determine whether b-carotene, vitamin C, and vitamin E as well as trace minerals (particularly zinc) will modify the course of this condition.

SUMMARY

Considerable progress has been made in the understanding and management of degenerative diseases of the retina involving photoreceptors. Nutritional approaches to treatment have proved successful in the case of the common forms of retinitis pigmentosa (supplementation with vitamin A), Bassen-Kornzweig disease (supplementation with vitamins A, E, and K), gyrate atrophy (low-protein, low-arginine diet and/or supplementation with vitamin B₆), and Refsum disease (low-phytol, low-phytanic acid diet). The night blindness associated with Sorsby fundus dystrophy can be reversed over the short term with vitamin A. A significant trend for decreased risk for advanced or exudative age-related macular degeneration has been reported among those whose diets contain a higher content of carotenoids, such as spinach and collard greens. A randomized trial is in progress to determine if b-carotene, vitamin C, and vitamin E as well as trace minerals, particularly zinc, will modify the course of age-related macular degeneration.

The difficulties that patients with retinal degenerations face as a result of their diminishing vision, sometimes over decades, cannot be underestimated. Nutritional therapy has proved effective in modifying the course of a number of these conditions; the therapeutic benefit of nutritional modification in diseases that have a genetic basis is of particular interest. Further research is warranted to determine the mechanisms by which these treatments provide their benefit, as well as to identify other conditions that may yield to nutritional intervention. Risk-factor analyses of well-defined populations followed over time with food-frequency questionnaires in conjunction with careful assessments of visual function may reveal other dietary constituents that can modify the course of degenerative diseases of the retina.

BACKGROUND AND DEFINITIONS

Hippocrates was among the first to record an adverse reaction to food over 2000 years ago. However, not until the turn of the century did scattered reports of food allergic reactions appear in the medical literature. Most accounts of food allergic reactions were based simply on histories provided by the patient, until 1950, when Loveless reported the first blinded, placebo-controlled food challenges; one study involving 8 patients for milk allergy (1) and one involving 25 patients for cornstarch sensitivity (2). Subsequently, Goldman et al. published a series of articles describing their studies in 89 children suspected of milk allergy (3, 4). The diagnosis of food allergy was considered established only when the patient had resolution of symptoms after withdrawal of milk from the diet and duplication of presenting symptoms on three successive challenges with milk. Although the “Goldman criteria” firmly established the diagnosis of food allergy, most investigators were reluctant to subject highly allergic patients to three challenges. In 1976, May introduced the use of double-blind, placebo-controlled oral food challenges (DBPCFC) to diagnose food allergy, ushering in the recent era of scientific investigation into food allergic disorders (5).

To facilitate investigation of adverse food reactions, the European Academy of Allergy and Clinical Immunology recently adopted standardized definitions for food reactions based solely on mechanism (6). An *adverse food reaction* is defined as any aberrant reaction following the ingestion of a food or food additive. Adverse food reactions are divided into *toxic* and *nontoxic* food reactions. Toxic reactions occur in anyone, provided a sufficient dose is ingested. Nontoxic reactions depend on individual susceptibility and may be the result of immune mechanisms (*allergy or hypersensitivity*) or nonimmune mechanisms (*intolerances*). Type I, IgE-mediated food allergies have been most clearly delineated, but non-IgE-mediated immune reactions are clearly responsible for a variety

of food allergic disorders, especially in the gastrointestinal tract. Food intolerances may be due to *pharmacologic* properties of the food (e.g., tyramine in aged cheeses, theobromine in chocolate), traits of the host such as *metabolic* disorders (e.g., lactase deficiency), or *idiosyncratic* responses. *Psychogenic* reactions can be reproduced only when patients are aware that they are ingesting a specific food.

PREVALENCE

The public “perceives” adverse reactions to foods and food additives as a common health problem. An American survey found that at least one family member was believed to have a food allergy in one-third of households (7). Similarly, approximately 20% of 7500 households surveyed in the United Kingdom reported a food intolerance (8). However, using DBPCFC to confirm patients' reports, the British study found the overall prevalence of adverse food reactions in adults to be 1.4 to 1.8%, while a comparable study in the Netherlands concluded that about 2% of the adult Dutch population is affected by adverse food reactions (9). A second large population survey in the United Kingdom evaluated the prevalence of adverse reactions to food additives in adults and following appropriate challenges, found a prevalence between 0.01 and 0.23% (10).

Adverse reactions to foods are more common in young children, which in part may relate to the feeding practices of the population evaluated. In a prospective study of 480 newborns followed in an American general pediatric practice for 3 years, parents reported adverse food reactions in 28% of the infants, but reactions were confirmed by oral challenge in only about one-third of suspected cases, or 8% of the total group (11). Reactions to fruits and fruit juices were analyzed separately. Overall, 56 (12%) infants experienced 60 positive challenges consisting of rashes and/or diarrhea following the ingestion of orange juice (14 children [3%]), tomato juice (14 children [3%]), apple juice (7 children [2.5%]), grape juice (4 children [1%]), and other fruit juices (21 children [4%]). Cow milk allergy has been studied extensively in young infants. Large prospective studies with appropriately performed milk challenges from four different countries revealed that 2.2 to 2.8% of infants experience cow milk allergy in the first 1 to 2 years of life (11, 12, 13 and 14). However, cow milk allergy is generally short-lived, with nearly 85% of sensitive infants losing their reactivity by 3 years of age (15). Adverse reactions to food additives also may be more common in children. In a study of 4274 Dutch school children, results of DBPCFC suggested a prevalence of about 1% (16).

Atopic individuals (i.e., atopic dermatitis [eczema], allergic rhinitis [hay fever], and/or asthma) appear to have a higher prevalence of food allergy. In children with moderate-to-severe atopic dermatitis, about one-third have skin symptoms provoked by food hypersensitivity (17). The more severe the atopic eczema in young children, the more likely they are to have food allergy (18). Studies of asthmatic children attending general pulmonary clinics indicated that 6 to 8% of children have food-induced wheezing (19, 20). Interestingly, infants with evidence of IgE antibodies to egg protein have a markedly higher risk of developing asthma than infants with no evidence of IgE sensitization (21, 22). Infants with non-IgE-mediated gastrointestinal allergy are not at

increased risk for atopic disease.

PATHOPHYSIOLOGY

Foods and beverages ingested in everyday life constitute the largest exogenous antigenic load to which human beings are subjected, estimated by some to be in excess of several tons over a lifetime. The gastrointestinal tract uses a variety of immunologic and nonimmunologic mechanisms to prevent foreign proteins from entering the body. Nonimmunologic barriers include gastric acid secretion, proteolysis by various intestinal and pancreatic enzymes, peristalsis, the mucous coat, and the microvillous membrane. The gut enterocyte selectively absorbs small peptides and amino acids, and lysosomal activity further breaks down small peptides into nonantigenic fragments. The main immunologic barrier to foreign proteins is the secretion of secretory-IgA molecules into the gut lumen, which complex with foreign proteins and block their absorption. In addition, immune complexes promote both mucus release from goblet cells and mucosal surface proteolysis. Serum IgG and IgA antibodies may bind foreign proteins that gain access to the circulation, which leads to their clearing by the reticuloendothelial system (23).

Despite the intricate barrier network evolved to prevent the entry of foreign protein into the body, Walzer and colleagues established unequivocally that food proteins readily gain access to the circulation and are transported to distal target organs. In a series of experiments using Prausnitz-Kustner (P-K) tests with serum from highly food allergic individuals, Walzer demonstrated that food antigens gain access to the body at all levels of the gastrointestinal tract (24). In addition, other investigators have presented evidence to suggest that antigen permeability is increased after gastroenteritis and in young infants. The increased susceptibility of young infants to develop hypersensitivity reactions appears to result from immature “gut-associated lymphoid tissue,” which is less proficient at developing normal oral tolerance, and immature, submaximal nonimmunologic mechanisms that allow increased antigenic penetration.

Food allergy results from an abnormal interaction between food allergens and the immune system and/or the gastrointestinal tract. The glycoprotein fractions of foods are implicated in allergic responses. The predominant allergenic glycoproteins are water soluble, largely heat resistant, acid stable, and commonly in the range of 10 to 60 kDa. Relatively few foods cause most allergic reactions: milk, eggs, peanuts, soy, and wheat in children and fish, shellfish, peanuts, and tree nuts in adults.

Normal individuals generate IgA, IgM, and IgG antibodies to the minute quantities of food antigens that pass the intestinal barrier or are selectively absorbed by M cells that overlie intestinal Peyer's patches and present antigens to resident lymphocytes. After a meal, circulating food antigen-antibody complexes often are found in normal individuals (25). In subjects developing food allergic reactions, food antigen-specific IgE antibodies and/or abnormal T cell responses develop.

IgE-Mediated Reactions

Food allergic reactions involving IgE antibodies are the best characterized. IgE antibodies bind to high-affinity Fc_E receptors on mast cells and basophils. Perivascular mast cells are prominent in all surfaces that confront the environment, such as the skin, respiratory tract, and gastrointestinal tract. When allergens react with IgE antibodies bound to mast cells, mediators such as histamine, prostaglandins, and leukotrienes are released. These mediators cause vasodilatation, smooth muscle contraction, and secretion of mucus, resulting in symptoms of immediate hypersensitivity. The activated mast cells also release a variety of cytokines, including interleukins (e.g., IL-4, IL-5, IL-6, and TNF_α), platelet-activating factor, and other mediators that promote the IgE-mediated late-phase response. Eosinophils and, to a lesser extent, basophils, lymphocytes, and monocytes infiltrate the area during the first 6 to 8 hours. These cells are activated and release a variety of mediators including platelet-activating factor, peroxidases, eosinophil major basic protein, eosinophil cationic protein, and cytokines. These mediators attract lymphocytes and monocytes in the subsequent 24 to 48 hours, which perpetuate the chronic inflammation. With repeated ingestion of a food allergen, mononuclear cells are stimulated to secrete “histamine-releasing factor” (HRF), a cytokine that interacts with IgE molecules bound to the surface of mast cells and basophils and increases their releasability (26). HRF production has been associated with bronchial hyperreactivity in patients with asthma (27) and cutaneous irritability in children with atopic dermatitis (28). IgE-mediated allergic reactions may provoke urticaria/angioedema, eczematous rashes, rhinoconjunctivitis, asthma, vomiting, and diarrhea.

Non-IgE-Mediated Reactions

Non-IgE-mediated reactions may consist of antibody-mediated (type II) hypersensitivity, immune complex reactions (type III), or cell-mediated (type IV) hypersensitivity, although few data are available to establish any of these mechanisms in food hypersensitivity disorders. In contrast to the IgE-mediated reactions, the non-IgE reactions may involve IgA, IgM, and IgG antibodies. The complexes formed by the interaction of non-IgE antibodies with antigen may or may not result in adverse reactions, but to date, support is minimal for type III, food antigen–immune complex–mediated disease (25). Studies in animal models reveal that cell-mediated (type IV) reactions can cause intestinal damage, including villus atrophy. Abnormal cell-mediated immune responses are responsible for some of the allergic gastrointestinal syndromes in humans, but data to delineate the exact mechanisms in man are absent. In both food allergic and nonallergic individuals, stimulation of peripheral blood lymphocytes with food antigens in vitro may result in cell proliferation, interleukin 2 (IL-2) production, and/or leukocyte inhibitory factor (LIF) production.

CLINICAL SIGNS AND SYMPTOMS

Symptoms attributed to food allergy are legion. However, relatively few specific symptoms have been documented as related to food hypersensitivity reactions. The most clearly delineated are the result of IgE-mediated reactions, but most reactions are

probably the result of non-IgE-mediated mechanisms ([Table 92.1](#)).

IgE-mediated
Skin
Urticaria/angioedema*

Gastroesophageal reflux
Inflamed colic tract
Other
Neutrophilic leukocytosis
Iron deficiency anemia associated with gastrointestinal blood loss
Autoimmune thyroid disease

*Symptoms also may be provoked by ingesting specific foods in combination with exercising but not by ingestion of the food alone or exercise alone.

Table 92.1 Food Allergy Reactions Substantiated by Blinded Challenges and Appropriate Laboratory Studies

IgE-Mediated Reactions

IgE-mediated reactions typically develop within minutes to hours of the ingestion of a food allergen. However, frequent ingestion of a food allergen can lead to a “blunting” of immediate symptoms, and the chronic inflammatory reaction initiated by the immediate symptoms may last for several days. Skin symptoms are thought to be one of the most common manifestations of food allergic reactions. Acute urticaria/angioedema following ingestion or contact with a food is relatively common, although the actual prevalence is unknown. Most individuals with this disorder are aware of the association between ingestion of a specific food and development of symptoms and therefore simply avoid the food. Chronic urticaria/angioedema related to food allergy is rare ([29](#), [30](#)). The development of atopic dermatitis has been associated with food allergy in children. During blinded food challenges, a pruritic, erythematous morbilliform rash develops within 10 to 90 minutes of allergen ingestion ([31](#)). Repeated ingestion of the offending allergen leads to activation of cutaneous mast cells and infiltration of lymphocytes, both of which result in pruritus, consequent scratching, and development of eczematous lesions ([32](#)).

Both upper and lower respiratory symptoms have been demonstrated as a result of food allergy by DBPCFC ([33](#), [34](#)). Recently it was established that ingestion of food by food allergic patients with asthma could provoke increased airway hyperreactivity (asthma) ([35](#)), and two studies evaluating children attending pulmonary clinics demonstrated food-induced wheezing in 6 to 8% of unselected asthmatic patients ([19](#), [20](#)).

Symptoms involving the oropharynx and gastrointestinal tract may occur within minutes of ingesting a food allergen. Pruritus and swelling of the lips, tongue, and soft palate, as well as nausea, abdominal pain, vomiting, and diarrhea have all been demonstrated

secondary to food allergy. The oral allergy syndrome consists of symptoms confined exclusively to the oropharynx and is most commonly reported in patients with seasonal allergic rhinitis following ingestion of one of a variety of fresh fruits and vegetables (36, 37). For example, patients with respiratory allergy to birch pollen may develop oral symptoms after ingestion of potatoes, carrots, celery, hazelnuts, and apples, whereas patients allergic to ragweed may develop oral symptoms after eating melons and bananas. Gastrointestinal anaphylaxis frequently accompanies symptoms in the skin or respiratory tract and presents as nausea, abdominal cramping, vomiting, and diarrhea. Repeated ingestion of food allergens in young children may induce partial “desensitization,” resulting in less obvious symptoms, e.g., gastroesophageal reflux instead of projectile vomiting (38). A minority of patients with allergic eosinophilic gastroenteritis (discussed below) (39) and infantile colic (40) (inconsolable “agonized” crying, drawing up of the legs, abdominal distention, and excessive gas associated with feeding during the first several months of life) have symptoms attributed to IgE-mediated food hypersensitivity.

Food-induced systemic anaphylaxis was reported to be the leading cause of anaphylaxis seen in the Mayo Clinic Emergency Department (41). In two reports of fatal anaphylactic reactions (42, 43), the authors noted that all subjects had asthma, had unknowingly ingested the responsible food allergen, and had tended to minimize the symptoms initially and that initiation of emergency medical management was delayed. Anaphylactic shock in association with exercise 2 to 4 hours after ingestion of certain foods is being recognized increasingly, especially in young women (44, 45).

Non-IgE-Mediated Reactions

Non-IgE-mediated allergic reactions are believed to take several hours to days to develop, and a variety of disorders have been delineated. Although specific cell-mediated mechanisms often are implied, insufficient information is available to determine the exact immunopathogenic process involved.

A variety of gastrointestinal disorders believed to have an immunologic basis have been described. Food-induced enterocolitis syndrome is seen most frequently in young infants ingesting cow's milk- or soy-based formulas. It generally presents between 1 week and 3 months of age, with protracted diarrhea and projectile vomiting, often severe enough to produce dehydration (46), and about one-third of infants develop acidosis and transient methemoglobinemia (47). Stools generally contain occult blood, polymorphonuclear neutrophils (PMN), and eosinophils and are generally positive for carbohydrate (reducing substances) (48). The syndrome is also seen in exclusively breast-fed infants (secondary to the passage of food proteins in maternal milk) and occasionally in older children, associated with ingestion of egg, wheat, rice, peanut, nuts, chicken, turkey, and shellfish.

Benign eosinophilic proctocolitis also presents in the first few weeks to months of life and is often secondary to cow's milk or soy, although about half the infants are being exclusively breast fed (49, 50). Patients appear clinically well and present only with bloody stools (gross or occult) or hematochezia. Lesions are confined to the distal bowel and vary from mucosal edema to ulceration and linear erosions. Both enterocolitis and

proctocolitis show dramatic clinical resolution within 72 hours of allergen elimination.

Food protein-induced enteropathy includes a spectrum of malabsorption disorders that generally present with protracted diarrhea, vomiting in up to two-thirds of patients, failure to thrive, and carbohydrate malabsorption. Increased fecal fat and abnormal *D*-xylose absorption generally are present. Cow's milk sensitivity is the most frequent cause of this syndrome, but it also has been associated with soy, egg, wheat, rice, chicken, and fish hypersensitivity. Patchy villous atrophy with cellular infiltrate on biopsy is characteristic of this disorder (51, 52). A more extensive enteropathy with total villous atrophy and extensive cellular infiltrate is associated with sensitivity to gliadin, a component of gluten (celiac disease). These patients often present with diarrhea or frank steatorrhea, abdominal distention and flatulence, weight loss, and occasionally nausea and vomiting (see Chapter 69 and Chapter 71). Dermatitis herpetiformis is a highly pruritic rash (sometimes mistaken for atopic dermatitis) associated with gluten-sensitive enteropathy (53). Biopsy of the rash reveals an infiltration of PMN and deposits of IgA at the dermal-epidermal junction. Administration of dapsone or other sulfones often relieves the skin itching within 24 hours. Like celiac disease, elimination of all gluten for 3 to 4 months may be required to normalize intestinal biopsy findings.

Allergic eosinophilic gastroenteritis (AEG) often presents as postprandial nausea with vomiting, abdominal pain, diarrhea, occasionally steatorrhea, and weight loss in the adult or failure to thrive in the infant (54). In the mucosal form, patients often have atopic disease, elevated serum IgE levels, positive immediate skin tests to a variety of foods and aeroallergens, peripheral eosinophilia, iron deficiency anemia, and hypoalbuminemia. Protein-losing enteropathy or pyloric obstruction may be the main feature in some infants with AEG (55, 56). A recent study of 10 patients with AEG and severe gastroesophageal reflux (GER) found that non-IgE-mediated food allergy may be a much more common cause of AEG than previously appreciated (57). Food hypersensitivity is a frequent cause of gastroesophageal reflux in young infants. Milk allergy was shown to be the cause of GER in 85 of 204 (42%) of infants less than 1 year of age (38). Removal of the suspect allergen for up to 12 weeks may be required to resolve symptoms and intestinal histologic changes.

Few non-IgE-mediated respiratory syndromes have been identified. Heiner's syndrome (a form of pulmonary hemosiderosis) is a chronic or recurrent pulmonary disease characterized by chronic rhinitis, pulmonary infiltrates and hemosiderosis, gastrointestinal blood loss, iron deficiency anemia, and failure to thrive. It is associated most often with a hypersensitivity to cow's milk, but reactivity to egg and pork have also been reported (58). Although peripheral blood eosinophilia and multiple serum precipitins to cow's milk are relatively constant features, the immunologic mechanisms responsible for this disorder are not known. Avoidance of the precipitating allergen leads to resolution of symptoms.

Given the presence of food antigen-immune complexes in many individuals after meals, several claims have been made for the use of fasting or hypoallergenic diets in the treatment of rheumatoid arthritis. However, only two patients have had exacerbation of arthritis associated with ingestion of a specific food established by DBPCFC (59).

Mechanism Unknown

In several clinical disorders, symptoms have been associated with reactivity to ingested foods, but an associated immune response is unclear. Reports since the turn of the century have suggested that oligoantigenic diets may be useful in the treatment of certain neurologic disorders. In one study, 15% of 104 adult patients with frequent migraine headaches had their headache cleared on a specific food elimination diet and their symptoms exacerbated during double-blind challenge with a single food (60). Two recent studies have raised the possibility that food allergic reactions may be responsible for some cases of sudden infant death syndrome (61, 62). Feeding pasteurized whole cow's milk to infants, especially those under 6 months of age, frequently leads to occult gastrointestinal blood loss and occasionally to iron deficiency anemia (63). Substitution of infant formula (including cow's milk-derived formulas that have been subjected to more extensive heating) for whole cow's milk generally normalizes fecal blood loss within 3 days. Considerable interest has resurfaced on the possible role of food allergy in inflammatory bowel disease (Crohn's disease and ulcerative colitis). Although considerable circumstantial evidence makes such hypotheses attractive, convincing proof is lacking.

Table 92.2 lists a variety of other symptoms reported to be related to food allergy. Convincing proof that any of these disorders manifest as isolated findings in association with food allergy is lacking. However, subjects experiencing a typical allergic reaction to a food may become irritable or lethargic following a reaction, and whether this response is due to the discomfort of the allergic symptoms or the release of various cytokines, such as IL-1, IL-6, and/or TNF_α, remains to be established.

General

Recurrent phlebitis
Cardiac arrhythmias

Table 92.2 Unsubstantiated Symptoms and Disorders Ascribed to Food Allergy

DIAGNOSTIC TESTS

Much of the confusion surrounding food allergy has resulted from the lack of sensitive, specific laboratory tests to confirm the diagnosis. Confirmation of the diagnosis usually depends on a clinical test, the DBPCFC, which is the current “gold standard” for diagnosing food allergy (64, 65). Initial evaluation of a patient with suspected food allergy should focus on a careful history and physical examination. The history should emphasize the following points: food suspected and the approximate quantity ingested, time between ingestion and development of symptoms, description of the symptoms, frequency and reproducibility of symptoms, the most recent occurrence, and whether other factors (i.e., exercise) are necessary for the reaction to occur. The physical examination should note any atopic features, which frequently are present in individuals with IgE-mediated food allergy.

Several laboratory tests have evolved for use in the diagnosis of IgE-mediated food hypersensitivity reactions and may be used in the initial screening of food allergy complaints. Skin tests with food extracts are used to demonstrate the presence of food antigen-specific IgE antibodies on the surface of cutaneous mast cells, which are presumed to reflect the IgE present on mast cells in the gastrointestinal and respiratory tracts. Compared with DBPCFC, the negative puncture or prick skin test is extremely useful for excluding IgE-mediated food allergy but inadequate for predicting clinical reactivity (i.e., low positive predictive accuracy) (66). Intradermal skin tests are even less specific than prick skin tests and therefore are not recommended in evaluation of IgE-mediated food allergy. Standard radioallergosorbent tests (RASTs) or similar in vitro tests measure food antigen-specific IgE antibodies in the blood. RASTs performed in a reliable laboratory provide predictive information that is not significantly different from prick skin tests. Once suspected foods are identified by history and skin testing (or RAST), they are eliminated from the diet for 1 to 2 weeks. Because DBPCFC are so time-consuming, often single-blind challenges are performed to eliminate foods considered unlikely to provoke an allergic reaction. DBPCFC is then used to establish a diagnosis of food allergy (65). All challenges suspected to provoke an IgE-mediated response must be conducted in a physician's office or a hospital setting because of the risk of a generalized anaphylactic reaction. Although a DBPCFC is rarely equivocal when investigating typical IgE-mediated symptoms, a variety of laboratory measurements may be used to quantitate the response: plasma histamine level, spirometry, and/or nasal lavage histamine concentration.

No satisfactory laboratory tests have emerged to assist in the diagnosis of non-IgE-mediated food allergic disorders. For ailments in which cell-mediated reactions are considered important, peripheral blood mononuclear cells stimulated in vitro with specific food antigens have been tested for ³H-thymidine uptake, leukocyte inhibitory factor production, and IL-2 generation. Although many patients with presumed food allergy have higher activity than normal controls, these tests are not discriminatory. In addition, no evidence exists that measurement of food antigen-specific IgG or IgG subclass antibodies or of food antigen-antibody complexes is of any diagnostic value. Other tests (e.g., cytotoxic tests, sublingual and intradermal provocation tests) have been suggested for use in diagnosing food allergy, but their diagnostic efficacies have never been validated.

Many gastrointestinal food hypersensitivities may be diagnosed with a single-blinded or open food challenge. In food-induced enterocolitis, up to 0.6 g of the implicated protein per kilogram of body weight is administered to the patient in a physician's office or hospital setting, because of the risk of protracted vomiting and hypotension (about 15% of cases). A positive challenge generally provokes vomiting and diarrhea, with occult or grossly apparent blood in the stools, an increase in stool PMN and eosinophils over baseline, and an increase in the total peripheral blood PMN count of 3500 cells/mm³ over baseline at 6 to 8 hours postchallenge (48). Food-induced eosinophilic proctocolitis often has a characteristic appearance on sigmoidoscopy. The bowel wall is edematous, erythematous, and friable with scattered ulcerations. Biopsy reveals an inflammatory infiltrate and prominent eosinophilia (67). Examination of the stools reveals significant numbers of leukocytes, and examination of the blood may reveal a mild elevation in the number of peripheral blood eosinophils. Exclusion of the responsible allergen generally leads to resolution of symptoms within 72 hours, and refeeding provokes a recurrence of hematochezia within 24 to 48 hours.

Both food-induced enteropathy and allergic eosinophilic gastroenteritis require endoscopy and intestinal biopsy while the patient is ingesting the suspected allergen, after being on an allergen-exclusion diet for up to 3 months and after reinstating the food allergen into the diet. Endoscopy and biopsy before challenge should reveal normal intestinal mucosa. Reintroducing the responsible allergen to patients with the malabsorption syndromes leads to villous atrophy, which may be partial or complete and is often patchy. In AEG, multiple food sensitivities are generally responsible for symptoms, so a 6- to 8-week trial on an elemental diet is often necessary for resolution of clinical symptoms. The characteristic eosinophilic infiltrate in AEG is frequently patchy, so multiple biopsies are required to exclude this diagnosis, especially in young children. Breath hydrogen and *d*-xylose absorption may be abnormal because of secondary disaccharidase deficiency. In celiac disease and dermatitis herpetiformis, both forms of malabsorption syndrome, IgA antigliadin and antiendomysial antibodies are present in over 90% of patients with untreated disease. In addition, IgA deposits in the dermal-epidermal junction is characteristic of patients with dermatitis herpetiformis.

Confirmation of infantile colic resulting from food allergy requires at least two double-blind, placebo-controlled crossover trials of the suspected food allergen. For a positive result, symptoms should be prominent during the allergen challenges and absent during the placebo challenges.

As depicted in [Table 92.3](#), many structural and enzymatic abnormalities in both children and adults can result in gastrointestinal symptoms that closely mimic food allergy reactions. The differential must be considered carefully in all patients undergoing evaluation, because many of these other disorders can also be life threatening (68). Foods may contain a variety of preservatives, dyes, and other chemicals that occasionally have been implicated in adverse reactions to foods. Many foods also have endogenous pharmacologic agents that can trigger symptoms in highly susceptible individuals. Occasionally, improper handling of food (scombroid poisoning) or ingestion of a toxin by an animal (ciguatera poisoning) results in symptoms that mimic an allergic

reaction.

Food intolerances	
Postinfectious malabsorption (secondary disaccharidase deficiency, villous atrophy, bile salt deconjugation)	
Viral	Rotavirus
Bacterial	Shigella, Clostridium difficile
Parasitic	Giardia, Cryptosporidium
Bacterial enterotoxins	
Vibrio cholera, toxigenic Escherichia coli, C. difficile	
Metabolic disorders	
Transient fructose and/or sorbitol malabsorption	
Primary carbohydrate malabsorption—lactase deficiency, sucrose deficiency	
Hypo- or abetalipoproteinemia	
Acrodermatitis enteropathica	
Anatomic abnormalities	
Intestinal lymphangiectasia	
Short bowel syndrome	
Hirschsprung's disease (especially with enterocolitis)	
Ileal stenosis	
Other disorders	
Cystic fibrosis	
Chronic inflammatory bowel disease	
"Chronic nonspecific diarrhea of infancy"	
Tumors—Zollinger-Ellison syndrome (gastrin)	
Neuroblastoma (catecholamines or vasoactive inhibitory peptides)	

Table 92.3 Disorders That Must Be Differentiated from Food Hypersensitivities

THERAPY

Once the diagnosis of food allergy has been established, the only proven form of therapy is strict elimination of the offending food. This action requires considerable time and effort (ideally with the help of a knowledgeable dietitian) to educate the patient (or parent). Teaching patients to read food labels is necessary to guarantee exclusion of many "hidden forms" of common foods (69). For example, most individuals are unaware that casein (milk protein) is found in some canned tuna fish; egg rolls often contain peanut butter; most nondairy creamers contain caseinate, etc. In addition, the importance of a nutritionally sound diet must be stressed. Many excellent educational materials can be obtained from the Food Allergy Network, a nonprofit organization (Fairfax, VA; phone: 800-929-4040).

In food-induced enterocolitis, a short course of corticosteroids may be lifesaving in the initial acute stages. However, long-term management involves identification and removal of the responsible food. Young infants diagnosed with cow's milk-induced enterocolitis should be placed on a "hypoallergenic" formula (e.g., Alimentum, Nutramigen), since up to 50% will develop soy-induced enterocolitis if placed on a soy formula (70). Allergic eosinophilic gastroenterocolitis often requires treatment with corticosteroids, especially when no food is clearly implicated. Although several other methods have been suggested for the treatment of food allergies (e.g., oral sodium cromolyn, ketotofin, desensitization), they have not been effective in controlled trials in which the diagnosis of food allergy has been established unequivocally.

NATURAL HISTORY

Results of follow-up studies on food allergic individuals indicate that food allergies may

resolve after several years. Although children under 3 years of age appear more likely to lose (“outgrow”) their food allergy (71, 72), loss of symptomatic, IgE-mediated food allergy occurred in approximately 40% of children and adults adhering to an allergen-exclusion diet for 1 to 3 years, even though results of skin tests and RAST did not change (i.e., food allergen-specific IgE was still present) (73, 74). The probability of symptomatic resolution appears to depend on compliance with the exclusion diet and the specific food provoking the symptoms; allergies to peanuts, tree nuts, fish, and other seafood are longer lasting, perhaps lifelong. In a cohort of cow's milk-allergic infants, 85% “outgrew” their milk allergy by their third birthday (15). Consequently, it is recommended that allergic children be rechallenged to most foods every 1 to 2 years and to peanuts, tree nuts, and seafood every 4 to 8 years to determine whether their clinical allergy persists. No evidence exists that individuals who lose a food allergy will redevelop symptomatic reactivity after reintroducing the food into the diet. In addition to the longevity of clinical allergy to peanuts, tree nuts, fish, and shellfish, patients with these allergies must be warned that these foods carry a greater risk of a generalized anaphylactic reaction.

Most infants with milk- or soy-induced enterocolitis and colitis syndromes “outgrow” their sensitivity in 1 to 2 years. However, infants developing both cow's milk- and soy-induced enterocolitis appear to have more persistent sensitivity, especially to soy protein. A similar presumption is that most infants with cow's milk-induced enteropathy “outgrow” their sensitivity. However, no studies have addressed this issue. Most clinicians agree that patients with celiac disease must exclude gluten-containing grains for life. Some patients with celiac disease can tolerate gluten-containing products with little gastrointestinal discomfort, especially after avoiding it for a time. However, the risk of malignancy of the mouth, pharynx, and esophagus and of non-Hodgkin's lymphoma is significantly increased in patients with celiac disease ingesting gluten, regardless of the presence of clinical symptoms (75). No information is available on the natural history of allergic eosinophilic gastroenteritis.

PROPHYLAXIS

The role of breast feeding and food allergen avoidance in prevention of atopic disease and food allergy remains highly controversial. Some studies suggest that breast feeding (especially with maternal avoidance of such major allergens as milk, egg, peanut, and fish during lactation) can prevent atopic dermatitis and food allergies in some high-risk infants. An infant is considered at “high risk” when both parents have atopic disease (i.e., atopic dermatitis, asthma, and/or allergic rhinitis), one parent and one sibling have atopic disease, or one parent or one sibling has atopic disease and the infant has an elevated cord blood IgE level (>0.9 IU/mL). In a large controlled trial, maternal and infant avoidance of allergenic foods (egg, milk, peanut, and fish) lowered the prevalence of atopic dermatitis, urticaria, and/or gastrointestinal disorders at 12 and 24 months but had no effect on the prevalence of asthma, allergic rhinitis, or positive skin tests to inhalant allergens (22, 76). Because of the difficulty in maintaining a prophylactic regimen, many investigators recommend prophylactic measures only in “high-risk” infants with highly motivated families until our understanding of immunologic sensitization to food allergens is more complete. This plan includes exclusive breast feeding, maternal avoidance of major food allergens, and supplementation with

hypoallergenic formula (Alimentum, Nutramigen), if necessary, for the first 6 months of life. However, it may be prudent for lactating mothers to exclude peanuts and nuts from their diet, since these proteins may pass in the breast milk and sensitize the infant with a potentially lifelong allergy. Highly allergenic foods (i.e., peanuts, nuts, and fish) should also be excluded from the child's diet for the first 3 years.

SUMMARY

Food allergy affects 6 to 8% of young infants and 1.5 to 2% of the adult population. It has been implicated in all forms of atopic diseases, including anaphylactic shock and death, and a variety of gastrointestinal disorders. IgE-mediated food allergy reactions have been best characterized, but several other immunologic mechanisms are believed responsible for many adverse food reactions. Appropriate diagnosis of these disorders requires a provocative food challenge, preferably blinded, and in several gastrointestinal syndromes, endoscopy and intestinal biopsy. Rechallenges should be done at set intervals to determine whether clinical sensitivity has been lost, because most food allergies are not lifelong. At present, strict allergen avoidance remains the only documented form of therapy that is universally successful.

Eating disorders are deviations in eating behavior that lead to disease or disability. Mild deviations from the “norm” are extremely common and occur with great variation at any age. The eating disorders are classified on the basis of their visible end result (extreme thinness or fatness) or on the basis of variations in eating patterns (fasting, food restriction, binge eating). The most common eating disorder, obesity, is discussed elsewhere (see [Chapter 87](#)). This chapter deals with the eating disorders anorexia nervosa and bulimia nervosa, usually classified among psychiatric disorders. It also discusses disordered eating in other psychiatric conditions in children and in adults.

ANOREXIA NERVOSA AND BULIMIA NERVOSA

Anorexia nervosa is characterized by self-imposed weight loss, endocrine dysfunction, and a distorted psychopathologic attitude toward eating and weight. The illness typically occurs in females shortly after puberty or later in adolescence, but onset can be premenarchal or later in life. Rarely, the illness occurs in males.

Bulimia nervosa is a severe disorder characterized by frequent binge eating and purging associated with loss of control over eating and a persistent overconcern about body shape and weight. The disorder occurs predominantly in young adult women. Milder

forms of binge eating and purging are common in normal-weight women.

Historical Note

Medical descriptions of anorexia nervosa exist from many centuries ago. The disease was formally identified simultaneously by Sir William Gull in England and Charles Lasègue in France (1). These authors recognized a psychologic cause, but for many years, no effective treatments existed. Bruch, in the 1960s, elucidated psychologic manifestations of the disorder and developed effective psychotherapeutic techniques (1). Recent research has focused on physiologic concomitants of the disorder and on the development of multifaceted treatment approaches (1).

The historical meaning of bulimia is ravenous appetite manifested by voracious eating. It was described in conditions of hypothalamic dyscontrol. In 1979, Russell (2) described bulimia nervosa as a distinct syndrome and serious variant of anorexia nervosa. Since then, much attention has been given to the many variants of eating disorders manifested by binge eating, self-induced vomiting, and other forms of purging.

Pathophysiology

The pathophysiologic changes in anorexia nervosa are similar to those in other states of semistarvation. For the most part, they are adaptive responses that allow the individual to survive a decreased dietary intake of sources of energy. Such adaptations, however, are not without their “cost”: functional impairment in other systems that limits the capacity of an individual to perform normal physical and mental activities. Many of the symptoms and signs of anorexia nervosa can be understood within the context of “normal” adaptations to semistarvation (3). (See also [Chapter 41](#).)

Starvation is associated with energy conservation, adaptations that spare glucose and protein while favoring use of fat, often dramatic shifts in fluid and electrolyte balances, and alterations in hypothalamic-pituitary function that result especially in amenorrhea and infertility. These adaptive changes may not account for all the decreased energy use. Diminished protein synthesis and turnover probably also contribute substantially. However, known alterations in insulin, thyroid, and catecholamine metabolism provide a framework for understanding some of the signs and symptoms experienced by semistarved patients, including reductions in pulse rate, respiratory rate, blood pressure, oxygen consumption, carbon dioxide production, cardiac output, gut motility, and other autonomic nervous system responses.

The alterations in thyroid hormone and catecholamine metabolism may also contribute to cold intolerance, dry skin, dry hair, hypercarotenemia, hypercholesterolemia, prolongation of ankle reflexes, constipation, and other symptoms of semistarvation. A more detailed discussion of fasting diuresis and refeeding edema, energy conservation, and endocrine adaptations in fasting and semistarvation, delineated in the classic studies by Benedict and Keys et al., is published elsewhere (3) (see [Chapter 41](#)).

The hypothalamic responses to energy deprivation are also adaptive, allowing the

organism to survive better than it would if without such adaptations. The most obvious example is the altered control of secretion of pituitary gonadotropins, resulting in disruption of normal cyclic patterns and producing anovulation, amenorrhea, infertility, and reduced libido. Such adaptations decrease the likelihood of becoming pregnant and also preserve the iron and protein stores that normally would be lost during menstrual flow.

To the extent that semistarvation is a feature in bulimic syndromes, changes similar to those in anorexia nervosa occur. The diversity of eating patterns among patients with bulimic syndromes, however, makes it impossible to generalize regarding their physiologic changes. Like anorexia nervosa, the bulimic syndromes have multiple determinants. A depressive diathesis has been suggested because some patients respond favorably to antidepressant medication. One study showed impaired cholecystokinin metabolism and reduced postprandial satiety (4). Studies of normal-weight bulimic women indicate that they are in a state of semistarvation because they had once maintained a higher weight and being in the statistically “normal” weight range was suboptimal for them. They tended to have had greater maximum weights than control subjects and to have had weight fluctuations with periods of low weight. Resting metabolic rate was lower in this group of women than in controls, but much individual variation was noted (5).

Etiology and Pathogenesis

The prevailing view is that eating disorders have multiple interacting causes. Biopsychosocial conceptualization identifies roots in three spheres—biologic, psychologic, and social. This model suggests a unique interaction of variables for each individual. An unexplained physiologic predisposition with possible genetic determinants leads to a variable degree of biologic vulnerability in persons at risk for development of eating disorders. Specific early experiences and family influences may create intrapsychic conflicts that determine the psychologic predisposition (1). Despite some studies delineating certain “psychosomatic” family patterns (6), accumulated evidence indicates a considerable variety of psychodynamic patterns in the families of patients with anorexia nervosa (7, 8).

Social influences and expectations that exert special pressures on modern women play an important role in the development of eating disorders (9). The biologic factors that initiate anorexia nervosa are mediated by pubertal endocrine changes. Psychologic conflicts lead to personality and behavioral changes that promote and support dieting. The social climate, such as the cultural obsession with thinness, tends to reinforce the psychologic motivation. Each of the three factors has greater or lesser importance for particular individuals in whom the disease develops. Thus, some appear to have a strong, innate tendency toward development of the disorder despite a supportive family environment; others react particularly to conflicted family experiences; and still others are strongly influenced by societal pressures (1).

Most commonly, dieting begins at puberty, shortly after menarche. Sensitive about her developing figure and rapid weight gain associated with puberty, a girl in whom anorexia nervosa develops typically restricts her food intake by eliminating sweets, snacks, and

calorically dense foods. This effort may at first seem like the innocent dieting so common among her peers. However, her efforts persist and become increasingly intense. Weight loss prompts further efforts at food restriction and setting lower and lower weight goals. Excessive exercise becomes ritualized. She becomes more and more compulsive, secretive, and idiosyncratic about her diet habits. Physical and mental signs of starvation begin to develop. The latter are often ignored or actively denied. She withdraws increasingly from social interaction, becomes quiet and seclusive, immerses herself in achievement-oriented activities, persists in dieting, and becomes increasingly active. Eventually, she becomes irritable and angry toward her family. School performance usually is maintained at a high level, but eventually it may decline, despite excessive hours of studying, as she becomes distractible, preoccupied and, ultimately, depressed and apathetic.

Overwhelming hunger may supervene as a reaction to chronic semistarvation. This urge may be suppressed for months or even years, or it may result in binge eating and rapid weight gain. If the bulimic individual with eating binges clings tenaciously to her pursuit of thinness, she will resort to vomiting or purging through laxative and diuretic abuse to maintain low body weight. This practice leads to chronic anorexia nervosa and bulimia nervosa.

Binge eating and purging also occur in normal-weight persons who have never had anorexia nervosa. Some may be overweight or may desire a much slimmer figure. A pattern characterized by meal skipping and choosing calorically restricted meals often starts the process.

Epidemiology

Anorexia nervosa most commonly begins in the second decade of life. Fewer than 10% of patients have premenarchal onset. Among females, more than one-half begin before age 20 years and about three-fourths before age 25 years ([Fig. 93.1](#)). The disorder occurs 8 to 12 times more frequently in females than in males. The prevalence in Rochester, Minnesota, in 1985 was 0.3% for females and 0.02% for males ([10](#)). Among 15- to 19-year-old girls, the prevalence was 0.5%. Among 15-year-old girls in Göteborg, Sweden, the prevalence was 0.84% ([11](#)).

Figure 93.1. Distribution of age at diagnosis of anorexia nervosa in Rochester, Minnesota, from 1935 to 1984. *Open bars*, females ($N = 166$); *hatched bars*, males ($N = 15$). (From Lucas AR, Beard CM, O'Fallon WM, et al. *Am J Psychiatry* 1991;148:917–22, with permission of the American Psychiatric Association.)

Estimates of the annual incidence in Western countries based on hospitalized patients and psychiatric case registers have shown an apparent increase from 0.5/100,000 population in 1950 to 5.0/100,000 in the 1980s (12). In a population-based study from 1935 to 1984, a higher average incidence rate of 8.2/100,000 (14.6 for females, 1.8 for males) was found. No change occurred over time in the rates for females age 20 years and older or for males. For females 15 through 24 years old, the most susceptible group, a linear increase was noted, with rates rising from 13.4/100,000 during 1935 to 1939 to 76.1/100,000 during 1980 to 1984 (10).

The severe form of the disorder is still relatively rare. The population-based study suggests that the occurrence of this form of the disorder has not varied over time. Anorexia nervosa is thought to be more frequent in higher socioeconomic classes, but data from population-based studies do not bear this out. Confirmed cases are not reported from underdeveloped nations, but they would be difficult to identify among other forms of malnutrition. The disorder is rare in black persons, perhaps because of biologic protective factors affecting vulnerability.

Studies of the epidemiology of bulimic syndromes have focused on the prevalence of the disorders. The reliability and validity of many of the studies are questionable because of great variation in the diagnostic criteria used and because many of the studies are based on questionnaires and self-reports. Nonetheless, evidence is accumulating that when strict criteria for bulimia nervosa are used, with interviews, the prevalence rate among adolescent and young adult women is 1 to 2%. It is rare among males. When broader criteria for bulimia are used and data are based on self-reports, the prevalence rates are higher, from 3 to 9%. With broader criteria for binge eating, more males are included (13). The community-based incidence of bulimia nervosa rose sharply from 1980 to 1983, after the description of the syndrome, and then remained relatively constant through 1990. The incidence rates for residents of Rochester, Minnesota, during the 1980s were 26.5/100,000 population for females and 0.8/100,000 population for males. The mean age for females at diagnosis was 23 years. Among 15- through 24-year-old adolescent and young adult females, bulimia nervosa had become at least twice as common as anorexia nervosa (14).

Clinical Aspects and Complications

The signs and symptoms, as well as laboratory findings, in anorexia nervosa and in bulimic syndromes are understood most easily in the context of the stage of the illness and the diet pattern that has been followed. At the onset of the illness and for a considerable time thereafter, the patient may have no observable signs other than

depletion of adipose tissue and no abnormalities on laboratory tests. The negative findings are simply confirmation that in a previously healthy individual, even starvation is compensated for by the homeostatic mechanisms of the body. The absence of abnormal findings tends to reinforce the patient's conviction that nothing is wrong. Bulimia (ravenous appetite) may lead to obesity. Occasional binge eating may be seen in normal-weight persons without complications. Bulimia alternating with prolonged fasting, vomiting, or purging leads to serious complications. Bulimia also occurs in certain forms of morbid obesity, notably Prader-Willi syndrome (15).

Anorexia Nervosa

Many clinicians thought that patients with anorexia nervosa have similar diet patterns characterized by specific carbohydrate avoidance, but a study of diet patterns in 96 patients indicated much diversity (16). All restricted their calorie intake, but 38% maintained satisfactory quality in the selection of their diets. Of the 62% whose diets were unsatisfactory in quality, most had irregular meal patterns, and many indulged in binge eating, vomiting, or fasting. The great variability in diet preferences among anorectic patients has implications for planning individualized treatment.

Physical signs in anorexia nervosa include dry thin skin, sallow complexion, and loss of body fat. Bradycardia, hypotension, hypothermia, and cold intolerance occur. Often, patients experience abdominal pain and a sensation of fullness. Constipation is common. Amenorrhea is a constant feature in females; males experience an analogous loss of sexual interest. Excessive loss of scalp hair may occur, and eventually fine downy hair (lanugo) may appear on the body and face.

Premorbid personality features include model behavior, compliance, perfectionism, and high academic achievement. The patient usually presents a rigid, unspontaneous demeanor and is unusually serious and polite but inhibited and brief in responses. Others may be inappropriately cheerful and energetic, insisting that they are perfectly fine. Excessive activity occurs but may be concealed. Sleep disturbance is common. Eventually, manifestations of depression appear.

Bulimia Nervosa

Among normal-weight persons with bulimia, binge eating generally occurs frequently, at least several times a week. Usually, the episodes tend to last less than 2 hours, although they may last for many hours at a time. High-calorie, easily ingested foods, such as ice cream, bread products, and candy, tend to be eaten during binges. Vomiting is often a part of the syndrome, and patients with the disorder may also abuse laxatives and diuretics. Personality features differ from those in patients with anorexia nervosa who restrict intake. Depressive symptoms are common, and suicide attempts are frequent among bulimic patients. Many have impulse-control problems in other areas of their lives. Shoplifting (frequently of food) and other forms of stealing are reported. The positive association among substance abuse, alcoholism, and bulimia is being recognized more frequently.

A person with bulimia may demonstrate no physical signs of it until vomiting or other

damaging behaviors have appeared. Nonpainful swelling of salivary glands suggests extreme variability in quantity of food intake. Erosion of dental enamel occurs with frequent vomiting, and calluses of the knuckles proclaim self-induced vomiting.

Laboratory Studies

Laboratory studies are of help chiefly in documenting the degree of physiologic adaptation to undernourishment, documenting complications of anorexia nervosa and bulimia, and identifying other illnesses resembling eating disorders. No laboratory profile is diagnostic. When a patient has physical signs and laboratory findings not usually associated with anorexia nervosa, such as increased heart rate, erythrocyte sedimentation rate, or leukocyte count, the physician should be alert to a possible medical complication or another disorder (17).

The laboratory profile varies considerably from normal to severely deranged and gives only a picture of these variables at the time of the test. In an illness that may last for many years, its stage is an important consideration in evaluating the laboratory findings. Abnormalities may not be observed until the illness is in an advanced stage. Serum electrolyte values usually are in the normal range, except when vomiting or laxative or diuretic abuse is a feature. The reported values may be high because of dehydration. The hematologic picture is variable because of changes in hydration. Anemia is a frequent finding in moderately severe cases, but it may be masked by hemoconcentration. Vomiting and laxative and diuretic abuse may be accompanied by serious electrolyte imbalances, notably hypokalemia, leading to cardiac arrhythmias, muscular weakness, renal impairment, and even death.

Dietary deficiencies lead to nutritional anemia in some patients. A peculiar morphologic change of erythrocytes resembling acanthocytosis is frequently present. The erythrocyte sedimentation rate usually is low. Leukopenia with relative lymphocytosis is common. Overt vitamin deficiencies are rare (18). Serum protein values tend to remain normal until the patient achieves advanced stages of starvation. The serum cholesterol level is increased in about one-third of patients, and the serum carotene value may be high.

Little documentation of the long-term complications exists in the literature, although various cardiovascular and renal complications can ensue. Demineralization of bone (osteoporosis) can be a long-term consequence (19). Kidney stones can occur. During the acute or subacute phases, gastrointestinal complications including decreased motility and atonic gut resembling paralytic ileus may occur. Pancreatitis has been reported, but its mechanism, like that of sialadenosis, is not known (20, 21).

Mortality Rates

Although mortality rates of up to 21.5% were reported in long-term follow-up of hospitalized patients, rates were less than 5% in over one-half of outcome studies (22). Preliminary findings suggest that the mortality rate in a community sample of subjects with anorexia nervosa will be lower (Lucas AR, unpublished data, 1997). Death from inanition is rare. It most often occurs from electrolyte disturbance or by suicide in persons with longstanding bulimia nervosa, but it also has been attributed to

overwhelming infection and to cardiopulmonary complications. Death has also been attributed to overzealous refeeding, specifically, aspiration during tube feeding, and to fluid and electrolyte imbalance during intravenous therapy (23).

Diagnosis and Differential Diagnosis

Anorexia Nervosa

Diagnosis of anorexia nervosa is not difficult. It should be suspected when significant weight loss cannot be explained by physical illness. The physician then should inquire about whether weight loss was intentional. Psychologic characteristics, including the fear of becoming fat and misperception of body image, often are features of the illness. Three major features are required to make the diagnosis: (a) self-inflicted severe loss of weight by avoiding foods considered to be fattening, by self-induced vomiting or abuse of purgatives, or by excessive exercise; (b) a secondary endocrine disorder of the hypothalamus–anterior pituitary–gonad axis manifested in the female by amenorrhea and in the male by a diminution of sexual interest and activity; and (c) a psychologic disorder that has as its central theme a morbid fear of being unable to control eating and becoming too fat, either specified or implied by the eating behavior. Loss of appetite is not a usual feature of anorexia nervosa; rather, there is an aversion to eating and to gaining weight.

Patients with anorexia nervosa often insist that everything is all right, and they resent the implication that they are eating inadequately. Once a nonjudgmental atmosphere is established, however, they usually become more forthcoming about their true eating habits. An experienced dietitian familiar with disordered eating behaviors is best able to obtain an accurate diet history. If patients persist in denying the facts, their general attitude and physical appearance will make it obvious that modifications in eating behavior are necessary.

Other disorders associated with weight loss must be differentiated from anorexia nervosa. The chief physical diseases to be differentiated are gastrointestinal diseases involving malabsorption. Among psychiatric disorders, depression often manifests with true loss of appetite and weight loss. In schizophrenia, bizarre eating habits and delusions about food can lead to a clinical picture resembling anorexia nervosa.

Bulimia Nervosa

Diagnostic criteria for bulimia nervosa include the essential features of episodic binge eating; fear of not being able to stop eating voluntarily; self-induced vomiting; use of laxatives, diuretics, fasting, or vigorous exercise to prevent weight gain; and persistent overconcern with body shape and weight. Patients seeking help are more likely to reveal their true eating habits; others tend to be deceptive. Bulimia nervosa is a frequent sequel to anorexia nervosa. It also occurs in individuals who have always been normal in weight and occasionally in overweight individuals. It is associated with frequent weight fluctuations. Conditions to be differentiated include rumination syndrome in

adolescence and involuntary vomiting.

Treatment

Although many cases of anorexia nervosa and bulimic syndromes can be managed by the family physician, internist, or pediatrician, they take time and sincere interest on the part of the physician. Patients mildly affected often respond to concerned counseling about adolescent growth, normal nutrition, and the consequences of starvation, bingeing, and purging. It has become customary to refer most patients to psychiatrists familiar with the treatment of eating disorders. Severe disorders are best managed by someone particularly experienced in treating the disorder. These patients need to be followed for a long time with various combinations of support, psychologic counseling, and diet counseling. When these symptoms are so severe that precipitous weight loss, bingeing, or purging continues despite outpatient treatment efforts, intensive hospital treatment is required.

Whether the patient remains at home or is hospitalized, the general principles of treatment involve education about the physiologic and psychologic consequences of starvation, encouragement to begin eating a healthy diet and control fasting, bingeing, and purging behaviors, and emotional support for the patient and the family.

Dietary Treatment

Treatment of anorexia nervosa and bulimic syndromes involves the joint efforts of a physician and a dietitian; they meet separately with the patient periodically, usually once a week, after the comprehensive evaluation. To achieve a working therapeutic relationship, the dietitian must first listen carefully to the patient, recognizing both the differences and the similarities among patients. It is helpful to know to what extent the evolution of the eating disorder was motivated by the patient's desire to be fit and healthy and how these goals can be supported but redirected by education. Patient education must begin early in the treatment and continue throughout. Included is a discussion of the effects of starvation and the extent to which disordered eating is not unique to eating disorders but rather occurs in starving people, whatever the cause. For many patients, understanding these issues as well as specific energy and nutrient needs (including growth needs) and the specifics of moderating practices in food choice leads to the realization that the dietitian and she have similar goals. This helps the patient to begin following the diet recommendations and then to experience a sense of relief and subsequently of greater well-being.

Both anorexia nervosa and bulimia nervosa patients benefit from these sessions. The goal for patients with anorexia nervosa is restoration of a normal weight. The goal for patients with bulimia nervosa is weight stabilization until eating behaviors are well regulated; additional emphasis is placed on education about, and control of, bingeing and purging.

Anorexia Nervosa. As in restoration of weight in other conditions involving starvation, a valid physiologic approach to treatment in anorexia nervosa is first to encourage the cessation of weight loss, to improve the nutritional state while low weight is maintained

for a time, and then to encourage a gradual weight increase through normal self-feeding. Supplemental food products or parenteral feeding is usually unnecessary. Contrary to the ideas espoused by some authors, clinicians do not need to encourage anorectic patients to consume above-average quantities of food. Instead, because of the low body weight and hypometabolic state, unusually small quantities are necessary at first (see Appendix [Table III-A-11-F](#)). Estimated basal calorie requirements should be adjusted on the basis of the measured basal metabolic rate. The initial use of small quantities meets the psychologic needs of the patient, who fears gaining weight rapidly and becoming fat. Because some anorectic patients are realistically guarding against overeating, encouraging them to eat large quantities and high-calorie snacks is countertherapeutic. As the patient becomes less fearful of weight gain, physiologically acceptable weight goals can be set on the basis of the patient's height, body build, and weight history.

Management involves several phases: obtaining a detailed diet history, determining the caloric content of the initial diet, designing an appropriate diet plan, planning gradual progression in the diet, considering weight gain expectations, and, finally, designing a diet plan for weight maintenance. Specifics of this approach have been described in more detail elsewhere ([24](#)).

Bulimia Nervosa. The initial goals of dietary guidelines in bulimic syndromes are to encourage regularity in eating habits so that the patient can gain control of eating binges, to minimize the likelihood of the eating binges, and to avoid periods of fasting that may contribute to the binging, purging, and fasting cycle. Emphasis during the initial stages usually is on stabilizing weight while more acceptable eating patterns are being established.

For weight stabilization, the kilocalorie level of the initial diet can be defined by determining the patient's basal caloric needs for present weight (see Appendix [Table III-A-11-f](#)). A diet planned at this caloric level usually results in weight stabilization. If the patient is more active, a kilocalorie allowance for activity should be added to prevent weight loss. During the last phases of treatment, when the patient has regulated the dietary intake and is feeling more confident about controlling eating behaviors while keeping weight relatively stable, the need for a gradual weight loss program can be reassessed.

Treatment phases used in anorexia nervosa can be adapted for use with bulimia nervosa. Treatment should begin with a thorough discussion of the health consequences of bulimia nervosa, making certain that the patient can see how her specific symptoms fit. The patient must understand how erratic food patterns and purging lead to malnutrition and all its consequences despite maintenance of normal or even increased body weight. True understanding usually does not come until later in treatment. Concrete guidelines for altering eating behavior are often accepted when the patient begins to trust the dietitian. Many patients appreciate the structure provided.

Additional information needed to use anorexia nervosa treatment phases for bulimia nervosa includes identification of factors that trigger binging, vomiting, and fasting as well as the frequency of these behaviors. Knowing the types of foods eaten for a binge

and what the patient identifies as a binge also helps in planning treatment strategies. This discussion usually allows the dietitian to understand the power food misconceptions and beliefs have in the patient's food choices and eating behaviors. The good-bad dichotomy about eating behaviors and exercise must be identified and explored for each patient before she is ready to risk modifying her behaviors to those recommended. Follow-up support and nutritional counseling need to continue even after weight has been stabilized and eating behaviors are regulated.

Psychotherapy

In addition to the dietary aspects of treatment aimed at normalizing eating patterns and weight, outpatient treatment deals with all aspects of the patient's functioning. Fears and misconceptions surrounding eating are addressed. Psychotherapy focuses on personal, family, and social conflicts that exist. With younger patients who are still living in their parental home, parents must be involved in the treatment, either with supportive counseling or in family therapy. A variety of individual and family treatment techniques have been developed, but the superiority of any one technique has not been established. These techniques have been described in detail ([25](#), [26](#)). Qualities in the therapist as well as characteristics of the illness and the patient are important in determining response to treatment. The individual needs of the patient are the most important considerations in planning a treatment program. Outcome studies are needed. Diet counseling alone can be effective in some cases, but data comparing it with psychotherapy are not available.

Hospital Treatment

The decision to hospitalize is based on the severity and rapidity of weight loss; the degree of malnutrition; the inability to control vomiting, laxative abuse, and other self-destructive behaviors; electrolyte disturbance or other hazardous complications; serious depression; suicidality; destructive family conflicts unresponsive to outpatient treatment; and the patient's lack of motivation for change. Hospital treatment requires a well-coordinated effort by the physician and hospital personnel on a unit that is geared to meeting the special needs of patients with eating disorders, not necessarily an "eating disorders unit." This may be a pediatric ward, an adolescent unit, a general medical ward, or a psychiatric unit for adolescents or adults. Essential considerations are that the staff have experience in treating patients with eating disorders and that patients be grouped by age. School-age children and adolescents need the opportunity to continue their education in the hospital ([27](#)).

Enteral nutrition and total parenteral nutrition have been used in severely undernourished patients with anorexia nervosa, particularly those who have failed to respond to treatment encouraging oral food intake. This group includes both patients who have steadfastly refused to eat and those who are so severely undernourished that it is difficult for them to take more than very small feedings. Although we encourage eating food orally, these alternative means of nutritional support may be necessary to sustain life and help the patient restore adequate nutritional uptake. These procedures can effectively improve the patient's nutritional state and, consequently, mental state. Nasogastric feeding no longer has all the negative implications of former times, because

small-diameter tubes are available that can be inserted with minimal discomfort. Enteral nutrition is preferable to parenteral nutrition because the intestinal tract is kept active. When enteral nutrition and, especially, parenteral nutrition are used, some oral food intake should continue to prevent intestinal mucosal atrophy.

Parenteral nutritional support requires special precautions because of its associated risks. Complications developed in almost half of reported patients with anorexia nervosa undergoing parenteral nutrition. Infection is one of the most frequent. Technical complications associated with central venous catheterization, including vascular perforations, hemothorax, and pneumothorax, may occur. "Refeeding syndrome," caused by excessively rapid refeeding, leads to respiratory failure and cardiac decompensation (28). To minimize complications, an experienced parenteral nutritional support team should manage this phase of refeeding. Close monitoring of caloric intake, electrolyte changes, and fluid retention is essential.

The use of legal constraints (i.e., committing patients to a hospital and their forcing feedings) is usually more harmful than helpful; it creates an adversarial situation and compromises patient trust. In our experience, the necessary nutritional support can almost always be instituted without legal recourse. When a trusting relationship and open communications are established, severely undernourished patients almost always, albeit reluctantly, submit to enteral or parenteral nutritional support. When patients are so severely undernourished that they cannot competently make decisions about their basic needs, however, those decisions must come from their treating professionals and families. In the U.S., a competent adult may choose to forgo treatment for any medical condition, but allowing a patient to die from a treatable illness, as exemplified in a case report of a 24-year-old woman with anorexia nervosa who chose to go to a hospice to die, raises profound ethical questions (29). Ethical implications of forced feeding have been discussed by Hebert and Weingarten (30).

Medication

No evidence exists that neuroleptic or antidepressant medications either shorten the course of anorexia nervosa or improve the chance of recovery. Trials of medication have focused on their effect on short-term weight gain, but rapid weight gain bears no relationship to long-term outcome. On the other hand, antidepressant medications can reduce the frequency of bingeing and purging in bulimia nervosa over the short term, apparently independent of an antidepressant effect (26).

Outcome

Anorexia Nervosa

The course and outcome of anorexia nervosa are extremely variable. Meaningful conclusions about outcome require follow-up for at least 4 years. In reviewing such studies, Hsu (26) found that between 50 and 60% of patients were at normal weight, and about one-half had normal menses. Between 11 and 20% of patients were still underweight. The mortality rate was 0 to 5%. Findings from the longest-term studies, in which investigators have observed patients for several decades, underscore the

conclusion that even after 6 years, some patients recover and others have recurrences. After 6 years of illness, about 50% of patients had recovered. As the observation time extended, more patients had recovered, but also more died. Twelve years after the onset of illness, 75% had recovered. The others had chronic illness, some with bulimic forms. Death from complications of starvation or from suicide continued to occur. Recovery after more than 12 years of illness was uncommon. After 33 years, 6% had poor outcomes and 18% had died (31).

Bulimia Nervosa

Outcome studies of bulimia nervosa are still rare, and few have more than 1 year of follow-up. Hsu (26) was encouraged about the short-term outcome in these studies. Two-thirds of patients no longer had symptoms of the disorder. Cautious optimism is justified until longer follow-up becomes available. Outcome is likely to vary greatly, with many patients recovering fully and others experiencing severe chronicity and complications.

DISORDERED EATING IN OTHER PSYCHIATRIC CONDITIONS

Attention-Deficit Hyperactivity Disorder

Estimates of the prevalence of attention-deficit hyperactivity disorder suggest that it affects between 3 and 9% of children (32). This disorder accounts for one-third to one-half of all referrals for child mental health services (33). The core clinical features of attention-deficit hyperactivity disorder are developmentally inappropriate activity levels, low frustration tolerance, impulsivity, poor organization of behavior, distractibility, and inability to sustain attention and concentration.

Multimodal treatment strategies that combine several forms of intervention have been considered the ideal. Sound clinical practice is necessary, including tailoring stimulant medication or psychosocial interventions (or both) to the particular needs of the individual children with attention-deficit hyperactivity disorder and their families.

Stimulant medications have been the major psychotropic agents used in the management of childhood behavior problems. The most commonly prescribed stimulants are methylphenidate (Ritalin), dextroamphetamine (Dexedrine), and pemoline (Cylert). Of these three, methylphenidate is by far the most widely used. The widespread clinical use of stimulant drugs stems from their demonstrated efficacy in dramatically treating a range of core attention-deficit symptoms. The most commonly reported side effects of stimulant medications are insomnia, anorexia, stomach pains, and weight loss. The anorexia and weight loss should not be surprising because these drugs are used as “diet pills” and were prescribed as appetite suppressors in the treatment of obesity in the past.

In 1972, Safer and Allen (34) suggested that growth-suppressant effects are present at all doses of dextroamphetamine and are dose dependent for methylphenidate. Subsequent studies of the influence of these medications on growth have conflicting

findings. Results of a 1990 study suggest that methylphenidate use does not noticeably impair early adolescent growth velocities during 6 to 12 months of treatment. This finding contrasts with reports of at least temporary growth suppression in children and may indicate that early adolescent growth is relatively insensitive to methylphenidate (35).

Periodic monitoring of growth is standard practice when children receive stimulant medication. Many children are treated with these medications during their elementary school years and, frequently, into adolescence. Reducing the dosage, when practical, is indicated if growth suppression occurs. Parents of children receiving stimulants need to be taught to observe their child's appetite and changes in interest in meals and snacks and to report these changes to the child's physician. Closer monitoring of growth is needed in this population. If slowing weight gain or growth is noted, a 7-day food record of the child's intake should be kept by the parents and evaluated by a dietitian. The dietitian can use these records to recommend ways of increasing calories: using more calorically dense foods, encouraging regular meals and snacks, or supplementing intake with commercial products, if acceptable to the child. Encouraging the child to eat meals and snacks even when not hungry usually helps to avoid compromising growth. Children can be engaged in these efforts if they are provided with age-appropriate descriptions of the relationship between food intake and growth. Having the parents and child work with a dietitian to address nutritional needs and identify ways of meeting them within the family eating patterns and the child's preferences is effective for most children experiencing slowed growth with medication use.

Mood Disorders

Mood disorders are classified as unipolar or bipolar. Patients with unipolar disorder have episodes of depression only, whereas those with bipolar disorder have alternating episodes of mania and depression. The prevalence of unipolar depression is about 10% in women and 5% in men. Bipolar disorder is less frequent, about 0.5 to 1.0% in the population. These illnesses usually begin during the 20s, although they may occur earlier in life. Unipolar depression is more common in midlife and later (36).

Typically in major depression, loss of appetite occurs as well as loss of interest in the patient's surroundings and social relationships. Anorexia is manifested by loss of interest in eating and its associated pleasure. Depressed patients tend to ignore mealtime and to say that they do not feel hungry. Weight loss occurs frequently, is unintentional, and generally amounts to less than 15% of body weight. This can easily be differentiated from anorexia nervosa, in which the weight loss is intentional. If depression is unrecognized or untreated, however, weight loss may be substantial, and differentiation from chronic anorexia nervosa may be difficult. A minority of depressed patients have increased appetite and weight gain. Patients during a manic episode have pressured speech, hyperactivity, and sleeplessness, often associated with weight loss.

Treatment with antidepressant medication usually alleviates anorexia as other symptoms of depression are relieved. If weight loss was slight and there are no nutritional deficiencies, no other intervention is necessary. If there are significant nutritional deficiencies, as determined by a diet history, the assistance of a dietitian may

be necessary to educate the patient about appropriate meal choices.

Treatment of depression with monoamine oxidase inhibitors such as tranylcypromine (Parnate), phenelzine (Nardil), and isocarboxazid (Marplan), requires that the patient follow a tyramine-controlled diet because of the risk of increased blood pressure with as little as 6 mg of tyramine; 25 mg of tyramine may induce a life-threatening hypertensive crisis. Thus, intake should be kept below 5 mg/day (37). With the availability of other antidepressants, these medications are now rarely used except in treatment-resistant patients.

Manic episodes are treated with lithium and antipsychotic medications. Almost half of patients receiving lithium gain weight. Lithium impairs glucose tolerance and may increase sensitivity to insulin. It also inhibits the effects of antidiuretic hormone, resulting in polyuria and polydipsia. If dietary sodium is restricted, lithium excretion decreases, and lithium toxicity may occur. Caffeine increases lithium excretion and may cause a decrease in plasma lithium levels. Dietitians should be aware of these metabolic effects in patients treated with lithium (36).

Schizophrenia

Schizophrenia is a chronic disorder characterized by hallucinations, delusions, illogical thinking, and bizarre behavior. Prevalence is 0.5 to 1.0%, with females and males about equally affected (36).

The patient with schizophrenia may have delusions about food and its effects on the body or command hallucinations (hearing a voice telling the patient not to eat) that lead to idiosyncratic or bizarre eating habits. Typically, patients believe that their food is poisoned or will harm their body. Those in an agitated state of psychosis may neglect eating. Others, such as those in a catatonic stupor, may be volitionally unable to eat. Untreated schizophrenic patients may lose a substantial amount of weight or acquire nutritional deficiencies because of prolonged fasting or idiosyncratic eating habits. Other patients with schizophrenia may eat ravenously (bulimia) and gain excessive weight. Effective treatment with antipsychotic medications restores rational thinking and eliminates the delusions. Eating habits usually normalize without specific nutritional intervention. When dietary irregularities of long duration have led to nutritional deficiencies, education by a dietitian may be necessary once the irrational thinking has resolved. Poorly functioning, chronically schizophrenic patients may need close monitoring of meals in hospitals or day treatment programs. Fluid retention and weight gain are common during long-term treatment with antipsychotic medications.

[Chapter References](#)

The interactions between nutrition and alcoholism occur at many levels and are complex. Alcoholic beverages contain calories but almost no other useful constituents (1). Ethanol-containing beverages alter appetite and affect food intake and use. They displace required nutrients from the diet. Ethanol and nutrients have multiple interactions at almost every level of the gastrointestinal tract. Ethanol alters the storage, mobilization, activation, and metabolism of nutrients.

Ethanol is directly toxic to many body tissues. Its interplay with malnutrition in causing damage, particularly with respect to the liver, the predominant site of its metabolism, still needs clarification. Alcoholism remains one of the major causes of nutritional deficiency in the United States; alcohol-related illness poses an enormous medical burden and often entails complex nutritional therapy. Nutritional therapy is frequently a balance between maximizing recovery while avoiding iatrogenic complications.

NUTRITIONAL VALUE OF ALCOHOLIC BEVERAGES

Alcoholic beverages contain water, ethanol, variable amounts of carbohydrate, and little else of nutritive value (see Appendix [Table IV-A-19](#)). The carbohydrate content varies greatly: whiskey, cognac, and vodka have none, red and dry white wines have 2 to 10 g/L, beer and dry sherry 30 g/L, and sweetened white and port wines have as much as 120 g/L (2). Protein and vitamin content of these beverages is extremely low except for

beer. Even if one used beer as a nutrient source, a liter would be necessary daily for nicotinic acid requirement, 15 to 20 L for protein, and 25 L for thiamin. Iron content may be appreciable, especially in wine (2). The amounts of iron, lead, or cobalt may reach harmful levels. The significance of congener content is mostly obscure (1).

Americans probably consume 4.5% of total calories as ethanol (3), and adult drinkers over 10%. Heavy drinkers may derive more than half their daily calories from ethanol. Combustion of ethanol in a bomb calorimeter yields 7.1 kcal/g; however, its biologic value is probably less than that of carbohydrates on a calorie basis. Lower body weight in alcohol drinkers than in nondrinkers is especially clear in women (4). Subjects given additional calories as alcohol under metabolic ward conditions did not gain weight (Fig. 94.1) (5, 6).

Figure 94.1. Effect of the isocaloric substitution of ethanol for carbohydrate calories on body weight. Substitution of ethanol as 50% of total calories results in body weight loss. (From Pirola RC, Lieber CS. *Pharmacology* 1972;7:185, with permission.)

Hospitalized alcoholics on an open ward also gained no additional weight when 1800 calories from ethanol were added to their 2600-calorie diet (7). Isocaloric substitution of ethanol for carbohydrate, as 50% of total calories in a balanced diet, conducted under metabolic ward conditions, resulted in a decline in body weight (6); and when given as additional calories, ethanol resulted in less weight gain than equivalent carbohydrate or fat (1, 6). Others have found variable responses in weight to additional calories as ethanol (8). Body composition measurements were not reported. The ability of ethanol to support body weight may vary according to the quality of carbohydrate fed with it (9).

There is evidence that ethanol increases metabolic rate, which would at least partly explain its reduced biologic energy value. Ethanol increases oxygen consumption in normal subjects and does so to a greater degree in alcoholics (10). Substitution of ethanol for carbohydrates increases metabolic rate in humans and rodents (11, 12). Thermogenesis increased by 15% in rats fed ethanol for only 10 days in one study. Resting energy expenditure (REE) (13) and diet-induced thermogenesis (DIT) also

increase in humans (11). Only a small portion of the energy waste in rats could be attributed to brown fat thermogenesis (14). It is theorized that energy waste during ethanol consumption may occur via oxidation (without phosphorylation) by the microsomal ethanol-oxidizing system (MEOS) (6). The MEOS is induced by chronic ethanol consumption, which aggravates energy waste (15, 16). The MEOS is unlikely to be solely responsible for energy wastage from ethanol metabolism. Oxidation of ethanol to acetaldehyde, catalyzed by the MEOS or alcohol dehydrogenase (ADH), represents only the first step in the metabolism of ethanol to carbon dioxide and water. Even when the MEOS is induced, much of the ethanol is metabolized by ADH to acetaldehyde, and most of the energy from ethanol is produced by oxidation of acetaldehyde to carbon dioxide and water. Acetaldehyde may contribute to energy wastage by promoting catecholamine release and by impairing various mitochondrial shuttles and mitochondrial oxidative phosphorylation. The appearance and metabolism of acetate, the next product in the oxidation of ethanol, is also associated with several energy-consuming features. Acetate increases myocardial contractility, coronary blood flow, and cardiac output. Hepatic damage itself, secondary to ethanol, decreases energy use, particularly from fat. A more detailed discussion of the energetics of ethanol metabolism is available (17). Some (18) have implicated uncoupling of mitochondrial NADH (the reduced form of nicotinamide adenine dinucleotide) reoxidation, perhaps abetted by a hyperthyroid state or catecholamine release (see above) to explain energy waste (18). The hyperthyroid state has been questioned (19).

NUTRITIONAL STATUS OF ALCOHOLICS

Alcoholism can undermine nutritional status. It was estimated that 20,000 alcoholics were suffering major illnesses due to malnutrition in the United States each year, accounting for 7.5 million days of hospitalization (20). Alcoholics hospitalized for medical complications of alcoholism have the most severe malnutrition. These alcoholics have inadequate dietary protein (21), signs of protein malnutrition (20, 22), and anthropomorphic measurements indicating impaired nutrition: their height:weight ratio is lower (23), muscle mass estimated by the creatinine-height index is reduced (22, 23), and triceps skin folds are thinner (22, 23 and 24). Continued drinking results in weight loss and abstinence results in weight gain (25, 26) in patients with and without liver disease (24).

Many patients who drink to excess are either not malnourished or are less malnourished than the group hospitalized for medical problems. Women drinking one or more drinks per day weighed on average 2.3 kg less than nondrinkers, and they and their male counterparts maintained a more stable weight over the next 10 years than nondrinkers, whose weight rose (27). Other surveys, however, found that alcohol intake, especially when accompanied by high fat intake and sedentary behavior (28) favors truncal obesity, particularly in women (29). Those with moderate alcohol intake (30), even those admitted to hospital for alcohol rehabilitation rather than for medical problems (31), often hardly differ nutritionally from controls (matched for socioeconomic status and health history), except that females have a lower level of thiamin excretion than control patients following a thiamin load test (31).

The wide range in nutritional status of the alcoholic population surely reflects, in part,

differences in what they eat. Moderate alcohol intake, alcohol accounting for 16% of total calories (alcohol included), is associated with slightly increased total energy intake (32). Perhaps because of the energy considerations already discussed, this group with higher total caloric intake has no weight gain despite physical activity levels comparable to those of the non-alcohol-consuming population. This level of alcohol intake and even slightly higher levels (23%) (33) are associated with substitution of alcohol for carbohydrate in the diet. In those consuming more than 30% of total calories as alcohol, significant decreases in protein and fat intake occur too, and their intake of vitamins A, C, and thiamin may fall below the recommended daily allowances (32). Calcium, iron, and fiber intake are also lowered (33).

The mechanisms underlying the altered pattern of food intake are not exactly known. Suppression of appetite has been postulated (34) but not been studied much. Depressed consciousness during inebriation, hangover, and gastroduodenitis due to ethanol partly explain the decreased food intake. The contribution of subtle nutritional alterations produced by ethanol to the pathogenesis of ethanol-induced or other disease states is largely undetermined. Nutritional therapy per se for alcoholism has not been successful (35).

EFFECTS OF ETHANOL ON DIGESTION AND ABSORPTION

Alcohol consumption is associated with motility changes in the gastrointestinal tract and affects the digestion and absorption of nutrients. Diarrhea and weight loss frequently occur in alcoholics. Ethanol effects may be direct or indirect, acute or chronic. One of the most intense changes, intestinal malabsorption secondary to folic acid deficiency, is not a direct effect of ethanol, but rather comes from diminished folic acid intake and abnormal metabolism accompanying alcoholism.

Gastrointestinal Tract

Patients with cirrhosis of the liver due to alcohol have edema, interstitial fat infiltration and fibrosis of the parotid glands, decreased basal- and citric acid-stimulated salivary flow, and lower salivary concentrations of sodium, bicarbonate, and proteins (36). Changes in esophageal peristalsis and lower esophageal sphincter pressure follow no consistent patterns (37, 38 and 39) and usually do not lead to clinically significant dysphagia. However, the changes in saliva and esophageal motility and the direct effect of ethanol may be important in causing esophagitis and stricture, which are common in alcoholics and interfere dramatically with food intake.

Alcohol ingestion is a cause of acute gastritis and duodenitis (40). These areas of the gut are exposed to the highest concentrations of ethanol for the longest times. Damage to the gastric mucosal "barrier" is important in making the mucosa more susceptible to acid and hyperosmolarity. Damage probably results from a combination of diminished gastric mucus production, altered mucosal blood flow, inhibition of active transport, increased permeability because of mast cell release of histamine and leukotriene C₄, cell membrane disruption, hyperosmolarity, changes in prostaglandin and cyclic adenosine monophosphate (cAMP) content of mucosa, and lipoperoxidative

mechanisms. Erosive gastritis occurs, as does nonerosive hemorrhagic gastritis consisting of subepithelial hemorrhage of the foveolar region with surrounding edema (41). The effects of ethanol on gastric emptying of meals are concentration dependent; higher concentrations cause more consistent delay of passage of solid contents (42) and even enhance movement of liquids (43).

Alcoholics frequently suffer from diarrhea (44) and malabsorption. Acute effects of ethanol on motility and acute and chronic effects on the mucosa are responsible. Concomitant nutrient deficiencies can contribute significantly to mucosal changes, particularly folate deficiency. In the jejunum, ethanol decreases type I (impeding) waves, while in the ileum it increases type III (propulsive) waves. Decreases in villus height (45) and disaccharidase activity (46, 47) in mucosal biopsy specimens have been found in alcoholics with associated lactose intolerance, especially in black cirrhotics (47) (Fig. 94.2). The possibility of lactase deficiency must be considered in dietary treatment. Monosaccharide absorption is variably affected by ethanol; glucose is absorbed less well in rabbits after acute ethanol exposure (48), but chronic ethanol exposure enhances galactose absorption in rats (49) and glucose absorption in humans (50).

Figure 94.2. Effect of lactase deficiency on rise in serum glucose after oral lactase administration. Blood glucose rose the least in subjects with the most severe lactase deficiency. There was good correlation between symptoms and the lack of rise in glucose. (From Perlow W, Baraona E, Lieber CS. *Gastroenterology* 1977;72:680–4, with permission.)

Acute depression of amino acid absorption can be readily demonstrated using high concentrations of ethanol (0.5 to 3.0%) in experimental models of ethanol exposure, using short segments of gut perfused *in vivo* or gut sacs bathed *in vitro*. It has not been easy to demonstrate depressed absorption acutely using smaller concentrations of ethanol in whole intestines of living animals or in experimental models fed ethanol chronically. Several relevant topics are virtually unstudied: the effect of ethanol on amino acid absorption from complex mixtures (including peptides) and the possible

effect of local changes in amino acid absorption on body nitrogen use.

Bile Salts

Steatorrhea, when it occurs in alcoholics, is mostly due to folic acid deficiency (see below) but luminal bile salt deficiency may contribute. Intraluminal bile salt levels are decreased by acute ethanol administration (51). In rodents, long-term ethanol administration delays the half-time excretion of cholic and chenodeoxycholic acids by decreasing the daily excretion and expanding the pool size slightly (52). Alcoholic cirrhotic patients may have bile low in deoxycholic acid, possibly because of impaired conversion of cholate to deoxycholate by bacteria (53). Thus, decreased cholic acid synthesis, decreased bile acid pool size (54), low concentrations of bile salts in intestinal juice, and bacterial deconjugation of bile salts by altered intestinal flora all promote steatorrhea in cirrhotics. Pigmented gallstones are more frequent in cirrhotics (55).

Pancreatitis and Pancreatic Insufficiency

Pancreatic function must be intact for optimal digestion and absorption of nutrients. The nutritional requirements of patients with acute pancreatitis or pancreatic insufficiency have to be met under conditions of handicap. Acute pancreatitis, with its associated hypermetabolic, hypercatabolic state, may increase energy expenditure by a sixth, in mild cases, and by half in severe ones. In many patients, oral food intake is limited by abdominal pain, nausea, and vomiting. Patients with chronic pancreatitis are often nutritionally depleted by inadequate food intake due to abdominal pain and by years of maldigestion secondary to insufficient exocrine secretion of digestive enzymes. Characteristically, patients have suffered weight loss. Initially, fat stores are diminished; eventually muscle mass is lost. Deficiencies of fat-soluble vitamins (A, D, and K) and minerals are frequently encountered. Nutritional repletion may be complicated by both abdominal pain, often exacerbated by oral intake, and maldigestion.

Acute alcoholic pancreatitis may be managed by oral feeding when the patient does not have ileus, nausea, or vomiting and when oral intake is not accompanied by increased abdominal pain. These conditions are often met in mild cases. Enteral feeding of elemental diets delivered via jejunostomy tube is theoretically attractive because the duodenal area is bypassed and release of pancreatic secretagogues is minimized, especially when low-fat mixtures are used; the requirement for digestion prior to absorption is small. However, the parenteral route is usual, since ileus is common. Standard total parenteral nutrition (TPN) formulations are used, which have glucose and lipid as energy sources. Usually the insulin requirement is reasonable, but if it exceeds 80 U/day, lipid substitution may be considered. Lipid has not been shown to be deleterious. Although nitrogen loss is diminished, improved survival has not been documented.

The nutritional approach to chronic pancreatic insufficiency requires alleviating abdominal pain to permit adequate oral food intake; replacing pancreatic exocrine secretion to prevent maldigestion, diarrhea, and energy wastage; and managing diabetes mellitus. Pancreatic enzyme replacement is effective given in adequate doses with meals. Lipase deficiency is usually responsible for symptoms such as steatorrhea

and should be given in amounts up to 30,000 units as active enzyme. Sometimes antacids such as H₂ blockers are needed to protect the enzymes from acid-mediated destruction, since the neutralizing action of bicarbonate secretion is lacking due to pancreatic damage. Diabetes mellitus due to pancreatic insufficiency may exhibit insulin sensitivity and hypoglycemia, perhaps because of concomitant glucagon deficiency. Insulin therapy has to be given with caution.

Alterations of Nutrient Metabolism

Water-Soluble Vitamins

Alcoholics tend to have clinical or laboratory signs of soluble vitamin insufficiency correlated with the increasing amount of alcohol they drink and a corresponding decrease in vitamin intake. This is true for thiamin, riboflavin, pyridoxine, folic acid, and ascorbic acid but has not been demonstrated for vitamin B₁₂. Alcohol effects on absorption, activation, and storage must also be considered. Alcohol clearly impairs thiamin absorption in rodents; human thiamin absorption may not be susceptible to alcohol. Alcohol interferes with riboflavin absorption in rodents, but this has not been studied in humans. Alcohol impairs folic acid absorption in malnourished humans, but the mechanism is unclear. Some experimental animals, even without malnutrition, have folic acid absorption impaired by alcohol; others do not. Hepatic retention of folic acid is inhibited by alcohol, which also interferes with hematologic use of folic acid and promotes its urinary and fecal loss. Whether alcohol interferes with the activation and storage of thiamin is controversial. Riboflavin and pyridoxine storage in the liver is adversely affected by alcohol, at least in experimental animals.

Thiamin. Thiamin deficiency is usually present in alcoholics in Western society and causes Wernicke-Korsakoff syndrome and beriberi heart disease and probably contributes to polyneuropathy. Neuroanatomic lesions comparable to the human syndrome can be produced in rhesus monkeys by prolonged thiamin deficiency without the need for alcohol intake (55, 56). There has been no confirmation of an inborn error of transketolase affinity for coenzyme in Wernicke-Korsakoff syndrome as was once claimed (57). Thiamin intake will be insufficient for those relying on alcoholic beverages for their energy needs. When obvious deficiency is not present, measuring the decrease in blood transketolase activity and its increase upon in vitro addition of cofactor thiamin pyrophosphate (TPP) is considered useful for diagnosis by some (58, 59) but not all (60). It is postulated that profound thiamin deficiency, alcohol intake (61), or liver disease (62) may affect levels of apoenzyme transketolase or its binding to cofactor and thus prevent the TPP effect. Others have found that decreased erythrocyte transketolase activity alone correlates best with thiamin deficiency in patients with Wernicke's encephalopathy (63). In any case, in experimental animals (64) and in well-nourished alcoholics who ingest normal amounts of thiamin or more, levels in the organs are maintained (65), and there is no abnormality in the relative amounts of phosphorylated species of thiamin (66).

Hospitalized alcoholics were reported to have poorer thiamin absorption than control patients when tested by radioactive thiamin excretion (67), a test also affected by steps not related to absorption. However, folic acid deficiency was not adequately excluded as

a cause of thiamin malabsorption in these studies. Refined testing reveals reduced thiamin absorption due to alcohol in a minority of subjects (68). Jejunal perfusion studies showed no effect of 5% alcohol on thiamin absorption in man (69). Interestingly, thiamin absorption is lower in middle-aged subjects (alcoholics and controls) than in younger individuals. Studies in rats have progressed farther, but they may not be relevant to human disease (discussed above). In rodents, thiamin absorption is accomplished by an active system with a low K_m and a passive system with a higher K_m . Alcohol interferes with thiamin absorption via the low-concentration active pathway, and presumably (if humans are similarly constituted) is an important factor for alcoholics with marginal or low thiamin intake. The effects of alcohol on thiamin activation and storage in the liver are controversial (65).

Thiamin is well absorbed from sorghum beer despite its 3% alcohol content (69). Therefore, it is feasible to add thiamin to alcoholic beverages, but this is prohibited by the current laws against “adulteration” of alcoholic beverages. Thiamin should be provided to all alcoholics for a number of reasons: thiamin deficiency is common in alcoholics, assessing any but the most glaring thiamin deficiency syndromes is difficult, it is important to reverse early neurologic disease, and thiamin replacement is easy and safe. Thiamin should be given parenterally, 50 mg/day, until oral intake can be established, then orally, 50 mg/day, for weeks or longer if neurologic problems persist.

Riboflavin. When there is a general lack of B vitamin intake, riboflavin deficiency may be encountered (70). In one study, deficiency was found in 50% of a small group of patients with medical complications severe enough to warrant hospital admission (71). Although none of the patients exhibited classic signs of riboflavin deficiency, they had an abnormal activity coefficient (AC) that returned to normal 2 to 7 days after intramuscular replacement with 5 mg riboflavin daily. The AC is measured as the ratio of erythrocyte glutathione reductase activity upon addition of flavin adenine dinucleotide (FAD) to the activity with no additions. A study showed that riboflavin deficiency could be induced readily by feeding alcohol to the Syrian hamster; the most severe deficiency was seen in animals also restricted in riboflavin intake (72). Ethanol also impaired hepatic accumulation of riboflavin in rats given vitamins and alcohol by acute gavage, with evidence that ethanol markedly inhibited the enzymes that hydrolyze the vitamin forms—flavin mononucleotide (FMN), phosphatase, FAD, pyrophosphatase—and may decrease vitamin absorption.

Riboflavin replacement is easy because absorption occurs readily, excess is excreted in the urine, and there is no known toxicity. It is usually given to alcoholic patients as part of a multivitamin preparation.

Pyridoxine. Neurologic, hematologic, and dermatologic disorders can be caused in part by pyridoxine deficiency. Pyridoxine deficiency, as measured by low plasma pyridoxal-5'-phosphate (PLP) levels, was reported in over 50% of alcoholics without hematologic findings or abnormal liver function tests (73, 74). Inadequate intake may partly explain low PLP levels, but increased destruction and reduced formation may also obtain. PLP is more rapidly destroyed in erythrocytes in the presence of acetaldehyde, the first product of ethanol oxidation, perhaps by displacement of PLP from protein and consequent exposure to phosphatase (73, 75). Fairly high levels of acetaldehyde were

used in the studies cited, so the significance of the proposed mechanism is uncertain. Previous studies showed that chronic ethanol feeding lowered hepatic content of PLP by decreasing net synthesis from pyridoxine (76, 77 and 78), which depended on alcohol oxidation in some studies. The acetaldehyde produced was thought to enhance hydrolysis of PLP by cellular phosphatases (73). Actual displacement of PLP from its binding protein by acetaldehyde has been shown in rat hepatocytes (79). In later studies of mice (79) and rats (80), ethanol actually increased total hepatic levels of vitamin B₆ (PLP and pyridoxamine-5'-phosphate, or PMP), primarily because of an increase in PMP. However, plasma PLP may be lowered by plasma phosphatase activity (74).

Clinical management generally involves providing pyridoxine in the usual multivitamin dosage unless neuropathy or pyridoxine-responsive anemia has been diagnosed. Because of ataxia due to sensory neuropathy, which has been ascribed to toxicity from as little as 200 mg/day pyridoxine, indiscriminate use of large doses of vitamin must be avoided (81, 82).

Folic Acid. Alcoholics tend to have low folic acid status when they are drinking heavily and their folic acid intake is reduced. For example, a group of unselected alcoholics showed a 37.5% incidence of low serum folate levels and a 17.6% incidence of low red blood cell folate levels (83). More-recent studies correlated low serum and red cell folate levels to increased serum homocysteine levels in alcoholics, implying impaired disposition of the amino acid by transmethylation or transsulfuration (84). In monkeys, folate deficiency can be created by ethanol feeding (50% of total calories) for over 2 years, despite an otherwise adequate diet: hepatic folate is low and there is evidence for decreased folate absorption (85). In pigs fed ethanol for 11 months, folic acid absorption is normal, but jejunal folate hydrolase, an early enzyme of folate polyglutamate breakdown, is decreased (86, 87). In vitro preparations of rat intestine absorb folate less well when exposed to a variety of alcohols (88). Malnourished alcoholics without liver disease also absorb folic acid less well than their better-nourished counterparts (89). Folic acid absorption, usually increased by partial starvation, is increased less in rats when alcohol is ingested (90). It has not been clearly shown, however, that either protein deficiency or alcohol (89, 91) decreases folate absorption in vivo. Thus, it is still unclear what aspects of malnutrition adversely affect folate absorption and under what clinical circumstances alcohol may interfere with folate absorption.

Alcohol accelerates production of megaloblastic anemia in patients with depleted folate stores (92) and suppresses the hematologic response to folic acid in folic acid-depleted patients (93). Alcohol also has other effects on folate metabolism, but their significance is not clear: alcohol given acutely decreases serum folate, which is partly explained by increased urinary excretion (94); alcohol administered chronically to monkeys decreases hepatic folate levels, partly because the liver cannot retain folate (95) and perhaps because of increased urinary and fecal loss (96).

The clinical approach to folate deficiency without anemia is straightforward. A diet providing adequate folate, perhaps with additional folate, repletes stores in a matter of weeks. If malabsorption persists after this period, causes other than folate deficiency should be sought. When the patient is anemic, diagnostic evaluation is more complex (92). In addition to folate deficiency, the direct effect of alcohol on the bone marrow, liver

disease, hypersplenism, bleeding, iron deficiency, infection, and use of anticonvulsants are all commonly encountered and will exert separate and combined influences on the hematologic picture. Remember, first, in well-nourished alcoholics folic acid deficiency is a rare cause of anemia (97), and second, a search for folic acid deficiency (serum or red cell folate levels) to explain anemia is unwarranted unless some or all of the morphologic features of the deficiency are present (macroovalocytes, hypersegmentation of polymorphonuclear leukocytes, megaloblastosis of the bone marrow).

The following sequence has been proposed for development of folic acid deficiency: negative folate balance (serum folate < 3 ng/mL); folate depletion (red blood cell folate < 160 ng/mL, serum folate < 120 ng/mL, neutrophil lobe average > 3.5, liver folate < 1.2 µg/g); folate-deficient anemia (low hemoglobin, elevated mean corpuscular volume, macroovalocytosis) (98). When there is combined iron and folate deficiency, the expression of macrocytosis is modified or a dimorphic red blood cell population may occur. Hypersegmentation of leukocyte nuclei and macroovalocytosis may persist for several weeks after folate replacement is started (92).

Some have proposed adding folate to alcoholic beverages because the taste of the beverage is not altered and vitamin absorption is adequate (99), but this is impermissible “adulteration” of alcoholic beverages under current law.

Vitamin B₁₂. Alcoholics do not commonly get vitamin B₁₂ deficiency. Their serum levels are usually normal even when they are deficient in folate, whether they have cirrhosis (100, 101) or not (89, 90). This is probably due to large body stores of vitamin B₁₂ and reserve capacity for absorption, since several factors in alcoholism would promote vitamin depletion. Pancreatic insufficiency, for example, results in decreased vitamin B₁₂ absorption as measured by the Schilling test, because there is insufficient luminal protease activity and alkalinity, which normally serve to release vitamin B₁₂ from the “R” protein secreted by salivary glands, intestines, and possibly the stomach (102). Alcohol ingestion also decreases vitamin B₁₂ absorption in volunteers after several weeks of intake (103). The alcohol effect may be in the ileum, because coadministration of intrinsic factor or pancreatin does not correct the Schilling test results. Whether the binding of intrinsic factor–vitamin B₁₂ complex to ileal sites is abnormal is controversial (104, 105).

Vitamin C. The vitamin C status of alcoholic patients admitted to a hospital is lower than that of nonalcoholics as measured by serum ascorbic acid, peripheral leukocyte ascorbic acid, or urinary ascorbic acid levels after an oral challenge (106). In addition to a lower mean ascorbic acid level, some 25% of patients with cirrhosis in one study had serum ascorbic acid levels below the range of healthy controls (106). Ascorbic acid status is low in alcoholic patients with and without liver disease. When alcohol intake exceeds 30% of total calories, vitamin C generally falls below recommended dietary allowances (RDAs) (107). Inadequate vitamin C intake provides only a partial explanation for low ascorbic acid status. The clinical significance is unknown for patients who have low ascorbic acid levels but who are not clearly scorbutic. Daily supplementation with 175 to 500 mg of ascorbic acid may be necessary for weeks or

months to restore plasma and urinary ascorbate to normal levels ([106](#)).

Fat-Soluble Vitamins

Vitamin A. The interaction of alcoholism and vitamin A involves the intake, possibly the absorption of the vitamin, and its metabolism; there is evidence that alcohol may modulate the role of vitamin A in hepatotoxicity and carcinogenesis.

Vitamin A ingestion is not significantly below normal for Americans taking up to 400 kcal/day as alcohol (or less than 20% of total calories) ([107](#)), probably because the vitamin A density of the nonalcoholic portion of the diet is similar to that ingested by nonalcoholic populations. Americans taking 24% of total calories as alcohol ingest only 75% of the RDA for vitamin A ([108](#)). Probably those with intense alcoholism (i.e., individuals ingesting 50% or more of daily calories as alcohol) eat even less vitamin A. Chilean wine drinkers, for example, eat only 25% of the RDA for vitamin A when they ingest 150 g (1050 kcal) of alcohol per day ([109](#)). Elderly American men who consume alcohol regularly have a lower vitamin A intake ([110](#)); the mean intake of carotenes for men of all ages consuming over 50 g/day ethanol is lower than that of those drinking less ([111](#)). In a single study, vitamin A absorption was diminished 17% by 120 mL of wine ([112](#)).

Alcohol consumption is associated with raised blood b-carotene levels in both men ([113](#)) and women ([114](#)). Population studies showing lower blood b-carotene levels in drinkers may be explained by the lowering effect of concomitant smoking ([111](#)). Chronic alcoholic pancreatic insufficiency may substantially reduce vitamin A absorption, and the mean plasma vitamin A content is lower for these patients than for normal controls, correlating with the severity of steatorrhea ([115](#)). Low blood b-carotene levels were found in 98% of chronic alcoholics (150 g/day alcohol for 5–25 years) admitted to a hospital despite the lack of clinical signs of vitamin A deficiency ([112](#)).

The effect of short-term ingestion of alcohol on vitamin A blood levels has been variously reported as unchanged in man ([116](#)), increased in dogs ([117](#)), or increased as lipoprotein-bound retinol in rats ([118](#)). Experimental feeding of baboons with alcohol raises their blood b-carotene ([119](#)). Serum and liver levels of carotenoids and retinoids were recently measured in patients with liver diseases of alcoholic and nonalcoholic etiology, normal livers of transplant donors, and sera of normal control subjects ([120](#)). Total retinoids were decreased in the livers of alcoholics and nonalcoholics with liver disease, and decreases were more profound as alcoholic liver disease progressed to cirrhosis. Serum and liver concentrations of a- and b-carotenes were compared, and a substantial number of subjects with low hepatic levels had normal serum levels, suggesting that liver disease impairs the hepatic uptake, excretion, and/or metabolism of these compounds. Impaired conversion of ingested carotenes to hepatic retinoids during alcohol consumption may partially explain the decreased liver retinoid content, especially at advanced stages of alcoholic liver disease when plasma b-carotene is not raised much by carotene feeding ([113](#), [119](#)).

The experimental effect of long-term alcohol consumption on hepatic vitamin A in experimental animals is profound and is consistent with observations in humans:

hepatic vitamin A stores are diminished whether dietary vitamin A is low, normal, or high. Rodents fed alcohol repeatedly in one study had lower hepatic vitamin A (121); 5 g/kg/day yielded a 20% decrease in the liver in another study (122). Higher intakes of alcohol—36% of calories or about 14 g/kg/day—decreased hepatic vitamin A by 60% in 4 to 6 weeks and by 72% in 7 to 9 weeks, without changes in serum vitamin A or retinol-binding protein (RBP) in another study (118). Five times the usual amount of vitamin A did not prevent hepatic depletion by alcohol. When baboons were fed 50% of calories as alcohol, a 60% decrease in hepatic vitamin A occurred after 4 months, and a 95% decrease after 24 to 84 months (118). Hepatic vitamin A levels decrease progressively with increasing severity of lesions to include cirrhosis in humans (Fig. 94.3) (123). Enhancement of hepatic vitamin A degradation due to alcohol consumption is one likely explanation for the drop in vitamin content. Vitamin A degradation by metabolism of retinoic acid to 4-hydroxy and 4-oxoretinoic acids and other polar metabolites is catalyzed by microsomal enzymes induced by ethanol consumption (123), but these enzymes are not active enough to deplete vitamin A stores. A more likely candidate for depleting hepatic vitamin A is a newly discovered microsomal pathway for oxidation of retinol to polar metabolites (124), also inducible by alcohol consumption (125). In addition, alcohol promotes vitamin A mobilization from the liver (125).

Figure 94.3. Hepatic vitamin A levels in subjects with normal livers, chronic persistent hepatitis, and various stages of alcoholic injury. (From Leo MA, Lieber CS. *N Engl J Med* 1982;37:597–601, with permission.)

An important clinical consequence of low tissue vitamin A status is night blindness. A study showed that abnormal dark adaptation occurred in 15% of alcoholics without cirrhosis and in 50% with cirrhosis (126). One can exclude retinal dysfunction with 95% confidence when the serum vitamin A level is 1.4 µmol/L (42.9 IU) or higher (127). The correlation of serum vitamin A with tissue stores is complicated by liver disease and protein deficiency.

The effects of vitamin A status and its related disease are widespread throughout the

body and are in turn affected by ethanol consumption. Hepatotoxicity from diminished vitamin A includes the presence of multivesicular lysosomes and is potentiated by concomitant alcohol intake (128). Hepatotoxicity from increased vitamin A includes fibrosis (129, 130), which is potentiated by concomitant alcohol (131). The squamous metaplasia of rodent trachea due to vitamin A depletion is also enhanced by ethanol (132). Ethanol increases vitamin A in lung and esophagus (133). The role of alcohol in increasing vitamin A content of some tissues while having the opposite effect in others, speeding or altering the conversion of vitamin A to metabolites, probably has important consequences for the hepatotoxicity, fibrosis, and squamous metaplasia described above. Alcohol-mediated alterations of vitamin A status could be relevant to the association of low vitamin A or carotene levels with malignant diseases (133, 134); in a case-control study, mean levels of serum b-carotene and vitamin A were lower in both smokers and drinkers with oropharyngeal squamous cancer than in control patients hospitalized for minor surgical procedures, and protection was noted with increased intake of vitamin C, b-carotene, fruit, vegetables, and fiber (135).

Several factors make vitamin A therapy a complicated affair in the setting of alcoholism: assessment of tissue stores of vitamin A is difficult, vitamin A in high doses is toxic, even usual doses of vitamin A are potentially toxic with continued intake of alcohol (or other microsome-inducing drugs), and monitoring vitamin A hepatotoxicity is difficult in the presence of continued alcohol intake. Replacement with b-carotene was considered less hazardous, but in association with continued alcohol intake, it too shows evidence of hepatotoxicity (119, 136). Vitamin A replacement must therefore be modest for patients who cannot be ensured an alcohol- and drug-free environment. Replacement of vitamin A should be considered for patients who are confirmed to be vitamin deficient and who can be ensured abstinence from alcohol. Night blindness (or abnormal dark adaptation) with low serum vitamin A (<30 µg/dL or <1 µmol/L) may be considered evidence of deficiency. Vitamin A given at 2000 µg/day for several weeks should provide an adequate trial. Especially in the presence of night blindness, a low serum zinc level (<80 µg/dL) should be treated with 600 mg/day ZnSO₄. Considering the interrelationship of vitamin A and zinc metabolism, zinc therapy might also be tried when vitamin A therapy fails to correct night blindness. Documented fat malabsorption should prompt parenteral replacement of vitamin A. These recommendations appear reasonable but are not based on extensive clinical trials.

Vitamin D. Alcoholics have illness related to abnormalities of calcium, phosphorus, and vitamin D homeostasis. They have decreased bone density (137) and bone mass (138), increased susceptibility to fractures (139), and increased osteonecrosis (140). Low blood calcium, phosphorus, and magnesium levels, and low, normal, or high vitamin D₃ levels have been reported, indicating disturbed calcium metabolism (138).

In patients with alcoholic liver disease, vitamin D deficiency probably derives from too little vitamin D substrate, which results from poor dietary intake, malabsorption due to cholestasis or pancreatic insufficiency, and insufficient sunlight. (Vitamin D metabolism is discussed in Chapter 18.) The status of 25-hydroxylation appears adequate, even in advanced liver disease (138, 141, 142), although some disagree (143). The concentration of vitamin D-binding globulin, a protein synthesized in the liver, decreases in alcoholic liver disease (141), but because of its excess binding sites, its

decrease is unlikely to cause 25-OH vitamin D₃ deficiency. Gascon-Barré says that although blood levels of 25-OH vitamin D₃ and 1,25-OH vitamin D₃ may be normal or even elevated in alcoholics, their stores of vitamin D₃ are often depleted, severely so in nutritionally depleted alcoholics (138). Insufficient intake of calcium and phosphorus or decreased calcium absorption in the presence of normal or increased 1,25-OH vitamin D₃ (and parathormone) might accelerate bone loss in alcoholics.

The diagnosis of osteopenia in liver disease may require bone densitometry because other clinical parameters of liver disease correlate poorly with osteopenia (144). Moreover, levels of free 25-OH vitamin D₃ may be normal in liver disease when total levels are low (145). Bone disease in patients with liver disease should be treated by increasing vitamin D₃ intake, ultraviolet light therapy, and correction of fat malabsorption to keep plasma calcium and phosphorus levels normal. Of course abstinence from alcohol is very important.

Vitamin K. Vitamin K deficiency in alcoholism may arise when fat absorption is interrupted by pancreatic insufficiency, biliary obstruction, or intestinal mucosal abnormality secondary to folic acid deficiency. Dietary vitamin K inadequacy is not a likely cause of clinical deficiency unless there is concomitant sterilization of the large gut, a reliable source of the vitamin. Alcohol-induced hepatocyte injury interferes with use of available vitamin K, with a consequent drop in blood levels of clotting factors II, VII, IX, and X, whose syntheses depend on this vitamin. Vitamin K is a cofactor for the microsomal carboxylase that effects posttranslational modification of these proteins, the conversion of glutamic acid (Glu) residues to d-carboxyglutamic acid (Gla) residues, which is necessary for function. Abnormally high levels of inactive factor II (prothrombin) are found in the plasma in the presence of cirrhosis or vitamin K deficiency (146). Vitamin K may be given intramuscularly to test whether hepatocellular dysfunction or lack of availability of vitamin K to the liver is responsible for low levels of vitamin K-dependent clotting factors in the blood (147).

Vitamin E and Selenium. Vitamin E and selenium serve protective roles as antioxidants and interact physiologically (148, 149, 150 and 151). Vitamin E is a powerful antioxidant that prevents peroxidation of cellular and subcellular membrane phospholipids. Selenium is also involved in antioxidant functions and is a component of red blood cell glutathione peroxidase. Vitamin E and selenium function synergistically: vitamin E reduces the selenium requirement, prevents its loss from the body, and maintains it in an active form; selenium spares vitamin E and reduces the requirement for the vitamin (150).

Vitamin E deficiency is not a recognized complication of alcoholism, although patients with chronic alcoholic pancreatitis have a lower vitamin E:total plasma lipid ratio (115). Vitamin E deficiency has occurred in adults with diverse causes of fat malabsorption (148) and primary biliary cirrhosis (152) with clinical manifestations including decreased erythrocyte survival and neurologic disturbances (areflexia, gait disturbance, decreased proprioception and vibratory sensation, and ophthalmoplegia).

When rodents were fed ethanol repeatedly in one study their hepatic vitamin E levels

(measured as α -tocopherol) were low (153); this was accompanied by increased hepatic lipid peroxidation when alcohol was combined with a low-vitamin E diet (154). The mechanism of hepatic vitamin E depletion by ethanol is probably enhanced oxidation of α -tocopherol (α -Toc) to α -tocopherol quinone (α -TQ) in liver microsomes (154). Alcohol-induced liver injury may be mediated, in part, by stress on cellular antioxidant mechanisms interrelated with vitamin E and selenium. Considering the findings in humans with fat malabsorption or severe cholestasis and the evidence of vitamin E depletion by chronic alcohol feeding of experimental animals, there would seem to be great potential for vitamin E deficiency in chronic alcoholics who may combine low vitamin E intake with steatorrhea from chronic pancreatitis or prolonged cholestasis. Indeed, low serum vitamin E levels have been reported in alcoholic patients with pancreatic insufficiency and fat malabsorption (115, 155). Vitamin E supplementation for 1 year to patients with chronic decompensated alcoholic cirrhosis significantly elevated serum vitamin E levels (156).

Selenium metabolism is of great theoretical interest to hepatologists in view of the proposed lipoperoxidative mechanism of drug- and alcohol-induced liver injury (133). Interestingly, serum selenium levels have been recorded as low in the alcoholic, especially in the presence of liver disease, but this may be a consequence of liver injury (133), because other nonalcoholic patients with liver disease also have low levels. Alcohol intake was not found to influence selenium excretion in the urine (157). No recommendation for dietary modifications of vitamin E or selenium intake in alcoholism can yet be made.

Water, Minerals, Electrolytes

Salt and Water Retention of Cirrhosis

Alcoholics with chronic liver disease often have disorders of water and electrolyte balance. Sodium and water retention are clinically apparent as weight gain, peripheral edema, ascites, and pleural effusions. Patients may have respiratory difficulties or umbilical herniation as further complications. Not only is sodium retained avidly, but a water load cannot be excreted normally (158). Low body potassium may result from vomiting, diarrhea, hyperaldosteronism, muscle wasting, renal tubular acidosis, or diuretic therapy. Potassium depletion may contribute to the appearance of renal vein ammonia and may worsen hepatic encephalopathy (159).

The pathogenesis of fluid retention and ascites is complex. At the hepatic level, portal hypertension, hypoalbuminemia, and alteration of lymph flow are important factors for ascites formation (160). Endocrine accompaniments and other phenomena suggest that the body is reacting to a diminished "effective circulating volume" (total blood volume is normal or elevated, but a disproportionately large fraction is sequestered in the splanchnic region) (161). Hyperreninemia, hyperaldosteronemia, and increased blood norepinephrine suggest diminished effective circulating volume. Reversal of salt and water retention by restoration of nonsplanchnic volume via head-out body immersion in water or via peritoneal venous (LeVeen) shunting of ascites suggests sequestration of blood volume in the splanchnic area. Additionally, there may be a relative insufficiency of factors (or insensitivity to such factors) that promote salt loss by the kidneys, such as

atrial natriuretic factor (ANF) ([162](#)), because the ANF level is raised ([163](#), [164](#)) and there is an abnormality of renal hemodynamics based in part on alterations in renal prostaglandins ([162](#)).

Patients with cirrhosis and fluid overload may require urgent relief, as when ascites and pleural effusion are causing respiratory difficulties or when imminent rupture of an umbilical hernia may result in lethal peritonitis. Thoracentesis, paracentesis, or both should be performed promptly. Usually, diuresis may be unhurried once a diagnostic tap has shown the fluid to be noninfected transudate. Treatment is aimed at preventing recurrence of fluid retention. Dietary management combines sodium and water restriction in selected cases of deficient water excretion. It is difficult to provide a palatable diet on a long-term basis with less than 0.5 to 1 g of sodium and 1500 to 2000 mL of total fluid daily. These amounts are recommended with addition of spironolactone, followed, if necessary, by small doses of diuretics (hydrochlorothiazide or furosemide), to achieve an initial daily weight loss of no more than 0.5 kg ([165](#)). More-rapid weight loss is probably safe when the patient has mobilizable peripheral edema and can be observed carefully ([165](#)). Accelerated diuresis risks renal failure. Use of prostaglandin inhibitors such as nonsteroidal antiinflammatory drugs (NSAIDs) carries the potential risk of altering renal hemodynamics and precipitating renal failure. Careful monitoring for development of hypokalemia (or hyperkalemia), hyponatremia, and renal failure is necessary. Recently, periodic large-volume paracenteses have again been used with intravenous fluid and albumin and seem to be as safe as diuretics ([166](#)). For patients in whom a reasonable program of salt and water restriction and diuretic therapy is not successful or for whom periodic paracentesis is cumbersome, a peritoneovenous (LaVeen) shunt may be useful ([167](#), [168](#) and [169](#)). Best results have been obtained for patients without encephalopathy, coagulopathy, or severe jaundice.

Magnesium

Neuromuscular excitability in acute alcohol withdrawal resembles that seen in magnesium deficiency; thus the status of magnesium in alcoholism has been investigated for some time. Acute doses of ethanol cause magnesium loss in the urine ([170](#)), although chronic ethanol feeding does not change urinary magnesium levels ([171](#)). Flink summarized much work in the field to show that alcoholism is associated with magnesium deficiency ([172](#)): alcoholics have low blood magnesium and low body-exchangeable magnesium levels; symptoms in alcoholics resemble those in patients with magnesium deficiency of other causes; alcohol ingestion causes magnesium excretion; upon withdrawal from alcohol, magnesium balance is positive; and hypocalcemia in alcoholics in the setting of magnesium deficiency has been ascribed in part to impaired parathyroid hormone (PTH) secretion as well as renal and skeletal resistance to PTH ([173](#)), and the hypocalcemia may only respond to magnesium repletion. The correlation of magnesium content of blood with that of other tissues and with the severity of clinical symptoms in individual cases is imperfect, although it is statistically obvious among groups. Recently, a group of hospitalized alcoholics with normal serum total magnesium (tMg) levels were found to have significantly lower serum ionized magnesium (iMg) levels ([174](#)). Magnesium replacement should be seriously considered for symptomatic patients with measurably low serum magnesium, for anorectic patients with low serum magnesium, and for hypocalcemic alcoholics who do not respond to calcium replacement. Most alcoholics

replete body stores of magnesium readily from normal dietary sources.

Iron

Iron metabolism is important in alcoholism in that there may be deficiency or there may be excess of iron in the body. The status of transferrin may provide a marker for chronic alcohol consumption. Alcoholics may be iron deficient as a result of the several gastrointestinal lesions to which they are prone that may bleed (esophagitis, esophageal varices, gastritis, and duodenitis). The usual laboratory indicators, red blood cell morphology (with alertness to altered morphology in the presence of folate deficiency), serum iron, and serum iron-binding capacity, are helpful. Iron therapy should be restricted to clearly diagnosed cases of deficiency.

Hepatic iron content is increased in autopsy studies of most patients with early alcoholic cirrhosis (175). Iron overload of the liver was described in Bantus who consumed alcoholic beverages prepared in iron containers that contributed a large amount of elemental iron to their diet. In most alcoholics, the iron content of the liver is normal or only modestly elevated, although there may be stainable iron in reticuloendothelial cells, possibly because of bouts of hemolysis. It is unclear whether increased intestinal absorption of iron because of alcohol (176) or hepatic uptake of iron from serum in established alcoholic liver disease (177) contributes significantly to increased hepatic iron levels. There should be little difficulty in distinguishing the hepatic iron increases of alcoholic liver disease from the much higher amounts characteristic of genetic hemochromatosis, by measuring absolute iron content per gram of liver with upward adjustments for age (178, 179). The contribution hepatic iron may make to liver damage via its role in lipid peroxidation (180) (perhaps in conjunction with the effects of alcohol) and its possible role in promoting fibrogenesis (181) are of great potential significance.

Alcoholism has been reported to result in qualitative changes in transferrin, the serum transport protein for iron: a higher fraction of molecules bear a reduced sialic acid content (182, 183). This provides a useful test for chronic alcohol consumption (184, 185). Synthesis of transferrin is decreased at the stage of alcoholic cirrhosis, as is serum transferrin concentration (186). At the stage of alcoholic fatty liver, the serum transferrin concentration is normal, although catabolic rate and presumably synthesis are both increased (186). The significance of these changes in transferrin is not apparent.

Zinc

Alcoholic cirrhosis is associated with abnormalities of zinc homeostasis, although the clinical implications are uncertain (for discussion of zinc metabolism, see Chapter 11). Patients have low plasma zinc (187), low liver zinc (188), and increased urinary zinc levels (188, 189). Acute ethanol ingestion, however, does not cause zincuria (190). The low zinc content of chronic alcoholics with cirrhosis is attributed to decreased intake and decreased absorption as well as increased urinary excretion. Many Americans have a diet marginal in zinc (191). Alcoholics fall into several of those groups with marginal intake. Interestingly, zinc absorption is low in alcoholic cirrhotics but not in patients with cirrhosis of other causes (192), although cirrhosis of varied etiologies is characterized by

low serum zinc levels ([193](#)). Some instances of night blindness not fully responsive to vitamin A replacement (see [vitamin A](#) discussion) respond to zinc replacement. It is possible that human hypogonadism of alcoholism may involve perturbations of vitamin A and zinc interactions, but this is largely unstudied. Currently, the therapeutic use of zinc in alcoholism is restricted to treatment of night blindness not responsive to vitamin A. Sullivan and his colleagues could not raise serum zinc levels in patients with alcoholic cirrhosis; zinc was increased in the urine ([194](#), [195](#)).

Copper

Hepatic copper content is increased in advanced alcoholic cirrhosis ([175](#)). Elevated serum copper content has been reported in alcoholics independent of the stage of liver disease ([196](#)), but others report normal levels ([195](#)). These findings have no known clinical significance.

Trace Metals

Nickel levels are consistently high in alcoholic liver disease; manganese and chromium are unchanged ([175](#)). Intracellular shifts in trace metals have been described upon acute administration of alcohol ([197](#)). These shifts, with possible effects on organelle function, may be important but are not revealed in measurement of whole organ content. Versieck et al. reported high serum molybdenum levels in patients with acute liver disease ([198](#)); increased levels were not seen in those with cirrhosis. The clinical significance of trace metal changes is obscure, except for the cardiotoxicity ascribed long ago to alcoholic beverages with high cobalt content.

EFFECT OF ETHANOL ON METABOLISM OF CARBOHYDRATES, URIC ACID, LIPIDS, AND PROTEINS

Carbohydrates

The clinical problems of carbohydrate metabolism include hyperglycemia (frequent, but rarely severe or life threatening), hypoglycemia (infrequent, mostly occurring in conjunction with fasting or prolonged poor food intake except in children, but which can be lethal), and disaccharide (mostly lactose) malabsorption.

In large population studies, alcohol intake correlates with hyperglycemia ([198](#)). Except in patients with chronic pancreatitis and endocrine (insulin) insufficiency, there was no ready explanation for this until recently. The suspicion was that ethanol per se impairs glucose tolerance ([199](#), [200](#)), but this was difficult to prove because the elevated insulin levels that accompanied alcohol intake could have reflected insulin resistance due to alcohol or to the augmentation of insulin release that alcohol itself causes ([201](#), [202](#) and [203](#)). Insulin resistance caused by alcohol has now been demonstrated in healthy subjects and in elderly men ([204](#)) by use of the insulin clamp technique in which glucose use is measured during glucose infusions at steady blood glucose and insulin levels ([205](#)).

In the fed state, when liver glycogen is abundant, glycogenolysis supports blood glucose levels. In the fasting state, concomitant metabolism of alcohol interferes with glycogenesis from amino acids and formation of glucose from glycerol, lactate, and galactose, pathways that can support blood glucose (206, 207). An increased NADH:NAD ratio from hepatic metabolism of alcohol is partly responsible for these metabolic changes. Changes in enzyme activities relevant to various metabolic steps of gluconeogenesis (208, 209) and lipogenesis (9) have also been described. Clinically, hypoglycemia must be suspected when an alcohol imbiber exhibits altered mental status (even in the fed state and especially children). Provision of glucose, usually intravenously, is simple and effective.

Monosaccharide malabsorption due to alcohol can be demonstrated experimentally, but as a clinical problem in alcoholics, malabsorption is probably restricted to those with folic acid deficiency. Malabsorption in alcoholics with folic acid deficiency can be documented by the xylose tolerance test (210, 211). Long-term ethanol ingestion depresses intestinal disaccharidase activities (sucrase, maltase, and lactase) (212) and is associated with lactose intolerance (Fig. 94.2 and Fig. 94.4) (47).

Figure 94.4. The effects of chronic alcohol consumption on lowering intestinal lactase activity. Black alcoholics were found to be especially sensitive. (From Perlow W, Baraona E, Lieber CS. *Gastroenterology* 1977;72:680–4, with permission.)

Uric Acid

It is an old observation that drinking alcoholic beverages is associated with precipitation of acute gouty attacks. Hyperuricemia accompanying bouts of intense alcohol intake has occurred in patients without known disorders of uric acid metabolism or renal function (212). An important mechanism of alcoholic hyperuricemia is decreased urinary excretion of uric acid secondary to elevated serum lactate. This is illustrated in data from one patient in Figure 94.5 (213). Lactate is produced in the liver from pyruvate by the action of NADH generated in the metabolism of ethanol by alcohol dehydrogenase.

Depending on the metabolic state of the liver, NADH generation either enhances hepatic lactate production or prevents the liver from completing the Cori cycle and using lactate originating in peripheral tissues, especially lactate produced from muscle activity during alcohol withdrawal (214). Alcohol-associated ketosis or starvation may also provoke hyperuricemia. The renal mechanism neither depends on urinary pH (212) nor is abolished by probenecid (215): it remains unexplained.

Figure 94.5. Effect of oral ethanol on blood and urine uric acid and lactate. (From Lieber CS, Jones DP, Losowsky MS, et al. J Clin Invest 1962;41:1863, with permission.)

Increased urate production partly due to increased adenosine nucleotide turnover has caused hyperuricemia in gouty volunteers (95). Urinary urate clearance was increased and urinary urate and oxypurines were higher in the study. This mechanism was demonstrated at lower blood alcohol levels than those in the lactate-related renal mechanism study, and blood alcohol levels were also lower than those usually seen in patients with alcoholic hyperuricemia.

The purine content (guanosine) of some beers may contribute to hyperuricemia and gout in alcoholic subjects (216). Patients with gout should refrain from significant alcohol intake, especially of purine-containing beers. The hyperuricemia encountered in the recent drinker should be observed during several days to a week of abstinence to allow alcoholic hyperuricemia to recede; a costly workup for other causes of hyperuricemia may thus be avoided.

Lipids, Fatty Liver, Hyperlipidemia, Ketoacidosis

Alcohol ingestion is associated with fatty infiltration of the liver, hyperlipidemia, and ketosis, each of which is largely explained by the effects that alcohol has on lipid metabolism (217). Fatty liver contains triglycerides with fatty acids derived from dietary sources, when available, but endogenously synthesized ones when dietary fatty acids are not available. High-fat diets increase the amount of fat that accumulates. Low-fat diets, high-protein diets, and even hypocaloric diets lessen the amount of fat that

accumulates because of alcohol but do not completely prevent fatty liver. Dietary fat composed of medium-chain-length triglycerides causes less hepatic fat accumulation than fat containing triglycerides of long-chain fatty acids. The increased NADH:NAD ratio resulting from oxidation of alcohol to acetaldehyde by ADH reduces NAD availability for fatty acid oxidation via the citric acid cycle and thus depresses fatty acid oxidation. Structural damage to mitochondria inhibits oxidation of 2-carbon fragments from all sources. The major pathway of fatty acid synthesis in the cytosol is not increased. Fatty acid elongation by mitochondria is stimulated, probably by the increased NADH:NAD ratio. Glycerolipid synthesis increases because of the greater availability of fatty acids (as described above), the conversion of dihydroxyacetone phosphate to glycerol-3-phosphate favored by the increased NADH:NAD ratio, and possibly the increased capacity of lipid-synthesizing mechanisms. Activity of the rate-limiting enzyme, phosphatidate phosphohydrolase, which removes phosphorus from phosphatidic acid to form diacylglycerol, and of diacylglycerol acyl transferase, which catalyzes the formation of triglycerides increases. These enzymes are present in both endoplasmic reticulum and cytosol.

Administration of ethanol to man consistently results in hyperlipidemia; the extent is modified by associated dietary and pathologic conditions. The major increase occurs in serum triglycerides, with some cholesterol elevation; the involved lipoproteins are very low density lipoproteins (VLDLs) and chylomicrons, dietary particles formed by the intestines (Fig. 94.6). High-density lipoproteins (HDLs) are also increased by ethanol. Alcoholic hyperlipidemia is usually classified as type IV according to the International Classification of Hyperlipidemias and Hyperlipoproteinemias because it is composed mostly of VLDLs, but it may be classified as type V when chylomicrons are also present. About 6% of alcoholics have type II hyperlipidemia, hypercholesterolemia due to an increase in low-density lipoproteins (LDLs). Alcohol-induced hyperlipidemia may change rapidly in composition when clearing, because triglycerides are cleared more rapidly than cholesterol and phospholipids. The postprandial hyperlipidemia is greatly exaggerated by fat-containing meals (118). When alcohol is administered for several weeks at a dosage of 300 g/day, the initial several fold increase in triglycerides gradually returns to normal (219). This may be due to liver damage or increased lipoprotein lipase activity. Hyperlipidemia is usually absent with severe liver injury (e.g., cirrhosis), and hypolipemia may be present (220, 221 and 222).

Figure 94.6. Serum lipids in the alcoholic and the effect of withdrawal from ethanol.

Lipid fractions decrease at varying rates. (From Losowsky MS, Jones DP, Davidson CS, et al. Am J Med 1963;35:794, with permission.)

Some patients may have marked hyperlipemia during alcohol ingestion. This most likely represents an underlying genetic defect in lipid metabolism, in addition to the effects of alcohol, such as hyperchylomicronemia (type I) due to decreased postheparin lipoprotein lipase activity (213), carbohydrate-sensitive hyperlipidemia (223), diabetes, obesity, or pancreatitis.

Treatment of alcohol-induced hyperlipidemia consists of abstinence from alcohol and provision of a normal diet. A low-fat diet is unpalatable, may lead to inadequate energy intake (224), and is not usually necessary. The lipemia should rapidly disappear. Associated factors such as obesity and diabetes should be appropriately treated. Persistent hyperlipemia requires investigation for genetic or other causes not related to alcohol.

Moderate alcohol intake is associated with an increase in the fasting levels of a species of HDL-cholesterol (HDL₃) whose significance regarding risk for heart disease, unlike that for HDL₂, has not been fully established. Male red wine drinkers (46 g/kg/day of ethanol) tended to have elevated serum apolipoprotein A1 (225). Alcohol withdrawal led to a rapid decrease in both apo A1 and HDL₃ (226). Therefore, it is not clear whether any decreased risk for coronary heart disease associated with moderate alcohol intake can be explained by increased levels of HDL due to alcohol. HDL₂ increases with more substantial alcohol intake, but this level of intake is not cardioprotective and may even be deleterious (227). There are other possible mechanisms for a coronary protective effect of ethanol, in addition to its effect on HDL₃. Modest ethanol intake is associated with enhanced fibrinolysis via its effect on plasma concentration of plasminogen activator (228). Platelet aggregation is decreased by an acetaldehyde-mediated increase in prostacyclins (229) and by congeners in wine (230). However, there may be factors other than the alcoholic beverages which are responsible for the coronary-protective effect observed in modest drinkers, since apparent protection has been noted in people taking only one drink per day (231) or per month (232).

Alcohol intake is often accompanied by ketosis with minimal or absent acidosis. The blood glucose level is usually normal (233). The extent of ketosis will be underestimated unless care is taken to measure b-hydroxybutyrate in addition to acetoacetate, more common with diabetic ketosis. Abstinence from alcohol and a return to normal diet is usually the only required treatment. Fluid and electrolytes may be given. Insulin is usually not required.

Protein

Ethanol per se, measured as nitrogen balance, is nitrogen sparing when given as additional calories but increases urinary urea when given as an isocaloric substitute for

carbohydrate (234, 235). Ethanol interferes with amino acid absorption in the gut in many experimental paradigms (see above), but the ultimate nutritional consequences are unknown because gross malabsorption of protein has not been demonstrated. An increase in urea nitrogen could represent protein that has escaped small bowel absorption, has been converted to ammonia in the colon, and subsequently has been converted to urea by the liver (235). Other explanations include protein catabolism in the heart (233), gastrointestinal tract (232), and other organs. As reviewed elsewhere (133), ethanol given in single doses impairs hepatic amino acid uptake, decreases gluconeogenesis, decreases leucine oxidation (234), increases serum branched-chain amino acids, and impairs synthesis of lipoproteins (236), albumin (237, 238, 239 and 240), and fibrinogen (234). Given over time, ethanol causes impaired protein secretion from the liver, probably related to alterations in microtubules and retention of proteins in enlarged hepatocytes (241). The importance of these effects on the hepatotoxicity of ethanol is being studied. Manipulation of dietary protein is not suggested during active alcoholism. The alterations in intermediary metabolism, including amino acids and nitrogen, in established cirrhosis and the implications for diet therapy are dealt with in Chapter 74.

EFFECTS OF DIETARY FACTORS ON ETHANOL METABOLISM

Alcohol is metabolized to acetaldehyde predominantly by ADH, a cytosolic enzyme, and also by the MEOS found in the endoplasmic reticulum. ADH is considered by some to be rate limiting for oxidation of ethanol (242). Low-protein diets reduce hepatic ADH in rats (243) and lower ethanol oxidation rates in rats (243) and in man (244). Prolonged fasting also decreases ethanol oxidation rates, as shown in isolated rat liver cells. A mechanism for lowered metabolism of ethanol during fasting is the lack of available metabolites to shuttle reducing equivalents from ethanol oxidation into mitochondria (245). For a given alcohol intake, malnourished alcoholics may develop higher blood alcohol levels and sustain them longer than normally nourished individuals (246), with possible deleterious consequences. An additional isozyme of ADH, s ADH, exists in the stomach and contributes to the metabolism of ethanol before it reaches the portal circulation and the liver (247, 248). Gastric ADH is lower in women (249), allowing higher blood alcohol levels for similar alcohol ingestion occurring in men. Gastric ADH is also inhibited by the histamine H₂-receptor antagonist cimetidine taken orally.

A study showed that MEOS activity in the liver showed greater induction with a normal diet than with a low-fat diet in rats, although induction of the P450E1 specific for ethanol metabolism was the same (250).

ALCOHOL, NUTRITION, AND ORGAN DAMAGE IN THE ALCOHOLIC

Liver

The role of nutrition in the pathogenesis of alcoholic liver injury (fatty liver, hepatitis, and cirrhosis) has been investigated from the perspectives of epidemiology, clinical therapeutic trials, and animal experimentation: the direct toxic effect of ethanol in each

case was considered.

Malnutrition was previously thought to be important for development of alcoholic fatty liver: fatty liver is present in protein deficiency, particularly in children with kwashiorkor; a highly visible subset of alcoholics with fatty liver is malnourished (the “skid row” denizens); and rodents could readily be given fatty livers when subjected to diets deficient in lipotropes (see [Chapter 73](#)). Our current understanding is that alcohol per se, given in sufficient quantities, can cause fatty liver in man (and lower animals) despite an otherwise adequate diet ([251](#), [252](#), [253](#), [254](#) and [255](#)). The lipid and protein composition of the diet modulates the amount and types of fat that accumulate in the liver. Reduction of dietary fat to 10% of total calories (but not lower) greatly lessens, but does not completely eliminate, hepatic fat accumulation. Fatty acids of the dietary chain length accumulate in the liver when available; otherwise, endogenously synthesized fatty acids deposit. Long-chain fatty acids in the diet have a greater tendency than medium-chain fatty acids to promote fatty liver in the presence of ethanol. However, providing more dietary protein than is usually recommended (25% of total calories) does not eliminate hepatic fat accumulation. The amount of fat accumulating in the ethanol-induced fatty liver is only one parameter of damage, and it must be considered along with organelle dysfunction and metabolic imbalances.

Lipotrope deficiency (choline and methionine) can cause fatty liver in rats ([256](#)), so attention was first directed toward the possible relevance of such deficiency for human alcoholic liver disease. However, there is no evidence that dietary choline deficiency causes human liver disease or is a part of ethanol-induced liver disease (see [Chapter 73](#)). Additionally, choline therapy is not effective when alcohol intake is continued ([252](#), [252](#), [254](#), [255](#) and [256](#)). The difference in susceptibility to choline deficiency between rats and man is not surprising in view of the low choline oxidase activity in human liver.

The inappropriateness of extrapolating choline deficiency data in experimental animals to human alcoholic liver disease is also manifested by the differences between choline deficiency and ethanol-induced liver injury. The lesions differ ultrastructurally ([257](#)), in the levels of hepatic carnitine with which they are associated (increased with ethanol [[258](#)] and decreased with choline deficiency [[259](#)]), in their response to orotic acid supplementation ([260](#)), and in the decreased lipoprotein production and serum lipoproteins in choline deficiency ([261](#), [262](#)) and the opposite changes with alcohol ([263](#)). Even in rats, choline supplementation failed to fully prevent ethanol-induced lesions ([264](#), [265](#)). Dietary supplementation with choline, at times to extraordinary levels, did not prevent ethanol-induced fatty liver, fibrosis, and ultrastructural lesions ([266](#)) in nonhuman primates and was associated with hepatotoxicity of its own at high levels. Side effects such as nausea, vomiting, salivation, sweating, and anorexia have been noted with choline supplementation ([267](#)).

The role of nutrition in the pathogenesis of alcoholic hepatitis has been studied in much less detail. It is considered too severe to be induced in volunteers.

Alcoholic cirrhosis was directly linked to the intensity of ethanol consumption by its drop in the United States during the Prohibition Era and during World War II when alcoholic beverages were rationed ([268](#), [269](#)). The studies of Lelbach also show the direct

influence of intensity of alcohol consumption (g/kg/day × years) on the incidence of chronic liver disease in patients admitted to alcohol rehabilitation spas in Europe (270). Neither the beverage source of ethanol nor concomitant malnutrition was noted to be an influence. These findings have been confirmed (271). The implied direct effect of ethanol in causing hepatic fibrosis and cirrhosis has been demonstrated in the baboon model of hepatic injury (272, 273 and 274).

The direct hepatotoxic effect of ethanol has been shown histologically (by light and electron microscopy) and biochemically in both alcoholics and nonalcoholics, regardless of dietary variation in fat, protein, vitamins, and lipotropes (275, 276, 277, 278 and 279). The mechanisms of ethanol-related cell injury includes alteration of the NADH:NAD ratio (a consequence of ethanol oxidation), alterations of calcium flux, and lipid peroxidation. Ethanol intake may influence lipid peroxidation via its induction of enzyme activities in the endoplasmic reticulum. Interactions of ethanol with selenium, iron, and copper, each of which is related to cellular control of peroxidation, are under study and have been reviewed (280). Dietary imbalances are not inferred, and dietary manipulations are not warranted from these very preliminary studies, except for such special circumstances as iron overload.

The role of nutrition in recovery from alcoholic liver injury was studied by clinicians before the pathogenesis of the injury was understood. Patek et al. (281, 282) and Morrison (283) demonstrated the efficacy of a normal-protein, normal-fat, vitamin-enriched diet in treatment of cirrhosis, as measured by clinical response and longevity. Erenoglu et al., extending previous work, treated cirrhotic patients with 198 mL of absolute ethanol daily and an adequate diet; they found no adverse effects and a possible benefit from higher dietary protein (284). This alcohol intake is much below the amount many alcoholics ingest spontaneously. In view of the current appreciation of the direct toxicity of ethanol and inability of most alcoholics to limit their alcohol intake, strict abstinence from alcohol is recommended.

The significance of congeners (285), moderate dosages of alcohol, genetic factors, and marginal nutritional deficiencies in alcohol-related tissue injury and in the recovery phase is under study. There is no established prophylactic regimen except abstinence. As discussed above, our best evidence indicates that acute liver damage consistently occurs if sufficient alcohol is ingested and cannot be prevented by a nutritious diet. There probably are safe levels of intake, although they have not been carefully established clinically. In any case, alcoholics are not usually able to confine their drinking to lower levels. Chronic liver injury from alcohol also appears to be dose and time related, with no indication that dietary manipulation will afford prevention. Patients with precursor lesions, such as perivenular fibrosis (280), require special attention, but the treatment approach is still mainly abstinence. Efforts to define populations with varying degrees of susceptibility to ethanol-induced liver disease on the basis of genetics or viral exposure have not been convincing; however, females are more susceptible than males (286, 287). We cannot advise a different approach for any group. Nutritional treatment of cirrhosis and its complications is described in [Chapter 74](#).

Stroke

The incidence of stroke is strongly associated with advancing age, black race, obesity, and hypertension. Moderate-to-heavy alcohol consumption, over 45 g/day, was identified as an independent predictor of stroke after the increased risk due to hypertension and cigarette smoking were accounted for (288). A review of most of the English language literature concludes that moderate alcohol intake (<60 g/day) has a complex association with ischemic stroke in white populations (very low levels are possibly protective and higher levels are definitely deleterious) but little, if any, association in Japanese populations; by contrast, moderate drinking increases hemorrhagic stroke (intracerebral and subarachnoid hemorrhage) in diverse populations (289). Alcohol consumption may contribute to stroke by raising blood pressure to hypertensive levels as shown by most (32, 290, 291 and 292), but not all (293), studies. Sodium intake and phosphorus intake were also positively identified as nutrient predictors of hypertension (32). Some authors have detected an immediacy of alcohol intake just prior to stroke (294) (although others have not [290]), which points to acute alcohol-induced changes that might precipitate stroke (295). If true, this finding is encouraging in that abstinence might yield early benefits.

Heart

Acute and chronic alcohol consumption affects the heart in some ways that are understood and in others that are obscure. The acute effects of even small amounts of hard liquor (several ounces) include measurable myocardial depression (296), a dose-dependent impairment of left ventricular emptying at rest (297), and such electrophysiologic effects as slight delay in atrial conduction and shortening of both the atrioventricular conduction time and the effective ventricular myocardial refractory period (298). These usually are not clinically apparent in people with normal hearts, especially because the impaired left ventricular emptying disappears with exercise (297). Patients with angina pectoris, even with congestive failure, have responses in left ventricular performance similar to those seen in controls at blood alcohol levels of 100 mg/dL (309). Patients with myocardial ischemia may experience an unfavorable distribution of coronary blood flow away from ischemic areas (299). The result of alcohol intake is thus not always predictable because it depends on the relative influence of alcohol on peripheral vasodilatation, coronary blood flow, direct myocardial depression, electrophysiologic changes, and the underlying cardiac reserve (300). Patients with chronic alcoholism or heart disease (300) and even normal nonalcoholic patients may develop atrial arrhythmias after substantial acute alcohol ingestion (301, 302).

Chronic alcohol consumption may result in heart disease by its association with hypertension, as discussed above in relation to stroke, or by its association with severe thiamin deficiency in the beriberi heart syndrome. Alcohol intake is associated with elevated serum homocysteine levels, as discussed in the sections on folic acid and the metabolism of one-carbon fragments. Elevated serum homocysteine levels have been linked to premature vascular disease (see Chapter 34 and Chapter 74). The relevance of alcohol-induced changes in serum HDL-cholesterol to the appearance of heart disease is not established (see above discussion of lipemia). Most epidemiologic studies of alcohol intake and either coronary artery disease or, more usually, total cardiac death rate, show a U-shaped relationship, with increased disease in abstainers,

the lowest incidence in moderate drinkers (1 to 2 ounces of hard liquor or the equivalent per day), and the greatest incidence in those who consume larger amounts of alcohol. These results were found in the Hawaiian study (303), the Milwaukee study (304), and a study of the elderly in Massachusetts (305), but not clearly in the Albany experience (306). A prospective cohort study of 85,000 women demonstrated a similarly decreased mortality associated with very low alcohol intake compared with either abstainers or those using alcohol more heavily (307). Very low alcohol intake, 1.5 to 4.9 g/day or 1 to 3 drinks per week, was associated with the lowest mortality, but the “protective” effect was sustained up to 29 g or 2 drinks per day. Decreased mortality associated with alcohol intake reflected diminished fatal cardiovascular disease and occurred in those over 50 years of age and at risk for cardiovascular disease; younger women drinking similar amounts experienced increased mortality from external injury.

A fairly characteristic syndrome known as alcoholic cardiomyopathy has been described in a subset of these individuals with alcoholism and heart disease. It is a congestive cardiomyopathy seen typically in men aged 30 to 55 years who have been drinking 30 to 50% of calories as alcohol for 10 to 15 years (300). Arrhythmias are frequent. Coronary artery disease, hypertension, valvular abnormalities, and congenital heart disease must be excluded before the diagnosis of this disorder is made. Treatment with rest, diuretics, and abstention from alcohol may yield dramatic improvement (308, 309) but many times does not.

Blood and Bone Marrow

In addition to the anemias due to blood loss and folic acid deficiency discussed above, alcohol has direct or at least unexplained effects on the blood elements. Alcohol ingestion is associated with vacuolization of erythroid precursors, which is not prevented by adequate diet and pharmacologic doses of folic acid (310). Alcohol ingestion also causes granulocytopenia (probably mediated by nutritional inadequacy [310]), thrombocytopenia, and impaired platelet function (311, 312), which are partly attributed to direct effects because they are not mediated by folic acid or other identifiable nutritional deficiencies.

NUTRITIONAL THERAPY IN ALCOHOLISM

Nutritional therapy in alcoholism is directed at preventing illness due to alcoholism, treating documented or presumed deficiencies, and managing complications of alcoholism. As discussed above, individuals consuming over 30% of total calories as alcohol have a high probability of ingesting less than the recommended daily amounts of carbohydrate, protein, fat, vitamins A, C, and B (especially thiamin), and minerals such as calcium and iron. It is sensible to recommend a complete diet comparable to that of nonalcoholics to forestall deficiency syndromes, although this will not prevent some organ damage due to direct toxicity of alcohol (e.g., alcoholic liver disease). The feasibility and desirability of adding thiamin and perhaps folic acid to alcoholic beverages has been discussed previously but has not been done.

Management of observed deficiencies of protein and calories is straightforward in the absence of organ damage. The treatment of gross malnutrition of proteins and calories

in the context of severe acute and chronic liver disease is discussed in [Chapter 74](#). Nervous system damage due to thiamin lack is serious and treatable with a great margin of safety; therefore thiamin deficiency should be presumed if not definitely disproved. Parenteral therapy with 50 mg of thiamin per day should be given until similar doses can be taken by mouth. Riboflavin and pyridoxine should be routinely given at the dosages usually contained in standard multivitamin preparations. Adequate folic acid replacement can be accomplished with the usual hospital diet. Additional replacement is optional unless deficiency is severe. Vitamin A replacement should only be given for well-documented deficiency and to patients whose abstinence from alcohol is ensured (see the above discussion on hepatotoxicity of hypervitaminosis A with alcohol). Vitamin A at doses of 2000 to 3000 µg/day may then be given. Zinc replacement should be given for night blindness unresponsive to vitamin A replacement. Magnesium replacement is recommended for symptomatic patients with low serum magnesium levels. Iron deficiency that has been clearly diagnosed may be corrected in the usual manner orally. Wernicke-Korsakoff syndrome requires at least 50 mg of thiamin daily (parenterally if necessary) for prolonged periods. Beriberi heart failure responds quickly to thiamin. Peripheral nerve damage necessitates months or years of vitamin B therapy. Acute pancreatitis may require withholding oral feeding for prolonged periods, during which time central venous alimentation must be given. Chronic pancreatic exocrine insufficiency is treated by dietary manipulation (often decreases in fat) with oral pancreatic enzymes at mealtime. The nutritional management of acute and chronic liver disease due to alcoholism aims to define feeding programs to reverse malnutrition, ameliorate liver disease, and decrease mortality, without promoting hepatic encephalopathy (see [Chapter 74](#)).

Nutritional deficiencies may result in a variety of disorders that affect either the peripheral nervous system (PNS) or central nervous system (CNS). More commonly, both the CNS and PNS are affected simultaneously. Nutritional diseases of the nervous system have been carefully studied for more than 100 years, and many that were common in the last century now occur infrequently in developed countries. In the 1800s, beriberi occurred in epidemic proportions throughout the world. Similarly, pellagra was once common in the southern United States, but since 1940 the incidence has greatly diminished as a result of supplementing bread with niacin as well as major improvements in the overall diet of the affected population. In some Third World countries, pellagra and beriberi remain common, and these as well as other nutritional deficiencies continue to be a major cause of disease. In contrast, developed countries may encounter a different set of nutritional deficiencies, most often related to alcohol abuse, dietary habits, and impaired absorption of dietary nutrients secondary to intestinal malabsorption syndromes.

PATHOPHYSIOLOGY OF DEFICIENCIES ON THE NERVOUS SYSTEM

Nutritional deficiencies may have a wide variety of effects on both the CNS and PNS (1). Clinical manifestations of vitamin deficiency states may include neuropathy, visual disturbances, or disorders of the spinal cord leading to spastic quadriplegia with disturbances of bowel and bladder function. Other manifestations may include memory loss, dementia, ataxia, coma, and death, depending on the nutritional deficiency. Other deficiency states (e.g., folic acid) may lead to a rise in homocysteine levels that may be associated with increased risk of stroke and other vascular diseases (2). All of the nutritional deficiency states are treatable, and morbidity can be greatly reduced with early recognition and treatment.

Just as deficiency states can produce neurologic dysfunction, excess ingestion of nutrients may also cause nervous system dysfunction. For example, excess pyridoxine intake can be associated with a peripheral neuropathy resulting in severe irreversible ataxia, and excess intake of vitamin A may be associated with pseudotumor cerebri (benign intracranial hypertension) as well as irritability and lethargy.

Most deficiency states affect both the CNS and PNS but may vary in the degree to which they affect different cellular elements. This is a major determinant of the manifestations of the particular nutritional deficiency or, more commonly, constellation of nutritional deficiencies. Cellular elements most commonly affected by nutritional deficiency include the neuron itself and the myelin sheath. In the CNS, the myelin is formed by oligodendrocytes. In the periphery, myelin is formed by Schwann cells. Myelin acts as an insulator along the axon and allows the axon to conduct impulses at very rapid rates in both the PNS and CNS. In vitamin B₁₂ deficiency, both CNS and PNS myelin degenerates, resulting in a host of clinical features including neuropathy, myelopathy, dementia, megaloblastic anemia, and behavioral abnormalities.

In deficiency states that affect the neuron, the axon usually shows the first signs of damage and will be most severely affected. The distal ends of longer axons are affected first, since they are most susceptible to nutritional deprivation. The result is a dying-back neuropathy in which the distal ends of the peripheral nerves slowly degenerate. Hence the PNS will be the major site of damage. With continued deprivation the process moves toward the cell body. This type of neuropathic process usually affects the largest and longest myelinated fibers as well as smaller unmyelinated neurons. There may be axonal degeneration as well as demyelination. The usual manifestation is a painful distal neuropathy in which the patient experiences loss of proprioception, touch, temperature, and pain. There is often a sensation of burning in the feet and a hypersensitivity to touch (hyperpathia). This can be extremely painful, and any contact with the affected extremity may be perceived as unpleasant and painful. With continued deprivation of the nutrient (most commonly thiamin), the pathologic process moves closer to the cell body, and the symptoms move proximally. Sensory loss worsens, and weakness may develop with continued damage to the neuron.

The prototypic nutritional polyneuropathy affecting the PNS is dry beriberi (alcoholic nutritional polyneuropathy). This disorder occurs commonly in well-developed countries

and is usually seen in alcoholic patients. As with other nutritional deficiency states, this rarely occurs in its pure form as thiamin deficiency alone but is usually associated with other nutritional deficiency states.

Nutritional deficiencies rarely occur in isolation, and this may complicate neurologic syndromes resulting from vitamin deficiency. Far more commonly, deficiency states involve a variety of different vitamins and nutrients. The reasons for this become clear when the most common causes of nutritional deficiencies are considered. In developed countries, the most common cause of nutritional deficiency is alcoholism (see [Chapter 94](#)). In severe alcoholics, caloric intake consists largely of alcohol and carbohydrate. In addition, intestinal malabsorption may further compromise the nutritional state of the individual. The result is a polydeficiency state. The same holds true for malabsorption syndromes due to intestinal disease and to surgical procedures involving the gastrointestinal tract. Peculiarities of diet may have the same consequences. In individuals with borderline deficiency states, fully developed clinical disease may be brought about by stress associated with chronic infection, hyperemesis of pregnancy, or other acute illnesses such as trauma. Again, recognition is of great importance because irreversible neurologic damage due to vitamin deficiency can be easily prevented.

NEUROLOGIC DISORDERS ASSOCIATED WITH VITAMIN DEFICIENCY

Wernicke-Korsakoff Syndrome

In the category of neurologic disorders associated with vitamin deficiency, two entities should actually be considered together, Wernicke encephalopathy and Korsakoff psychosis. Wernicke disease refers to a neurologic disorder characterized by nystagmus, ataxia, confusion, paralysis of the abducens nerve, and other disorders of conjugate gaze ([3](#)). Korsakoff psychosis refers more specifically to an amnesic state in which there is severe impairment of short-term memory and confabulation. Korsakoff psychosis may be seen in association with other disorders of the nervous system, whereas Wernicke disease is specific to thiamin deficiency. Nevertheless, they often occur together in the setting of thiamin deficiency seen in alcoholism and other states of nutritional deprivation in which reserves of thiamin are exhausted. Wernicke-Korsakoff syndrome remains very common in both developed and underdeveloped countries ([4](#)). Furthermore, recognition of the setting in which this disorder may occur is the key to its prevention in those cases in which it has not progressed to enough to cause irreversible damage to the nervous system.

Wernicke-Korsakoff syndrome may be seen in any malnourished individual including elderly patients, particularly those with chronic illnesses predisposing to malnutrition ([5](#)). [Table 95.1](#) lists common causes of nonalcoholic Wernicke-Korsakoff syndrome ([6](#)). In the hospital setting, Wernicke-Korsakoff syndrome can be precipitated in those with borderline thiamin deficiency by administration of intravenous fluid containing dextrose. Since metabolism of sugars and carbohydrates requires thiamin as a cofactor, the frank deficiency state can be precipitated with dextrose. This is particularly true in the emergency room setting where chronic, poorly nourished alcoholics may be brought for treatment of a variety of illnesses. In addition, thiamin is unstable in parenteral nutrient fluids containing amino acids with bisulfite, and storage time should be limited (see

[Chapter 101](#)).

Prolonged intravenous feeding with inadequate thiamin
Prolonged fasting
Anorexia nervosa
Refeeding after starvation
Gastric plication

Adapted from Reuler JB, Grad DE, Gooney TG. *N Engl J Med* 1985;312:1105-9

Table 95.1 Nonalcoholic Conditions Associated with Thiamin Deficiency

Despite the contention of some authors that Wernicke-Korsakoff is uncommon, pathologic changes of Wernicke-Korsakoff were seen in about 2.2% of 3548 random autopsies (77 cases) (7). If this is representative of the entire country, this may represent a very large number of patients. Furthermore, only 20% of cases may be recognized during life (8). Only 16% of patients exhibit the classic triad of ophthalmoplegia, gait ataxia, and confusion, and as many as 19% may have no clinical signs. Nevertheless, pathologic examination of these patients shows clear evidence of Wernicke-Korsakoff syndrome. This suggests that Wernicke-Korsakoff syndrome is underrecognized in both alcoholic and other malnourished patients. Wernicke-Korsakoff syndrome may be gradual or have sudden onset. Again, the classic triad of eye movement abnormalities, ataxia, and a global confusional state is not consistently seen (9). Other symptoms may be present including hypotension, hypothermia, cardiac failure, and coma (10, 11).

Wernicke-Korsakoff syndrome is the result of thiamin deficiency and is probably not due to any direct effect of alcohol on the CNS (4). Alcohol interferes with active transport of thiamin across the intestinal epithelium, and formation of thiamin pyrophosphate from thiamin is decreased in severe liver disease (12, 13). In addition, the diseased liver may have a decreased capacity to store thiamin. Thiamin as thiamin pyrophosphate is a coenzyme for transketolase and pyruvate decarboxylase; transketolase is involved in the pentose phosphate shunt and pyruvate decarboxylase is involved in the tricarboxylic acid cycle, which suggests that depletion of thiamin may result in impaired CNS glucose metabolism (14, 15) (see also [Chapter 21](#)).

The neuropathologic appearance of Wernicke-Korsakoff disease is necrosis of both neuronal and oligodendroglial elements in the mammillary bodies, superior cerebellar vermis, and hypothalamus (16). Petechial hemorrhages are frequently seen in the mammillary bodies and periaqueductal gray (4). In addition, there may be involvement

of the third and sixth nerve nuclei as well as the vestibular nuclei, accounting for the oculomotor palsies and nystagmus. In alcoholic cerebellar degeneration there are very similar pathologic changes, suggesting that it may also be related to thiamin deficiency (17).

Early on, the encephalopathic state is potentially reversible, and because of the risk of cardiac failure and sudden death, Wernicke-Korsakoff should be considered a neurologic emergency. Often the presenting symptoms of Wernicke-Korsakoff syndrome are stupor or coma. In one study, of 28 neuropathologically active cases, the diagnosis was made during life in only one instance (18). Suspected Wernicke-Korsakoff syndrome should be treated with 100 mg of thiamin given intravenously before starting dextrose infusion and periodically thereafter. The ocular manifestations of Wernicke-Korsakoff syndrome may begin to resolve as early as 6 hours after administration of thiamin. The ataxia and the confusional state may also improve rapidly following thiamin administration, but memory deficits are likely to persist.

Alcoholic beverages are not supplemented with thiamin. Though not all cases of Wernicke-Korsakoff syndrome are related to alcohol abuse and coexistent malnutrition, addition of thiamin to alcoholic beverages might go a long way toward prevention of this disorder.

Alcoholic Cerebellar Degeneration

Although alcoholic cerebellar degeneration has not been historically regarded as a vitamin deficiency state, indirect evidence suggests that it may be related to thiamin deficiency (19). Furthermore, it has been suggested to result from the same process as Wernicke-Korsakoff syndrome. This syndrome is usually seen in undernourished alcoholic patients following prolonged nutritional deprivation and weight loss. It has also been observed in nutritionally deprived nonalcoholics (6). Onset may be acute or subacute with stepwise progression. This disorder usually presents with wide-based gait and truncal ataxia. The upper extremities are frequently spared. Pathologically, there is severe atrophy of the anterior and posterior cerebellar vermis. Further research may help clarify the role of nutrition in this disorder.

Nutritional Polyneuropathy of Alcoholism

Another manifestation of poor nutritional status often associated with chronic alcohol abuse is nutritional polyneuropathy. While this disorder is considered to be primarily due to thiamin deficiency, other nutrients may also be involved (20, 21, 22, 23 and 24). Almost all patients with Wernicke-Korsakoff syndrome have a coexisting polyneuropathy. The converse is not true; many patients with nutritional polyneuropathy may have no evidence of Wernicke-Korsakoff syndrome. In addition, alcohol toxicity may have a more direct role in this neuropathy, as it has been reported in well-nourished alcoholics (21, 22). Although this neuropathy is generally uncommon in routine clinical practice, it is more frequent in inner-city hospitals where poor nutrition in alcoholics is common. As a result, nutritional polyneuropathy is among the most frequently encountered nutritional disorders of the nervous system.

Nutritional polyneuropathy related to alcoholism is a mixed sensory motor polyneuropathy that is symmetric in distribution. Initial manifestations include paresthesias and numbness of the distal lower extremities, although many patients may be initially asymptomatic (23). There may be mild aching over the calf muscles and pain in the soles of the feet. Many patients experience a burning dysesthetic component. The soles of the feet are affected first, and there may be aching pain or stabbing sensation that evolves into an intense burning sensation that is very sensitive to touch. Patients may not be able to sleep with sheets touching their feet as a result. Later, this neuropathy evolves further, and weakness may become apparent in the affected muscles. When weakness is present at the ankles, there will be loss of Achilles tendon reflexes. With further progression, weakness may extend into the proximal muscles of the thigh and leg. In very severe cases, the hands may become involved, and there may also be involvement of the cranial nerves with hoarseness of speech and impaired phonation. Such severe cases are rare. The pathologic findings in alcoholic nutritional neuropathy are consistent with those of a distal axonopathy (25); that is, the axon itself bears the brunt of the damage. Axonal degeneration results in demyelination. The injury can be widespread, with pathologic changes evident in the distal vagus and recurrent laryngeal nerves as well as in anterior horn cells and dorsal root ganglia (21).

The prognosis of this type of neuropathy is generally quite favorable if treatment is instituted in the early stages. The paresthesias may resolve rapidly, but recovery of muscle strength generally takes much longer, and recovery may take as long as a year. Treatment consists of abstinence from alcohol and a good overall diet. In addition, thiamin supplementation should be carried out with parenteral administration at doses of 50 mg/day given intramuscularly for the first week. This is followed by a daily oral supplement in addition to other vitamin supplementation.

Deficiencies of pyridoxine, niacin, pantothenic acid, vitamin B₁₂, folate, and niacin are also associated with polyneuropathies and could play a role in the commonly seen alcoholic nutritional polyneuropathy. In addition, the spinal cord, optic nerves, and cerebellum may also be affected in patients with this disorder, but manifestations of that involvement may be masked by the polyneuropathy. Systemic manifestations leading to the suspicion of nutritional deficiency include weight loss, seborrheic dermatitis, glossitis, cheilosis, angular stomatitis, anemia, and hair loss.

Nutritional Amblyopia (Nutritional Optic Neuropathy)

Nutritional optic neuropathy is a disorder in which nutritional deprivation leads to demyelination and axonal loss in the optic nerves (26). The usual early manifestation is dimness of vision and the presence of blind spots (scotomas) in the visual fields leading to decreased visual acuity. The disorder usually presents with dimness or blurred vision, difficulty with fine print and reading, photophobia, and retrobulbar pain associated with eye movement. Onset is usually insidious, and slow progression is the rule. This disorder is frequently seen in chronically undernourished alcoholics in Western countries, but its nutritional basis was firmly established in World War II and the Korean war, where it was observed in prisoners of war who had no access to alcohol or tobacco (27). It has not been associated with a deficiency state involving only one vitamin but is

seen in mixed nutritional deficiency states in which thiamin and other B vitamins are depleted (28). The syndrome has been observed in association with Crohn's disease, as a sequela of intestinal bypass procedures for the treatment of obesity, and in vitamin B₁₂ deficiency (28, 29 and 30).

Examination of the eyes usually reveals erythema at the temporal margins of the optic discs (31). Later, there may be frank optic atrophy that is bilaterally symmetric. On a cellular level, damage is confined to a region of the optic nerve known as the papulomacular bundle (32).

Treatment with high-caloric diets rich in protein and vitamin supplementation leads to rapid improvement in most early cases. Chronic severe deficiency states with severe visual loss may not respond as well to therapy.

Vitamin B₁₂ Deficiency

Deficiency of vitamin B₁₂ is one of the most commonly encountered isolated deficiency states in clinical practice. The spinal cord, brain, optic nerves, and peripheral nerves may be affected by vitamin B₁₂ deficiency (33). The spinal cord may bear the brunt of damage associated with vitamin B₁₂ deficiency, but a variety of neurologic manifestations are known to be associated with this deficiency state.

Vitamin B₁₂ deficiency states occur in a variety of clinical settings (Table 95.2) (see also Chapter 27 and Chapter 88). The prototypic deficiency state (pernicious anemia) occurs when antibodies are produced against intrinsic factor, which is produced in the parietal cells of the gastric antrum. When B₁₂ deficiency is due to a lack of intrinsic factor, the Schilling test result is subnormal because of failure to bind B₁₂ in the intestinal lumen and consequent poor absorption of B₁₂ in the terminal ileum (see Chapter 27 and Chapter 55). Proof of this diagnosis requires a normal response when the Schilling test is repeated with intrinsic factor. Regardless of the cause, vitamin B₁₂ deficiency should be considered serious; the cause should be investigated, and supplementation should be initiated promptly lest irreversible damage to the CNS continue to progress. Vitamin B₁₂ deficiency usually occurs in secondary association with diseases including celiac sprue, gastric or ileal resections, intestinal stasis with blind loop syndrome, and fish tapeworm infestations (Table 95.2)(33). Deficient intake of the vitamin is limited to those who subsist on vegetarian diets (see Chapter 88). At times, the cause may not be readily apparent.

Pernicious anemia
Celiac sprue
Gastric or ileal resection
Fish tapeworm infestation
Inadequate diet

Table 95.2 Etiology of B₁₂ Deficiency

While macrocytic anemia is usually present in patients who exhibit neurologic manifestations of vitamin B₁₂ deficiency, the neuropsychiatric manifestations of cobalamin deficiency may precede the appearance of macrocytic anemia by months or even years (34, 35). The likely reason for this is that ingested folate may suffice to prevent the macrocytic anemia even when B₁₂ continues to be deficient. The result is continuing damage to the CNS and PNS in the absence of macrocytosis or anemia. In one study, no evidence of anemia or macrocytosis was seen in 28% of patients with neurologic manifestations of vitamin B₁₂ deficiency (35).

The clinical manifestations of cobalamin deficiency are referable to disorders of both CNS and PNS myelin. Patients often show manifestations of myelopathy, peripheral neuropathy, dementia, or neuropsychiatric disorders (36, 37 and 38). The earliest manifestation is often tingling and paresthesias in the lower extremities. This is accompanied by a pins-and-needles sensation and the perception of muscle weakness. Sensory abnormalities may also occur in the hands and take much the same form as those in the legs. These early symptoms may be due to demyelination in either the peripheral nerves or the sensory tracts of the spinal cord. As the disease state progresses, patients typically develop a spastic paraparesis with weakness and greatly increased muscle tone in the lower extremities. At this stage, neurologic examination reveals hyperactive reflexes, muscle weakness, loss of vibration and position sense, extensor plantar responses, and impaired bowel and bladder function. Impaired bladder function is usually manifest by a sense of urinary urgency and urge incontinence. Bowel dysfunction appears as constipation. Symptoms that occur at this stage of the illness are due to demyelination in the posterior and lateral columns of the spinal cord. The motor and sensory changes that take place in subacute combined degeneration of the spinal cord due to vitamin B₁₂ deficiency tend to be symmetric, and generally, no sensory level is found.

Neuropsychiatric manifestations may include irritability, apathy, somnolence, excessive fatigue, suspiciousness or paranoia, emotional instability, confusional states, psychosis,

and cognitive decline (39, 40). The neuropsychiatric manifestations are very common and may be severe. These symptoms of cobalamin deficiency are due to demyelination in the deep white matter of the cerebral hemispheres.

In addition to the cognitive/neuropsychiatric manifestations of vitamin B₁₂ deficiency, patients may also complain of visual loss that is not dissimilar to that seen in nutritional amblyopia. There may be dimness of vision accompanied by central scotomas, and on examination, visual acuity is decreased. In late cases, there is bilateral optic atrophy. Prior to any clinical manifestations, evidence of demyelination in the optic nerves may be detected by visual evoked potentials (41).

Neuropathologic changes associated with vitamin B₁₂ deficiency include degeneration of myelin and axon loss in the white matter of the CNS and in the peripheral nerves (42). The deep white matter of the cerebral hemispheres, the optic nerves, the myelinated tracts of the spinal cord and brainstem, and the peripheral nerves are all affected. The earliest changes in the CNS are seen in the lower cervical and upper thoracic spinal cord. The demyelinating process spreads longitudinally and laterally to involve the dorsal and lateral funiculi. In some cases, these pathologic abnormalities are also seen in the optic nerves and cerebral white matter. In the periphery, there is demyelination, but axon loss tends not to be a part of the process. Nonhuman primates require 33 to 45 months to develop neuropathologic changes associated with vitamin B₁₂ deficiency (43). This is the same period of time required in humans with pernicious anemia after B₁₂ supplementation has ceased.

The biochemical process that leads to the neuropathologic changes associated with vitamin B₁₂ deficiency is incompletely understood. Vitamin B₁₂ is a cofactor for methylmalonyl-CoA mutase. This enzyme catalyzes the conversion of methylmalonyl-CoA to propionyl-CoA, which enters the Krebs cycle. Decreased activity of methylmalonyl-CoA isomerase leads to accumulation of propionyl-CoA. One theory holds that elevated levels of propionyl-CoA displace succinyl-CoA, which is the starting point for the synthesis of even-chain fatty acids. This may lead to synthesis of abnormal fatty acids that may be inserted into myelin, resulting in impaired metabolism. On the other hand, a hereditary form of vitamin B₁₂ deficiency has been described in which the activity of methylmalonyl-CoA mutase is normal despite the presence of the typical neurologic syndrome associated with vitamin B₁₂ deficiency (44).

Carmel (45) suggested that decreased activity of methionine synthetase may be responsible for the neuropathologic changes. Methionine synthetase requires methylcobalamin as a cofactor. Evidence supporting this hypothesis is derived from studies showing that prolonged administration of nitrous oxide may cause degeneration of the posterior and lateral columns of the spinal cord not dissimilar to that seen in true B₁₂ deficiency (46). In addition, it may also be associated with megaloblastic changes in bone marrow and polyneuropathy. These effects are believed to be mediated through inhibition of methylcobalamin-dependent enzymes.

The diagnosis of vitamin B₁₂ deficiency is usually suggested by the presence of low

serum vitamin B₁₂ levels (see [Chapter 27](#) and [Chapter 57](#)). The usual normal level is above 200 pg/mL. Levels below 200 are considered abnormal and should be investigated. Levels below 100 pg are very often associated with neurologic abnormalities. Increased levels of urinary methylmalonic acid occur and indicate vitamin B₁₂ deficiency ([47](#)). If low serum levels of vitamin B₁₂ are found, a Schilling test is indicated to determine whether absorption is impaired (see [Chapter 57](#) for test procedures). Since cobalamin is also necessary for conversion of homocysteine to methionine, homocysteine levels may also be elevated ([48](#)) (see [Chapter 34](#) and below).

In confirmed vitamin B₁₂ deficiency, treatment should be undertaken as soon as possible regardless of the cause. This should be initiated with intramuscular administration of 1 mg of vitamin B₁₂ daily for 7 days followed by 1 mg intramuscularly weekly for 1 month. Large doses of B₁₂ are required to replace tissue stores that have been depleted over a long period. Treatment should be continued with once-monthly injections of vitamin B₁₂ for the remainder of the patient's life if the underlying cause cannot be overcome.

The response to treatment depends mostly on the duration of symptoms prior to diagnosis. Much of the damage present when treatment is initiated will remain, but progression of neurologic impairment will stop. The best response is usually seen in patients who have exhibited symptoms for less than 3 months. While all patients tend to show some improvement with therapy, those with longstanding disease may show little response.

Pellagra

Niacin deficiency produces a variety of systemic manifestations including skin changes (especially in areas exposed to sunlight) and inflammation of mucosal surfaces resulting in glossitis, stomatitis, vaginitis, and achlorhydria (see [Chapter 23](#) and [Chapter 30](#)). The neurologic manifestations may vary from fatigue and lethargy to outright psychosis and dementia. In the early 1900s, pellagra reached epidemic proportions in the southern United States and was associated with a high case fatality rate because the deficiency state was far advanced at time of recognition ([49](#)). The prevalence of pellagra is now greatly diminished in the United States as a result of niacin supplementation in bread and better diets. However, this deficiency state is still common in developing countries where corn is a major staple and where alkaline treatment of the cereal is not routine (see [Chapter 23](#) and [Chapter 108](#)). In developed countries, the disease is almost entirely restricted to poorly nourished alcoholic populations with multiple other nutritional deficiencies.

The neurologic manifestations of pellagra often appear before the dermatologic signs. The initial stages may be as subtle as fatigue and lethargy. As the deficiency state progresses, patients may become apathetic, depressed, and fearful ([50](#)). This is often accompanied by insomnia, dizziness, and headache as well as a number of other nonspecific symptoms including anxiety and inability to concentrate. Later, patients develop an outright psychosis that may be accompanied by a delusional state, disorientation, confusion, and hallucinations. In short, they suffer from a severe

metabolic encephalopathy. Eventually, the encephalopathic state gives way to coma and death, though death in pellagra is usually due to complications associated with severe skin lesions and fluid loss from diarrhea. A minority of patients may exhibit spasticity of gait accompanied by ataxia (50). It is not clear whether this aspect of the disorder is due to coexistent deficiencies or to niacin deficiency itself. The most prominent manifestations are referable to the posterior columns of the spinal cord.

Pellagra may also be seen in association with carcinoid syndrome and in Hartnup's disease. In both disorders, tryptophan is depleted. In Hartnup's disease this is due to impaired absorption, and in carcinoid syndrome there is overuse of tryptophan in a pathway that is normally minor. Normal tryptophan metabolism is required for the synthesis of some niacin; hence depletion of this amino acid through an alternate pathway may predispose patients to niacin deficiency (see [Chapter 23](#)). In addition, other amino acids (e.g., leucine) may block the synthesis of niacin.

The symptoms of pellagra can be rapidly reversed by administration of niacin. Generally, 10 to 20 mg/day is sufficient in addition to a diet with adequate amounts of tryptophan.

Vitamin E Deficiency

Vitamin E deficiency in clinical practice is uncommon except in disorders with impaired absorption of fat-soluble vitamins because of either transport across the intestinal epithelium or intraluminal factors (see [Chapter 19](#)). These disorders include cholestatic liver disease in which there is impaired entry of bile into the lower bowel or ileal dysfunction so that bile salt concentrations fail to reach the critical micellar concentration needed for normal absorption. Diseases include cystic fibrosis, abetalipoproteinemia with defects in lipoprotein secretion, primary biliary cirrhosis, pancreatic insufficiency, short gut syndrome, and celiac sprue. The resulting deficiency depletes vitamin E in nervous tissue and results in a progressive spinocerebellar degeneration and neuropathy. The full symptomatic deficiency state is associated with ataxia, hyporeflexia, ophthalmoplegia, myopathy, retinal degeneration, and a sensory-motor polyneuropathy (51, 52). This constellation of neurologic abnormalities can be quite disabling and may be mistaken for a variety of other syndromes including multiple sclerosis and Friedreich's ataxia (53). There are also adult forms of spinocerebellar degeneration that may be associated with abnormalities of the α -tocopherol transfer protein.

Because vitamin E functions as an antioxidant, it has been studied in Parkinson's disease. In animal studies, vitamin E deficiency resulted in a 19 to 33% loss of tyrosine hydroxylase immunopositive neurons in the substantia nigra (54). While there has been no reported decrease in vitamin E levels in postmortem brain from patients with Parkinson's disease, it has been suggested that it might be useful to slow the progression of disease which may, in part, be related to oxidative injury to the substantia nigra (55).

Vitamin E deficiency states respond to supplementation with oral or parenteral α -tocopherol. In children with chronic cholestasis, large doses of oral tocopherol

(70–212 mg/kg/day) are often ineffective in ameliorating development of neurologic symptoms (56). A water-soluble form is available that was effective in improving or stabilizing most previously unresponsive to large doses of regular fat-soluble vitamin E (56).

Pyridoxine Deficiency

Pyridoxine deficiency has been associated with use of isoniazid for antituberculous therapy and with hydralazine treatment of hypertension (57). Its occurrence in the absence of these agents is extremely rare in adults. Hydralazine leads to formation of complexes composed of pyridoxal and isoniazid and a marked increase in pyridoxine excretion. The result is the appearance of a mixed sensory-motor polyneuropathy characterized by paresthesias and burning sensations in the feet and lower legs. With progression, this may be accompanied by weakness and loss of the Achilles tendon reflexes. This neuropathy can be easily prevented by concomitant administration of pyridoxine in doses of 50 mg/day.

Pyridoxine deficiency occasionally occurs in newborns. In infants, this is associated with hyperirritability and seizures (58). There is a familial syndrome in which seizures due to pyridoxine deficiency appear at birth or shortly after birth. The seizures respond to supplementation with pyridoxine, and this is associated with a normalization of the electroencephalographic pattern. The dose required to control seizures is 15 mg/day. Pyridoxine deficiency may also be seen in normal infants whose intake of vitamin B₆ is below 0.1 mg/day. This is rare even in underdeveloped countries but has occurred in infants fed powdered goats' milk devoid of pyridoxine.

NEUROLOGIC DISORDERS ASSOCIATED WITH VITAMIN EXCESS

Pyridoxine Neuropathy

Just as a deficiency of pyridoxine has been associated with a sensory motor polyneuropathy, an excessive intake of pyridoxine has been associated with a sensory neuropathy that can be quite disabling (59, 60). Excessive intake is a far more common occurrence in the age of widespread use of megavitamins, when large doses of vitamin B₆ are used as over-the-counter medicines for a variety of problems including fibrocystic breast disease, carpal tunnel syndrome, and premenstrual syndrome and as a general "health supplement." Doses in the range of 500 mg/day and above may cause a severe sensory neuropathy (60) which is generally associated with progressive ataxia that results from a loss of joint position sense and proprioceptive function. There is usually distal sensory loss and paresthesia as well as numbness in the lips and tongue. The neuropathy results from changes in the dorsal root ganglia that lead to degeneration of large axons and small myelinated fibers. The primary mechanism may have a direct toxic effect of pyridoxine on the dorsal root neurons. Withdrawal of excess vitamin B₆ usually results in some improvement.

Vitamin A Intoxication

Excessive intake of vitamin A has long been known to induce a toxicity syndrome characterized by lethargy, malaise, headaches, abdominal pain, and myalgias (61). The syndrome usually begins with irritability, loss of appetite, and myalgias. With continued ingestion, a number of other symptoms appear including desquamation of the skin, fatigue, confusion, lethargy, headache, and vomiting. This may be accompanied by abdominal pain, excessive sweating, and yellowish pigmentation in the soles of the feet, palms of the hands, and the nasolabial folds. Doses in excess of 25,000 IU/day ingested over a period of several months suffice to induce overt toxicity in most individuals, but infants and children are more susceptible. Patients with renal insufficiency and alcoholics are also at greater risk given comparable ingestion. The toxic state begins when the binding capacity of the plasma is exceeded and free retinol is present in relatively high concentration. It may bind to the plasma membrane or other cellular constituents and alter the permeability of the membranes. This is thought to be the case in patients with pseudotumor cerebri. In this condition, patients present with a severe headache syndrome accompanied by papilledema and raised intracranial pressure. This syndrome is not accompanied by focal neurologic deficits, and their presence would indicate another disorder, not pseudotumor cerebri.

Excessive intake of vitamin A during the first trimester of pregnancy has been associated with increased incidence of cleft palate, harelip, macroglossia, developmental abnormalities in the eyes, and hydrocephalus in the newborn (62). More-recent studies suggest an association between a vitamin A intake above 10,000 IU during pregnancy and a greater risk of congenital defects associated with cranial-neural-crest tissue (63). When women taking more than 10,000 IU/day of vitamin A were compared with women taking less than 5000 IU, the prevalence ratio of congenital abnormalities was 4.8. This suggested that in women taking excess vitamin A, 1 in 57 birth defects was attributable to vitamin A.

ROLE OF NUTRITION IN SELECTED NEUROLOGIC DISORDERS

Cerebrovascular Disease and Homocysteine

While dietary fat intake has long been considered a risk factor for atherosclerotic cerebrovascular disease, a newer awareness of other nutritional factors is slowly growing. It has long been appreciated that patients with homocystinuria were at high risk for stroke and other vascular disease despite their young age. This was first described by McCully (63) in a report of an infant who died as a result of an inborn error of cobalamin metabolism. Severe atherosclerotic disease was evident in this patient and appeared similar to that reported in patients dying from cystathionine synthetase deficiency (homocystinuria). Since elevated levels of homocysteine appeared to be the only common metabolic anomaly in these patients, hyperhomocysteinemia was suggested to be an important cause of atherosclerotic vascular disease. Considerable evidence now supports that idea (65, 66 and 67). Serum concentrations of vitamin B₁₂, folate, and pyridoxine as well as gender, age, and intake of alcohol play a role in

determining the levels of homocysteine and the consequent risk of premature cerebrovascular disease (68, 69, 70 and 71).

The formation and metabolism of homocysteine are described in detail in [Chapter 34](#); the pathophysiology of its excess is also discussed in [Chapter 61](#). In summary, homocysteine is formed by cleavage of S-adenosylhomocysteine; it is metabolized by one of two pathways. The first is through transulfuration to cysteine by cystathionine synthetase, which uses pyridoxal phosphate (the active form of pyridoxine) as a cofactor. The second pathway is through remethylation either through betaine-homocysteine methyltransferase or by way of methionine synthetase using folate as a cofactor to form methionine. The second pathway is probably of greater importance (48). Protein-bound homocysteine comprises 70–85% of the total homocysteine in plasma. Free homocysteine is present in three forms: homocysteine, homocystine, and cysteine-homocysteine disulfide conjugate. The total concentration of these metabolites is referred to as homocyst(e)ine (Hcy).

The level of methionine influences homocysteine synthesis and the proportion of homocysteine that is transulfurated or remethylated. Since methyltetrahydrofolate and homocysteine are substrates for methionine synthesis, a deficiency of folate may be associated with increased circulating Hcy, which is now known to be a risk factor for atherosclerotic vascular disease. For example, Selhub et al. (69), in a study of 1041 elderly patients, found that elevated plasma homocysteine concentrations were associated with a higher risk of carotid artery stenosis and that concentrations of folic acid and vitamin B₆ were inversely related to carotid artery stenosis. Furthermore, elevated levels of Hcy and related metabolites are more common in an elderly population than the prevalence of vitamin deficiency, suggesting that Hcy metabolites may rise before B₁₂, folate, or vitamin B₆ levels in serum decrease (76), and administration of vitamin supplements leads to a decrease in the concentration of Hcy metabolites. The proceedings of a major symposium on the relationships of homocyst(e)ine, vitamins, and cerebrovascular occlusive disease have been published recently (73).

These insights into the relationship between nutritional factors and vascular disease led to a number of clinical trials that are under way to determine whether supplementation of stroke patients with folic acid will decrease the risk of subsequent strokes. The cost benefit provided by positive clinical results would be enormous, considering that the average direct lifetime cost after stroke is \$60,000 and there are over 400,000 strokes annually in the United States.

Since deficiency of folic acid is a well-recognized risk factor for neural tube defects, anencephaly, and vascular disease through its effect on Hcy levels, it has been suggested that foods be supplemented with folate (73) as well as vitamin B₁₂ (75, 76). Addition of vitamin B₁₂ has been advocated because folic acid alone may mask the megaloblastic anemia that occurs in vitamin B₁₂ deficiency, with resulting progression of undiagnosed vitamin B₁₂ deficiency until serious neurologic damage becomes evident. However, as of February 29, 1996, the Food and Drug Administration approved addition of folic acid only in the amount of 0.43 to 1.4 mg/pound to bread and cereals in an effort

to keep the daily intake of folic acid below 1 mg (77).

Wilson's Disease (Hepatolenticular Degeneration)

Wilson's disease is a disorder of copper metabolism that is inherited as an autosomal recessive trait (78). The major defect is an impairment in the synthesis or function of ceruloplasmin, which binds copper. As a result, serum copper levels are markedly elevated as is urinary excretion of copper. Neurologic manifestations of the disease include a tremor of the head and limbs and slowness of movement in the initial stages. With progression, there is typically dysarthria, dysphagia, rigidity, dystonic posturing, mutism, and slowed cognitive function. Kayser-Fleischer rings in the eyes are pathognomonic for the disorder and are almost always present when neurologic symptoms manifest. This is accompanied by chronic hepatitis leading eventually to multilobular cirrhosis and hepatosplenomegaly due to deposition of copper in the liver.

Treatment of this disorder relies on limiting copper intake in the diet to less than 1 mg/day. Foods rich in copper include nuts, shellfish, liver, mushrooms, chocolate, cocoa, broccoli, and beans to name only a few. In addition to limiting dietary intake of copper, chelating agents such as D-penicillamine and triethylenetetramine (and more recently, zinc) are used to increase copper excretion (79). In most patients with early disease, treatment is followed by improved neurologic function. At times, there may be a latent period of several weeks before improvement is seen. Some patients worsen despite therapy.

Refsum's Disease

Refsum's disease is a rare neurologic disorder caused by accumulation of phytol. It has autosomal recessive inheritance, and onset is usually in childhood or adolescence. Manifestations include retinitis pigmentosa, cerebellar ataxia, polyneuropathy, cardiomyopathy, neurogenic deafness, cataracts, and ichthyosis (80). Phytol accumulates because of a deficiency of phytanic acid hydroxylase. Phytanic acid is found in a number of foods including coffee, nuts, vegetables, spinach, ruminant fat, and dairy products. Treatment depends on limiting dietary phytanic acid (Table 95.3). When this is accomplished, there is usually slow but steady improvement in neurologic function (81).

Disease	Defect	Dietary Therapy
Phenylketonuria	Phenylalanine hydroxylase	Restrict phenylalanine
Milde renal uremia disease	Biochemical ketacid decarboxylase	Restrict leucine, valine, isoleucine, methionine
One cycle defect (partial)		
Agmatinuria	Agmatinase	Restrict protein
Coupland's	Agmatinase	
Low citrulline	Citrulline transcarbamylase	
Hypomethioninemia	Cystathionine synthetase	
Hemostasis	Cystathionine synthetase	Restrict methionine, glycylglycine, folic acid, vitamin B ₁₂
Galactosemia	Galactose 1-epimerase and transferase	Lactose-free diet, low-galactose diet
Wilson's disease	Low serum ceruloplasmin	Low-copper diet, Zinc diet
Refsum's disease	α-Oxidation of phytanic acid to pristanic acid	Phytol-free diet

Table 95.3 Inborn Errors of Metabolisms with Neurologic Manifestations

Neural Tube Defects

Neural tube defects result from incomplete closure of the neural tube ([Fig. 95.1](#)), termed *spina bifida*, which refers to a defect in the bony structure. The underlying neurologic abnormality may take the form of a meningocele or outpouching of the meninges or it can be present as a meningocele in which a portion of the spinal cord is contained with the outpouching of the meninges. This is associated with paralysis and is often accompanied by hydrocephalus. In the most severe form, failure of neural tube closure results in anencephaly or absence of the cerebral hemispheres. Closure of the neural tube takes place by the end of the 4th week of pregnancy, a stage when many women are unaware that they are pregnant.

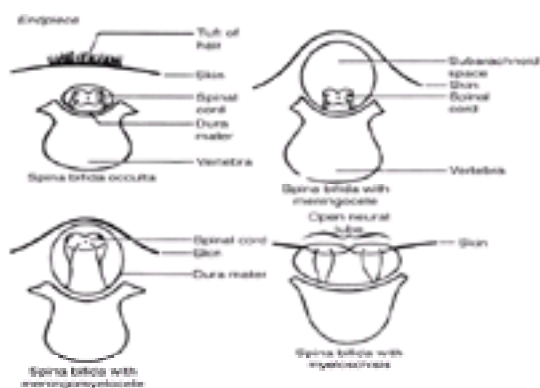

Figure 95.1. Spina bifida terminology. The term *spina bifida* refers to the bony abnormality—defective closure of the vertebral column; the terminology for other abnormalities is shown above. (From Chamberlain G, ed. *Turnbull's obstetrics*. Edinburgh: Churchill Livingstone, 1995;914, with permission.)

While the possibility that folic acid may be involved in neural tube defects was raised as far back as 1964, the first trials suggesting a preventive effect of folic acid supplementation were not carried out until the early 1980s. In 1991, a multicenter double-blind study was reported in which women were randomly assigned to receive to either 4 mg of folic acid or a mixture of vitamins including A, D, B₁, B₂, C, and nicotinamide. Results of this study showed that women receiving folic acid had a relative risk of giving birth to a second child with a neural tube defect of 0.28, a 72% reduction in risk for those taking folic acid supplements ([82](#)). Finding that folic acid supplementation

reduced the risk of neural tube defects in the offspring led to a recommendation that it be given as a supplement to all women likely to become pregnant (83, 84). An increase of 0.4 mg of folic acid daily could potentially reduce the risk of neural tube defects by as much as 48% (84).

An association has been observed between neural tube defects and impaired activity of methylenetetrahydrofolate reductase, including a mutated form that is susceptible to thermal inactivation (85, 86). The result is decreased enzyme activity and increased concentrations of homocysteine. Levels of homocysteine in serum samples taken during pregnancy are also elevated (87), presumably because of the decreased activity of tetrahydrofolate reductase. Folic acid supplements increase the enzyme activity.

Obesity has also been reported to be a risk factor for neural tube defects (88, 89). Women weighing 80 to 89 kg had a relative risk of 1.9, while those weighing 110 kg had a relative risk of 4. Obese women with a folic acid intake above 0.4 mg did not have the reduction in risk that was seen in women of normal weight. A reduction in the incidence of other fetal anomalies in addition to neural tube defects has also been reported with vitamin supplementation (83). However, a case-control study failed to find a protective effect of supplements taken periconceptually on the risk of orofacial clefts in newborns (90).

Hyperammonemic Disorders (Encephalopathy)

Symptoms of hepatic encephalopathy are increasing confusion, decreased levels of alertness, disorientation, and stupor. In the latter stages of this process, coma may ensue, and death may result. The condition is due to a bilateral disturbance of hemispheric function brought about by unknown metabolic “toxins.” The disorder deserves mention in this context because the encephalopathic state may be precipitated by an inability to metabolize branched-chain amino acids (e.g., maple syrup urine disease or those in the urea cycle) (Table 95.3). These are genetic disorders, discussed in detail in Chapter 61. Encephalopathy secondary to cirrhotic liver disease is discussed in Chapter 73.

Protein intake in patients with chronic liver disease should be limited to 30 g/day. With greater intake, bacteria in the gut act on the protein; nitrogen in the form of ammonia is absorbed into the circulation but cannot be converted to urea because of hepatic dysfunction. The result is overt encephalopathy. In recent years, a number of other hypotheses have been proposed to account for the mechanism at play in the encephalopathy. γ -aminobutyric acid (GABA), an inhibitory neurotransmitter, has been suggested to mediate the encephalopathic process on a neurochemical level. Elevated ammonia levels may contribute by providing the nitrogen for conversion of glutamic acid to GABA. Use of branched-chain amino acids in treatment is controversial.

A similar clinical syndrome may be seen in neonates with urea cycle deficits, disorders manifest by onset of an encephalopathic state shortly after feeding begins. These disorders are characterized clinically by mental retardation, seizures, ataxia, stupor, and coma and are inherited as an autosomal recessive trait in which absence of a urea cycle

enzyme results in elevated levels of urea nitrogen.

INHERITED VITAMIN-RESPONSIVE NEUROLOGIC DISORDERS

Vitamin-responsive disorders are those that have neurologic manifestations as a result of decreased activity of enzymes requiring vitamins as cofactors (58). In most of these disorders, the enzyme in question is present but in a mutated form that has decreased affinity for its cofactor. When the cofactor or vitamin is provided in a pharmacologic dose, enzyme activity increases, and the concentration of the toxic substrate falls to or toward the normal range. The level of the vitamin in question is not abnormally low prior to supplementation.

An example briefly discussed above is pyridoxine-dependent seizures in the newborn. In this disorder, infants develop status epilepticus that can be reversed by administration of pyridoxine. The disorder results from an abnormal form of glutamic acid decarboxylase with pyridoxal-binding sites of lower affinity than the normal form of the enzyme. When pyridoxine is supplied in supraphysiologic doses, activity of the enzyme increases and the concentration of glutamic acid returns to normal levels. This results in cessation of seizures and normalization of the electroencephalographic pattern. A variety of vitamin-responsive neurologic disorders in the newborn are noted in [Chapter 61](#).

Hartnup's Disease

Hartnup's disease is a rare familial disorder resulting from defective transport of neutral amino acids. The most prominent defect is a lack of absorption of tryptophan across the intestinal wall. Symptoms include photosensitive dermatitis, intermittent cerebellar ataxia, mental disturbances, and renal aminoaciduria. Since the disorder appears similar to pellagra, nicotinic acid (25 mg/day) has been used in the treatment (58). Because the symptoms are intermittent, the effectiveness of this therapy has been difficult to evaluate. In addition, tryptophan may still be absorbed in a di- or tripeptide. As a result, with adequate dietary protein intake, the disorder may at times be asymptomatic.

Anticonvulsant-Induced Vitamin Deficiency

Several drugs commonly used to treat seizure disorders can potentially induce vitamin deficiency states; they include phenytoin, phenobarbital, primidone, and valproic acid (91). Since seizure disorders occur in 1 to 2% of the entire population, the potential impact of such effects is considerable. Phenobarbital, primidone, and phenytoin may interfere with folate metabolism, and during pregnancy, this has been associated with an increased incidence of neural tube defects. Decreased folate levels in blood and cerebrospinal fluid are demonstrable after long-term administration of these agents (92). Consequently, patients being treated with these agents should receive concomitant folic acid as well as a multivitamin supplement.

These same agents have also been associated with decreased production of vitamin

K-dependent clotting factors and bleeding in the newborn. The factors affected prothrombin, factor V, and factor VII. To prevent bleeding in the newborns of mothers treated with phenytoin, phenobarbital, or primidone, vitamin K should be administered in the latter stages of pregnancy.

Another anticonvulsant agent that has been associated with diet-responsive neurologic disease is valproic acid. This drug is used in the treatment of primary generalized and partial complex seizures. It has been associated with liver dysfunction and development of hyperammonemia (93, 94), which may occur in the absence of hepatic dysfunction. The syndrome is more common in patients on multiple anticonvulsant agents, though it appears to be dose related and may occur after several years of therapy. Hyperammonemia has been suspected as a cause of lethargy and stupor in patients in whom it is observed. The mechanism may involve inhibition of carbamyl phosphate synthetase, which is involved in conversion of ammonia to urea. As a result, liver function tests and serum ammonia levels should be monitored periodically in patients being treated with valproic acid. Since venous ammonia levels may be artificially elevated due to hemolysis, an elevated level should be confirmed with an arterial blood sample. In patients who develop hyperammonemia, protein intake should be curtailed to decrease serum ammonia levels, and alternative anticonvulsants should be considered.

The hypercatabolic state is induced by endogenous production of a variety of mediators in response to diverse stimuli including trauma, sepsis, and specific advanced diseases. This state is characterized by progressive severe loss of body protein and lipid that may result in organ failure and which, at present, may be ameliorated to some extent by nutritional support but can be reversed only by major palliation or cure of the underlying disease process. The hypercatabolic state is characterized by hypermetabolism and implies a disruption of normal metabolic homeostasis. Since the pioneering work of Cuthbertson over 50 years ago, much research has focused on mechanisms underlying this often dramatic host metabolic response to injury or disease, as well as the means to modify such responses via direct nutrient intervention or modulation of the inflammatory milieu. This chapter describes the hypermetabolic state, the neuroendocrine and cytokine mediators of this response, the metabolic consequences of prolonged net hypermetabolism to the host, and, briefly, how this condition influences aspects of nutrient use. The clinical features of this response, in general, are qualitatively similar, regardless of the nature of the insult. However, the catabolic response to cancer and HIV are distinct and are reviewed separately.

METABOLIC RESPONSES TO INJURY AND DISEASE

The temporal sequence of postinjury metabolic events is well known from the careful evaluation of many investigators. Cuthbertson initially established the basis for understanding the biologic response to injury. He found that urinary excretion of nitrogen, potassium, and phosphorus was markedly increased in patients with long bone fractures. The relative concentrations of these excreted nutrients were similar to those of muscle, and he concluded that muscle was the source of these losses (1). These and subsequent isotopic dilution studies by Moore and his colleagues (2) characterized the ebb and flow phases of the postinjury response. The early ebb phase occurs immediately postinsult and is characterized by hemodynamic instability with decreased cardiac output and oxygen consumption, low core temperature, and elevated glucagon, catecholamine, and free fatty acid levels. This phase typically lasts from 12 to 24 hours and is modified to some degree by the extent and adequacy of fluid volume resuscitation. The subsequent flow phase is fundamentally a metabolic response that alters energy and protein use to preserve critical organ function and repair damaged tissue. Total body oxygen consumption, metabolic rate, and amino acid efflux from peripheral muscle stores all increase, counterregulatory hormone concentrations are elevated, glucose metabolism is altered, and lactate production, urinary nitrogen losses, and tissue protein catabolism all increase (3) (Table 96.1). Discussion below focuses on the flow phase response and the endogenous mediators that regulate this response.

Ebb Phase	Flow Phase
Increased blood glucose	Normal/slightly elevated blood glucose
Increased circulating free fatty acids	Normal/slightly elevated free fatty acids
Decreased insulin	Normal/increased insulin
Increased catecholamines	Increased catecholamines
Decreased cardiac output	Increased cardiac output
Decreased oxygen consumption	Increased oxygen consumption
Decreased core temperature	Elevated core temperature

Table 96.1 Metabolic Alterations following Injury

Energy Expenditure

Injury and Sepsis

During the postinsult flow phase there is increased energy expenditure by the body as well as an increased metabolic rate. Total body oxygen consumption increases because of increased oxidation of fuel sources (carbohydrates, amino acids, and lipids) to provide needed energy. These reactions produce heat, and the increased heat production indicates an increased metabolic rate. To some extent, the elevation of the

metabolic rate above basal levels correlates with the cause and/or the severity of the initial injury. Energy expenditure may increase minimally with mild injury (4), 15 to 25% following long bone fractures (1), and as much as double with burn injury over more than 40% of total body surface (5) (Fig. 96.1).

Figure 96.1. Effect of injury on metabolic rate. (Adapted from Wilmore DW. The metabolic management of the critically ill. New York: Plenum Medical Book, 1977.)

The increased metabolic rate requires mobilizing the body's nutrient stores to provide substrates for the increased energy demand. The body's stores of carbohydrates, primarily glycogen, are quickly depleted in the first 24 hours postinjury. Thereafter, fat and protein serve as the main energy sources. In the hypermetabolic state there is obligatory net protein catabolism in an attempt to provide substrates for gluconeogenesis and amino acids for increased synthesis of acute-phase proteins. Stored triglycerides are also mobilized and oxidized to provide substrates for the hypermetabolic state but are unable to prevent protein catabolism. During this state, there is also a marked rise in the counterregulatory hormones: glucocorticoids, catecholamines, and glucagon. These hormones promote a variety of metabolic effects as discussed below. Also important in the response to injury are the cytokines, whose effects are largely mediated by endocrine mechanisms. These acute alterations in metabolic and hormonal responses serve to maintain the vital organs necessary for survival by providing substrates for energy production during the hypermetabolic state (Fig. 96.2).

Figure 96.2. Neuroendocrine and metabolic consequences of injury.

Cancer

In contrast to the hypermetabolic state universally seen posttrauma, hypermetabolism is not an invariable finding in cancer patients. Because cancer patients in the advanced stages of disease often become cachectic, it was hypothesized that this weight loss was due to increased energy expenditure and net negative energy balance. Studies do not confirm this hypothesis but indicate a variable metabolic response to cancer; some investigators report a hypermetabolic response, while others observe no change or a hypometabolic response (6, 7 and 8) (Fig. 96.3). One study failed to demonstrate a correlation between resting energy expenditure (REE) and weight loss or tumor burden (9). Other studies demonstrated no significant difference in REE in patients who were losing weight or were weight stable with gastric or colon cancer (7).

Figure 96.3. Preoperative REE in cancer patients. (Adapted from Luketich JD, Mullen JL, Feurer ID, et al. Arch Surg 1990;125:337-41.)

Numerous studies show that the variations in REE seen in cancer may be influenced by tumor histology (10, 11, 12 and 13). One study found that patients with non-small-cell lung cancer had an elevated REE, while patients with gastric or colorectal cancer did not. Another study demonstrated a hypermetabolic state in patients with gastric cancer, while patients with esophageal or colorectal cancers were evenly distributed in their metabolic response, and patients with pancreatic or hepatobiliary neoplasms were mostly hypometabolic (12). In contrast, a recent study of cachectic patients with pancreatic cancer demonstrated an increase in REE (13). Thus the metabolic response to tumor burden varies and may depend in part on tumor type and/or other endogenous mediators involved in the host-tumor interaction.

AIDS

Another patient population in which a hypermetabolic response is often observed are those with HIV infection. Several studies suggest that the REE is elevated in patients with early HIV infection and increases further with subsequent AIDS (14, 15, 16 and 17). This REE increase may occur in an asymptomatic patient with normal CD4 lymphocyte counts (18). Certain secondary infections may cause even further elevations in the REE, although it appears that even latent HIV infection can cause an increase in REE above basal levels. Other studies have indicated that a small percentage of AIDS patients without secondary infection may in fact be hypometabolic and demonstrate a metabolic response similar to that seen in starvation (15). This response has been strongly associated with oral candidiasis or odynophagia, which suggests that poor food intake may impose a starvation metabolic response in addition to the hypermetabolic response (19).

Thus the hypermetabolic response in the host can be initiated by a variety of initial insults including trauma, burns, infection (including HIV), and cancer. The increased energy expenditure results in an alteration of fuel metabolism, leading to a breakdown of protein and fat and alterations in glucose metabolism to provide the necessary substrates for these increased energy demands.

Protein Metabolism

Injury and Sepsis

Protein represents a large reserve of body fuel. In response to the increased energy demands after injury, skeletal muscle protein stores are mobilized. This leads to increased amino acid efflux from peripheral stores and increased urinary nitrogen excretion. The extent of this urinary nitrogen loss correlates with the severity of the injury. The result is a net negative nitrogen balance as protein catabolism exceeds protein synthesis by the liver. This acceleration of protein catabolism generally parallels the increase in oxygen consumption and represents a constant fraction of total oxidation following injury (4). If allowed to proceed unabated, the net protein catabolism may result in critical organ failure (20).

The mechanism of muscle catabolism during sepsis involves increased protein breakdown (21), especially of myofibrillar protein, as well as reduced protein synthesis (22) and inhibition of amino acid uptake by muscle (23). In animal models, important mediators of this catabolism during sepsis include glucocorticoids as well as certain cytokines, particularly tumor necrosis factor (TNF) and interleukin-1 (IL-1) (24).

The intracellular mechanism involved in muscle protein breakdown in sepsis and injury is not clearly defined; however, recent animal studies indicate that sepsis induces a nonlysosomal, energy-dependent proteolysis (25). This involves activation of the ubiquitin-proteasome-dependent pathway that increases mRNAs encoding ubiquitin and proteasomes in muscle. In this pathway, proteins destined for degradation are ligated to the polypeptide ubiquitin and then degraded by a protease that acts on ubiquitinated proteins (26). Other studies indicate that the mRNA for ubiquitin increases during glucocorticoid excess and acidosis, and may occur in septic states (27). Therefore it is likely that the ubiquitin pathway is important in proteolysis in sepsis, but further studies are needed to delineate other possible mechanisms.

The increased amino acid efflux from peripheral stores postinjury provides substrates for enhanced hepatic gluconeogenesis and acute-phase protein synthesis. It also allows new protein tissue in wounds and proliferation of cellular components involved in the inflammatory response. There is increased splanchnic uptake of glucogenic amino acids, particularly alanine and glutamine. This increase in uptake in burn patients corresponds to the quantity and distribution of peripheral tissue amino acid release (28). The enhanced splanchnic uptake is achieved by increased glutamine uptake in the gut enterocytes while alanine is released by the gastrointestinal tract in increased amounts during stress (32).

During the postinjury response, alanine and glutamine are also preferentially released from muscle stores. While these amino acids make up approximately 6% of protein in muscle stores, they constitute 60 to 80% of the free amino acids released in response to insult (29, 30). This effect may be influenced by glucocorticoid activity; in a study using a canine model, both acute and chronic glucocorticoid excess increased glutamine and alanine release (31).

Despite net peripheral proteolysis, liver mass is usually preserved during injury, often with an increase in total liver protein, RNA, and DNA (33). Preservation of liver mass occurs with sustained or increased hepatic capacity for gluconeogenesis and synthesis of acute-phase proteins (34).

In summary, skeletal protein catabolism may serve three main purposes. First, it provides amino acids that can serve as substrate for protein synthesis by the wound or liver. Secondly, the released amino acids can be converted to glucose by the liver as an energy source during the hypermetabolic response. Thirdly, it provides a source of glutamine to be used as a fuel source by the gut and possibly by other tissues involved in the metabolic response to stress.

Cancer

Cancer patients with significant weight loss demonstrate protein kinetics similar to those seen in traumatized or infected patients. Whole-body protein turnover rates are increased, with increases in protein synthesis as well as catabolism (35, 36 and 37). Attempts have been made to correlate the increase in protein turnover rates with changes in REE or weight loss. Isotope infusion studies suggest a significant increase in whole-body protein catabolism in cancer patients with cachexia, compared with noncachectic cancer patients or patients with benign disease (38). However, although the protein turnover rate is increased in other studies, it does not appear to correlate with energy expenditure or weight loss in most evaluations of cancer patients (7).

AIDS

By contrast to other patient populations, those infected with HIV show an elevated REE with decreased protein synthesis and catabolism in the absence of secondary infection (39). Preliminary data indicate that protein catabolism and a negative nitrogen balance occur when an AIDS patient becomes secondarily infected (17).

Glucose Metabolism

Injury and Sepsis

Hyperglycemia is a common response to septic or traumatic insult. It results from both increased hepatic gluconeogenesis and decreased glucose uptake by insulin-dependent tissues. In the ebb phase, insulin levels are depressed, but they become normal to elevated during the flow phase, although remaining depressed in relation to the degree of hyperglycemia. The persistent hyperglycemia suggests injury-induced insulin resistance (3). In addition, studies using hepatic vein cannulations in thermally injured patients demonstrate increased uptake of gluconeogenic amino acids by the splanchnic tissues (28). These amino acids are then used for gluconeogenesis, resulting in increased splanchnic production of glucose and further contributing to the hyperglycemic state.

Altered glucose metabolism in response to stress results in decreased skeletal muscle uptake of glucose and decreased glucose incorporation into fatty acids by adipocytes (40). The decreased uptake by skeletal muscle is due to peripheral insulin resistance, which may be mediated in part by excess cortisol and catecholamines (41, 42). Recent evidence also indicates that TNF- α induces insulin resistance ([43] and references therein). In these stressed patients, hyperglycemia fails to suppress hepatic gluconeogenesis or glycogenolysis; administration of a dextrose infusion suppresses gluconeogenesis less effectively in septic or trauma patients than in healthy volunteers (44, 45). Amino acid infusions are also unable to inhibit gluconeogenesis in trauma patients (46). This alteration in glucose metabolism maintains glucose availability to non-insulin-dependent tissues such as the central nervous system (CNS), kidneys,

wound tissue, and hematologic cells, which are vital for survival.

During the stress response, another source of glucose results from the change to anaerobic glycolysis in skeletal muscle and hypoxic tissue (i.e., the wound) producing increased amounts of lactate. Lactate can be converted into glucose in the liver via the Cori cycle, which is increased in both burn and trauma patients (47, 48). In burn patients, lactate is the most important gluconeogenic substrate (49). The resultant lacticacidemia may be mediated in part by both catecholamines and cytokines (50, 51).

The efficiency of glucose oxidation is altered by injury (52) and in postoperative (53) and burn patients (54), further contributing to the hyperglycemic state. Maximum glucose oxidative capacity appears to be inversely related to severity of the injury. The decrease in oxidation may be due to reduced activity of intracellular enzymatic metabolic pathways, such as pyruvate dehydrogenase (55).

Cancer

Glucose intolerance has long been observed in association with malignancy and, as early as 1919, was proposed as a means to distinguish patients who were more likely to have gastric carcinoma than peptic ulcer disease (56). Since that initial report, many investigators have confirmed glucose intolerance in diverse cancer populations with advanced disease (57, 58 and 59). Glucose intolerance results from increased resistance to both exogenous and endogenous insulin (60). The mechanism underlying this insulin resistance is not well defined, but since monocyte insulin receptors from cancer patients are normal, a postreceptor defect has been postulated ([61] and references within). However, this effect may not be cancer induced per se but may be related to the effects of cancer, such as weight loss, since glucose intolerance also occurs in response to weight loss due to calorie deprivation in benign disease (62) as well as in response to sepsis (63, 64).

There are numerous reports of increased endogenous glucose production in cancer patients (57, 58, 65 and 66), with an observed increase in glucose turnover rate that is affected by tumor stage (67, 68), histology (58, 66), and type. In a study comparing patients with early (limited to gut wall) and advanced gastrointestinal malignancies (esophagus, stomach, and pancreas), rates of glucose turnover were significantly higher in patients with advanced lesions (67). Similar findings were observed in patients with advanced colon cancer (68), indicating that increased glucose turnover is consistent with an advanced disease stage. Other studies make it evident that tumor histology also affects glucose turnover rates. Studies in sarcoma (66) and leukemic patients (58) indicate a glucose turnover rate two to almost three times that seen in normal volunteers. In contrast, patients with lymphoma demonstrated a glucose turnover rate similar to that of normal volunteers (58). Other studies indicate that the increased glucose turnover is related specifically to the cancer. The increase in glucose turnover rate is significantly higher in cancer patients with weight loss than in a cancer-free population with comparable weight loss (62). Another study demonstrated that cancer patients with progressive weight loss had markedly elevated rates of glucose turnover while weight-stable cancer patients had glucose turnover rates similar to those in normal volunteers (64). These findings contrast with the decreased glucose turnover rates in

patients with weight loss due to uncomplicated starvation (69).

Regulation of hepatic glucose production is altered in cancer patients. While infusion of glucose in normal subjects suppresses hepatic gluconeogenesis, glucose infusion reduces glucose production by only 70% in patients with early or advanced gastric cancer (67). In sarcoma or leukemic patients, the hepatic glucose production was decreased by less than a third (58, 66).

Increased gluconeogenesis via the Cori cycle represents a substantial proportion of the observed increase in glucose turnover rate in cancer patients. During this cycle, lactate released from anaerobic glycolysis in peripheral tissue is recycled to glucose in the liver in an energy-requiring reaction. Increased Cori cycle activity occurs in cancer patients, particularly those with weight loss (64). The increase in Cori cycle activity seems to be a specific response to the neoplasm and not directly related to weight loss. The source of the lactate molecules remains a matter of debate. Tumor cells may be one source of lactate production (70). Other studies indicate that the tumor itself may exert distal effects on the host carbohydrate metabolism; the rates of glucose uptake and lactate release from forearm tissue of cancer patients were significantly higher than those in tissue from normal subjects (62, 71). Taken together, it seems probable that increased glycolysis in both the tumor and host tissues contributes to the increased lactate production.

Increased glucose oxidation is also observed in cancer patients with weight loss (64, 72 and 73). The increase in oxidation rate is not proportional to the increased glucose availability, which implies a loss of efficiency in the oxidative process (62, 67). The effects of alterations in carbohydrate metabolism incurred by cancer patients on energy balance and use are difficult to quantitate but are likely to influence whole-body kinetics and, to some extent, development of cancer cachexia.

AIDS

Although there are few studies on carbohydrate metabolism in HIV patients, hyperglycemia does not appear to be a prevalent finding in patients who are HIV positive. There is evidence that abnormal glucose metabolism in AIDS patients may be related to pentamidine toxicity. Also HIV infection has been reported to cause islet b cell dysfunction leading to insulin-dependent diabetes mellitus in the absence of islet cell or insulin antibodies (74).

Lipid Metabolism

Injury and Sepsis

Lipid is a major source of fuel for the body, representing 80% of the body's energy reserves. In response to stress, lipid mobilization and use can potentially preserve proteins. Immediately postinsult, there is enhanced lipolysis mediated by sympathetic stimulation of adipose tissue as well as activation of lipase by norepinephrine and glucagon (75). The result is an increase in free fatty acids and glycerol concentration in

the circulation.

Several studies have indicated that there may be a preference for oxidation of fat as a source of energy in septic or trauma patients (76). In the nonstressed condition, the normal respiratory quotient (RQ) is 0.85 (77). In the injured patient, the RQ is lower, indicating increased lipid oxidation (5). A decreased RQ is also seen in patients with worsening sepsis, and isotopic studies have corroborated increased fat oxidation in these patients (78, 79). The increased amount of free fatty acids serves as a fuel source for tissues except red blood cells and the CNS.

Cancer

A large body of evidence indicates that most of the weight loss seen in cancer cachexia is due to depletion of body fat (68, 80, 81). Fat is stored mainly as triglyceride in adipocytes, which is hydrolyzed to glycerol and free fatty acid. This is accomplished by the action of specific lipases that are regulated by hormones that may stimulate (e.g., catecholamines) or inhibit (e.g., insulin) lipolysis. The turnover rates of glycerol and free fatty acids have been used in studies as a measurement of lipolysis. The effect that cancer has on lipolysis rate is unclear. Whole-body lipolytic rates in cancer patients have been reported to be both increased and normal (82, 83). In a study using stable isotopes, the turnover rate of glycerol and free fatty acids in weight-stable and weight-losing cancer patients was compared with that seen in healthy volunteers. There were no significant differences in weight-stable patients and normal volunteers, but there was a significant increase in the rate of glycerol and free fatty acid release in the weight-losing cancer patients (84, 85). However, in a similar study using cachectic patients without cancer as a control group for weight loss, the rate of lipolysis was similar in cachectic patients with and without cancer (86). Thus the increased weight loss itself may account for the increased lipolysis.

In their discussion of lipolysis in esophageal cancer patients, Klein and Wolfe propose four possible mechanisms for increased lipolysis in cancer patients: (a) increased lipolytic rates caused by decreased food intake and malnutrition; (b) increased lipolysis when expressed per kilogram of body weight caused by body fat loss and an increased percentage of body weight as lean body mass; (c) stimulation of lipolysis caused by the stress response with adrenal medullary stimulation, increased circulating catecholamines, and insulin resistance; and (d) the release of lipolytic factors produced by the tumor or by myeloid tissue cells (86).

An increased rate of fat oxidation has been reported in many cancer patient populations (62, 72, 83). A study of patients with colorectal or gastric cancer found that patients with cancer and weight loss oxidized fat more rapidly than patients with cancer and no weight loss or patients with benign disease and weight loss (73). Therefore, as with stressed patients, it appears that the body responds to the tumor-bearing state with a preference for fat oxidation.

AIDS

In contrast to injury or sepsis, adipose tissue is often conserved in patients with AIDS at

the expense of body cell mass (87). Grunfeld and Feingold in their review of metabolic disturbances in AIDS describe alterations in fat metabolism that occur in the disease. There is decreased triglyceride clearance due to decreased lipoprotein lipase activity, with a resultant marked triglyceridemia (17). Hepatic synthesis of fatty acids increases (88), and the levels of circulating free fatty acids are elevated (89). There appears to be no correlation between the alterations in triglyceride metabolism and wasting in AIDS (17, 89).

MEDIATORS OF HYPERMETABOLIC RESPONSE

There is a characteristic postinjury neuroendocrine response, with an increase in catecholamines and glucocorticoids. However, despite extensive investigation of the hormonal milieu and response to injury and stress, hormone increase with normal subjects have not been able to reproduce the amount of protein catabolism seen in severe injury. This indicates that hormonal changes alone cannot account for all the metabolic consequences of severe stress and injury. Therefore, increased attention to other possible mediators of hypercatabolic stress mechanisms has largely focused on the role of immunopeptide regulation of host metabolic response to injury. These endogenous mediators of postinjury hypermetabolism, including the humoral mediators of the neuroendocrine system, the autonomic nervous system, and the cytokines, can integrate and transfer information from the injury site to effect a response beneficial to the host. The next section focuses on the role of these mediators in the postinjury response.

Another recent hypothesis attempts to correlate the amount of protein catabolism observed in the hypermetabolic state with the cellular hydration state (121). This hypothesis postulates that cellular dehydration is the common pathway to signal an antiproliferative and catabolic state. Cellular dehydration is influenced by many factors, including altered nutrition, hormones, cytokines, and oxygen radicals. While it proposes an interesting mechanism for the proteolysis observed in critically ill patients, this hypothesis remains to be substantiated by multiple clinical trials.

Neuroendocrine Response

Early studies by Hume and Egdahl established the importance of an intact CNS in mediating the early response to injury (90). Their original studies demonstrated that the increase in adrenocorticoid steroids after a burn injury could be blocked by sectioning the peripheral nerve, cervical spinal cord, or medulla oblongata in dogs. Other clinical studies show less adrenocorticotrophic hormone (ACTH) or growth hormone (GH) release in response to minor tissue injury (herniorrhaphy) in patients receiving spinal anesthesia than in those receiving general anesthesia (91). The CNS also appears instrumental in the hypermetabolic response to injury. One study demonstrated that administration of inert gas anesthesia to hypermetabolic burn patients lowered their core temperatures and metabolic rates (92). A study of patients with head injuries who were in a barbiturate coma established that metabolic rate and nitrogen excretion were reduced to basal levels with administration of the barbiturate (93).

Afferent signals from the site of injury, baroreceptors sensing hypovolemia, and infection

can elicit hypothalamic mechanisms to stimulate the anterior pituitary to secrete prolactin, ACTH, antidiuretic hormone (ADH), and GH (29). ACTH release stimulates a increase in adrenal glucocorticoid secretion. Evidence of increased ACTH secretion has been observed following elective operations, extensive trauma (94, 95 and 96), thermal injury (97, 98), and infection (99, 100). Circulating levels of GH are markedly increased immediately postinjury and tend to decrease to normal levels within 24 to 48 hours.

Thyroid-stimulating hormone (TSH) levels do not appear to be greatly affected by injury. However there is a characteristic pattern of normal T_4 , elevated rT_3 , and depressed T_3 during prolonged periods of stress, which is related in part to calorie deficiency (101, 102) as well as in response to an inflammatory stimulus (103).

Catecholamines

The catecholamines, specifically epinephrine and norepinephrine, are rapidly produced in response to a variety of insults. Elevated levels are most pronounced during the early postinjury period (48 hours) and decrease during recovery (104, 105). Postinjury levels of catecholamines correlate to some extent with the severity of initial injury (105). Mild injury may elicit a moderate increase in catecholamines, while more severe injuries may be associated with a prolonged rise in urinary or circulating levels of catecholamines ([3] and references within).

The net metabolic influence of catecholamines is to increase energy expenditure, hepatic glycogenolysis, glycolysis, and lipolysis with a resultant increase in free fatty acid concentration. Paradoxically, catecholamine excess acutely decreases the efflux of amino acids from peripheral tissue while increasing lactate release from skeletal muscle. This was confirmed by studies in which epinephrine infusion into healthy subjects resulted in increased energy expenditure, hyperglycemia, lactic acidosis, and decreased amino acid efflux (5, 106, 107). Although the precise effect of adrenergic stimulation on protein kinetics is controversial, studies indicate that β -stimulation promotes gluconeogenesis and may limit skeletal muscle nitrogen loss, whereas α -adrenergic stimulation leads to protein catabolism (108, 109). Taken together these studies indicate appreciable catecholamine influence on the extreme changes in protein metabolism seen in severe stress and injury (see also Chapter 44).

Cortisol

Glucocorticoid excess promotes negative body nitrogen balance (106) but exhibits little influence upon overall energy expenditure (107). Cortisol effects a slight increase in free fatty acid concentration, promotes hepatic gluconeogenesis, and increases peripheral tissue amino acid efflux. In normal subjects, cortisol infusion alone produced the same net sustained nitrogen loss as that produced by combined cortisol, epinephrine, norepinephrine, and glucagon infusion (106). Also, short-term cortisol infusion in high physiologic concentrations in healthy subjects increased plasma amino acid concentration, particularly the branched-chain amino acids (leucine, isoleucine, and valine) (110, 111).

Insulin

Insulin levels are initially decreased during the ebb phase after injury but are mildly to markedly increased during the early flow phase. Hyperglycemia and hyperinsulinemia are characteristic of the early stress response. As stated above, the body becomes resistant to insulin in such tissues as adipocytes and skeletal myocytes (41, 112). The splanchnic tissues also display a relative resistance to insulin, manifested by continued hepatic gluconeogenesis despite elevated glucose levels (112, 113). Insulin resistance may be mediated in part by cortisol (42) as well as by catecholamines (41). The role of the characteristic hyperinsulinemia observed after injury remains unclear, as critical organs, including the CNS, hematogenous cells, wounds, and the kidney, can incorporate glucose in a insulin-independent manner. Nevertheless, continuous infusion of glucose and insulin resulted in decreased urine urea nitrogen excretion as well as decreased amino acid efflux and decreased 3-methylhistidine excretion (a marker of protein catabolism) (114); therefore, the increase in insulin may serve to decrease protein catabolism during the flow phase.

Glucagon

Circulating glucagon levels increase during the hypermetabolic postinjury phase and correlate roughly with the severity of injury (94, 115, 116). Glucagon appears to exert little independent influence on peripheral tissue metabolism (117) but is a potent stimulant of the hepatic cyclic AMP system, facilitating hepatic uptake of amino acids (118) and gluconeogenesis (119). Glucagon is also influenced by the autonomic nervous system (120).

Cytokines

Proinflammatory Cytokine Peptides

Proinflammatory cytokine peptides were originally studied for their effect on immunologic homeostasis in several areas, but they also exert potent activity toward regulation of hemodynamic and metabolic responses (122). During early postinjury or infectious conditions, the initial cytokine response to such insults likely mediates beneficial protective signaling of the immune system. Nevertheless, excessive acute production of some cytokines, such as TNF, may promote septic shock. Prolonged production of tissue cytokines sustains some metabolic effects of the hypercatabolic state.

The proinflammatory cytokine peptides are produced by diverse cell types of both myeloid and nonmyeloid origin. These proteins may function by autocrine (acting on the same cell), paracrine (acting on cells in the immediate area), or systemic mechanisms of action. They produce local tissue responses by cell-to-cell interaction at very low concentrations but also may exert systemic effects in higher concentrations. While many cytokines are now well characterized, those exhibiting the more prominent proinflammatory activities include TNF- α , IL-1, IL-6, and γ -interferon (IFN- γ) have been

more widely studied from a metabolic perspective ([Table 96.2](#)).

Cytokine	Cell Source	Metabolic Effects
Tumor necrosis factor- α	Monocytes/macrophages, lymphocytes, Kupfer cells, glial cells, endothelial cells, natural killer cells, mast cells	Decreased PPI synthesis Increased lipolysis Increased peripheral amino acid loss Increased hepatic amino acid uptake Fever
IL-1	Monocytes/macrophages, neutrophils, lymphocytes, keratinocytes, Kupfer cells	Increased ACTH Increased hepatic acute-phase protein synthesis Fever
IL-6	Monocytes/macrophages, keratinocytes, endothelial cells, fibroblasts, T cells, epithelial cells	Increased acute-phase protein synthesis Fever
IFN- γ	Lymphocytes, pulmonary macrophages	Increased monocyte respiratory burst

Table 96.2 Major Cytokines Involved in Hypermetabolic Response

Tumor Necrosis Factor. TNF is a 17-kDa protein primarily secreted from monocytes and macrophages. Although originally isolated as a soluble factor that produced cachexia during infection and (as implied by the name) in vivo necrosis of some solid tumors ([123](#)), this cytokine has been implicated as the initiating signal for a variety of cellular and metabolic events seen in critically ill patients. TNF administration to healthy subjects elicits a systemic response resembling that observed during septicemia ([124](#)), including increased stress hormone release, temperature elevation, and increased acute-phase protein synthesis ([125](#)). The systemic effects of bacterial liposaccharide (endotoxin) are replicated, if not largely mediated, by TNF ([125](#)). Indeed endotoxin infusion induces a rapid increase in circulating TNF levels, and blocking TNF with antibodies in animal models alleviates many of the toxic effects of endotoxin ([126](#), [127](#)). TNF may circulate predominately as a complex with its soluble receptors, making detection of the bioactive ligand more difficult. Increased levels of these soluble TNF receptors are seen in response to diverse inflammatory stimuli including sepsis, cancer, and AIDS ([43](#)) and references therein). Nevertheless, elevated TNF levels are detected in many disease states including bacterial infections, infected thermal injury, tumor-bearing states, sepsis, and AIDS ([40](#)) and references therein ([128](#)). The metabolic effects of TNF and perhaps of the proinflammatory cytokines seem to promote redistribution of body protein and lipid stores ([124](#)). The result is a net loss of peripheral tissue protein with a concomitant increase in hepatic uptake. Alterations in fat metabolism elicited by TNF resemble the changes seen in infection. They include promotion of cellular lipolysis and hepatic lipogenesis with decreased free fatty acid synthesis and decreased clearance of extracellular lipids ([126](#), [129](#), [130](#) and [131](#)).

Interleukin-1. IL-1 is produced by macrophages/monocytes, neutrophils, lymphocytes, and keratinocytes ([122](#)). Its production is stimulated by TNF and endotoxin, and, like TNF, it may represent an early cytokine response to injury. Once released, it exerts multiple immunologic and metabolic effects including stimulation of ACTH ([132](#)),

induction of fever, hepatic acute-phase protein synthesis, and alteration of energy metabolism (122). Like TNF activity, IL-1 activity is regulated by shedding of soluble receptors, as well as by a unique, naturally occurring receptor antagonist (IL-1ra) (133). IL-1ra binds to the IL-1 receptor without an agonist influence.

Interleukin-6. IL-6 is the most frequently detected cytokine in patients with acute infection (134), injury, and tumor-bearing states (135) and after elective surgical procedures (136). The biologic actions of this protein include regulation of acute-phase protein synthesis after injury (137, 138) and differentiation of lymphocytes (139). It also induces fever via prostaglandin production (140). Administration of IL-6 to humans induced modest changes in the kinetics of glucose and protein. (141)

Interferon-g. IFN-g is secreted from lymphocytes and macrophages and exerts antiviral effects as well as protection against bacteria, fungi, and parasites. It enhances TNF production in response to endotoxin (142) and increases the cytotoxicity of monocytes, possibly by increasing their respiratory burst activity (143). A direct role for IFN-g in directing altered metabolic processes has not been defined in humans, although its administration does induce cachexia and loss of protein and lipid stores in animals (144).

Antiinflammatory Cytokines

Regulation of the various cytokines produced in response to injury or disease is complex and involves counterregulation by antiinflammatory cytokines such as IL-10, which downregulates secretion of proinflammatory cytokines (i.e., TNF and IL-1) as well as suppressing macrophage and T-cell functions.

Neuroendocrines and Cytokines

Recent work indicates that the neuroendocrine system also exerts a significant influence upon production of both pro- and antiinflammatory cytokines. For example, glucocorticoids can inhibit production of TNF or IL-6 (142, 145 and 146), and in the case of TNF, the mechanism appears to include altering transcription of the mRNA (147). Cortisol infusion attenuates the endogenous TNF response to endotoxin administration (142, 143). Catecholamine infusion also inhibits endotoxin-induced TNF production while simultaneously increasing release of IL-10 (148). Hence, the neuroendocrine milieu elicited by injury, infection, or other hypermetabolic conditions may serve to alter cytokine mediator activities in a complex manner. It remains to be determined to what extent these parallel signaling pathways direct the human metabolic response.

SYSTEMIC AND ORGAN REACTIONS

Gastrointestinal Tract

The gastrointestinal tract provides important nutrient absorptive and metabolic functions and recently has emerged as an immunologically important organ. TPN and bowel rest are associated with an exaggerated response to injury (152). The etiology of this

enhanced response is unclear, but bowel rest or TPN may alter intestinal flora or intestinal mucosal permeability. The gut mucosa normally provides a barrier to foreign material such as bacteria, their products, and other ingested particles. Enteral feeding is essential to maintain the integrity of this mucosal barrier (149, 150). In animal studies, bowel rest and parenteral nutrition produce increased translocation of bacteria to intestinal lymphoid tissue (151). Whether bacterial translocation is an important source of systemic bacteremia and sepsis during disease states in humans is a matter of debate. However, it may be that stimulation of splanchnic immune cells by foreign antigens that have crossed the mucosal barrier influences systemic immunologic and metabolic processes during disease states. Cytokines secreted by splanchnic cells or lymphocytes or macrophages influence both the immune and hemodynamic responses to injury as well as the metabolic response (153, 154). In this way, the intestine may partially regulate the immune response to injury or disease.

Cachexia

The hypermetabolic response may result in cachexia if it is allowed to proceed unabated. The clinical syndrome of cachexia is characterized by anorexia, tissue wasting, and weight loss and can occur in many different disease states such as cancer, chronic infection, and AIDS. Multiple mechanisms appear to be involved in the development of cachexia, including anorexia, decreased physical activity, decreased secretion of host anabolic hormones, and altered host metabolic response with abnormalities in protein, lipid, and carbohydrate metabolism. The degree of wasting is an important prognostic factor, with a weight loss to 66% of ideal body weight being predictive of death regardless of the specific cause of the weight loss (155). Therefore, a more thorough understanding of the pathogenesis of cachexia might lead to further therapeutic options that theoretically could improve survival (see also [Chapter 41](#)).

The degree of wasting does not correlate with the infective burden or tumor size; thus it appears to be the host response via endogenous mediators that effects the cachectic response in diseased patients. Much research has focused on possible mediators of the cachexia induced by disease, with much attention on cytokine mediators of anorexia, most notably TNF, but also IL-1, IL-6, IFN-g, and leukemia-inhibitory factor. TNF can induce weight loss when given in increasing doses or continuous infusion or when secreted from tumors genetically engineered to express TNF (156). However, TNF is not often found in cancer patients with cachexia (157) and generally is not found in patients with chronic infections that lead to wasting, including AIDS (158). In addition, it has been difficult to correlate levels of TNF or IL-6 with the degree of cancer cachexia (157, 159), and leukemic factor itself may be toxic (160).

Other work has focused on the leptin molecule, which appears to play a significant role in weight maintenance. Alterations in the leptin molecule or its receptor result in weight control abnormalities (161). Because leptin expression is increased in response to endotoxin, TNF, and IL-1, it may be an important factor in weight loss in the stress response.

Recent research has identified another potential mediator of cachexia which is a proteoglycan isolated from mice with adenocarcinoma and from the urine of cachectic

cancer patients ([162](#)). In this study using a murine adenocarcinoma, MAC16, transplantation of tumor cells in mice induced significant cachexia without anorexia. The proteoglycan was isolated from the mice and found to induce cachexia in non-tumor-bearing animals. Also, the proteoglycan was present in cancer patients with weight loss but absent in patients with weight loss attributable to other factors. Further characterization and study of this molecule may yield new insight into the pathogenesis of cachexia.

GENERAL NUTRITION AND ANABOLIC SUPPORT

Macronutrients

Treatment of patients who are hypermetabolic for extended periods of time should in all likelihood include nutrient supplementation. Nutritional management of stressed patients is reviewed in [Chapter 92](#), [Chapter 98](#), [Chapter 100](#) and [Chapter 101](#) of this textbook and is only briefly mentioned here.

The fundamental objectives of nutritional support of the hypermetabolic patient are to provide sufficient nonprotein energy sources and sufficient protein substrate to alleviate or at least minimize catabolism of endogenous energy and protein stores. Enteral and parenteral nutritional support in depleted patients often demonstrably improves nitrogen balance during the catabolic phase of injury ([163](#)). Enteral nutrient provision is clearly the preferred route of feeding in the presence of a functional intestinal tract. Recent studies indicate that there may be some clinically demonstrable benefit to enteral feedings in selected patient populations ([164](#), [165](#) and [166](#)).

There is also evidence to suggest that some nutrients may become conditionally essential during catabolic illness. Among these are the amino acid glutamine, which is a major component of the tissue free amino acid pool and appears to be rapidly depleted in periods of stress. It is also essential for nucleotide and glutathione biosynthesis, as well as gluconeogenesis. Other studies suggest that other amino acids, such as arginine, may also be limiting to the maintenance of lymphocyte function and wound healing ([167](#), [168](#)) (see also [Chapter 35](#)).

Anabolic Therapy

Although nutritional supplementation may improve body nitrogen and calorie balance during hypermetabolic states, progressive depletion of structural protein still continues. Consequently, additional means of adjuvant anabolic therapy, such as insulin, insulin-like growth factor (IGF-1), anabolic steroids, or GH, have been investigated in an effort to decrease muscle protein loss in hypermetabolic patients. Administration of GH or IGF-1 increases skeletal muscle amino acid uptake and muscle mRNA synthesis during full nutritional support ([169](#), [170](#)).

IGF-1 infusion in healthy humans also increases peripheral glucose disposal, reduces lipolysis, and decreases total branched-chain amino acid levels, suggesting a protein-anabolic effect ([171](#), [172](#)). Insulin administration also reduces protein loss in

burn and trauma patients, resulting in decreased urinary urea excretion and reduced protein breakdown rates (173, 174). Recent studies using a combination of GH and insulin in cancer patients indicate that this combination therapy may lead to whole-body nitrogen retention and skeletal muscle sparing (175). GH affects nitrogen balance positively by exerting an anabolic effect on proteins (176). In clinical trials, the effect of GH also seems to depend on the severity of injury. In patients under mild-to-moderate stress, GH does promote improved nitrogen balance, with an anabolic effect on protein synthesis. However, in severely stressed patients (those losing more than 1.5 g/kg/day protein), exogenous GH is not demonstrably effective as an anabolic agent (177). While most studies show anabolic effects of GH treatment of patients in mild-to-moderate catabolism, improved clinical outcome has been difficult to document in most hypermetabolic patient populations. A study of ventilator-dependent critically ill patients does suggest that prolonged GH treatment may promote pulmonary function in this group (178).

Micronutrients

The major intracellular elements—potassium, magnesium, and phosphate—follow patterns of nitrogen loss in response to acute infection (183). Zinc as well as iron is sequestered by the liver, with a decrease in circulating plasma levels. This may represent a host survival mechanism during infection by making zinc and iron unavailable to the replicating bacteria. Increases in serum iron concentration during infection may impair the host resistance to infection. Zinc is essential for wound healing, and thus adequate levels must be maintained in the stressed individual to ensure healing. Ceruloplasmin synthesis is increased by the liver with a concomitant rise in copper levels. There is catabolic destruction or urinary loss of many vitamins, most notably vitamin A, which may contribute to morbidity and mortality in some infections.

NUTRITIONAL SUPPORT IN ORGAN FAILURE

The hypermetabolic patient who responds to therapeutic interventions will proceed to an anabolic stage of recovery and, eventually, positive nitrogen balance. However, some patients continue to be hypermetabolic and may develop multiorgan system failure. The pathogenesis of organ system failure remains to be completely clarified, but it is multifactorial. With the onset of multiorgan system failure, nutritional requirements may be modified.

Pulmonary

Respiratory insufficiency may be the end result of protein-energy malnutrition leading to decrease in muscle mass of respiratory muscles as well as disturbances in respiratory drive (179). The net result is increased CO₂ retention and difficulty in oxygenation. This process may be exacerbated by vasoactive factors released during infection that increase pulmonary vascular permeability with an ensuing ventilatory mismatch. It is hypothesized that increased CO₂ production from the carbohydrate provided in supplemental nutrition increases CO₂ retention. Therefore an increased proportion of

calories from lipid might be used in these patients (see also [Chapter 90](#)).

Kidney

The etiology of acute renal failure in the injured or septic patient is multifactorial and can include shock, nephrotoxic drugs, glomerulonephritis, and urinary tract obstruction. The multiple metabolic consequences of renal failure include fluid and electrolyte abnormalities as well as alterations in protein, carbohydrate, lipid, trace element, and vitamin metabolism ([180](#)) with decreased clearance of phosphate, potassium, and magnesium and elevations in their concentrations as the result of impaired glomerular filtration. Acidosis develops from decreased renal excretion of acid and increased tissue catabolism. Uremia ensues due to increased protein breakdown and decreased urea clearance. When renal tubular disorder is present (e.g., as the result of nephrotoxic drugs), renal loss of minerals may occur. Dialysis is initiated to minimize these metabolic disturbances. Traditionally, patients with acute renal failure have been treated with low-protein nutritional support to decrease urea production. However, there are no data to indicate that a low-protein intake can decrease loss of renal function or improve recovery of renal function in acute renal failure ([180](#)). Therefore, protein should not be restricted; nutritively sufficient amounts should be given, with increased metabolites and waste products treated by appropriate dialysis. The protein requirements in dialysis patients are higher than normal because of increased catabolism in these patients and loss of nutrients in the dialysate ([180](#)). Data suggest that hypercatabolic patients with acute renal failure require 1.25 to 1.5 g/kg/day of protein, with higher requirements for patients receiving dialysis. Close regulation of magnesium, potassium, and phosphate is also necessary in patients with renal failure.

Liver

Hepatic dysfunction in the critically ill patient ranges from mild abnormalities in liver function tests to fulminant liver failure with severe jaundice and wasting. Nutritional requirements in such patients depend upon the primary disease process underlying the liver dysfunction. Infectious processes that affect the liver itself, such as hepatitis, localized abscesses, and pylephlebitis, may result in liver dysfunction. In the presence of encephalopathy, the protein load should be decreased, and parenterally administered amino acids are generally better tolerated than those administered enterally ([181](#)). Some have advocated use of solutions high in branched-chain amino acids with no aromatic amino acids, but the benefit of such solutions is controversial ([182](#)).

Occasionally, hypoglycemia may occur in end-stage liver failure. More often, minor elevations in liver function tests occur during the course of intravenous feeding. This generally resolves after cessation of parenteral feeding and, in the absence of drastically altered liver function or associated inflammatory processes, is of minimal consequence to the acute recovery process.

Heart

The goal of nutrition in patients with cardiac failure is to provide nutrient requirements in limited fluid volume with restricted sodium intake. This can be achieved parenterally with

a concentrated solution of hypertonic dextrose, but as with most patients, enteral feeding is preferred.

The temporal relationship between nutrition and infection has long been appreciated, and there are many historical references to the concurrence of pestilence and famine (1). Even the catabolic response to infection was known in history, as evidenced by the popular designation of tuberculosis as “consumption.” A more recent example of the obvious nature of the interaction of nutrition and infection is acquired immune deficiency syndrome (AIDS), which was first recognized in East Africa by the lay term “slim disease” because of the dramatic wasting in these patients (2).

Slower to develop has been an understanding of the mechanisms involved and an appreciation of the intricate coupling of the altered host metabolism, which underlies catabolic responses, to activation and amplification of host defenses. Much has been learned and many new interventions are being defined and investigated. Nonetheless, much remains to be done to critically assess the impact of individual and combined nutrient deficiencies on immunologic host defense mechanisms. This chapter explores these issues and describes the multifaceted relationships between nutrition, immune responses, and infection. To provide the background needed to understand the complexities involved, host defense mechanisms are reviewed first.

HOST DEFENSE MECHANISMS

The immune system is highly organized, and its function in the host response to infection represents an extraordinary integration of multiple functional components (3). Host defense is not synonymous with immunity, since there are both immunologic and nonimmunologic defense mechanisms. An example of a nonimmunologic defense is the ability of gastric acid to protect against infection with certain enteric pathogens, e.g., *Vibrio cholerae*, the causative agent of cholera, or nontyphoidal salmonellae, common causes of food- or waterborne diarrhea. These organisms are rather acid intolerant, and

the typical pH below 1 in gastric contents during a meal more than suffices to lower the viability of an ingested inoculum to a number too low to cause clinical infection. Individuals with defects in gastric acid production for any reason, whether due to prior ulcer surgery or current use of H₂ blockers, are thus at increased risk if exposed to the pathogens. This is clearly shown by epidemiologic evidence obtained during the present cholera pandemic. When cholera reached Europe during the 1970s, clinical disease was observed primarily among individuals with hypochlorhydria (4). While protection based on creating a hostile environment (such as low pH) is “nonspecific” in that no specific recognition events are involved, not all pathogens are affected by the gastric acid barrier. For example, no relation has been found between hypochlorhydria and *Shigella* infection, because these organisms have an adaptable acid-resistance response that is turned on as the organisms reach stationary phase (5). These conditions occur as the organism is excreted in the stool; hence, *Shigella* are in an acid-resistant stage when they reach the environment, ready to infect the next host who ingests the organisms.

In contrast, immunologic mechanisms are truly specific in the sense that they depend on stringent receptor-ligand recognition mechanisms. Similar specific recognition also underlies the typical species, organ, and cellular selectivity of infectious agents. On the host side of the equation, specific immune responses are mediated by effector cells, such as T lymphocytes, macrophages, and granulocytes, or soluble molecules, such as antibodies, complement (C)-derived peptides, and cytokines (also see Chapter 45). Given this organization of the immune system, and the *specificity* inherent to both infection and immune responses, it is not surprising that immune defenses exhibit *selectivity* as well; that is, individual responses are specialized for certain classes of infecting agents and not others. Convincing clinical evidence of this level of specialization comes from observations of patients with genetically mediated immunodeficiency states that predispose to some, but not all, types of infection (Table 97.1) (6). In general, humoral defects of antibody or complement predispose to pyogenic systemic bacterial infections; defects of T cells and cell-mediated immunity (CMI) commonly predispose to viral, fungal, and intracellular bacterial infections; and defects of phagocytes increase the prevalence and severity of pyogenic bacterial and certain fungal infections.

Nature of Defect	Associated Pathogenic Organisms			
	Bacteria	Viruses	Fungi	Parasites
Agammaglobulinemia	HB, SA, St, P ^a	EBV ^b	SI, P ^c	—
IgG deficiency	—	—	—	—
IgM deficiency	OM, S, CSP	—	—	—

Table 97.1 Infections in Congenital Immunodeficiency Syndromes

For example, X-linked agammaglobulinemic males develop recurrent pyogenic infections of the respiratory tract, middle ear, and skin, beginning in the second year of life after maternally acquired immunity wanes. The most common pathogen is *Haemophilus influenzae*; however, significant problems with *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and *Pseudomonas* spp. also are found. Yet these children have no difficulty with diarrheal diseases, urinary tract infections, or common childhood viral illnesses.

Congenital deficiency of complement components also results in specific heightened susceptibility to encapsulated bacterial organisms, even though complement activation products are critical to orderly and effective activation of the entire inflammatory response. Deficiencies of the early components of the classical pathway, C1, 2, or 4, are not ordinarily accompanied by increased systemic infections, but when these do occur, they are commonly due to *S. pneumoniae* or other encapsulated bacteria. No doubt the ability to activate complement via the alternative pathway serves an important protective function in these patients. When C3 is deficient, however, neither pathway can be effectively activated, and encapsulated bacteria such as *S. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis* cause severe and recurrent infections. Deficiency of either late components or properdin of the alternative complement pathway frequently leads to invasive infection with *N. meningitidis* in particular.

Severe combined immunodeficiency is a syndrome with different genetic causes, but all are characterized by marked reduction in T cells and a decrease in CMI competence. Affected children experience AIDS-like opportunistic infections with *Candida albicans* and other skin pathogens, chronic diarrhea, and interstitial pneumonia, commonly due to *Pneumocystis carinii*. If bacillus Calmette-Gu'rin (BCG) is given as a routine childhood immunization at birth, progressive systemic BCG infection may occur. Whereas varicella, herpesvirus, or adenoviruses cause disseminated and severe infections, the pyogenic bacteria are not especially troublesome.

Defects of phagocytic cell function (e.g., chronic granulomatous disease, in which neutrophils cannot generate normal oxidative bactericidal products) result in excess susceptibility to organisms positive for catalase, the enzyme that breaks down the bactericidal product, hydrogen peroxide, to water and oxygen. Catalase-negative organisms, such as *S. pneumoniae* or *S. pyogenes*, are not a problem because they cannot detoxify the hydrogen peroxide they produce during growth; therefore, these organisms are quickly eliminated. Chronic granulomatous disease (CGD) patients typically develop serious infections with *Staphylococcus aureus*, gram-negative bacilli such as *Pseudomonas aeruginosa* and *Serratia marcescens*, and fungi such as *Aspergillus*, but not with routine upper respiratory bacterial pathogens or usual childhood viral pathogens.

Based on these correlations between particular immune mechanisms and susceptibility to specific organisms, it should be possible to predict the effects of nutritional immunodeficiencies on clinical susceptibility to infection ([Table 97.2](#)). Such predictions

are less than perfect, however, because there is a built-in redundancy and capacity for adaptation in the immune system. Thus, specific defects in host responses may be measurable by in vitro functional tests and yet not be associated with increased clinical infections because alternative defense mechanisms are available to the host.

Congenital immunoglobulin (Ig)A deficiency is such an example in which production of IgM and IgG antibodies compensate for diminished mucosal immunity due to lack of IgA. Similarly, patients with congenital absence of myeloperoxidase, a neutrophil enzyme involved in generation of bactericidal oxygen radicals, usually do not experience recurrent or unusually severe infections because other bactericidal products are still produced.

Immune Defect	Associated Microorganisms
T-cell responses	Intracellular bacteria, measles, <i>Pneumocystis</i> , <i>Candida</i>
Antibody defects	Mucosal infections, pyogenic bacteria, fungi
Neutrophil defects	Pyogenic bacteria, gram-negative bacilli
Complement defects	Gram-negative bacilli

Table 97.2 Immune Defects and Infections in Protein Energy Malnutrition

FUNCTIONAL ORGANIZATION OF THE IMMUNE SYSTEM

Organization of the immune system is detailed in [Chapter 45](#). This section addresses interactions between components of the immune system and various infectious agents in more general terms. Activation of host responses may involve simply triggering biochemical reactions or proteolytic cascades such as the complement system, which result in production of biologically active products that alter the host-pathogen interaction. The other hallmark of immune responses is the proliferation of specific clones of T and/or B lymphocyte subsets that recognize specific antigens, as well as the division of bone marrow granulocyte precursors. Therefore, it is reasonable to predict that any nutritional deficit that impairs the ability of a host to sustain cellular proliferation can adversely affect host defense. This is particularly important because it is often the *speed* with which host responses are called into play that determines the difference between harmless encounters between host and microorganism and a fatal infection. Indeed, any reduction in the capacity to support growth and expansion of immunologically capable cells caused by nutrient deficiencies (or in some situations, even nutrient excess) can tip the balance toward more dire outcomes.

Once set in motion, however, host defense responses generate products able to

damage normal structures, and the host must be able to dampen and control these reactions. For this reason, elaborate mechanisms involving regulatory cells and proteins have evolved for all classes of immune reactions, to modulate responses and ultimately prevent “immunologic runaway.” There are also well-characterized situations in which the host response results in clinical pathology that is amplified in the presence of nutritional deficits because normal immunoregulation fails and leads to more extensive immunopathology. In contrast, nutritionally induced immunodeficiency may diminish immunopathology, as in *Schistosoma mansoni* infection. In this disease, granuloma formation and fibrosis are mediated by specific T cells, and nutritional deficiencies that reduce the ability to mount CMI reactions decrease the size of the granuloma formed in response to schistosome eggs deposited in the liver. Nutritional modulation of granuloma size and diminished organ damage and dysfunction have been documented in experimental murine schistosomiasis.

Separating the immune system into its *cellular* compartments (including T lymphocyte and phagocytic cell responses) and *humoral* compartments (including complement, antibody, and cytokine responses), while convenient, nonetheless obscures the extent of the *interactions* among these elements. For example, B lymphocytes are essential but not sufficient for antibody formation, which requires antigen-presenting macrophages and T cells; normal phagocytes cannot function without complement and antibody for opsonization; and various cytokines produced by either lymphocytes or monocyte-macrophages interact with all of these cells to up- or downregulate their function. The term *immune system* should be interpreted literally to suggest that the various “compartments” really do function as an interactive “system” in which communication among the individual parts is critical.

Viruses

Viruses are obligate intracellular pathogens because the number of viral genes is insufficient to encode the necessary life-support “housekeeping” functions for the organism. Therefore, viruses must usurp the metabolic machinery of the host cell to carry out their own life cycle. It is quite remarkable how intricate this simple life form is and how diverse are the habitats and the pathologic processes viruses induce, ranging from acute to chronic or even latent quiescent or relapsing infections of particular organ systems, to induction of tumors and autoimmune diseases, and to infection and destruction of CD4+ helper T lymphocytes, the distinctive feature of human immunodeficiency virus (HIV) infection, which leads to the dramatic immunosuppression of AIDS. Different viruses can enter the host across the skin or mucous membranes by inhalation or via inoculation from infected blood or tissues; viruses are versatile. Viremia or replication within specific organs or cell types, or both, can result in almost any combination of cellular dysfunction, inflammatory responses, damage, and destruction, which determines the nature of the subsequent clinical disease. Species specificity and both tissue and cell tropism can differ significantly among isolates of the same virus and may result from limited alterations in the virus genome.

As a general rule, soluble antigens produce good humoral immunity and poor lymphocyte-mediated cytotoxic cellular immunity, whereas antigens synthesized within cells and presented as a complex with the major histocompatibility complex (MHC)

glycoproteins generally induce cytotoxic cellular immunity. Viruses can stimulate both kinds of response. The MHC antigens in humans are called HLAs, for human leukocyte antigens, and they comprise several distinct groups of molecules. Class I MHC determinants are transplantation antigens and include three loci in humans (HLA-A, -B, and -C) present on the surface of virtually all nucleated cells. Class I molecules act as antigen-presenting sites for molecules from intracellular pathogens and are recognized by CD8+ cytotoxic lymphocytes (CTLs). In this way, virus-infected cells are killed by the CTL response, virus replication is interrupted, and the disease process is controlled. This is accomplished largely by production of a membrane-attack protein complex similar to the terminal complement C7,8,9 complex, which punches holes in the infected target-cell surface. Some viruses also induce suppressor lymphocyte responses among CD8+ cells, thus downregulating both virus-specific CMI and antibody mechanisms, and in a nonspecific manner, responses to unrelated infectious agents as well.

In contrast, MHC class II molecules are more restricted in distribution to macrophages and T and B lymphocytes and are used to present extrinsic soluble antigens to the humoral immune system. Thus, soluble antigens encountered by macrophages are internalized, processed, and placed on the surface of the antigen-presenting cell in association with the class II molecule. The complex is recognized by T-cell receptors on CD4+ helper T cells, which in turn interact with B cells capable of antibody responses. Certain viruses such as poliovirus are effectively neutralized by antibody present in secretions or plasma. Live oral polio vaccine, like natural infection, induces a local immune response in the gut, including neutralizing secretory IgA that inactivates orally ingested virus before it can invade through the intestinal mucosa and systemically spread to the central nervous system. Killed polio vaccine induces only systemic antibodies that to be effective must interact with the virus in the circulation before it reaches target neurons in the spinal cord. Both vaccine approaches work.

Interferons

Some antiviral effects are mediated or conditioned by soluble host products such as interferons (IFNs), a family of immunoregulatory proteins with direct or, more likely, indirect antiviral properties. Three related IFN classes include IFN- α (leukocyte derived), IFN- β (fibroblast derived), and IFN- γ , or "immune" interferon (produced by antigen- or mitogen-activated lymphocytes). These IFNs have diverse biologic effects, but all regulate expression of normally repressed cellular genes. Surprisingly, recent clinical trials of the antiviral effects of recombinant IFNs has shown that IFN- α , not IFN- γ , is of greatest efficacy; however, the underlying mechanism remains uncertain.

Complement

Complement can also contribute to antiviral effects by binding to the agent and preventing attachment to receptors, by opsonizing virus-antibody complexes for phagocytosis and later degradation, or by mediating direct lysis of lipid-enveloped viruses. Typical complement-antibody lysis of virus-infected cells is demonstrable in vitro as well. Viruses can also cause immunologically mediated pathology, and a variety of mechanisms are known. With per-sistent infections such as hepatitis B, measles, or cytomegalovirus, even normal antibody responses can lead to deposition of circulating

antigen-antibody complexes in tissues with fenestrated vessels such as the renal glomerulus, resulting in acute glomerulonephritis. Recent data indicate that IgE virus-specific antibodies to parainfluenza or respiratory syncytial virus cause local mast cell degranulation in the lung and may lead to the severe respiratory symptoms sometimes associated with these agents, especially in children with hyper-IgE responses. Viruses are also suspected as an inciting cause of autoimmune phenomena as in postinfection encephalitis after common viral infections such as measles, mumps, and varicella-zoster.

Bacteria

Bacteria, like viruses, are exceedingly diverse life forms, ranging from strict anaerobes, to facultative anaerobes able to survive in the presence or absence of oxygen, to organisms that absolutely require oxygen. Some can grow at very high temperature (e.g., in hot springs) while others prefer cool temperatures; some tolerate or require high salt concentrations (seawater organisms such as *V. cholerae*, the cause of cholera); most divide rapidly, but some grow very slowly; certain organisms possess polysaccharide capsules, others have a proteinaceous coat; many are motile, and many are not; a few make lethal toxins, and some others produce required nutrients for the host.

A major host defense response against bacteria is ingestion by phagocytic cells, with bacterial killing resulting from alterations in host cell metabolism. Ingestion may require the presence of immunoglobulin or complement-derived opsonins, which bind to the surface of the organism and assist in the close interaction of phagocytic cells and bacteria that is necessary for inducing phagocytosis. This requirement for opsonic help is particularly important when the infecting microorganism makes an antiphagocytic carbohydrate capsule, as is the case with *Streptococcus pneumoniae* or gram-negative organisms such as *Klebsiella pneumoniae*. Unless the ingested organism can inhibit the subsequent activation of antibacterial mechanisms within the phagolysosome (e.g., *Legionella pneumophila*), phagocytic ingestion of a microorganism triggers release of bactericidal oxidative and nonoxidative metabolic products. Not only must there be enough host cells able to produce these bactericidal substances (infection is much more likely when there are fewer than 500 neutrophils per mm³, as seen in neutropenic patients), but they must also be able to migrate to the site of infection and respond to external stimuli in appropriate fashion.

Some bacterial pathogens, termed *facultative intracellular pathogens*, can survive and multiply within phagocytic cells. They use a variety of strategies to accomplish this. Organisms that survive in the intracellular niche in neutrophils or, especially, within macrophages may sense unique signals in the phagolysosome in which they reside, however temporarily, such as low pH or Ca²⁺ concentration. These signals regulate bacterial genes controlling their ability to resist phagocyte antibacterial mechanisms. How to activate the latent bactericidal mechanisms for such “facultative intracellular” organisms remains a frontier question in microbiology. In many examples, later immunologic engagement of T lymphocytes leads ultimately to macrophage activation and production of interferons and other cytokines that induce acquired microbicidal

capability.

Specific immunoglobulins serve many functions in the immune response. Immunoglobulins recognizing and binding to bacterial surface structures via their antibody-combining site (Fab region) can opsonize and facilitate attachment of the organism to phagocyte receptors for the other end of the Ig molecule, the Fc portion. Binding of opsonized organisms to Fc receptors also initiates phagocytic uptake. Immunoglobulin on the bacterial surface can also lead to complement activation and assembly of the terminal complex of C7,8,9, directly resulting in bacterial lysis and death. Thus, it is not surprising that bacteria recovered from the bloodstream of septic patients are usually resistant to complement-mediated lysis. In many cases, complement resistance is not due to either the failure of complement activation or its assembly on the bacterial cell surface, but rather to a more fundamental failure in the microbe's response to complement deposition.

Antibody directed to specific virulence attributes of a bacterium can interfere with disease pathogenesis. For example, anti-colonization factor antibodies may prevent initial establishment of infections on mucosal surfaces, and such antigens are targets for vaccine development for mucosal pathogens of the oral, respiratory, intestinal, and genitourinary tracts. A variation of the same theme is to produce antibody to the invasins mediating epithelial cell penetration by invasive bacteria. These antibodies should restrict systemic infection by organisms such as *Salmonella* (including the typhoid bacillus), *Listeria monocytogenes*, and many others.

When disease results from the action of specific bacterial products, such as toxins, antitoxins can prevent symptoms even if the same antibodies arising during infection are too late to affect its course. In fact, this strategy was the first success of applied microbiology almost a century ago, when vaccines were developed for tetanus and diphtheria based on inactivated toxin antigens. Much contemporary research on microbial pathogenesis is therefore designed to identify molecular targets for immunization, although few infections have turned out to be as simple to deal with as tetanus or diphtheria. Protective antibody-mediated immunity can be induced by a proper vaccine even when antibody plays no role in recovery from natural infection. For example, an unimmunized patient surviving clinical tetanus remains susceptible to the disease unless immunized with toxoid because so little antigen is produced during the natural infection that no effective immune response results. Similarly, it is possible to protect against *Salmonella typhi* by immunizing with the Vi polysaccharide antigen of the organism; however, Vi antibodies arising during the course of established typhoid fever have no impact on recovery. This is because preexisting anti-Vi is bactericidal during the initial bacteremia of *S. typhi* infection, and by preventing initial invasion of macrophages by the organism, it prevents the clinical disease. But the antibody has little impact on the course of the intramacrophage phase of the infection.

Complement activation is essential for efficient activation of the inflammatory response and phagocytic cell function, especially for bacterial infections. Thus, products of complement activation are potent chemotactic factors for neutrophils; they increase vascular permeability and facilitate movement of intravascular phagocytic cells to tissue, and they serve as opsonins or mediate bacteriolysis. The complement cascade can be

activated by two different pathways (see [Chapter 45](#)): the classical pathway, which requires specific antibody to form a complex with the first, second, and fourth components of complement, or an “alternative pathway” that does not require specific antibody and involves a set of distinctive proteins including factors B and D. Once the system gets going, both pathways result in cleavage of C3, which triggers further activation of the system, and from then on, the biologic results are the same. Because specific antibody is not needed for complement activation via the alternative pathway, this system is of particular importance early in infection before antibody develops.

Fungi

Humans are normally rather resistant to systemic fungal invasion, although mucosal yeast infections are common. Severe mucosal yeast infections occur in patients with defects in CMI, as in AIDS. In the presence of severe neutropenia, however, invasive candidiasis becomes prominent. Risk of fungal infection is increased as well in the presence of debilitating illness, especially when patients have tracheal tubes, catheters, and/or multiple indwelling intravenous lines in place, including hyperalimentation lines.

Parasites

Relatively little is known about immune defenses against protozoa and worms. Many disease-causing parasites have evolved strategies to fool the host by turning off immune responses. They can masquerade as “self” by expressing host self-antigens on their surface or evade recognition by continuously shedding surface antigens recognized by the host immune system or by rapidly changing antigens. Some parasites may be able to subvert killing mechanisms directly within phagocytic cells. For example, they may be polyclonal B-cell activators, stimulating production of a large array of irrelevant antibodies instead of protective ones, or they may induce selective immunosuppression. In general, however, defects in CMI responses, but not antibody, complement, or phagocytic cell abnormalities, increase risk of parasitic infection.

NUTRITIONAL INTERACTIONS

Effects of Protein-Energy Malnutrition on Host Defense Mechanisms

The development of laboratory methods to study immune responses of relevance to host defense has permitted studies in patients with protein-energy malnutrition (PEM) (see [Chapter 45](#) and [Chapter 59](#)). A broad range of abnormalities have been identified, including both cellular and humoral immune defects, suggesting that an immunodeficiency state may be responsible for the high frequency of severe infections in these patients ([Table 97.2](#)). However, many subjects have been infected at the time of study, making it difficult to determine cause and effect of immunologic deficits (infection can be immunosuppressive), and few studies have been longitudinal, which would permit determination of the temporal impact of the defect on clinical responses.

PEM has been described as a mosaic of nutrient deficits resulting from diverse dietary inadequacies, complicated by infection-induced anorexia and catabolism ([7](#)). It is best

understood as a syndrome associated with variable losses of protein, carbohydrate, and fat stores, along with changes in micronutrients such as minerals and vitamins. However, in practice, the physical and biochemical markers of protein and energy depletion are most obvious and most likely to be recorded. The clinical definitions of PEM are broad and cover a range of physiologic abnormalities. Because PEM patients are not metabolically homogeneous, it is surely perilous to describe any associated immunologic abnormalities in general terms. Nevertheless, a common finding in these patients is depletion of lymphocytes from the central and peripheral lymphoid tissues, particularly in T-cell regions of thymus, spleen, and lymph nodes (8). On this basis, PEM has been dubbed the most prevalent acquired immunodeficiency syndrome in the world.

Based on current understanding of normal T-lymphocyte development, the importance of the thymus gland in this process, and the role of thymic peptide hormones, the reduced circulating thymic factor levels described in a few studies in PEM patients suggest that the T-cell defect in PEM may represent maturational arrest secondary to an abnormal thymic environment (9). In one study of severely malnourished Bolivian infants, thymic involution was documented by sonography, with a reduction of over 90% in the size of the thymus gland compared with normally nourished controls (10). The impact is a relative reduction in circulating mature T lymphocytes. Thus, blood samples obtained for study are enriched in immature and functionally defective cells, defined on the basis of lymphocyte cell-surface maturation antigen expression (Table 97.3). In addition, incubation of peripheral blood lymphocytes from these malnourished Bolivian infants with the thymic peptide thymulin dramatically decreased immature circulating CD1a+ T cells and increased mature CD3+ T cells, without a change in the percentage of CD21+ B cells (Table 97.3). The reduction in mature CD4+ helper T cells (T_H) and, to a lesser and more variable extent, an increase in CD8+ cytotoxic-suppressor T cells ($T_{C/S}$) result in impaired delayed-type skin hypersensitivity responses in vivo and inhibited mitogen- and antigen-driven lymphocyte proliferation in vitro. The clinical consequence of this finding is a reduction in the efficacy of host defenses that depend on T-cell function, including macrophage microbicidal mechanisms for intracellular pathogens and T cell-mediated cytotoxic responses to viruses.

Antigen	% Mono-Positive Cells, Controls			% Mono-Positive Cells, Malnourished Peers		
	None	With Thymulin	p	None	With Thymulin	P
CD1a	7.6 ± 0.8	3.0 ± 0.3	<.01	0.7 ± 0.1	15.2 ± 0.8	<.01
CD3	61.7 ± 1.3	65.1 ± 1.2	ns	51.3 ± 1.0	65.6 ± 1.1	<.01

Table 97.3 Lymphocyte Subpopulations in Patients with Protein-Energy Malnutrition:

Effects of in Vitro Incubation with the Thymic Hormone Thymulin

Antibody to most protein antigens is T-cell dependent and requires signals from primed antigen-specific T lymphocytes. T cells are also involved in switching antibody production from the first response, low-affinity IgM antibody, to the second response, high-affinity IgG antibody. Because serum Ig levels are usually normal or elevated in PEM, the ability of malnourished hosts to make Ig is unaffected (11), and in fact, in developing countries, very high levels of IgE are frequently detected (7). This finding probably reflects both the effect of helminths as stimulators of IgE production as well as loss of T-cell suppression of IgE, a normal control mechanism for this immunoglobulin (9). One of the current major limitations in our understanding of the effect of malnutrition on the immune system is the dearth of information regarding the mechanism underlying thymic dysfunction and the resulting impairment in T_H -cell maturation and why (and how) $T_{C/S}$ cells are altered in some, but not all, individuals. This most likely reflects multiple levels of control of these processes, with a multiplicity of maturational signals that become disrupted or disturbed and result in altered signaling events.

In the past decade, an additional refinement in our understanding of the biology of T_H cells has been the division of these cells into at least two groups, T_H1 and T_H2 , based on the pattern of cytokines produced by T_H clones when they are activated (12). T_H1 cells produce interleukin (IL)-2, tumor necrosis factor, and IFN- γ and are involved in CMI and delayed-type hypersensitivity responses to intracellular pathogens; T_H2 cells produce IL-4 (which stimulates IgG1 and IgE production), IL-5 (an eosinophil-activating cytokine), and IL-10 and IL-13 (which inhibit macrophage functions) and activate phagocyte-independent host defenses. Following the initial description of these distinctive T cells in mice, similar findings were made in humans by cloning T cells with different reactivities (13). Many of the phenotypic changes in immune function that accompany PEM will likely be found to be due to alterations in the normal $T_H1:T_H2$ ratios induced by different infectious stimuli. For example, T_H2 cells induce production of IgE (in addition to IgM, IgG, and IgA), whereas T_H1 cells provide B-cell help for IgM, IgG, and IgA, but not IgE synthesis and at low T:B cell ratios. The factors that regulate the $T_H1:T_H2$ cell ratio in vivo are not known; however, some of the signals in vitro include glucocorticoids (enhance T_H2), 25-hydroxy and 1,25-dihydroxy vitamin D_3 (evoke T_H2 responses), and perhaps other nutritional signals as well (14).

In contrast to simple measurement of Ig levels, the effect of PEM on formation of specific functional antibody in humans has not been studied systematically. Available data are derived principally from observing the response to vaccines. These studies are crude because no titration of antigen dose is possible and limited blood sampling precludes assessing the kinetics of the response. However, the results suggest that antibody responses to certain T cell-dependent protein antigens (e.g., tetanus toxoid) may be relatively preserved in PEM, whereas response to polysaccharide antigens (e.g., somatic carbohydrate antigens of *S. typhi*), classical T cell-independent

immunogens in mice, is often subpar. Breast-fed Swedish infants receiving “low”-protein cow-milk formula (1.6 g/kg/day) produced levels of serum, salivary, and fecal antibodies to oral poliovirus vaccine or parenteral diphtheria or tetanus toxoids similar to those of infants fed a conventional protein isocaloric formula (2.2 g/kg/day), but both groups were significantly less responsive than comparable breast-fed infants (15). The authors concluded that breast milk promotes antibody responses. However, no mechanism was suggested and the relevance of the observation to the malnourished child is unknown. In most studies, investigators have neither looked at very young infants nor compared breast-fed and formula-fed babies under controlled conditions.

Antipolysaccharide antibodies are mostly of the IgG2 and IgG4 subclasses that are either locally produced in the lungs or transported into respiratory secretions (16). If the difficulty in making antibody to polysaccharide antigens results from a special defect in synthesis of these IgG subclasses in PEM, it could contribute to the frequency and severity of infection by encapsulated bacteria in PEM patients. In addition, when levels and activity of secretory IgA have been evaluated, they typically are depressed in PEM patients. This defect could also be a factor in the frequency of mucosal infections of the gut, respiratory, and urinary tracts in these individuals.

The complement system is a typical proteolytic cascade resulting in formation of biologically active products during sequential proteolysis and activation of complement components. When the cascade is activated, complement proteins are cleaved and consumed. Enhanced production is required to sustain the response, and the normal host does indeed increase complement synthesis as part of the acute-phase response to inflammatory stimuli. In PEM patients, however, active complement levels are depressed, often in the presence of breakdown products of activation, suggesting simultaneous consumption and inadequate replacement of these proteins (17). The deficit is more profound for the less efficient and often early acting alternative pathway, suggesting that early responses to infection are particularly impaired. This deficiency may be significant in predisposing to gram-negative sepsis, a well-described complication during the course of PEM. It is not clear whether the complement deficit is secondary to consumption induced by infection and/or impaired acute-phase response (thus increasing the severity of the process) or whether it precedes and thus predisposes to infection, or possibly both.

When phagocytic cells from PEM patients are studied in vitro, they often display impaired chemotaxis and reduced oxidative metabolic response, while the initial and subsequent events in phagocytosis, including microbial ingestion, fusion of phagocytic vesicles with lysosomes, and degranulation, are preserved. In the presence of normal opsonins, intracellular killing of organisms in vitro by neutrophils from PEM patients remains intact or only mildly impaired. However, because these patients have reduced complement and may not make high-affinity antibody, serum opsonic activity should be depressed in vivo. This has been reported (17, 18), and thus phagocytic host-defense mechanisms are likely to be more impaired in vivo than they appear to be in vitro.

These data imply that PEM patients have the potential for problems in CMI and phagocytosis, as well as in antibody- and complement-mediated defense. Thus, PEM patients should exhibit increased frequency and/or severity of certain bacterial, viral,

fungal, and parasitic infections. This is generally consistent with clinical observations and is not only true for pediatric patients in developing countries, but also for hospitalized patients, usually the elderly, in the developed world. For example, in a study conducted in Scotland, 69 consecutive patients admitted to a geriatric ward were examined for nutritional deficits on admission, and the incidence of septic events was followed prospectively (19). The mean age of the group was 82.2 years, and approximately one-fifth were below the 5th percentile in body mass index, compared with a community sample. Episodes of sepsis were significantly more common in the severely undernourished than in better-nourished subjects (73 vs. 39%; $P < .04$). Mortality was also markedly increased in malnourished versus better-nourished patients. In one study of emergency admissions of elderly patients without cancer to a hospital in Sweden, 41 of 205 subjects (20%) were classified as malnourished, and their cumulative mortality increased to 44% over the 9 months of follow-up, compared with 18% in the better-nourished group (20).

Iron

Phlebotomy has a revered place in history as a traditional intervention for treatment of almost any ailment that did not respond to prayer, incantations, herbs, and other available remedies (21). It has been suggested that the apparent benefits of phlebotomy might have been related to removal of enough iron from the host to create a state of iron deficiency (22). In its more modern form, exchange transfusion, blood letting provides a significant benefit in a few specific infections, such as severe falciparum malaria or babesiosis, presumably because the procedure results in rapid and major reduction in the number of circulating parasitized erythrocytes. Whether or not actual removal of iron from the host enhances the response to these or other infectious agents remains controversial. The controversy has even spread to public health decision making, specifically, whether or not it is beneficial (or harmful) to provide iron supplements to repair iron deficiency anemia in malnourished populations at risk for infectious disease morbidity and mortality (23). The suggestion that low iron levels are helpful is based on limited in vivo observations, including the well-described reduction in circulating iron levels during acute infection and inflammation secondary to iron uptake into tissue stores and the susceptibility of patients with iron overload to certain infections (24). In addition, in vitro data show that removing iron from microbiologic culture media reduces microorganism growth (25). Protective responses based on nutrient alterations in the host have been termed “nutritional immunity” (26). In the case of iron, the benefits should theoretically be reversed by administration of iron, and clinical data have been advanced to support this thesis (27).

However, the basic concept has come into question, as other studies have demonstrated just the opposite, i.e., impaired in vitro immune function and increased infectious morbidity in vivo in iron deficiency states (28). These data have fueled the controversy over the impact of iron on susceptibility to infection. This section considers two opposing questions: does iron deficiency impair immune responses and increase susceptibility to infection (and consequently should be corrected by iron administration) and, conversely, does iron deficiency impede infection by withholding a required nutrient from pathogens so that iron replacement favors microbial virulence (29)?

Physiology

Iron ([Chapter 10](#)) is a highly reactive transition metal that readily catalyzes oxidative/peroxidative processes and interacts with oxygen to form unstable reactive intermediates able to damage cell membranes or degrade DNA. To prevent such destructive events and still safely deliver oxygen in mammals, virtually all iron is maintained tightly bound to metalloproteins and enzymes involved in oxygen transport and use, energy metabolism, and DNA synthesis; the bound metal is required for their activity ([30](#)). Excess free iron is precluded by the normal excess high-affinity iron-binding capacity in transferrin, lactoferrin, and ferritin ([31](#)). In normal iron balance, all mammalian hosts, including humans, maintain a highly iron-restricted environment.

Because mammalian pathogens encounter a “low-iron” compartment in the host, they must compete for this tightly bound iron to survive and multiply. They accomplish this primarily by making iron-chelating proteins (siderophores) with extremely high affinities for iron ([32](#)) that can strip bound iron from host proteins, as well as by making iron-siderophore receptors and transport proteins to transport the iron into the microorganism ([33](#)). A few microorganisms synthesize receptors for transferrin that resemble the natural receptors of the host, enabling them to acquire iron directly from transferrin ([34](#)).

Given sufficient environmental iron, microbes do not need to make these siderophores, microbial outer-membrane-protein (OMP) siderophore receptors, or transport proteins. However, human pathogens have evolved mechanisms to turn on synthesis of these same iron-regulated OMPs (or “IROMPs”) under conditions of limited iron ([32](#), [33](#)). IROMPs are made by bacteria growing *in vivo* in mammalian hosts, just as occurs *in vitro* in experimental conditions of iron deprivation ([35](#)). Pathogens should therefore be seen as constitutively adapted to respond to low iron levels. This ability to use low iron concentrations as a critical signal to indicate that the pathogen has found its host and to regulate transcriptionally the proteins needed to obtain iron when supply is limited certainly raises the question of whether additional iron restriction imposed by clinical iron deficiency states or the hypoferrremia of infection (nutritional immunity) can affect microbial growth *in vivo*.

Regulation of Microbial Genes

Many successful pathogens regulate production of virulence factors so that these are made only when needed in the host, and they have evolved mechanisms to monitor environmental signals such as temperature, cyclic nucleotides, or divalent cations such as calcium or iron ([36](#)) to determine their presence in a potential host. Only when detection of the signal triggers gene transcription are the needed virulence proteins made. One of the best known of these environmental regulators is an iron-responsive gene called *fur* (ferric uptake regulator) ([37](#)). In an iron-dependent manner, *fur* exerts control over the genes for iron acquisition and transport systems, as well as other genes, many of which are involved in disease causation ([38](#)). Thus, low iron states are used by disease-causing microorganisms to increase their pathogenic potential, overcoming the putative protection of the host, attributed to iron deficiency by the

nutritional immunity hypothesis.

Iron, Iron-Binding Proteins, and the Immune System

Because transferrin-iron is continuously required for all DNA synthesis (39), lymphocytes undergoing clonal expansion in immune responses must take up iron to synthesize ribonucleotide reductase, the rate-limiting iron-metalloenzyme for DNA synthesis. For this reason, receptors for transferrin appear on lymphocytes responding to IL-2 during the period of activation (40). Therefore, at some point during the development of iron deficiency states, cellular proliferation may be impaired.

Immune responses in iron-deficient humans have been studied primarily by testing skin reactivity to recall antigens *in vivo* or by assessing *in vitro* incorporation of ³H-thymidine by mitogen-stimulated cells. Reported results are somewhat variable, although a common theme is reduced skin-test reactivity in iron-deficient hosts, with enhanced reactivity after iron therapy (41). *In vitro* proliferation data are even more variable, more often than not showing decreased mitogen responses (42). It is at least possible in these *in vitro* studies that enough iron is present in the culture media to sometimes correct defects in cells obtained from iron-deficient subjects. Thus, iron deficiency most likely impedes rapid cell proliferation during lymphocyte activation and in this way may adversely affect the course of an infection.

A more constant finding in iron deficiency is diminished activity of the neutrophil iron-metalloenzyme myeloperoxidase (43). This enzyme generates reactive bactericidal halide radicals during the oxidative burst of phagocytosis. However, this defect alone is not likely to be of clinical significance, because congenital absence of myeloperoxidase does not increase the risk of infection. However, iron is also required to produce oxygen radicals used in phagocytic bactericidal reactions (44). Therefore, iron deficiency may have more pervasive effects on neutrophil function than just reducing myeloperoxidase activity. As evidence of this possibility, reduction of nitroblue tetrazolium by peroxide released from activated neutrophils is abnormal in iron-deficient subjects (45). This deficit predicts abnormal bactericidal activity, and some investigators have found a modest diminution in bacterial killing capacity (46); contradictory data also exist (47). Other neutrophil functions, such as chemotaxis, phagocytosis, and degranulation, are consistently reported to be normal in iron deficiency, as might be expected if the effects of iron deficiency on neutrophils are specific and related to the biologic functions of the metal.

The amount of human data on iron deficiency and macrophage function is small. Animal studies have shown reduced clearance of polyvinyl pyrrolidone and impaired generation of oxygen radicals in iron-deficient mice (48) and diminished IL-1 responses in iron-deficient rat leukocytes (49). If these findings mean that iron deficiency can adversely affect macrophage presentation of antigens, then one consequence may be a negative effect on antibody production. Limited data in animals support this possibility (50).

Effects of Excess Iron

The evidence for nutritional immunity includes finding enhanced microbial growth in vitro or increased infections in vivo in conditions of iron excess (51). Impaired growth of bacteria in the presence of iron-binding proteins in vitro is reversed when excess iron is added back. Serum from hemochromatosis patients supports the growth of *Vibrio vulnificus*, which fails to survive in normal human serum. It also has been suggested that clinical iron overload states (e.g., b-thalassemia, sickle cell anemia with multiple transfusions, idiopathic hemochromatosis, or so-called Bantu hemosiderosis resulting from grossly excessive oral iron loads) are associated with increased infection morbidity (52). In these patients, transferrin is fully saturated with iron, and iron is readily available to pathogens from circulating low-molecular-weight, loose complexes of iron and albumin (53). However, more-careful analysis puts these clinical findings into question, since it is difficult to separate the effects of excess iron itself from associated hepatic or splenic dysfunction or effects of secondary diabetes.

Review of infection deaths in thalassemia patients shows that nearly all occur in splenectomized patients, long before significant transfusion siderosis could develop. When experimental iron overload states in animals are examined, susceptibility is increased, but only to certain organisms that do not produce their own siderophores and depend instead on available environmental iron sources (54, 55). This finding is consistent with the clinical association of human iron excess with severe *Yersinia* infections in both chronic iron overload patients (56) and in patients after acute oral ingestion of iron (57). Many *Yersinia* strains are of low virulence and growth restricted in the normal host (58), except when transport proteins are iron saturated and free iron becomes available. These strains can also obtain iron from iron-desferoxamine chelates, and an association between desferoxamine therapy and *Yersinia* sepsis has been reported (59). Organisms with analogous mechanisms of iron acquisition, including the bacteria *V. vulnificus* (60) and possibly *Listeria* (61), and certain fungi, including *Mucor* (62), *Rhizopus* (63), and *Cunninghamella* spp. (64), seem to be associated with iron excess states.

Immune function is probably impaired as well because of tissue-damaging oxidative and peroxidative reactions associated with iron excess. This decreased function would explain why neutrophils, which use iron-catalyzed reactions to produce bactericidal oxygen radicals, are less able to kill microorganisms when obtained from patients with iron excess. Thus, superoxide and hydrogen peroxide production and nitro blue tetrazolium (NBT) dye reduction are decreased in cells from b-thalassemia or dialysis patients with transfusion siderosis (65, 66). Chemotactic responses and random migration are also said to be reduced in thalassemic cells (67), and peripheral blood monocytes from subjects with b-thalassemia show diminished capacity to kill *Candida pseudotropicalis* (68) or *S. aureus* (69).

Clinical Data in Excess States

The malaria parasite spends most of its lifetime within red blood cells, in close association with an enormous pool of iron in the form of hemoglobin, resulting in lysis of erythrocytes and hemolytic anemia. Malaria, therefore, is a well-recognized cause of iron deficiency. A number of studies in Africa have noted an association between

administration of oral or parenteral iron and a marked increase in the prevalence of malaria parasitemia (70, 71 and 72). However, these studies have been criticized for lack of simultaneous placebo controls, failure to control for the presence of PEM and associated reduced transferrin levels, and lack of proper blinding of the investigators. Subsequently, the association of parenteral iron with increased rates of smear-positive malaria has been confirmed in a carefully designed, properly conducted, double-blind study in Papua New Guinea (73); a 64% increase in parasitemia rate in infants given iron supplements was observed, although the parasite density did not differ from that in the control group. An associated clinical significance was suggested by an increase in malaria-related hospital admissions, measles, otitis media, and pneumonia in the iron group (74). Another study in Papua New Guinea of total-dose iron-dextran infusion in pregnant women, who are at increased risk of malaria morbidity, also found higher risk of malaria parasitemia in treated than in untreated women (75).

Several more-recent studies of oral iron have failed to demonstrate a major clinical or parasitologic effect on malaria (76). In one study of prepubescent school children given 200 mg of ferrous sulfate or placebo, there was no change in parasitemia rate or density, level of antimalarial antibody, spleen size, or clinical episodes of malaria, but iron status improved (77). Another study in patients with malaria being treated with antimalarials confirmed the lack of effect of oral iron on the clinical course of the malaria but found an increase in other causes of morbidity in the iron-supplemented group (78). Since there was no improvement in hemoglobin, the authors concluded that iron was not indicated in acute malaria. In pregnant women, iron supplements did not increase the peripheral blood or placental malaria infection rate but did increase maternal iron and hemoglobin levels and was associated with an increase in birth weight by a mean of 56 g (79).

Because the parasites use the globin portion of hemoglobin for nutrition, relative depletion of hemoglobin in red cells due to iron deficiency may be a key limiting factor for parasite growth, whether or not heme iron is used by the parasite to meet its iron requirements (80). When iron is given to deficient subjects, hemoglobin synthesis and iron uptake are stimulated, providing both protein and iron for parasite development, because parasites too require iron for essential metalloenzymes (81, 82). This is the basis for the strategy of iron chelation for treatment of malaria (83).

Hemolysis is a known risk factor for bacterial infection, particularly salmonellosis, regardless of the cause of erythrocyte lysis (84), but this is not due to the presence of iron-hemoglobin in the circulation. Rather, it is because macrophages ingest the released hemoglobin, which results in a state of reduced macrophage phagocytosis and intracellular microbicidal defects, sometimes termed “reticuloendothelial” or “macrophage blockade.” Consistent with this concept, hemolysis induced by the mouse malaria parasite *Plasmodium berghei* or phenylhydrazine administration dramatically increased the virulence of *Salmonella typhimurium*, whereas simple iron deficiency induced by bleeding did not (85).

Clinical Data in Iron Deficiency States

These examples indicate clearly that the relationship between iron and infection

depends in part on the causative organism, the metabolism of the pathogen, and its ability and mechanisms used to acquire the iron it needs. Although iron deficiency adversely affects certain host defenses and most pathogens appear to be well equipped to compete for available iron stores, clinical examples in which iron deficiency apparently protects the host have been published ([72](#), [86](#), [87](#) and [88](#)). However, contradictory results have also been reported ([89](#), [90](#)), with no difference being found in iron-supplemented or unsupplemented groups, while other investigators found increased prevalence and severity of infections in treated subjects ([91](#)).

Unfortunately, interpretation is difficult because published studies on iron deficiency and susceptibility to infection often are flawed in design, sometimes lack sufficient numbers of subjects to permit statistical analysis, or fail to control for the numerous confounders likely to be encountered in a field study. Thus, differences in the age of subjects, and route and form of the iron administered; failure to include simultaneous controls or to demonstrate the comparability of the control group except for iron status; presence of other nutritional deficiencies such as PEM; lack of laboratory confirmation of infection; use of imprecise criteria to characterize iron nutritional state of the host; and lack of correlation of infectious episodes with the severity of the nutrient deficiency or the effect of the supplement all complicate the final interpretation ([92](#), [93](#)).

Although conclusive proof is lacking, the impression from these various reports is that iron deficiency is likely associated with some increased incidence of common infections in children. Also, iron supplementation by the parenteral route in very young infants or use of iron chelators in disease states with iron excess appears to increase the incidence of some specific infections. There is no longer any justified rationale for use of parenteral iron in very young infants. Newborns normally have excess iron and highly saturated serum iron-binding proteins, they are immunologically immature and susceptible to invasive bacterial infections under any circumstances, and they are the group most likely to experience an adverse effect of the therapy. In addition, because severe PEM is known to result in reduced transferrin levels, it is unwise to administer iron in any form to patients with PEM while their iron-binding capacity is low. An association between low transferrin and severe systemic infection in PEM has been inferred ([94](#)), although such patients have multiple defects in all limbs of host defense. For these reasons, nutritional rehabilitation of PEM patients usually does not include iron supplements during the 1st week. This supplementation commonly is delayed until the 2nd week of treatment, when new protein synthesis is actively occurring and the circulating levels of export proteins, such as transferrin, are increasing ([95](#)).

Zinc

Like iron, altered distribution of zinc is part of the acute-phase response in infections, with the metal being rapidly removed from the circulation to an intracellular compartment primarily in liver, thymus, and bone marrow. This phenomenon is related to increased synthesis of the intracellular zinc-binding protein metallothionein ([96](#)), which is transcriptionally regulated by IL-1 ([97](#)), an important cytokine mediator of events during infection and inflammation.

Zinc is critical in the function of some enzymes involved in DNA transcription and RNA

translation (see [Chapter 11](#)) ([98](#), [99](#)). Thus, shifting zinc to the intracellular compartment of lymphocytes may prime the proliferation of lymphocyte clones involved in immune responses and host defense. These important responses to alterations in zinc distribution may be affected by zinc deficiency, which can restrict rapid multiplication and clonal expansion of critical cell populations in the immune response.

Zinc-binding finger loop domains, known as “zinc fingers,” are also involved in conformational stabilization of transcription-factor proteins, permitting sequence-specific DNA recognition and gene expression ([100](#)). Zinc deficiency severe enough to impede these regulatory signals further impairs the host response by limiting translation of proteins encoded by genes activated during the acute-phase response to infection.

Certain thymus-derived peptides, postulated to function as thymic hormones in the differentiation of T cells are noted above. These thymic factors are a family of zinc metalloproteins ([101](#), [102](#)), and their decreased production in PEM (which is almost always accompanied by zinc deficiency as well) may well underlie the T-cell maturational arrest seen in this condition. The depletion of mature T cells observed in other zinc deficiency states may be traceable to this defect. Zinc deficiency commonly results in lesions of skin and mucous membranes that disrupt these mechanical barriers and provide a route for both high- and low-virulence microorganisms to invade and initiate infection ([103](#)). Thus, in a number of ways, abnormal zinc nutrition can be related to heightened infection susceptibility and/or severity.

Effects on Immune Function

The relationship between zinc status and host defense is not well understood (see also [Chapter 45](#)). Whereas IL-1 induces metallothionein and shifts zinc from plasma to tissues, production and/or membrane binding of certain cytokines that regulate the immune system, including IL-1, IL-2, and IFN, may depend on zinc ([104](#), [105](#) and [106](#)). However, careful systematic studies of zinc status, cytokines, and immune function have not yet been reported. What seems clear is that zinc deprivation in animals affects the thymus, which undergoes involution associated with splenic atrophy and lymphopenia ([107](#), [108](#) and [109](#)). In the early stages of deficiency, cells are preferentially lost from the cortical regions normally populated by glucocorticoid-sensitive immature thymocytes. This change is actually independent of any glucocorticoid effect, because it occurs even when the adrenal glands are removed ([110](#)). Similar thymic involution occurs in Friesian cattle, a breed with a genetic defect that impairs zinc absorption and results in severe zinc deficiency, strongly suggesting that the lymphoid organ changes are in fact due to zinc deficiency per se ([111](#), [112](#)).

Despite an unresolved controversy over whether zinc deficiency affects particular T cell subpopulations ([113](#)), little doubt remains that the proliferative response to both T-dependent and T-independent mitogens is reduced ([114](#), [115](#)). This may happen in several ways, for example, indirectly by altered cytokine metabolism ([116](#), [117](#)) or directly by affecting lymphocytic DNA synthesis ([118](#), [119](#)). As a consequence of impaired T-cell function, delayed-type hypersensitivity responses are diminished in zinc deficiency ([120](#)); whether this is related to lymphocyte abnormalities alone or to additional changes in macrophage functions that are demonstrable in zinc-deficient cells

is not clear ([121](#), [122](#)).

Consistent with these abnormalities in the immune system, increased susceptibility to infection has been reported in zinc-deficient animals experimentally infected with a wide variety of pathogens, including bacteria (*Francisella tularensis*), protozoa (*Trypanosoma cruzi*), helminths (*Trichinella spiralis*), and fungi (*C. albicans*) ([123](#), [124](#)). Friesian cattle, nature's own experimental model for zinc deficiency and the equivalent of human acrodermatitis enteropathica ([125](#)), are also hypersusceptible to life-threatening infections.

Immunity and Susceptibility to Infection in Humans

Data concerning zinc and infection in humans are still limited. Most of the recent data have come from interventional trials in developing countries, in which zinc supplements have been provided to infants and children at risk of PEM with evidence of limiting zinc in their diet and low measured zinc in hair, nail clippings, or plasma. These trials were based on prior reports associating zinc deficiency, immune defects, and hypersusceptibility to infection. In one of the earliest reports in humans, zinc deficiency associated with geophagia in Iranian children was found to result in growth retardation, hypogonadism, and frequent infections ([126](#)). Subsequently, recognition of zinc deficiency in a series of clinical situations associated with immunologic deficits and infections, including acrodermatitis enteropathica, the clinical use of total parenteral nutrition formulas without added zinc, malabsorption states, Down's syndrome, and sickle cell disease, led to trials of zinc administration and have supported the notion that increased infections are associated with the lack of this mineral.

Development of a diet-induced zinc deficiency model in humans has helped establish this relationship ([127](#)). Dietary restriction of zinc results in negative zinc balance of about 1 mg/day, with a cumulative loss approaching 180 to 200 mg over a 6-month period. Because most zinc in the body is present in bone and muscle, only 200 to 400 mg is in a mobile exchangeable pool in the liver and the circulation. Because zinc is not stored in quantity, dietary restriction rapidly leads to a deficiency, mostly affecting tissues with high turnover rates such as liver and leukocytes ([128](#)). In some instances, abnormalities in zinc deficiency can be reversed by providing zinc supplements. For example, reduced serum thymic hormone activity in zinc-deficient subjects was related to circulation of inactive thymulin protein, and addition of zinc restored biologic activity ([129](#)). Similarly, the increase in immature T cells and decreases in the T4:T8 ratio, IL-2 production ([129](#)), and natural killer cell (NK) activity ([130](#)) are also reversed by correcting the zinc deficiency, as are the abnormalities in patients with acrodermatitis enteropathica.

These findings are consistent with observations in humans with genetic diseases associated with zinc deficiency, in whom thymic atrophy, lymphopenia, diminished NK activity and IL-2 production, decreased serum thymulin levels, and alterations in lymphocyte subpopulations are reported ([129](#), [131](#), [132](#) and [133](#)). Alterations in the zinc-dependent enzyme nucleoside phosphorylase may result in accumulation of toxic levels of nucleotides, leading to impaired cell division or cell death ([134](#)). In addition, zinc-reversible chemotaxis and motility abnormalities of granulocytes from zinc-deficient

rhesus monkeys and in experimental human zinc deficiency and acrodermatitis enteropathica have been described ([135](#), [136](#) and [137](#)). Few data currently attribute immunologic defects in PEM to zinc deficiency, but the concept is plausible ([138](#)). These data include enlarging thymic shadows on radiographs or improved granulocytic function in PEM children after zinc therapy or increased skin delayed-type hypersensitivity reactions when topical zinc is applied directly to the test site ([139](#), [140](#) and [141](#)). Interestingly, thymus gland thymulin content is diminished in PEM, although zinc levels are high and correlate best with infections ([142](#)). Experimental zinc deficiency in mice is associated with decreases in B-lineage cells in bone marrow ([143](#)); however, the residual cells respond appropriately to stimuli such as mitogens ([144](#)).

Zinc supplementation studies in poorly nourished infants and children in either community studies among low socioeconomic groups or in therapeutic trials in acutely ill subjects suggest decreased susceptibility to infection and/or shortening of the illness duration, primarily of diarrheal disease ([145](#), [146](#), [147](#), [148](#), [149](#) and [150](#)). Further trials are under way to evaluate the role of zinc in respiratory disease and malaria. Low levels of zinc have been noted in AIDS patients ([151](#)), and initial studies to evaluate the impact of zinc supplements in AIDS show an apparent reduction in infectious complications in one study but an increase in mortality associated with any level of zinc supplementation in another ([152](#), [153](#)). Because zinc may play important roles in HIV replication ([154](#)), the effect of zinc intake is clearly complicated and may have more to do with its impact on the virus than on immune responses. Further study is required.

Vitamin A

Animals maintained on low vitamin A diets are more susceptible to a wide variety of infections than those fed adequate diets ([155](#), [156](#)); vitamin A came to be known as the “antiinfective vitamin” soon after its discovery ([157](#)). On the basis of several field trials over the past decade, intense interest has focused on the potential use of vitamin A supplementation to reduce morbidity and mortality due to infectious diseases in humans. Vitamin A influences susceptibility to infection by alterations in both nonspecific (non-antigen-specific) and specific antigen-mediated host defense mechanisms. Vitamin A deficiency is associated with metaplasia of mucosal epithelia (see [Chapter 17](#)) and replacement of ciliated cells with keratinized cells; these changes reduce the efficacy of the ciliary ladder in clearing bacteria from mucosal surfaces. This is at least partly due to negative transcriptional regulation of keratin synthesis by retinoids. Furthermore, vitamin A deficiency alters production of mucous glycoproteins and/or other glycoconjugates. Thus, in vitamin A deficiency states, mucus-secreting cells are either reduced in number or replaced by multilayered keratinized cells. These changes are associated with a loss of the nonspecific barrier function of the mucosal epithelium.

Vitamin A also appears to be important in the normal functioning of the immune system. Vitamin A deficiency in animal studies has been associated with reduced mitogen-induced lymphocyte proliferation; delayed-type skin hypersensitivity reactions; reduced macrophage, cytotoxic T-cell, and NK cell function; and reduced B-cell proliferation and antibody production ([158](#), [159](#)). Fewer data are available regarding the specific effects of vitamin A deficiency on the human immune system. Abnormalities in T-lymphocyte subset proportions and reduced response to tetanus toxoid in vitamin

A–deficient (xerophthalmic) children were demonstrated (160, 161). In South African children with measles, vitamin A–supplemented children had significantly higher total lymphocyte counts and measles-specific IgG antibody than controls (162).

Study of vitamin A and its effects on immune function has been hampered by the complexities of assessing vitamin A nutriture, especially during episodes of infection. Plasma retinol is a relatively poor indicator of vitamin A stores in the best of circumstances (163). During an infectious illness, plasma retinol values become essentially meaningless, as the circulating concentrations of retinol and retinol-binding protein (RBP) are reduced as a part of the acute-phase response to infection and inflammation, similar to the hypoferrremia that rapidly develops at the onset of infection (164). Vitamin A–sufficient rats injected with endotoxin exhibit a 30 to 40% reduction in circulating retinol and RBP (165). Both poorly and well-nourished children demonstrate reduced plasma retinol levels during malaria (164). These findings have led to the suggestion that reduction of circulating retinoids and their distribution into extravascular fluids and tissues during acute inflammatory episodes may be an adaptive rather than harmful host response, delivering vitamin A to the sites where it is most needed. Other manifestations of the acute-phase response may contribute to losses of vitamin A, as some adults with acute febrile illnesses excrete almost 10 times more urinary retinol daily than afebrile controls (166).

How should these complex alterations be interpreted? It has been suggested that the acute-phase response may be beneficial overall to the vitamin A–sufficient host, accelerating tissue recovery, but when vitamin A status is poor to begin with, the resulting very low retinol levels may impair recovery and increase mortality (167). This assertion is largely supported by the results of human interventional trials (described below), in which morbidity and mortality benefits of vitamin A supplementation are limited to more severely malnourished subgroups.

Deficiency and Infection Mortality

The concept that vitamin A deficiency exacerbates mortality due to infectious diseases and, therefore, that vitamin A administration can reduce this originated from a large study of deprived Indonesian children over a decade ago (168). The proposition is attractive: a magic bullet to target the malnutrition/infection complex in developing countries. Over 3500 children were enrolled and then evaluated prospectively every 3 months over an 18-month period. Mildly symptomatic vitamin A deficiency was detected by the presence of early xerophthalmia (night blindness or the presence of Bitot's spots on the cornea). Children with severe xerophthalmia were treated immediately and excluded from the study; the remainder were followed. The prevalence of mild xerophthalmia increased during the first 3 years of life to a plateau of 7% and was associated with a fourfold increase in risk of death. This higher mortality was apparent even after controlling for differences in concurrent illnesses and PEM as assessed by weight for height. These findings were supported by a subsequent study among Sudanese children, which demonstrated a strong inverse correlation between vitamin A intake and mortality (169). The effects of “presymptomatic” (subclinical) vitamin A depletion on child mortality have not been studied, despite the availability of newer, more sensitive biochemical tests for measuring vitamin A stores, such as the relative

dose-response assay.

On the basis of the observations by Sommer et al. (168), eight large-scale vitamin A supplementation trials involving over 100,000 Asian and African preschool-age children at risk of vitamin A deficiency have been implemented in the last 10 years (Table 97.4). The trial designs varied, and different doses and regimens of vitamin A supplementation were used. Six of the eight trials demonstrated significantly reduced mortality rates in the supplemented children, compared with the unsupplemented controls.

Author (Ref.)	Vitamin A Dose Age Regim	Country	Observation Period	Change in Mortality
Sommer (168)	200,000 IU 6 monthly x 2 (1-4 years)	Indonesia	1 year	-34%
Dalrymple (171)	50-200,000 IU by age, once (1-59 months)	Nepal	6 months	-26%
West (172)	80,000 IU 4 monthly x 2 (6-12 months)	Nepal	1 year	-20%
Penahelah (173)	8,000 IU weekly (6-40 months)	India	1 year	-54%
Vijayapalan (175)	200,000 IU 6 monthly x 2 (1-4 years)	India	1 year	nl

Table 97.4 Mortality in Field Trials of Vitamin A Supplementation

For those studies in which disease-specific mortality data were available, the largest reductions in mortality were seen in diarrhea-associated deaths (170, 171, 172 and 173). Lesser reductions were also seen in deaths due to measles and respiratory tract infections. Causes of death were determined by “verbal autopsy” methods, which depend on interviews and parental recall of events. While there may not be a better method of assigning causality, the reliability of “verbal autopsies” is less than that of clinical and pathologic methods (174).

It is unclear why the results from two of the trials, one in India (175) and one in the Sudan (176), are discordant. Among the possible explanations are differences in the demographics of the populations studied, including differences in the baseline mortality rates or the prevalence of vitamin A deficiency, other nutrient deficiencies, or diarrheal disease frequency or severity. In addition, the doses of vitamin A used in these trials may have been too small or too infrequent to adequately supplement the children. Finally, the study protocols themselves may have obscured differences between groups, since the most seriously malnourished children were referred for care and dropped from the study. The frequent contacts between field workers and villagers in control villages could have led to transmittal of health advice that may have been heeded; for example, in the Indian study, there was a significantly higher mortality rate among children who did not participate in the trial than among those who did. It may also be explained by basic differences in health-related behavior between those who elect to join a clinical

trial and those who opt not to join.

Metaanalysis of these supplementation trials was reported in 1993 (174), prior to completion of the most recent study in Ghana (170), and in 1994 (177) including the Ghana study. Aggregation of all results, with adjustment according to study quality, yielded a highly significant reduction in all-cause mortality by about 30% (odds ratio 0.70; 95% confidence interval 0.62–0.79) (174) and by 23% in the second analysis (177). Figure 97.1 illustrates the results of eight individual studies and the combined results from metaanalysis (177). Overall, the effect of vitamin A was highly significant ($P < 1 \times 10^{-8}$). Recent placebo-controlled studies of vitamin A supplementation and mortality among very young infants in developing countries have produced more variable results. Among a group of 10,000 Nepalese infants under 6 months of age, a single vitamin A dose had no impact on short-term mortality (178). By contrast, vitamin A given once at birth to Indonesian neonates significantly reduced 1-year mortality, although the total number of deaths in the placebo and vitamin A-supplemented groups was small, yielding very wide confidence intervals (179). Prophylactic vitamin A supplementation was of no benefit in preventing mortality due to malaria in Ghanaian children (180), despite the observation that acute malaria almost invariably results in a sharp drop in plasma retinol levels (164).

Figure 97.1. Mean change in young child mortality in individual studies and by metaanalysis of eight studies. Bars show the mean \pm 95% confidence intervals. The overall effect of vitamin A, a 23% reduction in mortality, was highly significant ($P < 10^{-8}$). (From Beaton GH, Martorell R, Aronson KA, et al. Food Nutr Bull 1994;15:282–9, with permission.)

Deficiency and Infection Morbidity

Paradoxically, despite the marked reduction in mortality seen with vitamin A supplementation in poor children, an impact on infection-related morbidity has been more difficult to demonstrate. In the earlier observational study of Indonesian children, Sommer et al. (168) found that children with mild xerophthalmia had relative risks of 2

and 2.8 for respiratory and diarrheal disease, respectively, compared with children without eye signs. Subsequently, other groups examined the relationship between vitamin A status and morbidity with inconsistent results. Several placebo-controlled trials found no effect on morbidity attributable to vitamin A, even among populations that had significant reductions in mortality and in the same geographic regions where mortality benefits were seen ([170](#), [179](#), [181](#), [182](#), [183](#) and [184](#)). A randomized vitamin A supplementation trial was recently completed among a population of preschool-age Indonesian children ([185](#)) demographically similar to the group studied by Sommer et al. 10 years earlier ([186](#)). In the former study, an increased incidence of respiratory tract infection was found in the vitamin A-supplemented group, especially among adequately nourished children; there was no overall effect on the incidence of diarrheal disease ([185](#)). In other studies, vitamin A supplementation reduced morbidity due to diarrheal disease (but not respiratory disease) in children living in urban slums in New Delhi ([187](#)) and rural Brazil ([188](#)). It may be that vitamin A supplementation can reduce the frequency of severe and life-threatening illness among severely malnourished children without decreasing the frequency of less-severe illness ([170](#)).

A few studies have evaluated the role of vitamin A in infection in developed countries. Five small supplementation trials have been carried out, three in the United States and two in Australia—none are comparable to the use of vitamin A in developing countries. Two studies demonstrate modest but significant reductions in morbidity due to bronchopulmonary dysplasia in very low birth weight infants ([189](#)) or in preschool-age children prone to recurrent respiratory tract infections ([190](#)). Two more-recent studies failed to show a benefit of vitamin A compared with placebo in children with acute respiratory syncytial virus (RSV) infection ([191](#)) or a history of RSV in infancy ([192](#)). One study conducted among the elderly ([193](#)) demonstrated no effect of the supplement on the incidence of bacterial infections among a group of nursing home residents. Taken together, these studies suggest that vitamin A supplementation has little apparent benefit in reducing infectious morbidity in populations that are adequately nourished.

Vitamin A Deficiency and Measles Mortality and Morbidity

Measles remains a major public health problem in the developing world wherever measles immunization rates are low. Measles infects approximately 70 million children annually, and it is estimated that 2 million die each year from the disease itself or its complications. In addition to fever and rash, the consequences of measles include acute diarrhea or dysentery, pneumonia, encephalitis, and blindness due to acute vitamin A deficiency. Thus, in developing countries, case fatality rates may reach 10 to 20% ([159](#)). The interaction between measles and vitamin A deficiency was first reported in 1932 ([194](#)), and many subsequent reports have documented a synergistic interaction between the two ([195](#), [196](#) and [197](#)). It is not clear why there should be a special relationship between measles and vitamin A status. It is possible that the marked disruption of the respiratory mucosal epithelium in measles causes a massive increase in vitamin A requirements. In addition, measles itself is immunosuppressive, and it may act in concert with the adverse immunologic effects of vitamin A deficiency to increase the severity of the infection ([198](#)).

Several studies have examined the effect of vitamin A supplementation on measles-associated morbidity and mortality. Two reports from Africa demonstrate that administration of a large bolus of vitamin A to measles patients at the time of admission significantly reduces the associated in-hospital mortality. In one study from Tanzania (199), 12 of 96 controls died, compared with 6 of 88 treated children; the difference reached statistical significance only for children under 2 years of age. However, in another report from Cape Town, South Africa (200), patients with measles seen within 5 days of onset of the rash complicated by pneumonia, diarrhea, or croup were randomly assigned to receive an oral dose of 400,000 IU of retinyl palmitate (equal to 120 mg retinol) or placebo. Twelve (6.3%) children died, nearly all from associated pneumonia; 10 of the 12 deaths were in the placebo group. Vitamin A administration was associated with a significantly reduced risk of death (relative risk, 0.21). In addition, recovery from pneumonia as well as from diarrhea was significantly more rapid in the treated patients. Furthermore, when disease-specific mortality was analyzed in the large-scale community intervention trials in India and Nepal, measles mortality was significantly reduced in one study (172), and a trend in the same direction was noted in a second (173).

The effects of vitamin A supplementation on measles morbidity has been addressed in two trials. In Durban, South Africa, 60 children under 2 years old with measles rash documented for 5 days or less and no history of vitamin A administration in the past month were randomly assigned to receive retinyl palmitate or placebo at the time of hospital admission (197). The baseline data, including reduced plasma retinol levels in over 90%, were comparable in the two groups. Subjects were seen in follow-up at 6 weeks, when another dose of vitamin A or placebo was given, and again 6 months after discharge. A total morbidity score was calculated for each visit, based on cumulative episodes and severity of diarrhea, upper respiratory infections, laryngotracheobronchitis, and pneumonia. Initial in-hospital recovery from pneumonia, diarrhea, and fever was more rapid in the treated group, and the morbidity score was 85% lower than that of the controls. At the 6-week follow-up visit, the morbidity score was 61% lower in the vitamin A group; at 6 months, the morbidity score was 85% lower in the vitamin A group.

Analysis of markers of immune function in a subset of these children revealed significantly higher total lymphocyte counts and measles-specific IgG antibody levels among the vitamin A-supplemented children. These markers correlate most closely with clinical outcome in measles (198). The findings are supported by a randomized placebo-controlled trial of high-dose vitamin A for children hospitalized because of acute measles in Nairobi, Kenya (201). Modest but significant reductions in complications were observed in the vitamin A-supplemented group, with decreased rates of severe tracheobronchitis and otitis media and faster resolution of diarrhea.

Based on these findings, it has been suggested that vitamin A supplementation should be routinely given to children in vitamin A-deficient communities at the time of measles immunization (197). However, another study demonstrated that a large oral dose of vitamin A given at the time of measles immunization actually reduced seroconversion to the vaccine (202). The suggestion was made that the supplement may have impaired

the ability of the vaccine strain to replicate in the subject and thus reduced the immune response. In contrast, however, randomized, double-blind, placebo-controlled study of the effect of simultaneous measles vaccination and vitamin A supplementation showed no indication that vitamin A adversely affected measles immunity (203).

Vitamin A and HIV

The emergence of the AIDS epidemic in developing countries has focused attention on the potential of low-cost nutrition-based treatment strategies for populations unable to afford antiretrovirals and multiple drugs to suppress opportunistic infections. Considerable interest has centered around the potential of vitamin A deficiency to exacerbate or accelerate the immunosuppression of AIDS. There are some, albeit limited, in vitro data suggesting that vitamin A or its metabolites play a role in regulation of HIV gene expression and virus replication in human cells. Several laboratories have demonstrated that retinoic acid (the active intracellular metabolite of vitamin A) can inhibit transcription of HIV mRNA and replication of the HIV virion in tissue culture (204, 205, 206, 207 and 208). However, the effect was not consistent and depended on the cell type studied and the experimental conditions employed. Some workers found that retinoic acid actually increased HIV transcription and replication (209, 210).

Clinical studies have repeatedly shown that plasma retinol levels in HIV-1 seropositive patients are below population norms (211, 212, 213 and 214). As a follow-up, Semba et al. (215, 216) showed that low plasma retinol levels correlate strongly with low CD4+ counts and mortality. Similarly, in Malawi, HIV-infected pregnant women with low plasma retinol levels transmitted HIV to their fetuses at a much higher rate than women with normal retinol levels (217). However, plasma retinol is neither sensitive nor specific for detection of vitamin A deficiency, especially during an infectious or inflammatory illness. Thus, the low mean plasma retinol levels in the patients with progressing disease or vertically transmitting HIV infection may simply indicate concomitant inflammatory processes (218). Indeed, one small study of 25 HIV-infected patients in the United States that used the relative dose-response test to evaluate vitamin A status determined that all patients except one were normal (219). A randomized, placebo-controlled trial of vitamin A supplementation in South Africa involving infants given placebo or vitamin A found significantly reduced diarrhea-related morbidity in the AIDS patients (220). However, it is unclear if this represents the correction of an interaction between vitamin A and HIV infection or simply a confirmation of previous studies demonstrating the effect of vitamin A on diarrheal disease morbidity in children with diarrhea (159).

At the present time, the amount of data is insufficient to conclude whether vitamin A supplements benefit AIDS patients, have no effect, or are harmful, and more studies are needed to sort this out. In pregnant women, the benefit of reducing maternal-fetal transmission is balanced by the increased risk of major fetal malformations in women given vitamin A supplements during pregnancy (221). A variety of effects of retinoids on viral replication have been shown, presumably related to the effects of retinoids on inflammatory processes.

Recommendations for the Use of Vitamin A for Infection

Although the metabolic changes that occur during infection are complex, vitamin A deficiency compounds the problems and may be crucial in exacerbating morbidity and mortality due to measles and diarrheal disease and possibly respiratory disease as well (159). The need for vitamin A—supplementation programs differs from one country to the next and must be assessed for each population, region by region. Implementation should be undertaken whenever there is clinical evidence of vitamin A deficiency in the population, wherever PEM is common, and wherever there is an excess of measles deaths. Further studies are necessary to evaluate systematically the optimal dose, regimen, and timing of vitamin A supplements in the population for prevention or modulation of infection (222). Most nutritionists will agree that the best long-term measure to improve vitamin A status of a population is to ensure adequate dietary intake. At this time, the benefits and principles for use of supplementary vitamin A remain debatable, awaiting careful and well-planned studies.

[Chapter References](#)

Nutritional support is defined as provision of nutrients using the enteral (delivery into the gut lumen via a feeding tube) and/or parenteral (intravenous) routes. This expensive and sophisticated technology was not available prior to the 1970s, and many patients who could not eat died from starvation and its associated complications. Today, virtually all patients can be fed because of two important technologies: (a) central venous catheterization and infusion of hypertonic nutrient solutions and (b) specific enteral formula diets that can be administered intraluminally through a feeding tube. Both parenteral and enteral formulations deliver all essential nutrients, and many patients who cannot eat normally live productive lives while being nourished exclusively by one or both of these routes. The justification for providing nutritional support to patients has been to prevent or reverse host tissue wasting, broaden the spectrum of therapeutic options, improve the clinical course, and prolong survival.

In spite of these advances, definitive indications for use of nutritional support in many patients, however, are unclear, and its efficacy in many circumstances is unproved. Nonetheless, use of enteral and parenteral nutritional therapies is widespread for several reasons (1): (a) protein-calorie malnutrition is common in a variety of

hospitalized patients; (b) documented association between malnutrition and increased morbidity and mortality; (c) it seems intuitive that well-nourished patients respond more favorably to therapeutic interventions than malnourished patients; (d) nutritional support can be provided safely to most patients; (e) several randomized prospective clinical trials suggest that nutritional support benefits selected patients.

Unlike other groups of patients (e.g., cancer patients, patients with AIDS) in which a role for nutrition support remains controversial, use of nutritional support in specific groups of surgical patients is established. This chapter reviews the metabolic alterations that occur in patients undergoing elective operations, in patients with accidental injury, and in those with sepsis. Methods of nutritional assessment of individuals in each of these general groups are provided, along with current knowledge of the nutritional requirements of patients with these illnesses. The basis for selecting the safest and most effective route of nutrient administration is discussed, and newer methods of modifying the catabolic response to critical illness are reviewed.

IDENTIFYING THE PATIENT AT NUTRITIONAL RISK

Nutritional support is used most frequently in surgical patients as short-term adjuvant therapy to treat individuals who have preexisting weight loss or are at risk for developing malnutrition. The most common form of malnutrition in surgical patients is protein-calorie malnutrition (PCM), a state of undernutrition that results in a reduced body cell mass. PCM is common in hospitalized patients (1), and although its evolution during illness frequently reflects the severity of the underlying disease or toxicity associated with certain therapies, a cause-and-effect relationship between malnutrition and a poorer outcome has not been definitely established. Identification of PCM is based on objective measurements including weight loss (2), serum concentrations of proteins produced by the liver (3), anthropometric measurements (4), grip-strength, anergy (5), immunologic functions, body mass index, and nutritional risk index.

Patients become nutritionally “at risk” when their malnutrition reaches a point where they are at increased risk for a poorer clinical outcome than if they were not malnourished. As recently stated, it has been difficult to quantitate “at risk” malnutrition.

No single measurement is highly sensitive and specific for identifying malnutrition. For example, although serum albumin values are used to predict nutritional risk and a low serum albumin concentration at the time of hospital admission can predict death and length of stay, hypoalbuminemia is not specific for poor nutritional status. In many patients weight loss does not increase their risk for developing treatment-associated complications. There is a strong relationship between the absence of a delayed-type hypersensitivity response and mortality but, despite mild malnutrition in anergic patients, nutrition support failed to correct the response and the cellular immune dysfunction. The clinical assessment (history, physical examination) of the patient is as effective a method for assessing nutritional status as are objective measurements [see also [Chapter 54](#), [Chapter 55](#)]. The cheapest and simplest way to screen for malnutrition is to ask the patient about unintentional weight loss. If reliable criteria for identifying at risk malnourished patients were established, the value of nutritional intervention could be studied more scientifically. (1)

It has also been difficult to define the role of nutritional support because of the paucity of well-designed rigorous clinical trials. Many published studies suffer from problems with experimental design (inappropriate controls), heterogeneous study populations, small sample size, or inappropriate clinical endpoints or they are retrospective (1). Some studies have included well-nourished or minimally malnourished patients who were unlikely to benefit from nutritional intervention, thus possibly masking therapeutic

efficacy.

ELECTIVE OPERATIVE PROCEDURES

Physiologic Responses to Surgery

Although cytokines clearly play an important role in regulating the body's response to stress, their role appears more significant in patients with major injury and infection. Therefore, the importance of cytokines in the cellular response to injury and infection is discussed in the section under trauma (see also [Chapter 45](#) and [Chapter 96](#)).

Endocrine Changes and Their Metabolic Consequences

One of the earliest consequences of a surgical procedure is the rise in levels of circulating cortisol that occurs in response to a sudden outpouring of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. The pituitary gland is activated when afferent nervous signals from the operative site reach the hypothalamus to initiate the stress response. The rise in ACTH stimulates the adrenal cortex to elaborate cortisol. This hormone remains at 2 to 5 times normal levels for approximately 24 hours after a major operation ([6](#)). Cortisol has generalized effects on tissue catabolism and mobilizes amino acids from skeletal muscle that provide substrates for wound healing and serve as precursors for the hepatic synthesis of acute-phase proteins or new glucose. Associated with the activation of the adrenal cortex is stimulation of the adrenal medulla through the sympathetic nervous system, with elaboration of epinephrine. This circulating neurotransmitter is important in circulatory adjustment, but it may also elicit metabolic responses if the augmented secretion rate continues over a prolonged period.

In addition to increased circulating levels of epinephrine, norepinephrine levels rise during and following elective operative procedures ([7](#)). The excitement, pain, fear, and hypovolemia that may accompany the surgical procedure are potent stimulators of the sympathetic nervous system. Urinary catecholamines may be elevated for 24 to 48 hours after operation and may then return to normal. The major catabolic role of this regulatory system may be stimulation of hepatic glycogenolysis and gluconeogenesis in concert with glucagon and glucocorticoids.

The neuroendocrine responses to operation also modify the various mechanisms that regulate salt and water excretion. Alterations in serum osmolarity and tonicity of body fluids secondary to anesthesia and operative stress stimulate secretion of aldosterone and antidiuretic hormone (ADH) ([7](#), [8](#)). Aldosterone is a potent stimulator of renal sodium retention, whereas ADH stimulates renal tubular water reabsorption. Although the neural and humoral mediators that result from tissue trauma may stimulate aldosterone release, afferent signals from volume receptors appear to be the major stimuli for these hormonal adjustments.

The ability to excrete a water load after elective surgical procedures is restricted ([9](#)). The usual postoperative patient concentrates urine to 1 to 2 mL water/mosmol solute excreted, corresponding to a urine osmolarity of 500 to 1000 mosmol/mL, even in the

presence of adequate hydration. Hence, weight gain secondary to salt and water retention is usual following operation. Edema occurs to a varying extent in all surgical wounds and is proportional to the extent of tissue dissection and local trauma. Administration of sodium-containing solutions during operation replaces this functional volume loss as extracellular fluid redistributes in the body. This “third-spaced” fluid eventually returns to the circulation as wound edema subsides and diuresis commences 2 to 4 days after the operation.

Following elective operation, the response of the endocrine pancreas is altered. In general, insulin elaboration is diminished, and glucagon concentrations rise (10). This response may be related to increased sympathetic activity or to the rise in levels of circulating epinephrine, which is known to suppress insulin release (11). The increased sympathetic nervous system stimulation results in alterations in circulating mediators. The rise in glucagon and the corresponding fall in insulin are a potent signal to accelerate hepatic glucose production, and with other hormones (epinephrine and glucocorticoids), gluconeogenesis is maintained.

Postoperative hormonal responses are thought to orchestrate physiologic and biochemical changes that benefit the host. Salt and water conservation support the circulating blood volume. Augmented hepatic glucose production provides adequate essential fuel for the nervous system, red and white blood cells, and the healing wound. Skeletal muscle proteolysis provides amino acid precursors for gluconeogenesis and hepatic protein synthesis. Postoperative lipolysis provides abundant quantities of free fatty acids, as an additional energy source. Current techniques of postoperative care minimize, but do not reverse, these responses.

Stage of Surgical Convalescence

The period of catabolism initiated by operation, a combination of inadequate nutrition and alteration of the hormonal environment, has been termed the *adrenergic-corticoid phase*. This period is followed by onset of anabolism, which occurs at a variable time in the patient's convalescence. In general, in the absence of postoperative complications, this phase starts 3 to 6 days after an abdominal operation of the magnitude of a colectomy or gastrectomy, often concomitant with the start of oral feedings. This “turning point” from catabolism to anabolism is referred to as the “corticoid-withdrawal phase” because it is characterized by spontaneous sodium and free-water diuresis, positive potassium balance, and reduced nitrogen excretion. This transitional phase usually lasts only 1 to 2 days.

The patient then enters a prolonged period of early anabolism characterized by positive nitrogen balance and weight gain. Protein synthesis is increased as a result of sustained enteral feedings, and this change is related to the return of lean body mass and muscular strength. The positive nitrogen balance is usually in the range of 2 to 4 g of nitrogen/day in the average adult, representing a daily gain of 60 to 120 g lean tissue. The total amount of nitrogen ultimately gained equals the amount lost, but the rate of gain is much slower than the rate of initial loss.

The fourth and final phase of surgical convalescence is late anabolism, the hallmark of

which is much slower weight gain. During this period, the patient is in nitrogen equilibrium but in positive carbon balance, which results from the deposition of body fat.

Effects of Nutritional Support on Postoperative Metabolism

Most patients undergoing elective operations are adequately nourished. Following an operation of the magnitude of cholecystectomy with common duct exploration, aneurysmectomy, or colectomy, oral feeding is generally not tolerated for 2 to 6 days. In a patient without postoperative complications, the duration of postoperative ileus depends on the extent of manipulation of the abdominal viscera and the length of the operation. Nasogastric decompression is frequently required, and the patient is routinely supported by 2 to 4 L intravenous fluids, usually containing 5% dextrose and appropriate electrolytes. Unless the patient has suffered significant preoperative malnutrition, characterized by a weight loss of more than 15%, or has had a major intraoperative or postoperative complication, solutions containing 5% dextrose may be administered for 10 days before initiation of enteral nutrition (EN), with no detrimental effect on outcome. With no dietary nitrogen and with insufficient calories, negative nitrogen balance occurs, in which urinary nitrogen excretion averages 10 to 15 g/day for 2 to 3 days, and then gradually diminishes. This nitrogen excretion is associated with a loss of potassium and phosphorus and indicates a loss of lean body mass.

Early investigators who studied the catabolic responses to operation concluded that the negative nitrogen balance was “obligatory” and an irreversible consequence of the metabolic response to injury. This view was challenged by data from two studies in postoperative patients. Riegel et al. fed patients who had undergone gastrectomy and neurosurgical procedures with tube-feeding techniques and showed that nitrogen equilibrium could be achieved when 0.30 g nitrogen and 30 kcal/kg were provided daily (12). Subsequently, Holden et al. nutritionally supported gastrectomy patients in the early postoperative period with intravenous nutrients and noted that body weight was maintained and near nitrogen balance was achieved when adequate calories and nitrogen were administered (13). These investigators concluded that the catabolic response to operation is largely due to inadequate food intake and is not an obligatory consequence of operative stress.

In general, if the patient is well nourished preoperatively and is expected to eat by the 10th postoperative day, 5% dextrose solutions provide adequate calories to prevent detrimental loss of endogenous body protein. Although a balanced nutrient intake administered in the postoperative period reduces the brief negative nitrogen balance associated with elective surgery and may maintain body weight, such an approach appears to be unwarranted in most patients undergoing elective operations. Such feedings have not accelerated recovery or decreased hospital stays in this group of patients. Therefore, the increased cost of feedings and the potential complications associated with intravenous nutrition cannot be justified. Jejunal feedings in the postoperative period may benefit some patients, especially those undergoing extensive upper gastrointestinal surgery. Such feedings are considerably less expensive than total parenteral nutrition (TPN) and can be administered safely. Studies evaluating the effectiveness of postoperative nutrition are reviewed below.

Nutritional Support of Elective Surgical Patients

Nutritional Assessment

The two major objectives of nutritional assessment are (a) to determine the patient's nutritional status and (b) to determine energy, protein, and macro- and micronutrient requirements. The nutritional status of a patient is determined by a careful history and physical examination, followed by additional tests to confirm the clinical impression (see [Chapter 55](#)). The medical history should include inquiries about associated disease processes, medication, and history of weight loss and dietary habits. The physical examination may establish the diagnosis of cachexia, protein-energy malnutrition, or specific nutrient deficiencies. Weight loss exceeding 10% of the weight before illness may compromise the patient's ability to combat infection or heal wounds.

Anthropometric measurements include measurement of body weight and height. The features are compared with population norms ([14](#)). Measurements of skinfold thickness are helpful to determine fat mass, and a 24-hour urine collection with measurement of creatine allows determination of the creatine-height index (CHI), a factor proportional to the size of muscle mass ([15](#)). More-sophisticated techniques to determine body composition include isotopic dilution methods, underwater weighing, total-body computerized axial tomography, and g-neutron activation; these methods are not generally practical in routine screening of most elective surgical patients. Detailed evaluation of assessment procedures is given in [Chapter 54](#), [Chapter 55](#), [Chapter 56](#), [Chapter 57](#) and [Chapter 58](#).

Immunologic status has been used to evaluate nutritional status; total peripheral lymphocyte count, delayed hypersensitivity using a skin-test response to common antigens, and lymphocyte transformation have all been used to indicate immunocompetence in the critically ill patient ([16](#)). Depressed immune function often returns to normal with nutritional repletion, but altered immunologic responses are not specific for nutritional deficiencies and are observed in patients with advanced malignant disease or in those who have had a severe injury. Moreover, delayed hypersensitivity may return on resolution of the disease process, despite inadequate nutrient intake.

Laboratory tests are useful to confirm the clinical suspicion of malnutrition (see [Chapter 57](#)). Serum albumin and transferrin are the most common serum proteins measured, and they correlate well with body protein deficiency in isolated cases of malnutrition. Most nutritional deficits in surgical patients are secondary to a disease process, however, and the presence may alter these indicators. Other laboratory studies that may be useful in nutritional assessment include red blood cell indices to determine iron and micronutrient deficiencies, plasma glucose to assess insulin resistance, blood urea nitrogen to determine renal status, and liver function tests to evaluate hepatic function.

Determining Nutritional Requirements

Nutritional therapy should be directed to a specific goal; depending on the patient's nutritional status, this goal should be (a) to diminish the rate of weight loss and body protein breakdown, (b) to maintain body weight and protein stores, and (c) to achieve weight gain and anabolism. In general, patients with normal body composition (no major nutritional deficiencies) and who are not hypercatabolic do not develop significant nutritional deficits and tolerate isotonic dextrose solutions for about 10 days. For example, the uncomplicated postoperative patient may receive intravenous infusions of 5% dextrose in water or inadequate oral intake for this period of time without any detrimental effect on recovery or ultimate health. The malnourished patient who has lost more than 15% of normal preillness weight often requires vigorous nutritional support, however. The immediate goal in such an individual is nutritional maintenance; the ultimate goal is restoration of body mass, which generally occurs in the later phases of surgical convalescence.

Total energy requirements are based on several factors: (a) the basal metabolic rate, (b) the degree of stress imposed by the disease process, and (c) the amount of energy expended with activity. Available nomograms relate normal metabolic requirements to a person's age, sex, height, and weight (14). Once basal metabolic requirements of the nonstressed individual have been determined, additional factors such as the stress of the disease and hospital activity should be considered. These relationships are expressed in [Table 98.1](#).

Body weight (kg)	50	55	60	65	70	75	80
Normal BMR (kcal/day)	1315	1411	1508	1602	1694	1784	1872

Condition	Stress Factor
Mild starvation	0.85-1.00
Postoperative recovery (no complications)	1.00-1.25
Cancer ¹	1.10-1.40
Long bone fracture	1.25-1.50
Peritonitis	1.50-1.75
Severe infection or multiple trauma ²	1.50-1.95
Burns >40% body surface area	2.0

¹ The basal metabolic requirements of the stressed patient are adjusted upward or downward 20 to 25% for hyperactivity and the stress associated with treatment. The adjustment is a precaution for patients receiving artificial ventilation who are paralyzed or are heavily sedated.

² The maximum energy gain on the part of a stressed individual is 1000 kcal/day. The maximum maintenance requirements are provided for a weight gain of approximately 100 g/d. Weight maintenance for weight gain involves the provision of protein at a rate of 0.5 g/kg/d.

³ 1 cal/kcal = 4.184 joules (J).

⁴ Repeat every 4 hours if the patient is stressed.

Table 98.1 Formulas for Determinations of Total Energy Requirements

The principal influences on nitrogen balance in surgical patients are total energy intake, nitrogen intake, and the metabolic state of the patient. Energy and nitrogen relationships are altered in nutritionally depleted and hypermetabolic patients. Persons with nutritional deficits have intact protein-conserving mechanisms that allow nitrogen equilibrium when 7 to 8% of total caloric needs are provided as protein. This translates into a calorie:nitrogen ratio of approximately 350:1. Hypermetabolic, catabolic patients, on the other hand, have a diminished protein economy and require much more protein. For

example, Duke et al. showed that in injured patients, protein contributes 15 to 20% of the total energy expenditure, such that the optimal calorie:nitrogen ratio is approximately 150:1 (17).

Route of Feeding

For patients who can eat and who have a functional gastrointestinal (GI) tract, adequate nutrition can best be provided by the regular hospital diet. This diet may be supplemented with between-meal snacks if necessary. Daily calorie counts and body weight determinations are necessary to monitor intake and the response to therapy. Some patients with a functional intestinal tract will not or cannot eat. Such patients include neurosurgical patients, those with oropharyngeal or esophageal obstruction, the elderly, and small children. In these patients, nasogastric or nasojejunal feedings may be indicated. Gastric feedings can be delivered five to six times daily by bolus feedings. Jejunal feedings require continuous administration. When permanent feedings are anticipated, a gastrostomy or feeding jejunostomy should be considered (18). A variety of nutrient formulas are now available for enteral feedings. In general, intact or partially hydrolyzed nutrients are most appropriate. These diets should be nutritionally complete and free of lactose (see [Chapter 100](#)).

Often, surgical patients require nutritional support but have a diseased or nonfunctional GI tract. These persons are candidates for parenteral nutrition, which can be infused through a peripheral or central vein. Peripheral venous feedings provide dilute nutrients in a large fluid volume and rely on fat emulsions as a principal calorie source. Central venous feedings consist of hypertonic glucose and amino acid solutions infused through a catheter placed in the superior vena cava. Adequate calories can be administered in a small fluid volume, but this method of feeding requires placement and care of a central venous catheter (see [Chapter 101](#)).

Formulating a Nutritional Support Plan

Most patients undergoing elective operative procedures recover quickly, resume oral feeding early in the postoperative period, and require no specialized nutritional support. Other surgical patients do not fit this description and require formal nutritional care. This group includes patients with preoperative malnutrition, those with dysfunctional GI tracts (prolonged ileus, inflammatory bowel disease), or those with specific diseases associated with a catabolic course (severe infection, major injury). These patients generally fall into one of these categories. In normally nourished patients, the nutritional goal is to maintain body weight and protein stores. In malnourished, nonstressed patients, weight gain and repletion of lean body tissue are indicated and are usually accomplished by providing an extra 1000 kcal/day. Anabolism is difficult to achieve in stressed catabolic patients, but body mass is generally restored simultaneously on resolution of the disease process. Hence, the nutritional goal in these patients is weight maintenance and treatment of the underlying disease process.

Perioperative Nutritional Support—Is It Beneficial?

Many of the studies undertaken to evaluate the effectiveness of perioperative nutritional

support have study design flaws that make interpretation difficult. Collectively, these studies indicate that the vast majority of patients undergoing elective operative procedures do not require formal nutritional support. In those that do, enteral feeding is always the route of choice if feasible. There are specific indications for the use of preoperative and postoperative nutrition. Surgeons should be familiar with these indications and how to monitor during feedings ([Fig. 98.1](#)).

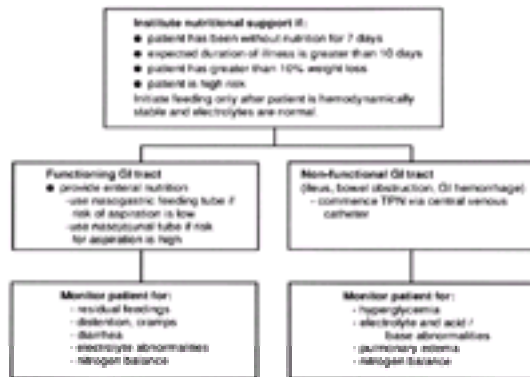

Figure 98.1. Nutritional management of the critically ill patient.

Preoperative Nutritional Support

Parenteral Nutrition. Randomized prospective clinical trials ([19](#), [20](#)) and a metaanalysis ([21](#)) strongly suggest that use of preoperative parenteral nutrition (PN) in severely malnourished patients, defined as those with weight loss exceeding 10 to 15% and/or serum albumin concentration below 3 g/dL, reduces the rate of postoperative complications. In one study ([19](#)), reduction in major postoperative complications (intraabdominal abscess, peritonitis, anastomotic disruption) was associated with improved serum protein levels and immunologic parameters and reduced mortality. This study has been criticized because it included well-nourished patients and because the actual nutrient intake by the control group was not apparent. The Veterans Administration Cooperative Trial ([20](#)) was a large multiinstitutional study, but it has been criticized because the control group (oral intake ad libitum) consumed fewer calories than the PN group. Unfortunately, none of these studies included a preoperative enteral arm.

Enteral Nutrition. Beneficial effects of preoperative nutrition were observed in two trials. The first study demonstrated that 10 days of a preoperative polymeric diet decreased the complication rate, death rate, and length of hospital stay in patients undergoing surgery for a variety of diseases ([22](#)). An Italian study by Foschi et al. ([23](#)) indicated that preoperative enteral hyperalimentation following percutaneous transhepatic biliary drainage for obstructive jaundice was beneficial. Patients in this study received an average of 20 days of enteral feedings via a feeding tube or were

allowed ad libitum intake of a regular hospital diet. The patients receiving the enteral diet had a reduced incidence of complications (anastomotic disruptions and organ failure) and a decreased mortality rate. Although neither of these studies compared EN with PN, in the very small group of severely malnourished patients who may require nutritional support, the enteral route is recommended over the parenteral route.

Postoperative Nutritional Support and Its Indications

Rigorous studies evaluating the use of postoperative nutrition are limited. One study (24) in minimally malnourished patients with hepatomas showed that the combination of preoperative and postoperative PN resulted in a statistically significant reduction in infectious complications (pneumonia) and a decreased diuretic requirement to control ascites, compared with patients who ate ad libitum. The relative contributions of preoperative and postoperative nutrition to the observed benefits were not studied. In contrast, Brennan et al. (25) reported that use of TPN (vs. a 5% dextrose infusion) after pancreatic resection was associated with a statistically significant increase in the incidence of intraabdominal infection. Although the Brennan study had no enteral arm, it is apparent from this and other trials that postoperative undernutrition in the elective surgical patients is well tolerated for as long as 14 days. Sandstrom et al. evaluated the effects of postoperative PN (vs. a 5% dextrose infusion) on outcome in 300 patients undergoing major elective surgery (26). Some 60% of patients were eating normally by postoperative day 9—PN was of no benefit in these individuals. Patients receiving 5% dextrose for more than 2 weeks had a higher mortality rate and more postoperative complications. PN improved outcome in 20% of the group overall, but the authors could not identify these “at risk” patients by preoperative criteria. Thus, surgical patients who develop a postoperative complication that precludes oral intake for more than 10 days are candidates for nutritional support.

High-Risk Surgical Patients. Only an occasional previously healthy patient undergoing elective operation develops complications and subsequently requires nutritional support. Most such surgical patients requiring nutritional support are individuals at increased operative risk. For example, TPN can induce remissions in 60 to 70% of patients with inflammatory bowel disease, but bowel rest alone, as an independent variable from nutritional support, is not a major factor in inducing remission in patients with Crohn's disease, and long-term outcome is unaffected by nutritional support (1). There are no trials comparing EN with PN in patients with active inflammatory bowel disease. Other high-risk patients are those with diabetes, cirrhosis, heart disease, renal failure, or marked obesity and those known to abuse drugs or alcohol. In addition, immunocompromised patients should be carefully evaluated, and their nutritional deficits should be restored before operation.

A major complication observed in the high-risk patient is wound dehiscence. This separation of the wound is most impressive when it occurs following laparotomy. When abdominal evisceration occurs, the patient should be taken to the operating room, and the wound should be debrided and approximated. Because wound disruption is frequently associated with infection and results in a massive inflammatory reaction, caloric and nitrogen demands increase and should be provided by intravenous feedings.

Hepatic failure occurs most commonly in the alcoholic cirrhotic patient who has a major gastrointestinal hemorrhage that requires operative intervention. Although the origin of hepatic encephalopathy is unknown, central nervous system function may be influenced by circulating levels of amino acids (27). The branched-chain amino acids (leucine, isoleucine, and valine) circulate at unusually low levels in patients with liver failure, whereas levels of the aromatic amino acids (phenylalanine, tyrosine, and tryptophan) are elevated. The hypothesis states that branched-chain amino acids compete with neutral amino acids for uptake across the blood-brain barrier. Because of the low blood levels of the branched-chain amino acids, preferential uptake of several of the amino acids that serve as precursors for synthesis of false neurotransmitters may occur (28).

It has been postulated that nutritional support may have beneficial effects on liver tissue and on the biochemical abnormalities that develop in the livers of patients with hepatic insufficiency and may improve survival. The principal data supporting this contention are from a multicenter study (29) in which the mortality rate in patients receiving PN enriched with branched-chain amino acids was 50% lower than that in persons treated with 25% dextrose and enteral neomycin. Results of other studies (30, 31) and a metaanalysis (32) did not show improved survival in patients receiving nutritional support. Collectively, the studies indicate that branched-chain amino acid-enriched formulas improve mental status in encephalopathic patients. Appropriate nutritional therapy for encephalopathic patients continues to be under investigation (see also Chapter 94 and Chapter 96).

When acute renal failure follows a major operation, the kidneys cannot excrete waste solute (nitrogen) or solvent, although occasionally, polyuric renal failure occurs. Provision of the usual amounts of amino acids in the diet exacerbates the already elevated level of blood urea nitrogen. These patients should be provided adequate nonnitrogenous calories to minimize protein breakdown, and nitrogen intake should be restricted if the patient does not require hemodialysis. Potassium, magnesium, and zinc are administered with caution. Solutions of essential amino acids (e.g., Nephramine) may improve protein synthesis and reduce urea generation. These amino acids are mixed with a 50 to 70% dextrose solution to minimize fluid intake and is administered through central venous catheters.

This renal-failure formula has been evaluated in patients with postoperative acute renal failure. Abel et al. reported that such PN improved survival rates and diminished renal dysfunction in patients with acute renal failure following aortic aneurysmectomy (33). In this prospective, randomized, double-blind trial, patients given glucose and essential amino acids had a better chance of surviving acute renal failure than those receiving only glucose (75 vs 44%; $P=.02$). These results may only be applicable to a select group of individuals with postoperative acute renal failure, as other studies have failed to observe similar beneficial effects of essential amino acids in patients with acute renal failure (34, 35) (see also Chapter 89).

What Is the Optimal Route of Delivery of Nutritional Formulations?

The recommendation that the enteral route be preferentially used (when the gut is

usable and functional) for nutritional support is based on studies in injured patients (see below). The effects of TPN on the human GI tract include decreased brush border hydrolase activity (36), reduced amino acid transporter activity (37), increased mucosal permeability (38), and a slight decrease in villus height (38). The splanchnic response to endotoxin appears to be exaggerated in volunteers fed parenterally, compared with subjects fed enterally, suggesting that TPN may amplify the metabolic alterations that develop during sepsis (39). Several studies (20, 21) have shown that intravenous nutrition increases the risk of septic complications. Thus, it seems prudent to use the enteral route of feeding unless use of the gut is contraindicated (e.g., bowel obstruction, intractable diarrhea, inadequate surface area, feeding intolerance).

TRAUMA

Usual Response to Injury

General Overview and Time Course

Accidental injury is followed by a well-described pattern of physiologic responses. The events are generally related to the severity of injury; that is, the greater the insult, the more pronounced the specific response (Fig. 98.2). Alterations following injury were first described in the 1860s, but not until the 1930s were changes in injured humans carefully studied and an integrated response pattern described. Cuthbertson studied patients with long-bone fractures and reported that these patients lost large quantities of nitrogen, potassium, and phosphorus in their urine following injury and that this accelerated excretion rate could not be reversed by vigorous oral feeding (40). Cuthbertson also noted that the injured patient's oxygen consumption gradually rose, with simultaneous elevation in body temperature. Because no apparent site of infection was identified, this febrile response was referred to as "posttraumatic fever." Cuthbertson described the time course for many of posttraumatic responses, and two distinct periods were identified. An early ebb or shock phase was usually of short duration (12 to 24 hours) and occurred immediately following injury. Blood pressure, cardiac output, body temperature, and oxygen consumption were reduced. These events were often associated with hemorrhage and resulted in hypoperfusion and lactic acidosis. With restoration of blood volume, ebb-phase alterations gave way to more accelerated responses. The flow phase was then characterized by hypermetabolism, increased cardiac output, increased urinary nitrogen losses, altered glucose metabolism, and accelerated tissue catabolism (Table 98.2).

Figure 98.2. With time, the rate of glucose disposal (M) progressively increases in the control subjects during the hyperglycemic glucose clamp. In contrast, glucose removal was constant in these patients over the 2 hours of study and averaged approximately 7 mg/kg/min. (From Black PR, Brooks DC, Bessey PQ, et al. *Ann Surg* 1982;196:420–33, with permission.)

Ebb Phase	Flow Phase
Blood glucose elevated	Glucose normal or slightly elevated
Glucose production normal	Glucose production increased
Free fatty acids elevated	Free fatty acids normal or slightly elevated; flux increased
Insulin concentration low	Insulin concentration normal or elevated
Catecholamines and glucagon elevated	Catecholamines high normal or elevated; glucagon elevated
Blood lactate elevated	Blood lactate normal
Oxygen consumption depressed	Oxygen consumption elevated
Cardiac output below normal	Cardiac output increased
Core temperature below normal	Core temperature elevated

Table 98.2 Metabolic Alterations following Injury

The flow-phase responses to accidental injury are similar to those seen following elective operation; however, the response to injury is usually much more intensive and extends over a long period of time. For example, following soft tissue injury, patients often have an impaired ability to excrete a water load because of heightened elaboration of aldosterone and ADH. The retention of large quantities of sodium and water that may occur during fluid resuscitation results in a dramatic increase in body weight, which may rise 10 to 20% over the preinjury weight. During recovery, the edema fluid reenters the vascular compartment, and the salt and water load is gradually excreted by the kidneys. Although sodium and water retention may occur following elective operation, the magnitude is much lower, and subsequent events (fluid mobilization followed by volume

expansion and diuresis) are much less dramatic than in injured patients.

Characteristics of the Flow Phase of the Injury Response

The flow phase is characterized by hypermetabolism and alterations in the metabolism of glucose, protein, and fat.

Hypermetabolism. Hypermetabolism is defined as an increase in basal metabolic rate (BMR) above that predicted on the basis of age, sex, and body size. Metabolic rate is usually determined by measuring the exchange of respiratory gases and by calculating heat production from oxygen consumption and carbon dioxide production (see [Chapter 5](#)). The degree of hypermetabolism (increased oxygen production) is generally related to the severity of the injury. Patients with long-bone fractures have a 15 to 25% increase in metabolic rate, whereas the metabolic needs of patients with multiple injuries increase by 50%. Patients with severe burn injury (more than 50% of body surface area [BSA]) have resting metabolic rates that may reach twice basal levels ([14](#)). These rates of heat production in trauma patients are contrasted with those in postoperative patients, who rarely increase their BMR by more than 10 to 15% following operation.

Concomitant with development of hypermetabolism, the trauma patient usually develops a 1 to 2°C elevation in body temperature. This posttraumatic fever is a well-recognized component of the injury response and represents an upward shift in the thermoregulatory setpoint of the brain ([41](#)). In general, if the patient is asymptomatic, the fever will rarely be treated.

Altered Glucose Metabolism. Hyperglycemia commonly occurs following injury, and the elevation of fasting blood sugar levels generally parallels the severity of stress in the ebb phase. At that time, insulin levels are low, and glucose production is only slightly elevated ([42](#)). Later, during the flow phase, insulin concentrations are normal or elevated; yet, hyperglycemia persists. This phenomenon suggests an alteration in the relationship between insulin sensitivity and glucose disposal. Hepatic glucose production is increased ([43](#)), and the accelerated gluconeogenesis is generally related to the extent of the injury. Studies in injured patients show that much of the new glucose generated by the liver arises from 3-carbon precursors (lactate, pyruvate, amino acids, and glycerol) released from peripheral tissues ([43](#)).

To determine which peripheral tissues use the large quantity of glucose produced by the liver, investigators measured substrate exchange across injured and uninjured extremities of severely burned patients matched for age, weight, and extent of total-body-surface burn ([44](#)). Net glucose flux across uninjured extremities was low, suggesting that fat, not glucose, is the primary fuel for resting skeletal muscle in the postabsorptive state. Similar observations have been made in a study of normal volunteers; however, glucose uptake was increased across the burned extremity. In addition, the injured extremity released large quantities of lactate, which accounted for as much as 80% of the glucose consumed. This finding is consistent with our knowledge of the biochemistry of the specialized cells of the wound and inflammatory tissue (fibroblasts, macrophages, leukocytes), which undergo anaerobic metabolism and have a large capacity for lactate production. Additional measurements of blood flow

and substrate concentration differences across the kidney and the brain further characterized the glucose disposal in stable trauma patients. (44, 45). The glucose consumed by the central nervous system in the injured patient is approximately normal (120 g/day), whereas that consumed by kidney is approximately twice normal (75 g/day). Only a small fraction of the glucose is taken up by the resting skeletal muscle, and the remainder is consumed by the wound. The wound converts most of the glucose to lactate, which is recycled to glucose in the liver via the Cori cycle.

These alterations in glucose metabolism have a profound impact on the handling of exogenously administered glucose contained in enteral or parenteral feedings. To characterize glucose disposal during the flow phase of injury, six traumatized patients who did not have sepsis were studied by means of the hyperglycemic glucose “clamp” technique for 5 to 10 days after the injury (46). The results were compared with those from 11 age-matched control subjects. After an overnight fast, a 20% glucose solution was infused intravenously to elevate plasma glucose concentrations suddenly to 125 mg/dL above basal levels. This elevation was maintained for 2 hours with bedside glucose monitoring and negative feedback servocontrol. The results showed a progressive increase in glucose disposal with time in normal control subjects, whereas the injured patients maintained a constant glucose disposal throughout the study (Fig. 98.2). Moreover, the quantity of insulin elaborated in the patients was greater than in control subjects; nonetheless, the rising insulin concentrations failed to increase glucose clearance in these patients.

Other studies have demonstrated a failure to suppress hepatic glucose production in trauma patients during glucose loading or insulin infusion (47). Either of these perturbations usually inhibits hepatic glucose production in normal subjects. Wolfe et al., using tracer methods, found that endogenous suppression comprised only 73% of the infused glucose load in burn patients (2.6 mg/kg/min) (48). This rate of glucose infusion completely suppresses glucose production in normal subjects. When investigators used the hyperglycemic glucose “clamp” technique combined with tracer methods, endogenous glucose production was only partially reduced in trauma patients, in spite of high concentrations of both glucose and insulin (46).

To quantitate the insulin resistance in peripheral tissues, Brooks et al. measured glucose uptake across the uninjured forearm in conjunction with hyperinsulinemic-euglycemic clamp studies in 11 normal subjects and 5 patients with multiple trauma (49). Glucose uptake by uninjured forearm skeletal muscle of trauma patients was much lower than that observed in control subjects.

Thus, profound insulin insensitivity occurs in injured patients. Direct measurements show that liver and skeletal muscle are resistant tissues, and studies by Carpentier et al. suggest that lipolysis is not attenuated in trauma patients after glucose administration (50). The cause of this marked insensitivity to insulin is unknown; however, similar effects are observed following alterations in the hormonal environment. For example, insulin-mediated forearm glucose uptake is diminished in normal subjects following 2 hours of epinephrine infusion (51). Similarly, 3 days of glucocorticoid administration decreases glucose consumption (52).

Alterations in Protein Metabolism. Extensive urinary nitrogen loss occurs following major injury. Because of the magnitude of these losses and the progressive wasting of skeletal muscle mass and associated muscle weakness, it was originally hypothesized that the nitrogen loss represented a generalized and accelerated breakdown of muscle protein. Like other responses, the loss of nitrogen following injury is related to the extent of the trauma, but it also depends on the previous nutritional status, as well as the age and sex, of the patient, because these factors determine, in part, the size of the muscle mass ([Fig. 98.3](#)).

Figure 98.3. Metabolic rate (*A*) and nitrogen excretion (*B*) are related to the extent of injury. The two responses generally parallel each other. Patients received 12 g nitrogen daily. (From Wilmore DW. *The metabolic management of the critically ill*. New York: Plenum Medical Book, 1977, with permission.)

Although nitrogen balance studies demonstrate marked negative nitrogen balance following injury, these studies reflect only net nitrogen catabolism, not the absolute rate of nitrogen breakdown. In normal subjects, nitrogen equilibrium is maintained by a careful balance between rates of protein synthesis and rates of degradation. Negative nitrogen balance occurs if the breakdown rate increases and protein synthesis remains the same or if the breakdown rate remains the same and the rate of synthesis decreases. The use of isotopically labeled, nonradioactive amino acids allows quantification of the alterations in synthesis and breakdown rates associated with many disease processes. Herrmann et al. ([53](#)) administered ^{15}N -glycine to achieve a steady state and measured ^{15}N -urea nitrogen enrichment using the two-pool model of Picou and Taylor-Roberts ([54](#)). Turnover rates of protein were measured, and rates of synthesis and catabolism were calculated in fed and fasted states in normal subjects. During feeding, synthesis and catabolism were equal. Restriction of food intake caused a marked reduction in synthesis, with minimal impact on rates of protein catabolism. Birkhahn et al. described protein kinetics in four patients following multisystemic injury, including long-bone fractures ([55](#)). In contrast to patients undergoing elective orthopaedic operations, these patients had a marked increase in catabolic rate and a

slight increase in synthesis; because catabolism exceeded synthesis, the patients were in marked negative nitrogen balance while receiving standard infusions of 5% dextrose and water.

Thus, trauma accelerates nitrogen turnover. In unfed patients, breakdown rates exceed synthesis, and negative balance results. Providing exogenous calories and nitrogen increases synthesis, and when adequate nutrients are provided, the two rates are matched and nitrogen balance is maintained (Table 98.3).

	Synthesis ^a	Catabolism
Normal: patient starved	↓	○
Normal: patient fed, during bedrest	↓	○
Elective surgical procedure	↓	○
Injury/sepsis: patient receiving intravenous dextrose	↑↑	↑↑↑
Injury/sepsis: patient fed	↑↑↑	↑↑↑

^a↓, decrease; ○, no change; ↑, increase.

Table 98.3 Alterations in Rates of Protein Synthesis and Catabolism That May Affect Hospitalized Patients

Cuthbertson (56) initially suggested that the nitrogen lost in the urine following extensive injury originates in muscle. In his patients with long-bone fractures, he suggested that this reaction was a uniform response of the entire muscle mass, and nitrogen was not lost solely from damaged muscle at the site of injury. This concept is supported by a variety of studies that measured important markers of muscle catabolism, such as creatinine, creatine, zinc, and 3-methylhistidine. Further evidence of net skeletal muscle breakdown comes from quantification of amino acid loss from extremities of severely injured patients. Aulick and Wilmore used plethysmographic techniques to measure leg blood flow and simultaneously determine arterial and femoral venous amino acid concentrations in traumatized patients (57). They found a three- to fourfold higher amino acid flux from the extremities of injured patients than from normal subjects. Alanine efflux was the most highly elevated of the amino acids measured, but glutamine was not measured. The increase in alanine release from the legs of severely traumatized patients was generally related to the extent of injury and the oxygen consumption of the patient, but it was not related to the size of the limb injury or to blood flow in the leg. The accelerated rate of α -amino nitrogen release from the limbs of these patients appeared to be a generalized catabolic effect of injury, rather than a response to local inflammatory or metabolic events in the injured extremities. This response may be the result of chronic hypercortisolism, which occurs in injury.

Using dogs catheterized on a long-term basis to study hindquarter amino acid metabolism, Muhlbacher et al. observed that long-term administration of dexamethasone (a potent glucocorticoid) resulted in a fourfold increase in glutamine and alanine release from skeletal muscle (58). Although glutamine stores in muscle were reduced by 50% within 10 to 14 days, the accelerated glutamine release was exceeded by an accelerated consumption of this amino acid, and plasma glutamine levels fell by 30%.

Although it is now recognized that amino acids are released by muscle in increased quantities following injury, it has only recently been appreciated that the composition of amino acid efflux does not reflect the composition of muscle protein. Alanine and glutamine comprise 50 to 60% of amino acids released, whereas each makes up only about 6% of muscle protein. The branched-chain amino acids (valine, leucine, and isoleucine), on the other hand, make up approximately 6% of the released amino acids, but constitute nearly 15% of muscle protein. To explain these observations, Goldberg and Chang proposed that the branched-chain amino acids serve as amino donors for α -ketoglutarate, yielding the corresponding branched-chain ketoacids and glutamate (59). The ketoacids can be converted to tricarboxylic-cycle intermediates in skeletal muscle, or they can be exported through the circulation. Glutamate may be a precursor for glutamine synthesis or an amino donor for alanine synthesis. These coupled reactions could explain the synthesis and increased release of alanine and glutamine as well as the diminished release of branched-chain amino acids (Fig. 98.4). Oxidation of branched-chain amino acids by skeletal muscle is accelerated following injury (60), and skeletal muscle release of glutamine and alanine is increased. (See also Chapter 35.)

Figure 98.4. Major biochemical reactions that lead to synthesis of glutamine (*GLN*) and alanine in skeletal muscle.

Glutamine is also extracted by the kidney, where it contributes ammonium groups for ammonia generation, a process that excretes acid loads (61). This effect can be augmented in the dog by administration of glucocorticoids. Glutamine is taken up by the

GI tract and serves as an oxidative fuel (62). The gut enterocytes convert glutamine primarily to ammonia and alanine, and these two substances are released into the portal venous blood. This ammonia is then removed by the liver and is converted to urea; the alanine may also be removed by the liver and may serve as a gluconeogenic precursor. Following elective surgical stress, glutamine consumption by the bowel and kidney is accelerated (63), a reaction that appears to be regulated by increased elaboration of glucocorticoids (64). Although skeletal muscle releases alanine at an accelerated rate, the GI tract and kidney also release increased amounts of alanine. This amino acid is extracted by the liver and used in the synthesis of glucose and acute-phase proteins. Hence glutamine and alanine are important participants in the transfer of nitrogen from skeletal muscle to visceral organs; however, their metabolic pathways favor production of urea and ammonia, both of which are lost from the body (Fig. 98.5).

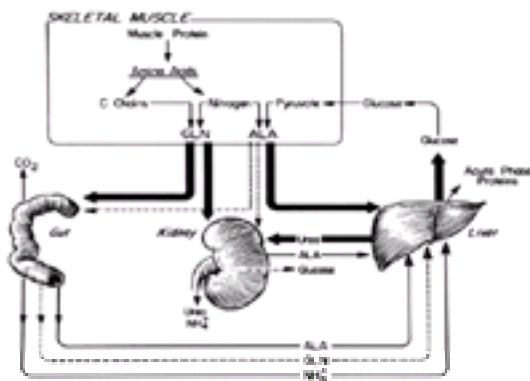

Figure 98.5. Major pathways of “obligatory” loss of nitrogen from the body. *ALA*, alanine; *GLN*, glutamine.

Alterations in Fat Metabolism. To support hypermetabolism, increased gluconeogenesis, and interorgan substrate flux, stored triglyceride is mobilized and is oxidized at an accelerated rate. Lipolysis is poorly attenuated following glucose administration (50); this phenomenon may result from continuous stimulation of the sympathetic nervous system. Although mobilization and use of free fatty acids are accelerated in injured subjects, ketosis during brief starvation is blunted, and the accelerated protein catabolism remains unchecked (65). Unfed, severely injured patients rapidly deplete their fat and protein stores. Such malnutrition increases their susceptibility to added stresses of hemorrhage, operations, and infection and may contribute to organ system failure, sepsis, and death.

Mediators of the Injury Response

Hormonal Environment Associated with the Injury Response

A variety of hormonal alterations occur in patients following injury; yet, the

cause-and-effect relationships have only recently been established. In all phases of injury, one sees a marked rise in the counterregulatory hormones glucagon, glucocorticoids, and catecholamines (66). During the ebb phase of injury, the sympathoadrenal axis primarily maintains the pressure-flow relationships necessary for an intact cardiovascular system. With onset of hypermetabolism, characteristic of the flow phase, these and other hormones exert a variety of metabolic effects. Glucagon has potent glycogenolytic and gluconeogenic effects on the liver, and these effects signal the liver to make new glucose from hepatic glycogen stores and gluconeogenic precursors. Cortisol mobilizes amino acid from skeletal muscle, increases hepatic gluconeogenesis, and maintains body fat stores. The catecholamines stimulate hepatic gluconeogenesis and glycolysis and increase lactate production from peripheral tissues (skeletal muscle). Catecholamines also increase metabolic rate and stimulate lipolysis. The level of growth hormone is elevated, even in the presence of hyperglycemia, and thyroid levels are reduced to low-normal concentrations.

Cytokines and the Metabolic Response to Injury

Although the classic counterregulatory hormones of stress (cortisol, catecholamines, glucagon) are important in mediating the body's response to injury and infection, they exert their influence largely via endocrine mechanisms. Other mediators, peptide compounds known collectively as cytokines, are produced both at the site of injury by endothelial cells and by diverse immune cells throughout the body and also occupy a pivotal position in the stress response (67). The cytokines that have been studied most extensively and appear to play the most important role in the injury response are tumor necrosis factor- α (TNF, cachectin), interleukins 1, 2, and 6 (IL-1, IL-2, and IL-6), and interferon- γ (IFN).

Originally it was thought that cytokines' primary influence was on immune cell function. It is now clear that cytokines are key regulators of the metabolic response to injury and infection (Fig. 98.6). These polypeptide signals, produced by the organism in response to bacteremia or endotoxemia, induce many of the adverse responses following severe infection (68, 69). A large number of these reticuloendothelial cell products have now been described (see Chapter 45, Chapter 46 and Chapter 96). TNF, IL-1, and IL-6 have been convincingly demonstrated in the circulation of humans following administration of endotoxin (67, 70).

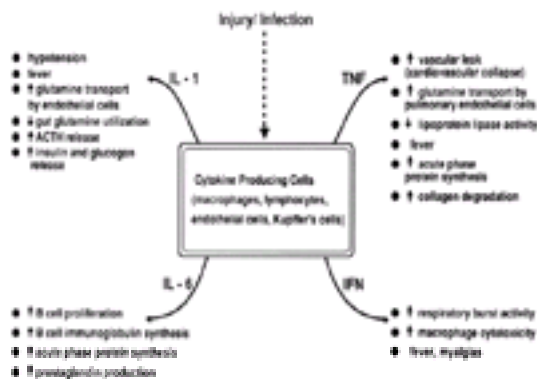

Figure 98.6. Some metabolic activities of selected cytokines as they relate to the body's response to injury and infection.

TNF is considered the primary signal that initiates many of the metabolic responses to injury and infection. The host response to endotoxin includes a rapid increase in circulating TNF levels, which are no longer detectable after several hours. Although infusion of TNF to patients results in fever, malaise, tachycardia, and chills indicating an acute-phase response, the potent effects that TNF exerts on body metabolism may in concert benefit the host because they promote mobilization of nitrogen and carbon from the periphery, which are transported to the splanchnic circulation. TNF has no effect on skeletal muscle protein balance or amino acid efflux when it is administered to healthy animals or incubated with skeletal muscle. However, TNF stimulates amino acid uptake by the liver and endothelial cells (71).

IL-1 is a protein with a molecular mass of about 17 kDa. Previously called lymphocyte-activating factor, or endogenous pyrogen, this peptide plays a central role in the acute-phase protein response, including an increase in myofibrillar protein breakdown, and in the release of amino acids from skeletal muscle, in particular glutamine. Like TNF, IL-1 also stimulates glutamine transport by endothelial cells (71) and by the liver. Its effects on intestinal glutamine metabolism are similar to those of endotoxin and include a decrease in glutamine extraction from the blood and a fall in mucosal glutaminase activity (72).

The pattern of appearance of various cytokines in the circulation has been examined in animals receiving intravenous infusions of bacteria. TNF levels peak at about 90 minutes, while IL-1 peaked at 3 hours. IL-6 levels continued to rise for up to 8 hours. Thus, the pattern of cytokinemia appears to be monophasic and probably explains the occasional failure to detect these mediators in the blood of infected patients. In addition, many of the biologic responses to cytokines may be due to tissue levels of cytokines rather than circulating levels. Clearly, cytokines may exert their effects in a paracrine, autocrine, or endocrine fashion (74, 75). They also appear to work in synergy to produce the metabolic derangements found in traumatized and septic patients.

Nutritional Support of the Injured Patient

Usual Course: Case Example

A 28-year-old, nonobese male (6 ft tall; 170 lb; BSA, 2.0 m²) is admitted to the hospital with a pelvic fracture and soft tissue injury following a motor vehicle accident. He was always in good health prior to this accident. He is resuscitated without incident with intravenous fluids and blood products. The patient is admitted to the trauma intensive care unit of the hospital, and a nasogastric tube is placed. Over the next 24 hours, his blood volume is restored, and he is given maintenance solutions with 5% dextrose and

appropriate electrolytes at the rate of 125 mL/h (3 L/day). His urine output on his first hospital day is 1500 mL, and he gains 5 kg following fluid resuscitation. Because of a prolonged ileus, the patient is not fed, and he continues to receive intravenous fluids. On day 7 of the injury, the ileus resolves, and a spontaneous diuresis of 3000 mL ensues. On day 8 following the accident, the patient starts taking clear liquids and is gradually advanced to regular diet over the next 4 days. He is discharged from the hospital 4 weeks later, when his fractures have stabilized.

Nitrogen balance studies from hospital day 1 through day 7 reveal a cumulative 7-day nitrogen loss of 108 g. During this 7-day period, the patient had 0 nitrogen intake and 600 kcal glucose/day. On the day 8 of hospitalization, the patient lost 5 kg. Approximately half the weight represented loss of lean body mass (108 g nitrogen = 675 g protein=2.5 kg lean body mass), and the remainder, loss of fat. On discharge from the hospital a month later, the patient had regained his initial body weight (Fig. 98.7).

Figure 98.7. Metabolic response of a previously healthy individual to an injury of moderate severity.

Response to Fixed Enteral or Parenteral Nutrition

The elective surgical patient can tolerate the mild catabolic responses following operation, with inadequate food intake, but the trauma patient cannot because of accelerated tissue catabolism. This “obligatory” nitrogen loss can, in part, be reversed nutritionally, but the accelerated nitrogen excretion only returns to normal when the wound is closed and the fracture is stabilized and is healing. Nutritional support does not affect the hypermetabolic response associated with severe trauma, but provision of adequate calories and amino acids does reduce the magnitude of net lipogenesis, skeletal muscle proteolysis, and negative nitrogen balance.

Suppose the patient described above sustains the same injury but has his postinjury period modified by administration of all essential nutrients. The patient receives 3 L of a parenteral solution that delivers, 2800 kcal plus 15 g nitrogen/day as a balanced amino

acid mixture (Fig. 98.8). This caloric intake is judged adequate to maintain body weight. Nitrogen balance studies show cumulative loss of 140 g from hospital day 1 through hospital day 7, so his net loss for the 7 days equals 35 g. The patient lost 1 kg during this time, primarily lean body tissue.

Figure 98.8. Injury response with nutrition provided by central vein infusions.

Administration of nutrients to this patient is designed to combat the negative nitrogen balance and weight loss associated with injury. The benefits of such feedings in patients with extensive injury have been translated into reduced morbidity and mortality rates when nutritional support is combined with other improvements in intensive care.

Consequences of Malnutrition

The metabolic response to injury results in increased energy expenditure. If energy intake is less than expenditure, oxidation of body fat stores and erosion of lean body mass will occur, with resultant loss of weight. Most injured patients can tolerate losing of 10% of their weight prior to injury without a significant increase in the risks of injury. When weight loss exceeds 10% of body weight, the complications of undernutrition interact with the disease process, with increased morbidity and mortality rates. Undernutrition to this extent following injury may impair the body's ability to respond appropriately to the injury and inhibit responses to added stress such as infection.

The major impact of nutritional support in the trauma patient is in aiding host defense. These patients are exposed to a variety of infectious agents in the hospital, and their injuries and requirements of care increase the risk of infection. The normal barrier defense mechanisms are disrupted by multiple indwelling catheters, nasotracheal and nasogastric tubes, and breakdown of skin and mucous membranes. Undernutrition may compromise the available host defense mechanism and may thus increase the likelihood of invasive sepsis, multiple-organ system failure, and death. Additional consequences of malnutrition include poor wound healing, decreased mobility and activity, occurrence of pressure sores and decubitus ulcers, altered GI function, and

occurrence of edema secondary to reduced colloid osmotic pressure. Whereas these complications are most frequently observed in patients with severe malnutrition (>15% body weight loss), adequate nutritional support helps prevent them.

Priorities of Care

Nutrition should be integrated into the overall care of the critically ill patient to maximize the benefits of nutritional support yet minimize complications in a complex intensive care setting. Priorities in care should be established at various points following injury. Resuscitation, oxygenation, and arrest of hemorrhage are immediate priorities for survival. Wounds should then be repaired or stabilized as expeditiously as possible. During wound repair, a patient's intensive metabolic demands abate, and nutrients become more effective in achieving anabolism. Early excision and grafting of burns and internal fixation of fractures are examples of early definitive wound care; yet even these procedures may be followed by several weeks of posttraumatic hypermetabolism. While the wound is treated, care should be taken to minimize other potential stresses that heighten metabolic demands in addition to those imposed by the injury alone. Such factors include pain, fever, mild cold exposure, acidosis, and hypovolemia. The greatest acceleration of catabolism occurs with infection, however, and every effort should be made to prevent sepsis.

Nutritional support is an essential part of the metabolic care of the critically ill trauma patient. Adequate nutrition allows normal responses that optimize wound healing and recovery. Nutritional support should be instituted before significant weight loss occurs. Development of techniques for intravenous administration of hypertonic nutrient solutions, the use of peripheral venous feedings with fat emulsions, and the availability of specific enteral diets have made it possible for virtually all injured patients to receive safe and effective nutritional support.

Goals of Nutritional Support

Most injured persons are not malnourished at the time of injury, but the increased metabolic demands following injury will quickly lead to a malnourished state if the patient is not nutritionally supported ([Fig. 98.9](#)). Thus, nutritional support should be considered for all injured patients. Provision of full nutritional support early after injury may be fraught with metabolic complications, however. Hyperglycemia, hyperosmolarity, and electrolyte disorders are frequently observed. Thus, intravenous feedings are not usually begun immediately following the admission of the patient to the hospital. After stabilization of the patient's condition and development of a care plan, nutritional support can be gradually initiated. The goal of nutritional support is maintenance of body cell mass and limitation of weight loss to less than 10% of preinjury weight. Considerations include nutritional evaluation, requirements, monitoring, routes of administration, and specific formulas.

Figure 98.9. Weight loss with starvation is accelerated after major injury and infection.

Nutritional Assessment and Requirements. Nutritional assessment of the trauma patient helps to determine energy and protein requirements. A careful medical history and physical examination are essential, but the usual indicators of malnutrition are frequently misleading in the trauma patient. For example, body weight is increased in these patients because of edema, and serum albumin and transferrin decrease in concentration because of an enlarged distribution space. Hence nutritional support should be considered for all injured patients, with the goal to maintain usual (preinjury) body weight and body tissue mass.

Basal energy requirements are determined from standard tables based on age, sex, and BSA (14). These requirements are adjusted for the increase in metabolic rate due to the injury or disease process by multiplication by a stress factor based on the severity of injury (see [Table 98.1](#)). An additional 25% is added to account for the energy expenditure associated with treatment and activity, but this addition is not required in inactive patients (e.g., those sedated or paralyzed while receiving artificial ventilation). The product of the factors (BMR times stress factors times 1.25, if needed) is an estimate of the patient's energy requirements.

The next step is to calculate nitrogen requirements. In normal subjects, the ratio of nitrogen to nonprotein caloric intake is usually 1:300 to 350; that is, for every 300 to 350 kcal, 1 g nitrogen is provided. Because of the heightened protein catabolism associated with the posttraumatic response, more dietary protein is required to achieve nitrogen balance. For critically ill patients, the optimal nitrogen:calorie ratio is thought to range between 1:100 and 1:200. This ratio indicates that approximately twice the quantity of protein is required to achieve "balance" in the injured patient than in healthy persons. Approximately 15 to 20% of caloric intake should be protein.

Once energy and nitrogen requirements have been determined, the proportions of fat and carbohydrate must be estimated, to maximize nitrogen retention. Long et al. studied the nitrogen-sparing effects of different isocaloric mixtures of glucose and fat in patients receiving 11.7 g nitrogen/m²/day (76). They found no additional nitrogen-sparing effects

when glucose calories exceeded the measured metabolic rate. Nitrogen equilibrium was approached when glucose made up 60 to 70% of the caloric needs, approximately 7 mg/kg/min. In addition, Wolfe et al. studied oxidation rates of postoperative patients receiving glucose (77). No increase in oxidation of administered glucose was observed when patients received glucose infusions above 7 mg/kg/min. Black et al., using the glucose clamp technique, demonstrated that injured patients had an upper limit to glucose disposal of approximately 6 to 7 mg/kg/min, a value that represented 60 to 70% of the estimated caloric needs (46). In contrast, normal subjects could dispose of increasing quantities of glucose and approached an upper limit of 15 to 17 mg/kg/min. The results of these 3 independent studies using different techniques point to the same conclusion: no clear-cut gain is made in providing glucose calories in excess of 60 to 70% of daily metabolic requirements to injured patients. Administration of larger glucose loads has been associated with increased incidence of complications such as hyperglycemia, hyperosmotic states, hepatic dysfunction, and respiratory insufficiency (78). For patients who tolerate large caloric loads, provision of 60% of caloric needs as glucose and the rest as fat should minimize complications and maximize protein synthesis.

Multivitamins are administered daily (see [Chapter 101](#) for parenteral formulations). Supplemental vitamin C is believed by some to be required in increased amounts following injury (79). Electrolytes are present in standard diets or tube feedings as are trace elements ([Chapter 100](#)), and they must be added to parenteral infusions ([Chapter 101](#)). Potassium, magnesium, and phosphate supplements in addition to those in tube formulas may be required to maintain normal serum concentrations of these electrolytes. They must be added to parenteral fluids to meet needs, except when present in amino acid–electrolyte combinations. Although the need for zinc has been demonstrated experimentally, clinical reports of zinc replacement therapy in burn patients provide no definitive answers about the benefit of this supplement following injury (80). Zinc supplements should be administered to severely malnourished individuals and those with a history of poor nutrient intake (alcoholic patients) who have a major injury or major intestinal fluid losses.

In summary, the nutritional requirements of the trauma patient can be determined as follows:

1. Determine BMR for age, sex, and BSA from the tables of Fleisch or the Harris-Benedict equation (BMR in kcal/day) (14).
2. Determine the percentage increase in metabolic rate due to the injury (see [Table 98.1](#)), multiply by BMR, and add to 1 ($\% \times \text{BMR} + \text{BMR}$).
3. Add $25\% \times \text{BMR}$ for hospital activity (walking, physical therapy, sitting, treatment).
4. The sum of steps 1 to 3 is an estimated daily caloric requirement for maintenance of body weight.
5. Divide step 4 by 150 to determine nitrogen requirements (protein=6.25 \times nitrogen).
6. Give approximately 60% of caloric requirement (determined in step 4) as glucose.
7. Give remaining caloric requirement as fat (glucose can be used if tolerated by the patient). Glucose is much less expensive, and a central venous catheter will be necessary to administer the glucose solution. If glucose is used as the remaining caloric source, insulin may need to be given to avoid hyperglycemia. Fat emulsion should then be given 2 to 3 times per week to provide essential fatty acid

requirements.

8. Reassess energy and nitrogen needs at least twice weekly. Weigh the patient daily.
9. If nutritional support seems unsatisfactory because of progressive weight loss, consider direct measurement of oxygen consumption or measurement of nitrogen loss and calculation of nitrogen balance.

Nutritional Monitoring. Once the trauma patient is nutritionally assessed, feedings can be gradually commenced. Protein and caloric intake should be measured and recorded daily. If nutritional requirements are not met by current therapy, then other feeding techniques should be used. Combined nutritional support techniques may be necessary during the convalescence of a severely injured patient (Fig. 98.10).

Figure 98.10. Subjects with moderate-to-severe injury require various techniques to provide safe and efficient nutrition.

If the patient continues to lose more weight than can be attributed to postresuscitation diuresis, then additional nutritional assessment using such techniques as indirect calorimetry or nitrogen balance testing should be performed. Plasma glucose levels should be determined regularly, especially when one is beginning or increasing nutritional support. Insulin should be administered to maintain a plasma glucose level of 100 to 150 mg/dL. Urine sugar content should be evaluated by the hospital nursing staff every 6 to 8 hours. Levels of serum electrolytes, blood urea nitrogen (BUN), and creatinine and liver function should be determined regularly, as consistent with proper care. Serum potassium concentrations may need to be followed more closely because of increased potassium losses after injury and a tendency toward metabolic alkalosis.

Additional Nutritional Assessment Techniques. Energy requirements may be estimated with reasonable accuracy in 85% of hospital patients. If estimated requirements are delivered by current nutritional support but therapy seems inadequate because of persistent weight loss in excess of estimated net fluid losses or an unsatisfactory clinical course, energy requirements may be measured by indirect

calorimetry. Oxygen consumption ($\dot{V}\text{O}_2$) and carbon dioxide production ($\dot{V}\text{CO}_2$) are determined under resting, unstressed, basal conditions. These respiratory parameters are interrelated to energy expenditure by the following relationships:

$$\text{Metabolic rate (kcal/h)} = 3.9 \times \dot{V}\text{O}_2 \text{ (L/h)} + 1.1 \times \dot{V}\text{CO}_2 \text{ (L/h)}$$

This value, the resting energy expenditure of the patient, should be increased 20 to 30% to account for minimal daily activity when used to determine energy requirements.

Nitrogen balance studies help define the effectiveness of nutritional support. These should be performed in patients whose clinical course is unsatisfactory or in whom nutritional efficacy cannot be estimated on clinical grounds alone. Nitrogen balance is the quantity of nitrogen taken in or administered to the patient minus the quantity of nitrogen lost:

$$N_{\text{bal}} \text{ (g/day)} = N_{\text{in}} - N_{\text{out}}$$

Most nitrogen is lost in the urine, mainly as urea. The urine is collected for 24-hour periods and is stored in acidified containers. Urinary urea nitrogen (UUN) is measured. This represents approximately 80% of urinary nitrogen. Additionally, about 2 g/day are lost in the feces and from the skin. If the BUN changes during the 24-hour period, the whole body changes in urea nitrogen (DBUN) in grams per day should be estimated as follows:

$$\text{DBUN} = [(\text{BUN}_{\text{day 2}} - \text{BUN}_{\text{day 1}})^a \times (0.6 \times \text{body weight})^b] \div 1000$$

where term a represents the daily change in concentration in milligrams per deciliter, and term b the estimated quantity of total body water in kilograms.

$$N_{\text{out}} = \text{UUN} \div 0.8 + 2 \text{ g/day}^c + d$$

where *c* is estimated stool and skin losses, *d* is measured nitrogen losses from wounds or drains, and all values are expressed as grams of nitrogen per day. Nitrogen is conventionally taken to be 16% of the total protein intake, thus

$$N_{\text{in}}/\text{day} = \text{protein intake (g/day)} \times 0.16.$$

Route of Nutritional Support and Nutrient Formulas. The routes of nutritional support are the same as those described elsewhere: oral, enteral, and parenteral. In general, oral and enteral routes are preferred over intravenous administration. Injured patients rarely take the required quantity of calories spontaneously from their hospital food tray. Hence oral liquid supplements should be administered. Nutrient intake is monitored daily by the dietitian, and each nursing shift is assigned a quantity of supplement to be provided. Free water or low-calorie drinks are not offered. All liquid is

a calorie-dense nutrient supplement.

Three different clinical trials (81, 82 and 83) and a comprehensive metaanalysis (84) documented the superiority of immediate postoperative enteral (jejunal) feedings over PN in patients with blunt and penetrating trauma. EN initiated within 24 hours of injury was well-tolerated and resulted in a statistically significantly lower incidence of postoperative pneumonia, intraabdominal abscess, and catheter sepsis. Other studies in injured patients also suggest benefits of aggressive early EN (85). Burned children who received a high-nitrogen enteral diet displayed improved hepatic synthetic function, fewer bacteremic days, and improved survival (86). Aggressive early nutritional support of patients with severe head injury also improves outcome (87, 88 and 89). Head injury patients are candidates for TPN only if they exhibit enteral feeding intolerance. Early enteral feeding of injured patients (within 24 h) has established benefits over feeding later in the course of the hospitalization. Tube feeding should discontinue when adequate oral intake is achieved.

The patient's injuries may, however, preclude the use of oral feeding (e.g., patients with facial trauma may have their jaws wired together). Children, older adults, patients with head injuries, and those receiving artificial ventilation are all potential candidates for tube feeding. Retro- or intraperitoneal hematomas, intraabdominal sepsis, severe GI injury and extensive repair, or other factors may lead to reduced intestinal motility (ileus) or intolerance to enteral feedings. Jejunal or duodenal tube feedings are often successful even if the stomach must be continuously decompressed. Thus, for all patients who have undergone abdominal operations, feeding jejunostomy placement should be considered. Alternatively, the jejunum or duodenum can be intubated perorally with special tubes, with or without the aid of fluoroscopy. Development of diarrhea in a patient receiving enteral feedings may limit the caloric load given by these routes. When the nutritional needs of the patient cannot be met by oral and enteral feedings, intravenous techniques can be used.

Enteral formulas are usually balanced mixtures of fat, carbohydrate, and protein. Several recently developed formulas are particularly rich in calories and protein, yet have low osmolarity. In light of the injured patient's nutritional requirements, these formulas would seem particularly advantageous; however, a variety of formulas are available and may be preferred in selected cases.

Intravenous feedings may be necessary to supplement enteral feedings, or they may be required to provide adequate nutritional intake if enteral feedings cannot be tolerated or are inadequate. Peripheral nutrient solution can be given to supplement enteral feedings. These dilute solutions of glucose and amino acids should be minimized and fat infusion should be maximized while high-carbohydrate tube feeding is provided. This approach ensures adequate carbohydrate loads in a minimal fluid volume. Trauma patients, particularly burn patients, are usually young adults without cardiovascular disease and with large daily fluid requirements. Thus, these patients are ideal candidates for peripheral-vein nutrient infusion. Unfortunately, however, adequate carbohydrate calories can rarely be provided solely by this route, and when PN is required, central venous feedings are usually indicated. The hypertonic solution provides glucose, amino acids, and other essential nutrients. Fat emulsion and

supplemental fluids are easily administered through a second intravenous access site, usually a peripheral vein.

SEPSIS

Unlike in elective operations and uncomplicated trauma, major infections often have unpredictable response patterns. The variability in metabolic and physiologic responses is related in part to the patient's age, previous state of health, preexisting disease, previous stresses, site of infection, and specific pathogens. Moreover, organ-system failure, such as septic shock or pulmonary insufficiency, may mask the more subtle manifestations of systemic infection. In spite of numerous advances in treatment of infection and a better understanding of its mediators and pathophysiology, mortality and morbidity rates for septicemia remain as high as 50%.

In general, two physiologic response patterns have been described, based on cardiac output (90). The first is characterized by increased cardiac output and heightened systemic perfusion. This state varies, depending on the patient's physiologic compensation and the administered fluid volume. The second response pattern is characterized by cardiac decomposition, inadequate tissue perfusion, and profound acidosis. This pattern is described as "low-flow sepsis." Both these responses reflect the body's reaction to systemic infection. These patterns are also modified by the underlying disease process and the physiologic reserve of the particular patient. This section reviews the metabolic responses to sepsis and the priorities for safe nutritional support. Sepsis is defined as the presence of infection, resulting in systemic signs and symptoms, and diagnosed by bacteremia. Low-flow sepsis is difficult to reverse and usually results in death. Most of this discussion focuses on the metabolic responses that occur during the hyperdynamic high-flow state.

Physiologic Responses to Systemic Infection

General Overview and Time Course

Invasion of the body by microorganisms initiates many host responses. Local penetration of tissues stimulates mobilization of phagocytes, initiates an inflammatory response at the local site, and may activate additional host immunologic mechanisms. If the infection progresses, fever, tachycardia, and other systemic responses occur; these more generalized reactions may reflect direct or indirect effects of the inflammatory response. Systemic events during the hyperdynamic phase of sepsis can be categorized into two general types of responses: (a) those related to the host's immunologic defenses and (b) those related to the body's general metabolic and circulatory adjustments to infection. The predominant alterations in host defense mechanisms include fever, leukocytosis, changes in acute-phase protein synthesis, and activation of a variety of immunologic reactions. Metabolic changes are related to altered glucose, nitrogen, and fat metabolism, as well as redistribution of trace metals. These events are initiated by invasion of the microorganism and evolve as the infectious disease progresses through its period of incubation, initiation of metabolic responses

and fever, and into early convalescence and recovery.

- These responses appear stereotyped and can be produced by administering many microorganisms or their toxins. While the systemic responses to infection are similar in many respects to events that follow injury, these processes are not the same.
- The magnitude of the responses varies with the extent and duration of the infection.
- The complex sequence of systemic events that follows infection appears to change with time, and hence sequential studies must be performed to locate the responses precisely within that time.
- Although the systemic responses to infection are stereotyped, these processes are modulated by the physiologic reserves of the individual. The magnitude of the responses to infection depends on the patient's age and sex, previous nutritional state, function of vital organs, immunologic memory, and associated disease processes. The classic response to infection has been observed in young, previously healthy, well-nourished, active adults with no other medical problems. These patients are rarely admitted to surgical services, however. Surgeons usually see patients at extremes of life or those who are hospitalized because of disease processes and who have additional stress, usually an operation or injury, that limits physiologic, biochemical, or immunologic responses to infection. Thus, infection complicating the recuperative course of a surgical patient may not evoke standard systemic responses. Limitations in the patient's capacity to respond to infection may affect recovery or survival.
- As infection progresses, additional functional limitations may be imposed on one or more specific organs and may further impair the host systemic response. These limitations can be observed in patients with severe pneumonia and marked pulmonary dysfunction causing hypoxemia, associated with circulatory failure and hypotension related to severe gram-negative sepsis.

In spite of the complexities of unraveling and understanding the systemic responses to infection in critically ill surgical patients, a large body of investigative and clinical data is available to aid our understanding of these host defense mechanisms.

Beisel described the time course of metabolic and immunologic responses during the course of a typical febrile illness (91). Phagocytic activity, an early response, occurs shortly after exposure to the pathogen. The febrile period is the hallmark of systemic effects. With the onset of fever, negative nitrogen balance, accelerated loss of potassium, phosphate, and magnesium, and retention of salt and water occur. On resolution of the sepsis, one sees spontaneous diuresis and a return to positive nitrogen balance. Associated with the loss of elements from the body is an internal redistribution of substances, particularly iron and zinc, which are sequestered in the body, presumably to make them unavailable to the invading organisms (Fig. 98.11).

Figure 98.11. Nutritional responses that evolve following a generalized febrile, infectious illness. (From Beisel WR. Am J Clin Nutr 1977;30(1):236, with permission.)

Systemic Metabolic Responses

Because many of the metabolic responses to infection are similar to those observed following injury, investigators have speculated that a final common pathway may apply to all catabolic states. Severe infection is characterized by prolonged fever, hypermetabolism, diminished protein economy, altered glucose dynamics, and accelerated lipolysis. Anorexia is commonly associated with systemic infection and contributes to the loss of body tissue. These effects are compounded in the patient with sepsis by multiorgan system failure, which includes the GI tract, liver, heart, and lungs.

Hypermetabolism. Oxygen consumption is usually elevated in the infected patient. The extent of this increase is related to the severity of infection, with peak elevations reaching 50 to 60% above normal (14). Such responses often occur in the postoperative and postinjury periods secondary to severe pneumonia, intraabdominal infection, or wound invasion. If the patient's metabolic rate is already maximally elevated because of severe injury, no further increase will be observed. In patients with only slightly accelerated rates of oxygen consumption, infection causes a rise in metabolic rate that appears additive to the preexisting state. A portion of the increase in metabolism may be ascribed to the increase in reaction rate associated with fever (Q10 effect) (14). Calculations suggest that the metabolic rate increases 10 to 13% for each elevation of 1°C in central temperature. On resolution of the infection, the metabolic rate returns to normal.

Altered Glucose Dynamics. Blood glucose levels are generally elevated in the infected patient, but the descriptive term *diabetes of infection* is inappropriate because plasma insulin concentrations are generally normal or elevated in previously healthy individuals who develop infection (92). Increased glucose production in infected patients appears to be additive to the augmented gluconeogenesis that occurs following injury. For example, uninfected burn patients have an accelerated glucose production rate approximately 50% above normal; onset of bacteremia in similar individuals increases

hepatic glucose production to twice basal levels. Glucose dynamics following infection are complex, and profound hypoglycemia and diminished hepatic glucose production have also been described in both animals and human patients (93, 94). The best clinical example of the imbalance in hepatic glucose production and tissue glucose consumption is found in neonatal hypoglycemia associated with gram-negative septicemia (95). Studies in animals and in human patients show that deterioration in gluconeogenesis is associated with more-progressive stages of infection and may be related to altered splanchnic blood flow. Hepatic dysfunction this profound is usually associated with other complications of sepsis, such as respiratory insufficiency and renal failure, and usually heralds impending cardiovascular instability and death.

Alterations in Protein Metabolism. Accelerated proteolysis, increased nitrogen excretion, and prolonged negative nitrogen balance occur following infection, and the response pattern is similar to that described for injury. Protein catabolism is increased in infected patients; this enhanced rate of breakdown may be partially offset by vigorous feeding, which can stimulate protein synthesis (96). Amino acid flux from skeletal muscle is accelerated in patients with sepsis (97) and this flux is matched by accelerated visceral amino acid uptake. In infected burn patients, splanchnic uptake of amino acids is increased 50% above rates in uninfected burn patients with injuries of comparable size (14). These amino acids serve as glucose precursors and are used for synthesis of acute-phase proteins. In addition, acidosis frequently occurs in the patient with sepsis, and this stimulus serves as a signal for accelerated glutamine uptake by the kidney. Glutamine liberates an ammonia ion that combines with a hydrogen ion and is excreted in the urine, thus participating in acid-base homeostasis. The amino acid glutamine undergoes marked changes in interorgan metabolism following critical illness and may become conditionally essential. These issues are discussed in [Chapter 35](#).

Alterations in Fat Metabolism. Fat is a major fuel oxidized in infected patients, and increased metabolism of lipids from peripheral fat stores is especially prominent during a period of inadequate nutritional support. Lipolysis is most probably mediated by the heightened sympathetic activity that is a potent stimulus for fat mobilization and accelerated oxidation (14). Serum triglyceride levels reflect the balance between rates of triglyceride production by the liver and use and storage by peripheral tissues. Marked hypertriglyceridemia has been associated with gram-negative infection, but plasma triglyceride concentrations are usually normal or low. The use of free fatty acids is coupled with increased hepatic fat clearance. During starvation, hepatic uptake of free fatty acids is associated with ketosis, and concentrations of β -hydroxybutyrate and acetoacetate rise. This change does not occur in infected patients, and it has been hypothesized that the accelerated proteolysis seen during infection is a consequence of this hypoketoneic state. This hypothesis was tested by infusion of β -hydroxybutyrate into infected animals (98). Following infusion, the accelerated gluconeogenesis and proteolysis were not diminished.

Changes in Mineral Metabolism. Changes in balance of magnesium, inorganic phosphate, zinc, and potassium generally follow alterations in nitrogen balance. Although the iron-binding capacity of transferrin is usually unchanged in early infection, iron disappears from the plasma, especially during severe pyrogenic infections; similar alterations are observed with serum zinc levels. Both iron and zinc accumulate within

the liver, and this accumulation appears to be another host defense mechanism (14, 99). Administration of iron to the infected host, especially early in the disease, is contraindicated because increased serum iron concentrations may impair resistance (see Chapter 97). Zinc may be required during a prolonged, infective illness because zinc is both sequestered in body tissues and excreted in the urine. Zinc deficiency, however, is not reflected in serum concentrations, which are usually diminished as an initial host response. Unlike iron and zinc, copper levels generally rise, and the increased plasma concentrations can be ascribed almost entirely to the increase in ceruloplasmin produced by the liver.

Mediators of the Catabolic Response

The hormonal and cytokine responses during the hypermetabolic phase of infection are similar to those described following injury. Serum cortisol levels are elevated and lose their usual circadian rhythm. Glucagon levels are increased, and the insulin:glucagon ratio, a hormonal relationship considered to indicate hepatic stimulation of gluconeogenesis, remains below normal, however. Levels of catecholamines, growth hormone, ADH, and aldosterone are all elevated. The growth hormone level persists into convalescence, presumably to promote anabolism.

Gut Mucosal Barrier Function and Gut-Origin Sepsis

Although the intestinal tract is generally viewed as an organ of digestion and absorption, it also protects the host from intraluminal bacteria and their toxins (Fig. 98.12).

Maintenance of an intact brush border and intercellular tight junctions prevents the movement of toxic substances into the intestinal lymphatics and circulation. Bacteria that do translocate appear to do so in small numbers, and the mesenteric lymph nodes effectively dispose of them without deleterious systemic effects. Bacterial endotoxins that are absorbed into the portal venous blood are rapidly detoxified by the Kupffer cells of the liver.

Figure 98.12. The gut hypothesis proposes that local and systemic insults can damage the gut epithelium and allow egress of luminal bacteria and toxins. If systemic responses such as hypermetabolism and persistent catabolism are self-perpetuating,

multiple organ failure can develop.

Gut immune function is the term applied to the structural and functional characteristics of the GI tract that make it resistant to the entry of infectious or toxic agents into the systemic circulation (100). This function is a combination of nonimmunologic processes (physical factors, intestinal flora) and the local mucosal immune system function. Immune factors include secretion of secretory IgA (S-IgA) and the function of macrophages and lymphocytes in the Peyer's patches, mesenteric lymph nodes, and lamina propria of the intestinal mucosa. These collections of cells of the immune system within the GI tract are known collectively as the gut-associated lymphoid tissue (GALT). Maintenance of a gut mucosal barrier that effectively excludes luminal bacteria and toxins requires an intact epithelium and normal mucosal immune mechanisms.

Stimulation of gut S-IgA secretion begins in the Peyer's patches of the small intestine (100). Enteric antigens are presented to immunocompetent cells through M cells, which are specialized epithelial cells overlying the Peyer's patches. The antigens are processed by macrophages and presented to T and B lymphoblasts. The B cells are then committed to production of antigen-specific S-IgA. These cells are released from the Peyer's patch, pass through mesenteric lymph nodes, and eventually enter the systemic circulation via the thoracic duct. The B cells then come to the intestinal lamina propria where they mature and secrete specific S-IgA in response to enteric antigen presentation. B cells are also distributed to other tissues such as the liver, and thus S-IgA is found in bile as well as intestinal succus. In the GI tract, bile appears to contribute about 90% of the S-IgA present in the intestinal lumen. S-IgA prevents the binding of enteric pathogens to the cells of the intestinal mucosa and acts in conjunction with the indigenous intestinal microflora to control enteric pathogenic bacteria.

Bacterial translocation is the process by which microorganisms migrate across the mucosal barrier and invade the host (101). The most extensive work on bacterial translocation has been done in animal models, where the number and pathogenicity of the endogenous flora can be precisely controlled and the microorganisms that invade the host, carefully quantified. Generally, three principal mechanisms promote bacterial translocation: (a) altered permeability of the intestinal mucosa (as caused by hemorrhagic shock, sepsis, distant injury, or administration of cell toxins), (b) decreased host defense (secondary to glucocorticoid administration, immunosuppression, or protein depletion), and (c) an increased number of bacteria within the intestine (as caused by bacterial overgrowth, intestinal stasis, or feeding bacteria to experimental animals). A number of retrospective and epidemiologic studies have associated infection in specific patient populations with bacterial invasion from the gut (102, 103). These reports suggest that bacterial invasion occurs in patients after injury, multiorgan system failure, or severe burns and in cancer patients after chemotherapy or bone marrow transplantation. Nonmetabolizable markers of known size, such as lactulose or mannitol, have also been used to determine permeability. These studies demonstrated an increase in mucosal permeability in normal volunteers receiving endotoxin and in infected burn patients. Because many of the factors that facilitate bacterial translocation

occur simultaneously in surgical patients and their effects may be additive or cumulative, patients in an intensive care unit may be extremely vulnerable to invasion by enteric bacteria or to absorption of their toxins ([Fig. 98.12](#)). Such patients do not generally receive enteral feedings, and current parenteral therapy results in gut atrophy, and methods currently used to support critically ill patients neither facilitate repair of the intestinal mucosa nor maintain gut barrier function.

Nutritional Assessment and Requirements

As with accidental injury, the onset of sepsis is generally sudden and unplanned. On the other hand, in contrast to trauma victims who are well nourished and healthy prior to their injury, infected patients are often nutritionally depleted when bacteremia develops. Malnutrition is inseparable from the occurrence and effects of infectious diseases, and their interaction is synergistic.

As with all patients, the primary objectives of nutritional assessment are to evaluate the patient's present nutritional status and to determine energy, protein, and macro- and micronutrient requirements. Assessment of patients with sepsis should start with a medical history and physical examination, which is frequently difficult because of the severity of the patient's illness. Use of anthropometric measurements is helpful, but weight may be an inaccurate reflection of nutritional status because of fluid retention. Serum protein concentrations (albumin and transferrin) are low because of redistribution secondary to the infection; hence these values are not useful indicators of malnutrition.

The immediate goal of nutritional therapy is weight maintenance. Weight gain and anabolism are generally difficult to achieve during the septic process, but they do occur once the disease process has abated. Total energy requirements can be calculated using the stress equation; mild-to-moderate infections increase energy requirements 20 to 30%, and severe infection increases caloric needs about 50% above basal levels. The optimal calorie:nitrogen ratio is approximately 150:1, although providing more nitrogen has been proposed.

The following case example illustrates the value of nutritional support in the overall integrated care of a patient with prolonged sepsis. A 65-year old man (6' tall; 175 lb; BSA, 2.0 m²) appeared in the hospital emergency ward with right-upper-quadrant pain, a temperature of 103°F, and mild jaundice. A recent ultrasound had shown the presence of gallstones, but the patient was otherwise well nourished and in good health. Initial laboratory studies showed a white blood cell count of 17,000, with a left shift, total bilirubin level of 5 mg/dL, and an alkaline phosphatase level of 550 Bodansky units. Shortly after hospital admission, the patient became confused, and his blood pressure fell to 70 mm Hg systolic. His skin was warm and pink, and a diagnosis of ascending cholangitis and septic shock was made. Intravenous fluid was administered, and the patient's blood pressure returned to normal. Antibiotics were started, and shortly thereafter the patient was taken into the operating suite, where he was found to have an impacted gallstone in the common bile duct. A cholecystectomy and common duct exploration were performed, and the impacted stone was removed. Pus was present in the gallbladder and the biliary tract.

Postoperatively, the patient required ventilatory support. On postoperative day 1, he was no longer dependent on cardiotoxic agents to maintain normal blood pressure. He had a marked ileus and remained febrile. He received 5% dextrose solutions containing appropriate electrolytes. He gradually became alert, but remained dependent on the ventilator. On postoperative day 5, the patient's fever increased to 103.6°F, and he had marked leukocytosis. Diagnostic studies showed an intraabdominal abscess, and the patient returned to the operating room for surgical drainage. Postoperatively, the patient received large doses of antibiotics, and 3 days after a second operation, he was weaned from the ventilator. Results of liver function tests gradually returned to normal, and the patient's ileus resolved. On postoperative day 15, the patient started a clear-liquid diet, and he was discharged from the hospital on postoperative day 22. Nitrogen balance studies from postoperative day 1 to day 16 showed a cumulative 15-day negative balance of 225 g (Fig. 98.13). The patient had lost 11 lb by postoperative day 15, half of which was lean tissue, the remainder fat. By day 15, the patient had started oral intake, and by discharge day (day 22), he was clearly afebrile and anabolic, taking adequate quantities of nutrients.

Figure 98.13. Metabolic responses to sepsis.

Response to Fixed Nutrient Intake

To evaluate the effect of fixed nutrient intake in sepsis, suppose that the above patient with ascending cholangitis is supported vigorously with PN throughout his course. A combination of sepsis, anesthesia, and tissue trauma increased his metabolic rate by 50%, so his energy needs are approximately 2900 kcal/day. The patient receives 3 L of central venous nutrition, which provides 21 g of nitrogen and 3000 kcal/day. Nitrogen balance studies from postoperative day 1 to 16 show a cumulative loss of 375 g, and cumulative nitrogen balance for this 15-day period is ~60 g. On postoperative day 16, the patient has lost only 4 lb, half of which is body fat, and the remainder lean body mass (Fig. 98.14).

Figure 98.14. Metabolic responses to sepsis with constant intravenous nutrition.

Prompt initiation of nutritional support in patients with sepsis who cannot eat enough or should not eat is mandatory. On the other hand, provision of nutrients requires integration into the patients' management and support plan. The patient in the case example was started gradually on nutritional feedings, to avoid untoward complications of hyperglycemia, and the infusion was diminished during the second septic interval. Fat should compose a moderate proportion of the infused energy, to avoid the complications of hyperglycemia and to diminish the possibility of increased carbon dioxide production complicating hypercaloric glucose infusions. Severe erosion of lean body mass is possible in such a patient, and nutritional support helps to diminish such erosion. Provision of calories and nitrogen cannot attenuate the hypermetabolism characteristic of sepsis, but it does reduce accelerated catabolism.

Route of Feeding

The routes of nutrient administration are similar to those for the elective surgical patient and the trauma victim. The enteral route should always be used when possible, but patients with sepsis usually have an ileus and therefore require PN. In general, this condition requires central venous nutrition because peripheral nutritional support cannot provide adequate calories in a moderately restrictive fluid volume. The risks of catheter sepsis are minimized by dedicating the central line solely to infusion of the hypertonic nutrient solutions and maintaining strict asepsis at the catheter entrance site. In addition, the catheter may be changed over a guide wire using a strict aseptic technique, and the catheter tip may be cultured. This culturing, done at intervals of 3 to 5 days, ensures that the catheter has not become the focus of the septic process.

Nutritional Support in Surgical Patients with Sepsis

A role for nutritional support in septic patients has been difficult to prove because improvements in nutritional markers such as serum proteins, nitrogen balance, and weight gain have generally not translated into clinical benefits (1). In most studies,

nutritional support failed to correct multiple biochemical and immune parameters and did not affect outcome. Similarly, provision of nutritional support to critically ill patients with a poor outcome did not alter the plasma amino acid profile (104) and does not appear to prevent muscle protein loss (105).

Nutritional support is often used aggressively in septic patients because erosion of lean body mass will, at some point, have a negative impact on outcome. It is unclear how long such patients can tolerate inadequate nutrition before outcome is adversely affected. Limited data reported to date in patients in intensive care units have not shown an effect of nutritional support on mortality (106). As a general rule, nutritional support should not be withheld in septic or other critically ill patients who are anticipated to be unable to eat for more than 7 to 10 days (1). As mentioned above, the impact of nutritional support on organ function also requires further study (Table 98.4). When nutritional support is used, the enteral route is preferred if the gut is functional and usable. Unfortunately, septic patients often develop an ileus, and advancement to full feedings often demands perseverance and may take several days. Gastric residuals, diarrhea, abdominal distention, and physician practice habits can be barriers to the use of enteral feedings.

Problems with establishing recommendations	
Consistently reliable criteria for diagnosing "at risk" malnutrition have not been identified	
Limited number of well-designed prospective, randomized clinical trials	
Nutritional support is indicated	
Indication	Benefit of nutritional support
Patients who cannot eat or absorb nutrients for long periods of time or relatively permanent neurologic impairment, premature infant, anaphylactic dysfunction, short gut syndrome	Life saving
Severely malnourished patients who require a major surgical procedure	Preoperative nutrition decreases the incidence of major septic complications
Patients sustaining major trauma	Enteral nutrition is superior to parenteral nutrition in decreasing the incidence of septic complications. NS improves outcome in head injury patients
Role of Nutritional support is unclear	
Patient group	Some areas requiring further study
Liver failure	Impact of NS on survival
Renal failure	Impact of NS on outcome in patients with acute renal failure and in patients on chronic dialysis
Critically ill patients (CCI) severe pneumonia who cannot eat for variable periods of time	How long is too long to go without nutrition?
Small organ transplantation	Impact of NS on graft survival

Table 98.4 Nutritional Support (NS) in Patients With Surgery, Trauma, and Sepsis

Complications, Organ Failure, and Other Special Feeding Problems

The most severe complication of sepsis is the failure of essential organs, which may result in death. The current treatment of systemic infection consists of (a) bacteriologic control by removal and drainage or containment of the source; (b) use of appropriate antibiotics; (c) support of cardiovascular and respiratory function; (d) supportive therapy of specific organ failure, whether cardiac, pulmonary, hepatic, renal, or gastrointestinal; and (e) vigorous nutritional support of the host.

Respiratory Insufficiency

A common problem associated with systemic infection is oxygenation and elimination of carbon dioxide. A variety of endotoxins and vasoactive factors mediated by the infectious process can alter pulmonary vascular permeability and may lead to pulmonary insufficiency. Patients often require intubation and vigorous ventilatory support with volume-cycle ventilation and positive expiratory pressure. Ongoing problems include development of pneumonia and pulmonary insufficiency secondary to increased capillary permeability. Most of the enteral and parenteral formulas used to provide nutritional support for critically ill patients contain large amounts of carbohydrate, which generate large quantities of carbon dioxide following oxidation. A large carbon dioxide load may worsen existing pulmonary dysfunction or may delay weaning from the ventilator (107). If this becomes a problem, the carbohydrate load should be reduced to 50% of metabolic requirements and fat emulsion administered to provide additional calories.

Renal Failure

The origin of renal failure associated with sepsis is unclear. Circulating factors are associated with increasing blood flow to the kidney. However, if cardiac output is inadequate, such a response is not possible, and this failure, coupled with redistribution blood flow, may cause progressive deficiency of the cortical portion of the kidney. In addition, the use of aminoglycoside antibiotics, which are nephrotoxic, may also cause progressive impairment and malfunction. When renal failure becomes progressive, early use of hemodialysis, with or without filtration, minimizes the effects of uremia superimposed on the metabolism of sepsis. Adequate caloric support limits ureagenesis and normalizes alterations in serum electrolyte levels. Because uremia itself is a potent catabolic signal, this condition further impairs the hypercatabolic infected host. Metabolic studies in patients with acute and chronic renal failure have limited intake of nonessential amino acids, in an attempt to lower urea production. Proteins of high biologic value, but in much smaller quantities (<0.5 g/kg/day) than usually given, are administered along with adequate calories, usually in the form of glucose. When enteral feedings are not feasible, a central venous infusion of an essential amino acid solution and hypertonic dextrose provides calories and a small quantity of nitrogen, to reduce protein catabolism while simultaneously controlling the rise in BUN. Whether such nutritional therapy reduces mortality rates for renal failure associated with sepsis remains controversial (33, 34 and 35). During dialysis, protein intake is liberalized, but the BUN is maintained below 100 mg/dL.

Gut Dysfunction

Sepsis causes marked changes in GI function. The most common abnormality is ileus, which can result from intraabdominal disease or from the effects of bacteria elsewhere. Stress ulcers lead to upper GI bleeding, which may require operative treatment. The factors that promote breakdown of the gut mucosal barrier and lead to translocation of luminal bacteria and their toxins have been discussed. Nutritional support may be

necessary in such patients, particularly if the gut dysfunction persists.

TPN increases the spontaneous rate of closure of enterocutaneous fistulae that occur in patients with abdominal sepsis, but reduced mortality rates are due to improved fistula care rather than nutritional intervention ([108](#), [109](#)). Local wound care of the skin site reduces problems such as irritation and wound infection. Similarly, the amount of fistula output can be quantitated and fluid and electrolyte adjustments made accordingly. Fistula closure occurs in 40 to 60% of patients treated with TPN (90% close within 5 weeks). During this period of medical management, TPN will maintain nutritional status should surgical intervention be required.

Although TPN does not alter the clinical course of severe acute pancreatitis and results in a higher rate of catheter sepsis ([110](#), [111](#)) and total hospital costs ([111](#)), it is unclear how long nutritional support should be withheld in these individuals. There are no randomized prospective trials comparing enteral with parenteral nutrition in patients with acute pancreatitis, and thus treatment decisions are empiric rather than based on scientific evidence.

Hepatic Failure

Hepatic dysfunction is a common manifestation of septicemia. The degree of dysfunction varies; it may appear early, as a slight elevation of liver enzymes, or it may cause severe jaundice and hyperbilirubinemia. Specific bacteria overwhelm the reticuloendothelial system of the liver and result in fulminant hepatic failure. Localized infections, such as hepatic abscesses, pyelophlebitis, and hepatitis, may cause profound liver dysfunction because of the direct effect of infection on this organ. Occasionally, hypoglycemia accompanies ascending cholecystitis because of the direct effect of hepatic inflammation. Fulminant hepatic failure in the patient with sepsis has a high mortality rate, especially when hepatic encephalopathy occurs. As discussed in the section on [trauma](#), the effects of normalization of amino acid concentration and reversal of hepatic coma remain controversial. More common, however, are alterations on liver function studies, such as elevations in levels of alkaline phosphatase, hepatic enzymes, and serum bilirubin, which appear secondary to the septic event but may worsen with intravenous feedings. Hepatic dysfunction generally resolves on resolution of the sepsis, but if the inflammatory process persists, adjustments in the feeding formulation are necessary. The carbohydrate load is usually reduced to consist of no more than 50% of metabolic requirements, with the additional calories provided as fat emulsion. A patient whose serum bilirubin level becomes elevated (generally above 12 mg/dL) should be observed for the presence of encephalopathy; if this complication occurs, the protein load should also be reduced.

Cardiac Dysfunction

The myocardial dysfunction that occurs in sepsis may be secondary to the elaboration of cytokines or to heart failure secondary to pulmonary insufficiency. Malnourished patients with sepsis may be sensitive to volume overload, and use of a concentrated solution of hypertonic dextrose (D-70%) mixed with amino acids may be indicated to maximize calories and minimize volume. In addition, a 20% fat emulsion can be

administered to provide additional energy.

Organ Transplantation

The benefits of nutritional support have been established in patients undergoing bone marrow transplantation (BMT) (1), but the role of nutritional intervention in patients undergoing solid organ transplantation is less clear. In one of the BMT studies, 137 patients with normal nutritional status were randomized to receive PN (plus ad libitum oral intake) beginning 1 week prior to and for 4 weeks after transplantation or to receive hydration with 5% dextrose (plus ad libitum oral intake) (112). Patients randomized to prophylactic PN exceeded their basal energy and nitrogen requirements, while those in the dextrose group received only about half of their nutrient requirements. Use of parenteral nutrition was associated with weight gain, increased serum protein concentrations, and improved survival and time to relapse, compared with 5% dextrose. In another study, 61 patients received PN or EN for 4 weeks after BMT (113). EN was well tolerated, but three-quarters of the patients required supplemental peripheral amino acid infusions for an average of 1 week to meet nitrogen needs. Although the enteral feeding program was less effective in maintaining body cell mass, hematopoietic recovery rate, length of hospitalization, and survival did not differ between the groups. Nutrition-related costs were considerably higher in the PN group, suggesting that EN be used if feasible.

Most patients undergoing kidney or heart transplantation can eat within several days of surgery. Therefore, formal nutritional support in these individuals is not generally indicated unless they develop a complication that precludes use of the GI tract. Likewise, many patients undergoing liver transplantation are discharged from the hospital within 1 week of operation and usually do not require nutritional support. When nutritional support is used, the enteral route is preferred (114). As in other patients, provision of nutritional support is based on two different rationales: to prevent starvation-induced complications (e.g., infection) and to alter favorably the natural history (i.e., reduce rejection) of the transplanted organ. This second rationale is based on correcting existing nutritional or metabolic deficiencies in the transplanted patient or organ so that outcome will improve. One study (24) in minimally malnourished patients undergoing major hepatic resection demonstrated the benefits of preoperative and postoperative PN in reducing postoperative complications. Extrapolating from this study, there may be a role for nutritional support in patients undergoing organ transplantation.

Small bowel transplantation continues to pose a challenge in the field, in part because the organ is highly immunogenic. Simultaneously, home parenteral nutrition for patients with the short gut syndrome is expensive (~\$100,000/year) and is associated with well-described metabolic complications. A recent study (115) demonstrated that the requirement for TPN could be decreased or even eliminated in patients with short gut syndrome by providing a nutritional regimen consisting of supplemental glutamine, growth hormone, and a modified high-carbohydrate, low-fat diet. There was a marked improvement in absorption of nutrients with this combination therapy, and a decrease in stool output. In addition, the cost associated with care of these individuals was substantially reduced. Discontinuation of growth hormone did not significantly increase TPN needs in these patients once they had undergone successful gut rehabilitation (see

also [Chapter 101](#)).

The indications for postoperative nutritional support in patients undergoing solid organ transplantation are similar to those for other elective surgical patients. It remains unclear how long transplant patients can tolerate undernutrition without adverse consequences. If the patient develops a posttransplant complication that precludes oral intake, formal nutritional support should be instituted. Such complications include ileus, sepsis, or failure of other organs. Fluid and electrolyte abnormalities must be carefully monitored, as these patients often have substantial fluid requirements, and electrolyte shifts commonly occur.

The potential for nutritional intervention to influence graft rejection is an area of research that is likely to have promise, since it is well established that nutritional status can modulate cytokine production by inflammatory cells.

CHOICE OF NUTRITION IN SURGICAL PATIENTS

Enteral or Parenteral?

Although the physiologic advantage of EN is apparent, preoperative nutritional repletion via the enteral route has not been as extensively studied as preoperative TPN. Although its use can be associated with development of nausea, diarrhea, and distention, we recommend use of EN (via a feeding tube or as between-meal supplements) in malnourished patients who need elective surgery. Candidates must have a functional GI tract and must be able to receive adequate amounts of calories and nitrogen. In general, such preoperative nutritional support should be limited to 7 to 10 days.

Studies in elective surgical patients comparing the efficacy of PN and EN in the postoperative elective surgery setting have failed to show significant differences. However, significant benefits of enteral feeding have been shown in trauma patients; septic complications were significantly reduced in trauma patients fed via feeding tube immediately after blunt trauma. Luminal nutrition is beneficial even when relatively small amounts of the formula, below caloric requirements, are provided.

In an effort to evaluate the cost effectiveness and metabolic consequences of nutritional support, investigators have compared postoperative TPN and EN. The cost of EN is considerably lower than the cost of TPN, and home administration is easier in patients who are nourished enterally. Bower et al. ([116](#)) randomized 20 patients undergoing major upper GI or pancreaticobiliary surgery to receive either postoperative TPN or an elemental diet via a needle catheter jejunostomy (NCJ). Early nitrogen balance was improved in the TPN group, but late nitrogen balance was similar between groups. Complications were minimal, and insignificant differences in serum albumin concentration and transaminase levels were noted. The major difference between groups was the estimated cost of nutritional support: \$2313 in the TPN group compared with \$849 in the NCJ group.

Nutrition and the Gastrointestinal Tract: Supporting the Gut in Critically Ill

Patients

The intestinal tract was long considered an organ of inactivity following operation or injury. Ileus is generally present, nasogastric decompression is often necessary, and the gut is usually unused in the immediate postoperative period. Digestion and absorption were thought to be the only physiologic role of the gut. However, studies have shown that the gut functions as a central organ of amino acid metabolism, a role that may become more pronounced during critical illness (117, 118). Disuse of the GI tract, via either starvation or nutritional support by TPN, may lead to numerous physiologic derangements as well as changes in gut microflora, impaired gut immune function, and disruption of the integrity of the mucosal barrier. Thus, maintaining gut function in the perioperative period may be essential to minimize septic complications and organ failure. Treatment strategies designed to support the gut during critical illness should be directed toward provision of appropriate nutrition and maintenance of mucosal structure and function. Presumably, such efforts will assist the gut in its roles as a metabolic processing station and as a barrier.

Nutritional Support: Enteral Feedings

Enteral feedings are probably the best single method of maintaining mucosal structure and function (Table 98.5). The trophic effects of luminal nutrition are key, and the beneficial effects are well documented, even if relatively small amounts of nutrients are provided. Elegant studies using Thiry-Vella loops (119) to study the effects of excluding a segment of small intestine from the nutrient stream demonstrated the superiority of enteral stimulation. On the other hand, potentially detrimental effects of TPN include mucosal atrophy characterized by a fall in mucosal mass and brush border activity (120, 121). Elemental diets provided to rats promote translocation, but the incidence is significantly lower than that observed when an identical solution is administered intravenously for 2 weeks. In rats subjected to an intraperitoneal injection of hemoglobin and *Escherichia coli*, the survival rate was clearly enhanced when the same nutrient solution was given enterally rather than parenterally (122). Mochizuki et al. (123) studied endocrine and gut responses to burn injury in guinea pigs and demonstrated that early EN blunted the catabolic response and helped preserve mucosal integrity.

Decreased villous height
Decreased cellular mass
Decreased brush border enzyme activities
Increased gut permeability
Changes in gut microflora
Decreased gut immunity

Table 98.5 Proposed Effects of Lack of Enteral Stimulation on the Gut

Nutritional Support Using the Gut-Specific Nutrient Glutamine

It is now clear that both the composition of the diet and the route of delivery are important in maintaining gut structure and function. Several gut-specific nutrients have been studied, but glutamine has received the most attention. The role of glutamine as a nutritional supplement is discussed in [Chapter 35](#).

The Use of Growth Factors to Support the Gut Mucosa

Specific growth factors that may promote intestinal mucosal growth have been implicated in a number of physiologic processes including growth, tissue repair, and regeneration. Among these is epidermal growth factor (EGF), a polypeptide secreted by submaxillary glands and by Brunner's glands of the small intestine. The most widespread effect of EGF on the gastrointestinal mucosa is overall stimulation of DNA synthesis as evidenced by thymidine incorporation. Provision of EGF subcutaneously to rats receiving TPN decreases the degree of villous atrophy that otherwise occurs ([124](#)).

Adjuncts to Nutritional Support That May Modify the Catabolic Response to Critical Illness

Beside nutritional intervention, several other methods of modifying the physiologic and biochemical responses to an elective operative procedure have been studied in an effort to reduce the stress of operations and to provide insight into mechanisms of these responses. A variety of human studies have shown that many postoperative responses can be ablated following denervation of the wound ([125](#), [126](#)). These studies suggest that regional anesthetic techniques block afferent signals from the wound and interrupt sympathetic nervous efferent signals to the adrenal gland and possibly the liver. The effect of sympathetic blockade is a reduction in the apparent magnitude of the stress response. These techniques have also been used during the postoperative period. Bromage et al. suppressed hyperglycemia and hypercortisolism with maintenance of an epidural anesthetic for the first 24 hours after operation ([127](#)). Brandt et al. reported better 5-day cumulative nitrogen balance in patients undergoing elective abdominal hysterectomy with epidural anesthesia than in a similar group receiving general anesthesia ([128](#)).

Several investigators have studied stress responses in sympathectomized animals by blocking the efferent limb of the neuroendocrine reflex response. Propranolol has been shown to improve postoperative nitrogen balance and decrease muscle protein breakdown. Herndon et al. reported that administration of propranolol to burned children decreased cardiac work without affecting wound healing or mortality ([129](#)). Brandt et al. reported that large doses of morphine (4 mg/kg) given prior to skin incision diminished

the normal rise in plasma ACTH, cortisol, growth hormone, and glucose in patients undergoing aortic valve replacement (130). These reports indicate that central nervous system blockade interrupts afferent signals stimulated by operative procedures.

Studies in the 1960s and 1970s demonstrated that short courses of growth hormone (GH) promoted nitrogen retention following thermal injury. More-recent studies have documented the safety of long-term exogenous recombinant GH administration. GH promotes anabolism and favorably affects a number of biochemical parameters (131, 132, 133, 134, 135 and 136), but it is unclear whether such improvements translate into clinical benefits. Thus, the potential synergistic effects of specialized nutrition in combination with GH require further study.

Cyclooxygenase inhibitors such as aspirin and ibuprofen attenuate the symptoms and endocrine responses that occur in critical illness without altering cytokine elaboration. For example, pretreatment with ibuprofen may attenuate the undesirable symptoms associated with the inflammatory response (137). It is anticipated that researchers will eventually be able to selectively block the deleterious effects of excessive cytokines and preserve their beneficial effects. Specific antibodies are already being used in the clinical setting to block the TNF and IL-1 receptor. Clearly, the type of nutrition used in critically ill patients can influence the metabolic alterations seen with infection (138, 139). No doubt patient care strategies in the future will use combination therapies designed to minimize the undesirable consequences of the body's response to critical illness and simultaneously accelerate wound healing, immune function, and recovery.

This chapter discusses the interactions among diet, nutritional status, and drugs. It is intended as a general account of these interactions, with illustrative examples. More specific accounts concerning individual drugs, drug preparations, and routes of administration can be found in the references to this chapter. New drugs and drug preparations are coming onto the market constantly and may be administered in new ways or added to new nutrient formulations. In caring for a patient, the practitioner should always consider the literature and experience concerning the specific drugs a patient may be taking.

DEMOGRAPHICS, DISEASE STATE, AND RISK OF DRUG-NUTRIENT AND DRUG-NUTRITIONAL STATUS INTERACTIONS

Medical conditions, age, and gender dictate the drugs a patient may be taking and may

influence a person's diet and nutritional status. These medical conditions determine not only the therapeutic drugs prescribed but also the types of over-the-counter drugs patients take for symptom relief.

Patients who are under the care of different specialists for multiple conditions and who are likely to self-medicate for symptoms such as arthritic pain or heartburn are at greatest risk for adverse drug-nutrient and diet interactions, because no single practitioner may be aware of all medications the patient may be taking or the diet the patient may have adopted. Therefore, to estimate the likelihood of drug-nutrient and diet interactions, the practitioner should consider all the patient's medical conditions, their metabolic consequences, and the drugs administered for these conditions; should have a high index of suspicion concerning the possibility of self-medication; and should be aware not only of any prescribed diet but also of the patient's actual dietary habits and the possibility of alcohol or substance abuse.

The complexity of the influences imposed by both medical conditions and age on the risk of drug-nutrient interactions is exemplified by the risk of severe iron deficiency anemia in an elderly diabetic patient with an autonomic neuropathy of the colon (1). If this patient also has osteoarthritis, it is likely he or she will also be taking a nonsteroidal antiinflammatory drug (NSAID), either over the counter or by prescription. Such a patient is at risk for colonic ulceration and secondary NSAID-induced bleeding, which in turn leads to loss of iron and anemia (2). The risk of anemia is further increased if the patient uses anticoagulant drugs concurrently (e.g., to prevent coronary thrombosis) or abuses alcohol (3).

Patients receiving enteral nutrition via a feeding tube are at additional risk, because drugs that are normally administered orally may be added to the nutrient formula. These patients may develop problems because of physical incompatibilities between the drug and the formula, pharmaceutical incompatibilities resulting from the form in which the drug must be administered (e.g., as an elixir of high osmolality, which may render the tube feeding hyperosmolar), and constipation (or, more commonly, diarrhea), which may be erroneously attributed to the tube feeding itself (e.g., diarrhea caused by excess ingestion of sorbitol, a common excipient of syrups).

Given the complexities of these interactions, it is not surprising that adverse consequences of drug-nutrient and drug-diet interactions are sufficiently common for the Joint Commission on Accreditation of Healthcare Organizations, in the 1996 accreditation standards (4), to require that hospitals implement a program to ensure that "patients are educated about the potential for drug-food interactions." At the same time, Lasswell et al. (5) reported that 80% of the family practice residents they surveyed said they had received little or no formal training in drug-nutrient interactions.

EFFECTS OF DIET AND NUTRITIONAL STATUS ON DRUG ABSORPTION, DISPOSITION, METABOLISM, AND ACTION

Pharmacokinetics and Pharmacodynamics

The term *pharmacokinetics* refers to the characteristics of a drug's absorption, distribution, biotransformation, and excretion; the term *pharmacodynamics* refers to the mechanisms of drug action and the relationships between a drug's concentration at the active site and its pharmacologic effects. While drug-nutrient interactions may affect drug pharmacodynamics, the most commonly encountered and best studied interactions concern their effects on pharmacokinetics.

Bioavailability

The term *bioavailability* refers to the extent to which a drug reaches its site of pharmacologic action. For practical purposes, this definition includes the extent to which the drug reaches a fluid (e.g., blood or spinal fluid) that bathes the site of action and via which the drug can readily reach the site of action. The bioavailability of a drug depends directly on the extent to which the drug is absorbed and distributed to the site of action and depends inversely on the extent to which it is metabolized and excreted prior to arriving at the site of action.

Absorption

The term *absorption* refers to the rate at which, and the extent to which, a drug leaves its site of administration. Factors that affect absorption include the route and site of drug administration; the site and area of absorption; the concentration of the drug at that site; the physical form of the drug and the vehicle in which the drug is administered; local conditions that affect the drug's solubility, and therefore its ability to reach a site of entry into the bloodstream or cerebrospinal fluid; and, finally, the circulation at the site of absorption. Drug absorption is influenced by physicochemical processes that influence both the extent and the rate at which the drug crosses the mucosal barrier and enters the bloodstream. [Table 99.1](#) lists factors that specifically enhance absorption of an orally or enterally administered drug.

Lack of complex formation with diet ingredients
Maintenance of drug's chemical stability at stomach/small intestinal pH
Presence of a specific transporter
Small size (<200 Da) for transportation with bulk water flow
Lipid solubility—nonionized at local pH
High circulation to the site of absorption, to maintain concentration gradient
Appropriate stomach-emptying rate
Low small intestinal motility

Table 99.1 Factors That Enhance the Extent and Rate of Absorption of an Orally/Enterally Administered Drug

Routes of Drug Administration

Drugs can be administered orally, enterally, or parenterally. The most common route of drug administration is the oral/enteral route. The main parenteral routes include intravenous, subcutaneous, and intramuscular routes. Drugs can also be administered through the lung, rectum, spinal fluid, artery, and peritoneum. Because drug-food and drug-nutrient interactions at the level of absorption occur primarily when the drug is administered via oral/enteral routes, the following discussion concentrates on these routes. [Table 99.2](#) shows the sites of drug absorption in the gastrointestinal tract and their characteristics.

Site	Absorption	Characteristics
Mouth	Poor	Short residence time Drug can make contact only if in solution
Stomach	Poor	Small surface area Thick, mucus-covered, electrically resistant mucosa
Proximal small intestine	Excellent	Large surface area Thin, low-electrical-resistance mucosa can absorb both unionized and ionized drugs

Table 99.2 Sites of Drug Absorption and Their Characteristics

Effects of Food Components on Drug Absorption and Bioavailability

Food components affect drug absorption and bioavailability through three general mechanisms: physicochemical interactions between the drug and food components in the gut lumen, alterations in gastric emptying time, and competitive inhibition between the drug and food components for absorption. Erratic responses to drugs can often be explained by their administration in a haphazard way in relation to mealtimes, if their bioavailability is affected by the presence or absence of food in the stomach and intestine. [Table 99.3](#) lists common drugs whose absorption is decreased by concomitant consumption of food. Absorption of the drugs listed in [Table 99.4](#) is significantly enhanced when they are taken with food.

Given these differences in pharmacokinetics, the reader is strongly cautioned to examine the literature and individual experience concerning different formulations of drugs of interest, particularly of formulations of drugs with narrow therapeutic windows.

Physicochemical Interactions between Diet Ingredients and Drug Ingredients

Physicochemical interactions between diet ingredients and drug ingredients include adsorption, complex formation, precipitation, and the effects of one interactant on another whereby stability of one or both is altered. Physicochemical interactions require the simultaneous presence of the drug and the food component at the site of interaction. Therefore, physicochemical interactions occur in the gut lumen for orally and enterally administered drugs and in the reservoir or tubing containing the nutrient formula when drugs and the formula are administered simultaneously via parenteral or enteral routes.

Physicochemical interactions usually result in reduced absorption of the drug, the nutrient, or both. For orally administered drugs, decreased absorption due to physicochemical incompatibilities occurs primarily because of errors in the timing of food intake with drug intake. When the drug is administered via a feeding tube, incompatibilities can also occur when the drug is added to the feeding formula or when it is administered without adequately flushing the tubes.

Disintegration and Dissolution of Drugs Administered Orally. Common dosage forms of drugs designed for oral administration include solid forms (tablets, capsules, or granules) and liquid forms (suspensions, syrups, elixirs, and solutions). Sublingual tablets (e.g., nitroglycerin) are designed for rapid drug absorption through the oral mucosa and contain very small dosages that are absorbed before hydrolysis can occur. Slow-release formulations contain granules of coated medication designed to dissolve at varying rates and release medication over hours.

When taken orally, solid forms of drugs must disintegrate and dissolve before being absorbed. Most preparations are designed to undergo these processes in the stomach. However, certain drugs that may be destroyed by the pH and enzymes of the stomach or may irritate the stomach mucosa are often administered in enteric-coated preparations designed to resist breakdown at acid pH. By contrast, an acidic environment is required for the dissolution of ketoconazole, so patients with achlorhydria or those taking drugs to diminish stomach acidity (such as antacids, H₂ histamine blockers, or proton pump inhibitors) may have problems obtaining therapeutically effective doses of this drug (8).

The rate of dissolution of a pill or capsule is increased by the presence of liquid in the stomach. Solid drugs taken with a beverage dissolve more rapidly and more completely than when taken dry. However, if large amounts of fluid are consumed, the concentration of the drug in solution may decrease, leading to a decrease in the rate of absorption.

Physical Interactions between Enteral Formulas and Drugs. Physical interactions

between drugs and enteral formulas in formula reservoirs or feeding tubes lead to sometimes subtle changes in the appearance of the formula, with clouding, curdling, flocculation, phase separations, and changes in the formula's viscosity (sometimes thinning, but more often thickening, coagulation, and gelling). These changes generally clog feeding tubes and decrease delivery of both drug and feeding formula to the patient (9). [Table 99.5](#) lists methods of avoiding incompatibilities due to physical interactions between drugs and enteral formulas.

Avoid mixing the drug and formula

- No direct mixing of drug and formula
- Flush tubing with water before and after administering drug
- Change the formula to one compatible with the drug
- Change drug dosage, dosage form, or drug
- Lower the concentration of the drug in the formula by decreasing or dividing the dosage
- Use an alternate dosage form
 - Substitute the dosage form an opened capsule rather than from an acidic solution if the carrier of the drug is responsible for the incompatibility
- Use an elixir, rather than an enteric-coated tablet
- Use an acid-stable salt that is more amenable to crushing and delivery directly to the stomach
- Use an alternate route of drug administration (intramuscular, intravenous, subcutaneous, etc.)
- Substitute a therapeutically equivalent but chemically distinct drug that is compatible with the formula (examples of equivalent drug pairs: loperamide and diphenoxylate for diarrhea; promethazine and prochlorperazine for nausea and vomiting)

Data from Rollins C. Pharmacological impact of drug-nutrient interactions. Handout for the 26th Clinical Congress, American Society of Parenteral and Enteral Nutrition, January 1998.

Table 99.5 Approaches to Avoid Physical and Pharmaceutical Incompatibilities between Drugs and Enteral Formulas

Pharmaceutical Incompatibility of Drugs and Enteral Formulas. Pharmaceutical incompatibility refers to adverse interactions between drugs and enteral formulas that occur because the form of the drug must be altered (e.g., by crushing) so that it can be administered through a feeding tube. When the form of a drug is altered, safe delivery of the drug to its site of absorption may not occur. For example, drugs that are enterically coated to prevent destruction by stomach acid are not good candidates for crushing and delivery in an enteral formula, because crushing destroys the enteric coat. Similarly, crushing slow-delivery preparations leads to immediate release of the drug in a single dose and the possibility of overdose. Instead, the complete contents of a capsule of slow-release drugs should be administered as intact beads, making certain that the beads pass successfully through the feeding tube. Approaches to avoiding pharmaceutical incompatibilities are listed in [Table 99.5](#).

Chemical Stability. The chemical stability of a drug is affected by pH, enzyme activity, and drug-nutrient binding reactions (chelation). Certain salts of drugs are resistant to acid hydrolysis in the stomach, while other drugs are inactivated in an alkaline environment. For example, erythromycin is available as four different salts: base, stearate, ethylsuccinate, and estolate. To avoid acid hydrolysis, the first two salts are delivered in enteric-coated tablets, while the other two salts (particularly the estolate) are acid stable and can be administered without enteric coating (10). Misoprostol, whose active form is misoprostol acid, is an example of a drug that is less bioavailable

in an alkaline environment, although the *rate* of absorption and the peak concentration reached in plasma are not changed by the presence of antacid (11).

Drug-Nutrient Chelation. Certain drugs chelate minerals and render both the drug and the mineral unavailable for absorption. The best-known example of this effect is the chelation of divalent and trivalent cations by tetracycline and its congeners (12). This effect is less pronounced with minocycline (13) and controversial with doxycycline (14, 15). These drugs should not be taken within 2 hours of consuming foods containing calcium, magnesium, iron, or zinc. The other drugs that interact with iron include the dopa drugs (methyldopa, levodopa, carbidopa), ciprofloxacin, penicillamine, and trientine; thyroxine and captopril form stable complexes with iron (15a).

Gastric Emptying and Drug Absorption Kinetics

A drug leaves the stomach at a rate that depends on gastric emptying. Gastric emptying, in turn, depends on the general functioning of the stomach and gastrointestinal tract (e.g., a person with autonomic neuropathy affecting the gut has very slow gastric emptying), on the physiologic changes in the gastrointestinal tract in the fed versus the fasted state, and on the effects of the drugs themselves on gastric emptying. In the fasted state or when little food is in the stomach, drugs usually leave the stomach rapidly and thus reach the small intestine rapidly. If a drug is formulated as a solid preparation—such that disintegration of drug particles as well as dissolution of the drug in stomach fluid must precede absorption—then rapid stomach emptying militates against rapid drug absorption. The aspects of drug pharmacokinetics that are affected by gastric emptying time include the time to peak plasma level, the number of plasma level peaks (i.e., one or more), the heights of the peak plasma levels, and the area under the curve of plasma drug concentration (AUC).

When a drug or food is delivered to the stomach, the stomach initially empties some of its contents within a few minutes. This emptying, termed the *adaptive phase of gastric emptying*, may be of varying volume (16). When this initial emptying delivers some of the ingested material into the duodenum, hormones are released that decrease antral contractions and increase pyloric contractions, which lead to retention of material in the stomach. Fatty foods are the most potent inducers of these changes in contractions, through the release of cholecystinin (17). Note that erythromycin counteracts this effect and speeds up gastric emptying (17). Carbohydrates in the ileum can also alter the contraction pattern and decrease gastric emptying, so that carbohydrates ingested in one meal can affect gastric emptying in the next (18).

The initial gastric emptying leads to the first opportunity for a drug to be absorbed by the small intestine and delivered to the bloodstream. This initial absorption results in development of the first plasma drug peak (19). The height of this peak also depends on the transit time through the rest of the gastrointestinal tract, with more rapid transit lowering the height of the peak and decreasing the AUC. Drugs delivered without food but with water have only one peak in plasma concentration (19). The height and duration of the peak depends on the size of the drug particles, the extent to which they are dissolved in the gastric juices and water, the size of the initial emptying, the

intestinal transit time, and the rate of drug absorption in the intestine.

While rapid delivery of a drug into the small intestine may increase the initial rate of absorption and the peak concentration of the drug in the bloodstream, the total AUC may be decreased, particularly if the intestinal transit time is also decreased, because the drug's residence time in the small intestine is short (20). Under these circumstances, the drug may be better absorbed after food intake. Coated drugs may also be better absorbed with food because the capsules may disintegrate better in the small intestine after longer residence in the stomach (21).

When drugs are taken with food, there is usually a second peak in the plasma concentration-time curve. The second peak corresponds to absorption of the drug as it is delivered with food to the intestine in the second phase of gastric emptying. The height and duration of the peak depend on the gastrointestinal transit time, the surface area over which the drug can be absorbed, the kinetics of absorption, and the size and timing of the first peak with respect to the second phase of delivery of the drug to the absorptive sites (19). The dependence of the second peak on the first peak reflects the fact that the systemic levels of a drug influence the drug's further absorption from the gastrointestinal tract. This effect can be clearly seen for drugs absorbed by simple diffusion, because the drug concentration *gradient* directly influences the amount of drug absorbed.

Particles up to about 1.1 mm in diameter are emptied from the stomach with food prior to the interdigestive phase, although there is great interindividual variability, and not all particles of the same size may be released with food (22, 23). Larger particles are released from the stomach during the interdigestive phases, with the very largest particles requiring the "housekeeper" phase-three contractions of the stomach that occur well after a meal, when the stomach is empty (24). This phenomenon accounts for the observation that certain drug preparations are not cleared from the stomach until night, even though they may be consumed during the day, if there is not sufficient time between meals and snacks to ensure complete emptying of the stomach (25). There is evidence that taking enteric-coated pills or capsules with meals severely delays their delivery into the duodenum, sometimes as much as 10 to 12 hours (25). If given in multiple doses throughout the day, these drugs may accumulate in the stomach and be dumped into the duodenum at night when the stomach finally empties. This problem, which deserves further investigation, can be prevented by taking these drugs on an empty stomach and avoiding between-meal snacks (25). Release of a drug from the stomach also depends critically on its particle size, with larger particles being retained for longer times.

Note that gastric emptying may differ considerably from individual to individual in the fasting state. These differences may contribute to some of the unpredictability of drug absorption in this state (26). Gastric emptying is delayed in neonates irrespective of fasting (27), so that the oral route for drug administration is unreliable. By contrast, gastric emptying may be normal (28) or prolonged (29) in healthy fit elderly persons. Women may have slower gastric emptying times than men, even when controlled for menstrual stage (29). Pregnancy appears to have no effect on gastric emptying, although intestinal transit time is increased (30). Chronic alcoholics experience striking

delays in gastric emptying, which may affect both drug pharmacokinetics and nutrient consumption and absorption (31). Note that gastric emptying is delayed by acute cigarette smoking, although it is not delayed in smokers if they are not smoking at the time of drug administration (32).

A delay in gastric emptying may also enhance drug absorption because the drug is delivered more slowly and efficiently to its intestinal absorption site. This is especially true if drug transport across the intestine is saturable and site specific. This effect may explain the enhanced absorption of chlorothiazide after food intake (33). Hydrochlorothiazide, by contrast, is absorbed equally well whether taken with or without food. Although food slows absorption and decreases the height of the plasma concentration peaks of this drug, the 48-hour dose recovery in the urine is the same whether the person has fasted or not (34).

Transport across the Enterocyte Lipid Membrane

To be absorbed, drugs must be transported across the lipid membrane of the mucosal barrier, either by diffusion or by a specific carrier. Although a drug's pK_a influences its absorption in the stomach, most drugs are absorbed in the small intestine, irrespective of pK_a , because the surface is optimized for absorption. Most drugs are transported across the lipid membrane by simple diffusion that depends on the concentration gradient of the drug across the intestinal mucosa. As a result, food-induced increases in splanchnic blood flow may increase the bioavailability of drugs, although this may not be a simple effect, as noted.

Competitive Inhibition of Absorption. Drugs absorbed through transport mechanisms may be subject to competitive inhibition by the individual nutrients that are the normal substrate for the transport mechanism. For example, L-dopa and methyldopa are transported across the small intestine via the aromatic amino acid transporter. Therefore, absorption of these drugs is reduced when they are taken with a high-protein meal or with an amino acid mixture that contains aromatic amino acids (35, 36).

Transport of L-dopa across the blood-brain barrier also depends on the aromatic amino acid transporter, so consumption of a high-protein meal inhibits entry of the drug into the brain (37, 38). Patients with “on-off” effect, who fluctuate between good function and severe bradykinesia, are particularly sensitive to the interaction between dietary protein and L-dopa efficacy (39). Daytime restriction of protein intake can provide a more acceptable level of function during waking hours (38), provided that the diet consumed before bedtime adequately compensates for any potential deficiencies (40).

Distribution

The term *distribution* refers to the dissemination of the drug via the bloodstream to the interstitial and intracellular fluids. Distribution of a drug depends on (a) its lipid solubility and ionization state (e.g., lipid-soluble drugs cross the blood-brain barrier readily, while acidic or basic drugs do not); (b) the blood flow to the body compartments from which the drug is absorbed and to which the drug is distributed; (c) the size and nature of

these compartments; (d) the solubility of the drug in the compartment, so that the compartment can act as a drug reservoir (e.g., lipid-soluble drugs are distributed to adipose tissue, where they may be retained for long periods of time); (e) the degree to which the drug is bound to the components of the compartment (e.g., the extent of binding to plasma proteins); and, finally, (f) the time over which distribution is examined—drugs move from compartment to compartment over time, depending on the local concentration gradients of the drug and the barriers to diffusion.

Neonates have an increased fractional volume of extracellular fluid to total body water, with a resultant increase in drug half-life relative to a similar dosage in adults (27). The effects of edema on the half-life of drugs in adults is not so clear (41).

Protein Binding and Drug Availability at the Site of Pharmacologic Action

To be pharmacologically active, drugs must be in a free, unbound state. However, a proportion of many drugs circulates bound to plasma proteins. The major proteins involved in drug binding are albumin and α_1 -acid glycoprotein (AAG), although other proteins, such as the lipoproteins, also bind certain drugs. Albumin has two major drug binding sites, I and II. Site I binds phenylbutazone, oxyphenbutazone, warfarin, and long-chain fatty acids. Site II binds benzodiazepines, indoles, ibuprofen, flufenamic acid, and ethacrynic acid, as well as long-, medium-, and short-chain fatty acids and certain amino acids (42).

In conditions characterized by low plasma albumin levels, such as liver disease, nephrotic syndrome, and renal disease, drug binding is decreased. Thus, overdosing may occur. Glycosylation of albumin, which occurs when blood glucose levels are chronically elevated, as in poorly controlled diabetics, appears to decrease site II binding (43, 44). Disagreement exists on this point, possibly because of the probes used (45). Free fatty acids increase dissociation of drugs from albumin site II, so postprandial elevations of free fatty acids as well as the increased free fatty acid levels in the fasting state and in poorly controlled diabetes mellitus may decrease drug binding and increase drug bioavailability and thus the potential for toxicity (44, 45).

Both albumin and AAG levels change with age: albumin decreases while AAG increases (46). The effects of these changes on drug pharmacokinetics are unknown.

Biotransformation

Most drugs must undergo biotransformation for excretion and some for activation. Lipophilic drugs are most easily absorbed from the gastrointestinal tract and cross membrane barriers best. However, to terminate drug action through excretion, drugs must be water soluble. Biotransformation reactions, then, generate compounds that are more polar than their parent compounds. In most instances, these compounds are inactive and are readily excreted, primarily through the urine. However, biotransformation occasionally leads to either formation of the active form of the drug or formation of toxic metabolites.

Phases of Biotransformation

Phase I Biotransformation. Phase I transformations either expose a functional group on a parent compound or introduce a functional group to that compound. These transformations are carried out (primarily in the liver) by the cytochrome P450 monooxygenase system, found in the endoplasmic reticulum. Humans have 12 genetically determined cytochrome P450 enzyme families, of which three, the CYP1, CYP2, and CYP3 families, are involved with most drug transformations (8). Large interindividual differences in drug metabolism can be attributed to genetic polymorphisms of the cytochrome P450 enzymes, which lead to classification of individuals as rapid or slow metabolizers for a given class of drugs.

The role of intestinal phase I biotransformation in drug bioavailability and the role of foodstuffs in inducing and reducing cytochrome P450 function have not been well studied. Evidence obtained in rats suggests that the P450 enzymes in the intestine are affected by food and ethanol but that the effects differ from those seen in the liver (47). The clinical importance of any differences in humans remains to be determined.

Phase II Biotransformation. Phase II biotransformations involve the conjugation of a parent compound's functional group with a polar group (acetate, glucuronic acid, sulfate, glutathione, or amino acids). Such transformations inactivate most drugs. Rarely, the more polar compound is the more active form of a drug. The resultant conjugated drug is excreted either in the urine or the feces. When the drug is excreted in the feces, bacteria can deconjugate the drug, which then may be reabsorbed, thus undergoing repeated cycles of activity and prolongation of its effect.

Most compounds undergo phase II biotransformation via glucuronidation. However, the sulfotransferases have a higher affinity than the glucuronyl transferases for their common substrates, so at low doses, given a sufficient quantity of sulfur-containing amino acids, sulfation predominates, while at higher doses, glucuronide formation predominates (8).

A number of drugs, including isoniazid (INH), procainamide, dapsone, and caffeine, are metabolized through acetylation of an amino or hydrazino group, primarily through one of several *N*-acetyl transferases. This acetylation process is under genetic control, with rapid acetylation caused by an autosomal dominant gene. Slow acetylation leads to slow clearance of the drug, so that slow acetylators need lower doses of a drug for therapeutic effects than do rapid acetylators. However, for some drugs, the acetylated form may be less water soluble than its parent compound, which may prolong its residence in the body (8). Rifampin is acetylated to a form that is as potent as the parent drug. However, this form is excreted into the bile. Its reuptake is lower than uptake of the parent drug and is further reduced by food. The result is that bioavailability of rifampin and its active metabolites is highly variable (8).

First-Pass Metabolism

Melander and McLean (48) pointed out that drugs can have low oral bioavailability despite complete gastrointestinal absorption. Their explanation is that some drugs undergo extensive presystemic metabolism during their first passage through the gut mucosa and liver. By decreasing first-pass metabolism, food consumption can increase the bioavailability of certain drugs known to undergo presystemic metabolic clearance, including the lipophilic bases propranolol, metoprolol, labetalol, and hydralazine. With aging, decreases in liver blood flow and liver mass contribute to a decline in biotransformation capacity with a corresponding increase in bioavailability. The decrease in phase I biotransformation is more severely affected than that in phase II.

Dietary Factors That Affect Drug Biotransformation

Drug biotransformation is affected by enzyme induction and inhibition, substrate availability, and phenotypic differences in enzyme expression caused by genetic polymorphisms, disease, and age. Dietary factors can affect both enzyme induction and enzyme inhibition, while overall liver and intestinal function may modulate the effects of enzyme function through changes in tissue mass and perfusion.

Whereas relatively few dietary factors have been examined in human subjects for their effects on drug metabolism, a wide range of macro- and micronutrients, including vitamins and trace elements, have been investigated in rodents (49). The findings in rodents should be extrapolated to humans with caution, however, because of the differences in drug handling between the two species and because many of the studies of diet-drug interaction were performed before we understood the individual P450 enzymes and their functions (49).

Epidemiologic and metabolic studies of effects of diet composition on drug toxicity are greatly needed, particularly in the elderly (50, 51). Studying the roles of diet in drug metabolism in the elderly is difficult because they are usually taking multiple drugs. A number of different drugs act on the phase I transforming enzymes, which may mutually alter their metabolism. However, these inhibitory interactions are usually not the result of drug-nutrient interactions, with the exceptions noted below. By contrast, phase II biotransformation may be inhibited by the lack of necessary cofactors; this lack may be of nutritional origin.

Dietary Components and Drug Biotransformation. The substrates needed for drug biotransformation include a sufficient energy source, because biotransformations are energetically expensive; protein for formation of the enzymes themselves; fatty acids of the appropriate composition for presentation of the enzymes in the microsomal membrane; iron for formation of the cytochromes; and, finally, substrates for phase II biotransformation: glucose, sulfur-containing amino acids, specific amino acids such as taurine (which may be limiting in the neonate), and glutathione. The availability of these dietary components appears to regulate not only the function of the enzymes involved in biotransformation but also their expression, as discussed below.

Starvation. Short-term starvation is a common experience for persons with illness and may occur under other circumstances as well. While the literature contains references to

alterations in drug bioavailability in starvation, there is relatively little information on the effects of starvation on phase I and phase II biotransformation (52). Rat studies suggest that short-term (48 hours) starvation leads to induction of a number of different cytochromes and a decrease in the functional amounts of others in the liver (53). The effects of starvation on drug biotransformation in humans has not been adequately studied.

Protein. In rodents, high-protein diets enhance drug metabolism, and protein-deficient diets slow drug metabolism. Humans metabolize theophylline and antipyrine more rapidly when they are on a high-protein diet (49). The rise in metabolism appears to be due to an increase in CYP1A2, as there is an increase in catabolism of 17 β -estradiol by 2-hydroxylation, which is a function of CYP1A2, but not by 6-hydroxylation, which does not depend on CYP1A2. This effect of protein is particularly noticeable when a person is placed on total parenteral nutrition (TPN) after receiving dextrose in water for a period of time (49). By contrast, children with kwashiorkor have a generalized decrease in drug metabolism, although this decrease may be associated with the fatty liver and overall liver malfunction seen in this condition. In support of the notion that the changes in kwashiorkor result from liver dysfunction, there is evidence that people with anorexia nervosa do not have altered drug metabolism (49).

With respect to phase II biotransformation, when animals are fed a low-protein diet that is adequate in energy content, glucuronidation increases. Diets low in the sulfur-containing amino acids methionine and cysteine reduce sulfate conjugation rates (54, 55). Whether a similar effect occurs in humans is not known.

Carbohydrate. Short-term carbohydrate restriction leads to depletion of the cofactors needed for oxidation and glucuronide formation, and thereby a decrease in both phase I and phase II biotransformation (56). Chronic high-carbohydrate diets and the high blood glucose levels seen in uncontrolled diabetics decrease phase I biotransformation, probably through inhibition of the synthesis of d-aminolevulinic acid, a precursor of the heme component of the cytochromes (57). The importance of the carbohydrate and protein effects is underscored in persons (especially children) taking theophylline for asthma. This drug has a very narrow therapeutic range. Increasing the protein:carbohydrate ratio can decrease the effectiveness of a given dose of theophylline; decreasing this ratio may lead to development of toxicity (58). Persons taking theophylline should therefore maintain a consistent diet (with a consistent content of caffeine and other methylxanthines, which compete for theophylline for biotransformation, as well) to establish and maintain therapeutic blood levels of the drug.

Enzyme Induction and Inhibition by Specific Compounds in Food. Exposure to foods, drugs, and environmental pollutants can induce increased synthesis of (usually specific) cytochrome P450 enzymes or can inhibit their induction. Induction of P450 enzymes can be accompanied by induction of the conjugation enzymes. The dietary inducers and inhibitors of these enzymes are usually nonnutritive components of foods, such as heterocyclic amines, flavones, indolic compounds, and terpenoids, as well as ethanol, although the fatty acid composition of the diet may have important effects on

P450 enzyme activity.

Fatty acids are metabolized by the cytochrome P450 enzymes and in turn affect enzyme expression. When fat-free diets are fed to laboratory animals, cytochrome P450 function decreases (59, 60). This decrease may be the result of polyunsaturated fatty acid deficiency, which in turn may affect the microsomal membrane's composition, fluidity, and ability to present enzymes (60, 61).

CYP2E1 is responsible for lipid peroxidation, which is enhanced in the presence of highly polyunsaturated fatty acids, such as fish oils. The activity of this enzyme increases with ethanol feeding in rats and may be responsible for the centrilobular fatty liver seen with excessive ethanol consumption (62, 63, 64 and 65). In fact, Nanji et al. (65) have suggested that consumption of saturated fatty acids may suppress development of a fatty liver in alcoholism. On a parenthetical note, watercress appears to inhibit CYP2E1 activity (66).

Char-broiled meats, which contain large amounts of heterocyclic amines, are highly potent inducers of CYP1A2 (67, 68). Induction of this enzyme increases the oxidation of caffeine, theophylline, antipyrine, bufuralol, acetaminophen, ondansetron, tacrine, and warfarin. The indoles in cruciferous vegetables and their metabolites also activate CYP1A2. This effect may contribute to the presumed anticancer effects of cruciferous vegetables (49). At the same time, the phenylethylisocyanate in cruciferous vegetables acutely decreases CYP2E1 activity in rats (69). Whether a similar effect occurs in humans is not known.

Flavonoids can induce, directly activate, or inhibit P450 enzymes. The targets for this activity are CYP3A4 and CYP1A2 (49, 70, 71). Some interactions of these enzymes with flavones lead to induction and others to inhibition, which makes predictions about the effects of dietary flavones particularly difficult. For example, flavones markedly enhance activation of aflatoxin B1, a carcinogen. By contrast, the flavonoids in grapefruit juice (naringin, naringenin, limonin, obacunone) inhibit CYP3A, as measured by 6b-hydroxylation of testosterone by rat and human liver microsomes (71). Quercetin and kaempferol in grapefruit may also inhibit metabolism of midazolam and quinidine by inhibiting CYP3A4 (71a).

Studies of the interaction of components of grapefruit juice with CYP3A have ascribed the clinically significant inhibition of metabolism of the dihydropyridine calcium channel blockers (nifedipine, felodipine, and nisoldipine) by small quantities of juice to 6',7'-dihydroxybergamottin, a furanocoumarin (psoralen) (71, 72) present in grapefruit but not in orange juice. Previous studies have ascribed this action to the flavonoids in citrus juices, which are indeed effective in inhibiting liver CYP3A (49, 70). However these compounds are present in grapefruit at too low a concentration to account for the effectiveness of this fruit in CYP3A inhibition (71). Interestingly, the increased bioavailability of the calcium channel blockers following consumption of grapefruit juice appears to be due to inhibition of intestinal, rather than liver, CYP3A4 (73).

Terpenoids, which are plentiful in citrus fruits, increase the total level of P450 enzymes in rat liver, but their role in human P450 activity and drug metabolism has not been

established (49).

Acute ethanol consumption reduces the activity of the P450 enzymes by depriving them of the reducing equivalents derived from mitochondrial metabolism. Ethanol also competitively inhibits CYP2E1 (63). Thus, phenytoin metabolism is decreased when it is consumed at the same time as ethanol. Chronic ethanol consumption, by contrast, induces the CYP2E1 family of enzymes, so that when a chronic alcoholic takes phenytoin after a period of abstinence, metabolism of the drug is enhanced. Similar effects occur with metabolism of tolbutamide and related agents. Note that chronic alcohol consumption depletes liver glutathione and thereby decreases phase II biotransformation of a host of drugs (8).

Pyridoxine supplementation decreases the effectiveness of L-dopa in patients with parkinsonism, possibly through increased peripheral decarboxylation of the drug, which results in decreased L-dopa delivery to the brain (74, 75). For this reason, L-dopa is routinely administered in combination with a peripheral decarboxylase inhibitor, such as carbidopa. Pyridoxine supplementation appears to have no effect on the efficacy of L-dopa administered with a peripheral decarboxylase inhibitor (76).

Propranolol, a Drug Whose Pharmacokinetics Are Significantly Affected by Food Consumption

The effect of food consumption in increasing bioavailability of a single dose of propranolol illustrates the complex interactions between drug characteristics and metabolism on one hand and the physiologic alterations induced by food consumption on the other. Propranolol is a highly lipophilic drug that is almost completely absorbed from the intestine on oral administration, with or without the consumption of food (8). In humans, it is metabolized by two different P450 enzyme families, CYP2D and CYP1A2 (77, 78). At least two enzymes are involved in each metabolic transformation (79). On average, only about 25% of a dose of propranolol reaches the systemic circulation, while 75% undergoes first-pass metabolism (8). The drug circulates tightly bound to α_1 -acid glycoprotein. The bioavailability of propranolol can vary 20-fold from individual to individual, mostly because of differences in first-pass metabolism (8).

There are numerous reasons for the food-induced decrease in first-pass metabolism of a single dose of propranolol; these run the gamut from alterations in liver function induced by the mere thought of food to changes in phase I and phase II metabolism of the drug. One or more of these effects may be operative in a given individual, which may account for the very large interindividual differences in systemic bioavailability of a single dose of the drug.

Simultaneous oral administration of a dose of propranolol and presentation of an appetizing meal without allowing it to be eaten, significantly increased the bioavailability of propranolol in healthy human volunteers (80). This observation (which was replicated in dogs) suggests preprandial anticipatory changes in splanchnic function—including increased hepatic blood flow and cephalic-phase secretion of insulin and glucagon—which may be responsible, although the exact mechanism is unknown. In

experimental animals, propranolol undergoes phase I biotransformation in the small intestine, a process that is diminished when the drug is administered with food (81).

In most (but not all) humans, consumption of a high-protein meal with a single dose of propranolol significantly enhances the bioavailability of the propranolol, whereas a high-carbohydrate meal appears to have little effect (82). This observation appears to be true when volunteers are fed a single high-protein meal. The opposite is true when the volunteers are habituated first to high-carbohydrate meals and then switched to high-protein meals (58). The increased bioavailability following a single high-protein meal appears to be due to decreased first-pass hepatic metabolism, because production of metabolites is delayed rather than reduced (82).

In a nonhabituated person, a high-protein meal increases hepatic blood flow. Initially the increased hepatic blood flow was thought to cause the decreased hepatic extraction of propranolol, because extraction of propranolol by the liver was assumed to be primarily limited by the fact that the P450 enzymes involved in phase I biotransformation of propranolol are saturable and obey Michaelis-Menten kinetics (83), as they do in the rat (84). Under these assumptions, increased flow would be expected to result in *decreased* propranolol extraction per unit blood per unit time (85). However, increasing blood flow to the liver by changing posture does not change propranolol bioavailability, so increased blood flow per se probably is not the only reason for the increased bioavailability of the drug caused by a high-protein meal (86).

In fact, the increased bioavailability with food may be due to the combination of increased blood flow, the lipophilicity and protein binding of the drug, and the effects of meal-induced hormones on phase I and phase II metabolism. The primary site of CYP1A in the healthy liver of a healthy person (and a healthy rat) is the centrilobular area (87, 88), which is also the location of CYP2D in rat liver (89). With increased hepatic blood flow, propranolol is extracted by a larger proportion of the liver, including the periportal areas that do not efficiently metabolize the drug. This extraction is enhanced by the drug's binding to AAG (90) and by its lipophilicity (91).

The sight of a meal induces an anticipatory phase of insulin and glucagon secretion. In rats, glucagon (but not insulin) increases hepatic uptake of propranolol, although it does not affect metabolism (92), so plasma levels of the active drug are higher than without the sight of a meal. By contrast, hepatic uptake of propranolol is decreased with a glucose meal. As a result, plasma propranolol concentration initially decreases because more drug is metabolized when hepatic uptake is relatively low, as noted above (93). Whether a similar effect occurs in humans is not known. If so, this effect could explain the paradoxical differences in propranolol bioavailability between persons who have been habituated or not to high-carbohydrate meals. Habituation to high-carbohydrate meals induces a basal hyperinsulinemia, which dampens the rise in glucagon induced by consumption of a high-protein meal. Because no glucagon-induced decrease in phase I metabolism occurs, first-pass metabolism is unchanged, and a high-protein meal fails to enhance bioavailability of the drug.

Phase II biotransformation may also be decreased by coconsumption of propranolol with food. Liedholm and Melander (94) have shown that in women, administration of

propranolol with a meal not only increased the bioavailability but also decreased the ratio of conjugated:unconjugated drug. This decrease was not seen when a slow-release formulation was administered.

Despite the intensive study of propranolol bioavailability and its relationship to meal consumption and the important biologic issues this question engenders, ultimately this question is of relatively little clinical importance for those receiving *maintenance* dosages of the drug. With chronic administration, propranolol decreases its own first-pass metabolism to a maximal extent (95). Its lipophilicity means that adipose tissue can serve as a reservoir to dampen fluctuations in blood levels. Finally, the β -adrenergic blockade induced by propranolol lasts well beyond what would be expected from its approximately 4-hour plasma half-life (8). Therefore, a twice-a-day dosage usually yields adequate clinical effect, regardless of the timing and nature of meals.

Dietary Effects on Drug Function

When a drug acts on processes that involve dietary components, we can anticipate that dietary components may affect that drug's function. The following interactions are probably not the only ones that occur. However, they are either the most common or ones that deserve further study.

Dietary Electrolytes and the Functions and Side Effects of Drugs Used to Treat Cardiovascular Disease

The digitalis glycosides block $\text{Na}^+\text{-K}^+$ ATPase. Hypokalemia potentiates the ATPase block and leads to toxicity. Therefore, dietary maintenance of normal plasma potassium levels is critical for prevention of this side effect, particularly if the patient is also taking a potassium-losing diuretic. Note that persons taking potassium-sparing diuretics (e.g., triamterene or amiloride) may develop a life-threatening hyperkalemia if they are given a high-potassium diet, potassium supplements, or drugs with a high potassium content, including potassium penicillin.

A dose-dependent side effect of the thiazide diuretics, which occurs in up to 3% of subjects, is development of glucose intolerance and overt diabetes mellitus, through mechanisms that are not completely elucidated (96, 97). Maintenance of adequate plasma potassium and magnesium levels through diet or, if necessary, supplements may prevent development of this complication (97). Hypomagnesemia may also play a role in development of thiazide-induced glucose intolerance (98), so monitoring of magnesium levels may be indicated with supplementation or dietary change recommended as needed.

Potentiation of MAO Inhibitors

Foods containing tyramine and other phenylethylamines should be avoided by persons taking first-generation monoamine oxidase (MAO) inhibitors. These include not only the antidepressants such as phenelzine, tranylcypromine, pargyline, and selegiline, but also the cancer chemotherapeutic drug procarbazine (8), the antiprotozoal drug furazolidone

(99), and the analgesic meperidine (100). Dietary phenylethylamines, including tyramine, are normally oxidatively deaminated via MAO in the gastrointestinal tract and the liver. When a person is taking MAO inhibitors, the phenylethylamines are not deaminated by the gut and liver, so they are absorbed systemically and taken up in the brain, where they displace norepinephrine from storage vesicles. The resulting flood of norepinephrine released into synapses leads to severe acute hypertension with the potential for stroke or myocardial infarction. Attacks of hypertension of short duration are associated with headaches, palpitations, nausea, and vomiting. The newer antidepressant MAO inhibitors such as moclobemide, which act much more selectively in the central nervous system, do not lead to severe reactions with dietary components (101).

Foods accumulate phenylethylamines through the action of bacterial or fungal tyrosine decarboxylase. Thus, fermented foods and protein-rich foods that have begun to spoil contain large amounts of phenylethylamines (8). Table 99.6 lists common foods containing large quantities of tyramine. Note, however, that the amount of phenylethylamines in a food varies from sample to sample and depends on storage method and time since preparation. Those at greatest risk of a hypertensive crisis due to phenylethylamines are vegetarian, have poor appetites, and/or are on a weight-reduction diet, because the phenylethylamines consumed are not “diluted” by other foods. Iron deficiency may increase susceptibility to hypertensive crisis. Consumption of yeast supplements also presents a significant risk. Tyramine consumed with a meal may diminish tyramine absorption (102).

Foods that contain significant amounts of tyramine
Broad beans
Raspberries
Banana peel
Cheese (except cream cheese and cottage cheese)
Imitation cheese
Prepared meats: sausage, chopped liver, pate, salami, mortadella
Meat extracts
Concentrated yeast extracts/brewer's yeast
Liquid and powdered protein supplements
Fermented soy products: fermented bean curd, soy bean paste, miso soup
Hydrolyzed protein extracts for soups, soups, and gravies
Fermented cabbage products: sauerkraut, kimchee
Chianti, vermouth
Nonalcoholic beer
Some non-U.S. brands of beer
Foods that may contain significant amounts of tyramine
Anchovies
Yogurt
Cream from fresh pasteurized milk
Soy sauce
Peanuts
Chocolate
Red and white wines, port wines
Distilled spirits

Data from Smith CH, Wren J. Food-medications interactions. Tampa, FL: Ann Moore; 1991:344.

Table 99.6 Tyramine in Foods

The amino acid dopa or its amine derivative, dopamine, present in broad beans (fava beans), may also trigger hypertension in patients on MAO inhibitor drugs (103).

Dietary Effects on the Coumarin Anticoagulants

The coumarin anticoagulants (warfarin, Coumadin, dicumarol) act through antagonism

of vitamin K. Consumption of vitamin K–enriched foods or supplements may counteract the effects of the anticoagulants. Because the dosage of the coumarin antagonists is based on the patient's prothrombin time rather than on vitamin K levels, it is more important to maintain a steady, consistent intake of vitamin K–containing foods while receiving anticoagulants, than it is to decrease intake.

Certain herbal teas (woodruff, tonka beans, melilot) contain natural coumarins that can augment the effects of Coumadin and should be avoided (104). Large amounts of avocado also appear to augment the effects of warfarin (105). Brussels sprouts and possibly other cruciferous vegetables increase the catabolism of warfarin and thereby decrease its anticoagulant activities (106).

Interactions of Caffeine and Other Methylxanthines with Drug Function

Caffeine and other methylxanthines have numerous effects on the function of other drugs, both through induction of P450 enzymes (as observed in rats [107]) and through other pathways. For example, methylxanthines enhance the cytotoxicity of alkylating agents by hastening passage through the G₂ phase of the cell cycle, thereby decreasing the time for repair of sublethally “hit” DNA (108). In vitro, caffeine binds to DNA-intercalating drugs such as the antitumor drug doxorubicin; in vivo consequences of this binding are not known (109). Caffeine also decreases the effectiveness of a number of antiepileptic drugs, including phenobarbital and valproate, in preventing electroshock seizures in mice, probably through adenosine-mediated inhibition. These findings suggest that persons taking these drugs should probably not take caffeine-containing foods and beverages, or if they do, they should maintain their intake at a constant level (110).

Interactions of Diet with Hypolipidemic Drugs

Although the hypolipidemic effects of the hypolipidemic drugs may be augmented by a lipid-lowering diet, the effects are usually additive and do not result from a specific interaction between diets and the drug (e.g., see [111] and Chapter 75). There may be exceptions to this statement. Fibrates bind to proteins known as peroxisome proliferator-activated receptors (PPARs). PPARs, members of the steroid hormone receptor superfamily, have recently been found to play distinctive roles in the regulation of fat and cholesterol metabolism. Their role in drug function and metabolism and the effects of dietary fatty acids and retinoids on the function of fibrate drugs as mediated through PPARs are just beginning to be elucidated (112).

Drug Excretion

Drugs are primarily excreted via the kidneys and the gastrointestinal tract, with minor excretion via other routes. However, many drugs are excreted into breast milk, and nonelectrolytes (e.g., ethanol) reach the same concentration in breast milk as they do in plasma (8).

Effects of Diet on Drug Excretion

Diet can affect drug excretion by altering either the clearance by the drug's organ of excretion or the drug's volume of distribution. The half-life of a drug in circulation is a direct function of the volume of distribution of the drug and an inverse function of its clearance.

The clearance of a drug depends on the amount of drug delivered to the organ of excretion and the extent to which the drug is extracted from the blood for excretion (the extraction ratio). In the case of renal excretion, clearance of the drug depends on the concentration of free drug in the plasma, on the glomerular filtration rate, and on the amount of drug secreted and/or reabsorbed in the tubules per unit time.

Low-Protein Diets and Hypoalbuminemia. The concentration of free drug in the plasma depends on the chemical characteristics of the drug. For example, if a drug binds to albumin, a decrease in plasma albumin levels (due to inadequate protein intake or disease) may increase the proportion of free drug to bound drug. However, the effect on excretion of an increase in the unbound fraction of the drug may be counteracted by an increase in the drug's volume of distribution. An increase in distribution volume may occur for two reasons. First, hypoalbuminemia leads to an increase in total body water. Second, if the drug binds to particular tissues (e.g., adipose tissue), a larger proportion of the drug is sequestered by these tissues and therefore is unavailable for immediate excretion.

Thus, low-protein diets can in theory affect renal clearance of drugs in potentially opposing ways. Acutely, low-protein meals decrease glomerular filtration rates (113), so less drug is available for excretion per unit time. However, tubular reabsorption may be more efficient, so the clearance of the drug may be decreased out of proportion to the decrease in filtration rate (114). Chronic low-protein consumption with hypoalbuminemia leads to an increase in free drug available for excretion, if the drug is bound to albumin, and to alterations in the volume of distribution, as noted above. However, the result of a low-protein diet on actual clearance varies from drug to drug and depends on the severity and duration of the low-protein intake. For example, dietary protein restriction decreases clearance of the antigout drug allopurinol and promotes renal tubular reabsorption of its chief metabolite, oxypurinol (114). Because high levels of the drug may lead to an acute attack of gout, the protein content of the diet is particularly important in patients with compromised renal function.

Another effect of a low-protein diet, albeit an indirect one, is to increase net renal excretion of base. The increased excretion of base is due to decreased production of acid residues (phosphate, sulfate, and chloride) from protein metabolism, coupled with decreased renal secretion of hydrogen ions due to increased extracellular fluid volume. This effect lessens the rate of excretion of basic drugs such as the antibiotic gentamicin or the antiarrhythmic drugs procainamide and quinidine because less of the ionized form of these drugs is presented in the renal tubule and thus more of the drug is reabsorbed. A similar effect is produced by intake of antacids. In patients receiving basic drugs, urinary pH should be monitored, and if the pH is increasing, the drug dose should be

reduced or an alternative drug considered ([115](#)).

Dehydration and Starvation. Dehydration, and starvation without hypoproteinemia, may significantly decrease the distribution volume of a drug because of decreases in the size of the aqueous compartment. Glomerular filtration rates may also be decreased. In addition, starvation decreases the distribution volume of lipophilic drugs because of a loss of adipose tissue. By contrast, people who are lean but not starved have a higher proportion of body water per kilogram than nonlean people, so the half-life of drugs that are primarily distributed in the aqueous compartment is prolonged in lean persons ([116](#)). The result of these changes in compartment size varies from individual to individual and from drug to drug, so that drug regimens should be individualized and drug levels and clinical effect should be monitored in critically ill or malnourished persons whenever feasible.

Competition between Drugs and Nutrients for a Common Excretory Pathway.

Competition between drugs or between drugs and nutrients for a common renal pathway can also change the rate of drug excretion. Renal tubular reabsorption of lithium chloride is increased in sodium depletion. Because of the potential for toxicity, a patient receiving lithium chloride should not be placed on a low-sodium diet unless close attention is paid to blood lithium levels ([8](#)).

EFFECTS OF DRUGS ON FOOD INTAKE, BODY WEIGHT, NUTRIENT REQUIREMENTS, AND GROWTH

Alteration in Food Intake

Drugs can alter food intake by causing either a perversion or loss of appetite or an increase in appetite.

Appetite Suppression

Drugs may suppress appetite either as their primary effect (e.g., the anorexigenic drugs used to treat obesity) or as an unwanted side effect. Drugs designed to suppress appetite ([Table 99.7](#)) usually act at the level of the central nervous system. Appetite suppression as an unwanted side effect can result from a number of different mechanisms, from development of food aversions because of nausea associated with a drug's action on the central chemoreceptor trigger zone to food avoidance associated with a sore mouth or slow gastric emptying.

-
- A. Primary appetite suppression
 - 1. Centrally acting
 - a. Catecholaminergic, e.g., dextroamphetamine
 - b. Dopaminergic, e.g., levodopa
 - c. Serotonergic, e.g., fenfluramine
 - d. Endorphin modulators, e.g., naloxone
 - 2. Peripherally acting
 - a. Agents that inhibit gastric emptying, e.g., levodopa
 - b. Bulking agents, e.g., methylcellulose
 - B. Secondary adverse response to food, loss of appetite
 - a. Drugs causing nausea and vomiting, e.g., digoxin
 - b. Drugs causing loss of taste, e.g., penicillamine
 - c. Drugs causing stomatitis, e.g., 5-fluorouracil
 - d. Hepatotoxic agents, e.g., alcohol
-

(Based on Pawan GUS. Proc Nutr Soc. 1974;33:239-44.)

Table 99.7 Classification of Anorexigenic Drugs

Centrally Acting Drugs Used for Appetite Suppression. Appetite-reducing drugs that act centrally include those that act via catecholamine pathways and those that appear to act via serotonin pathways (117). The former include unsubstituted and substituted amphetamines and related compounds (amfepramone, phentermine, mazindol, and phenylpropanolamine). Amphetamines are sometimes used to treat obesity, although tolerance to appetite suppression develops rapidly (117). These drugs are also undesirable because of their stimulant properties. The halogenated amphetamine fenfluramine and dexfenfluramine (its dextrorotatory stereoisomer) act through pathways that are yet unknown, although they profoundly deplete brain serotonin, suggesting a neurotoxic action. However, in experimental animals, fenfluramine's neurotoxic and anorexigenic effects can be distinguished (118), suggesting that the anorexia is not a consequence of neurotoxicity. Fluoxetine, a serotonin reuptake inhibitor, can increase appetite when it is used to relieve depression (119), but generally, this drug is anorexigenic, an effect that has been used clinically in the treatment of obesity (117).

Appetite Change and Decreased Food Intake As an Unwanted Side Effect.

Unwanted changes in appetite and, hence, changes in food intake may be caused by nausea and vomiting, development of food aversions, impaired oral function, dysgeusia or ageusia, gastric irritation, and changes in gastrointestinal tract function. The class of drugs most commonly associated with these side effects are the cytotoxic antineoplastic drugs. At effective therapeutic dosages, these drugs commonly have an acute anorectic effect due to their action on the chemoreceptor trigger zone in the brain, which is an integral part of their systemic toxicity. However, food intake may be reduced on a more chronic basis because of changes in taste, oral or intestinal ulcerations, or development of food aversions (120).

Risks Associated with Drug-Induced Loss of Appetite. Risks from the effects of drug-induced loss of appetite depend on both the primary toxicity of the substance and the secondary effects of the loss of desire to eat. The latter includes not only weight loss but also specific nutrient deficiencies that may ensue because of diminished intake of

nutrients. For example, dextroamphetamine, which has been used to treat attention deficit hyperactivity disorder in children, causes growth retardation, partly due to appetite suppression (8). Fortunately, rebound growth occurs when the drug is discontinued.

Nausea/Vomiting. Virtually every drug can cause nausea and vomiting, either centrally through activation of the chemoreceptor trigger zone in the area postrema of the brain or, more commonly, peripherally through irritation of the gastrointestinal tract. Drugs that act centrally include cytotoxic drugs (in particular cisplatin, doxorubicin, methchloroethamine, cyclophosphamide, chlorambucil, melphalan, dacarbazine, dactinomycin), opioids, cholinomimetics, L-dopa, bromocriptine, and cardiac glycosides (8). Any drug that induces nausea is likely to reduce food intake and hence contribute to weight loss. For example, digitalis preparations can cause severe wasting (digitalis cachexia) because nausea diminishes the desire for food at dosages below those that lead to cardiac toxicity (121).

Food Aversions. Food aversion develops when eating the food is associated with development of nausea and vomiting, even though the nausea and vomiting may be due to another agent (e.g., a cytotoxic drug). Food aversions develop in more than half of all patients who undergo cancer chemotherapy and usually affect consumption of two to four foods. The aversions are usually transient, however, lasting several weeks to several months after cessation of therapy (121).

Impaired Oral Function. Drugs that cause a dry or sore mouth and make eating difficult or painful lead to avoidance of food intake. Patients may develop sore mouths because of drugs that cause stomatitis (e.g., busulfan and other antineoplastics), gum inflammation and hyperplasia (cyclosporine and phenytoin), delay in wound repair and healing (antineoplastics), gingival bleeding (Coumadin and related drugs), microbial infections (antineoplastics, captopril), and oral candidiasis (broad-spectrum antibiotics). Dry mouth may be caused by drugs that decrease salivary flow, including atropine, amantadine, opioids, phenothiazines, tricyclic antidepressants, and α -adrenergic agents.

Dysgeusia and Ageusia. Drugs can alter the taste of saliva or food by excretion in the saliva, often leading to a metallic taste (e.g., acetazolamide); alteration or decrease in taste receptor function (e.g., captopril—possibly because of decreased salivary magnesium concentration (122); penicillamine—possibly because of decreased zinc availability); and alteration of olfactory function (e.g., chronic use of antihistamines or bronchodilators). Some drugs may not taste good (e.g., potassium preparations, penicillin) or may have a disagreeable texture (e.g., cholestyramine). Antineoplastics may cause dysgeusia and ageusia by inhibiting replication of taste bud cells.

Gastric Irritation. All drugs can potentially cause nausea and vomiting because they all can potentially cause gastric irritation. In a given individual, gastric irritation may not lead to frank nausea but to disagreeable sensations that lead to a loss of appetite. The most commonly consumed drug that causes notable gastric irritation is aspirin.

Altered Gastric Emptying and Intestinal Motility. Alterations in intestinal motility,

whether an increase or a decrease, may cause a loss of appetite. Prokinetic agents such as metoclopramide, domperidone, and cisapride as well as erythromycin increase the rate of gastric emptying and the overall motility of the upper and lower gastrointestinal tract. Patients with gastroparesis may exhibit improved appetite because they no longer feel full after small amounts of food (123). However, the increased lower gastrointestinal motility may suffice to cause decreased appetite, which would counteract the improvement due to more rapid gastric emptying.

Opioids cause considerable delays in gastric emptying and marked constipation (124), which may pose problems following a myocardial infarct and for management of cancer pain (125). Morphine coupled with bed rest leads to loss of appetite and constipation, so increasing dietary fiber intake is important to relieve discomfort and, postinfarct, to prevent arrhythmias caused by straining with bowel movements.

Drugs with anticholinergic activity (e.g., atropine, scopolamine, Pro-Banthine, benztropine mesylate, trihexyphenidyl, tricyclic antidepressants, diphenhydramine) or sympathomimetic activity (e.g., epinephrine, b-adrenergic agents) delay gastric emptying. Delayed gastric emptying may lead to discomfort and loss of appetite, which in turn lead to malnutrition, particularly in the elderly and others whose appetite may already be limited.

Anticholinergics also decrease intestinal motility and cause constipation. The constipation caused by antihistamines, antiparkinsonian drugs, phenothiazines, and tricyclic antidepressants is due to their anticholinergic effects. Drugs that may lead to diarrhea or constipation are listed in [Table 99.8](#).

Constipation
Antacids
Anticholinergic drugs
Anticholinergic agents
Antihistamines
Phenothiazines
Tricyclic antidepressants
Corticosteroids
Clonidine
Ganglionic blocking agents
Iron supplements
Laxatives when abused
Lithium
MAO inhibitors
Muscle relaxants
Opioids
Prostaglandin synthesis inhibitors
Nonsteroidal antiinflammatory drugs
Diarrhea
Adrenergic neuron blockers: reserpine, guanethidine
Antibiotics, particularly broad-spectrum agents
Cholinergic agonists and cholinesterase inhibitors
Erythromycin
Osmotic and stimulant laxatives
Prokinetic agents: metoclopramide, domperidone, cisapride
Quinine

Table 99.8 Drugs That Cause Constipation or Diarrhea

Bezoars. Bezoars, balls of unabsorbed material residing in the stomach, may form from undissolved portions of drugs and from masses of food matter, in particular plant fiber (phytobezoars). Bezoars tend to form in patients with achlorhydria, in whom tablets may not dissolve, and in those with poor gastric emptying, often because of surgical

intervention (126); in patients with autonomic neuropathy due to diabetes mellitus (127); or in patients with alcoholism, especially following variceal sclerotherapy (128). Typical drugs found in bezoars include sucralfate, cholestyramine, aluminum hydroxide gel, and iron and antacid tablets. All of these preparations either form precipitates with foods or require stomach acid for dissolution or both. Bezoars may cause feelings of gastric fullness, pain, nausea, vomiting, and gastric outlet obstruction. Bezoar prevention in susceptible persons consists of changing the drug formulation from solid to liquid when possible; changing the drugs to therapeutically equivalent forms; using drugs to enhance gastric emptying; and using low-fiber diets with restriction of foods listed in [Table 99.9](#) (129).

Table 99.9 Foods to Be Avoided for Prevention of Bezoar Formation

Appetite Enhancement. Several drugs are used therapeutically to enhance appetite in patients with cancer and AIDS (130, 131 and 132). Megestrol acetate, a progesterone analogue, may prove significant for management of poor appetite in patients with a good prognosis (130). In double-blind trials, some (but not all) patients respond to treatment with this drug with increased appetite. At high doses, this drug appears to have a positive metabolic effect, increasing lean and particularly fat body mass. Patients taking the drug report increased feelings of well-being, with relatively few side effects, although development of deep-vein thrombosis and emboli may prove to limit the usefulness of this drug (133).

Dronabinol, a metabolite of cannabinal, the active ingredient in marijuana, is an effective antiemetic. At high doses it increases appetite, sense of well-being, and weight but is associated with side effects such as dizziness and sleepiness (131).

The mechanisms whereby corticosteroids increase appetite are unknown, although the increase is associated with euphoria and may be a central effect (132). Unfortunately, corticosteroids increase total body water rather than lean tissue mass. Cyproheptadine, a serotonin blocker, probably acts by decreasing the antiappetitive effects of serotonin in the central nervous system (132). It also appears to interfere with the regulation of

growth hormone secretion and thereby leads to weight gain and increased growth in children (8).

The phenothiazine and benzodiazepine tranquilizers and lithium carbonate have appetite enhancement as a side effect. These effects are related to both direct pharmacologic effects and the fact that administration of the drugs reduces mental agitation (134).

Drug-Induced Maldigestion and Malabsorption

Drug-induced maldigestion and malabsorption may be due to interactions between the drug and the nutrient or to global changes in gastrointestinal tract function. Unless a drug causes widespread destruction of the intestinal villi or fat malabsorption, drug-induced maldigestion and malabsorption primarily affect minerals and vitamins, rather than macronutrients. One example of an interaction between drugs and nutrients is that between bile acid sequestrants or mineral oil and fats and fat-soluble vitamins. The clinical importance of this drug-induced malabsorption lies in its potential effects on mineral and vitamin absorption.

Global changes leading to maldigestion and malabsorption include increases or decreases in gut motility and changes in the mucosal surface. For example, cancer chemotherapeutic agents and colchicine, which damage the intestinal mucosa because of their antimetabolic effects, may cause generalized malabsorption.

Effects of Drugs on Vitamin and Mineral Status, Requirements, and Activity

Drugs can affect vitamin and mineral status by interfering with absorption, metabolism, and function. The antivitamin or mineral-related effects of drugs may be used intentionally in the treatment of disease or may be an unwanted side effect of drug therapy. Changes in vitamin status that occur as a side effect often have a relatively slow, insidious onset, so the practitioner should anticipate these drug-nutrient interactions by appropriate monitoring.

Antacids

By increasing stomach pH, antacids decrease the bioavailability of vitamin A, folate, thiamin, and phosphate.

Vitamin A and Carotene Malabsorption. Absorption of vitamin A and carotenoids requires release of these compounds from dietary proteins via pepsin proteolysis. Pepsin is rapidly inactivated, and autoactivation of pepsin from pepsinogen is suppressed at pH 5. In addition, aluminum hydroxide adsorbs pepsin above pH 3.

Thiamin Degradation. Thiamin is unstable at high pH and hence is inactivated when taken with antacids.

Folate Malabsorption. When the pH of the upper part of the jejunum is increased after ingestion of sodium bicarbonate, folate absorption is reduced. The clinical significance of this malabsorption is not clear, although it may contribute to the folate deficiency seen in persons who chronically consume alcohol and take sodium bicarbonate for gastrointestinal distress.

Sodium Overload. Sodium overload with development of congestive heart failure can result from intake of antacids containing sodium bicarbonate. The risk is most severe in elderly people with preexisting heart disease who are also consuming high-sodium diets.

Phosphate Depletion. People taking heavy doses of antacids containing aluminum or magnesium hydroxide or mixtures of these substances may develop a phosphate depletion syndrome. Dietary phosphate combines with aluminum and magnesium hydroxide to form insoluble aluminum and magnesium phosphates, which are excreted through the gastrointestinal tract. The risk of phosphate depletion is greatest when the person consumes a low-phosphate diet. Effects of phosphate depletion include muscle weakness (which may be limited to the proximal limb muscles), malaise, paresthesias in the limbs, anorexia, hemolytic anemia, and convulsions (8). Myocardial depression may occur, although not frank congestive heart failure (135). Low-phosphate osteomalacia has developed in a few patients with phosphate depletion (136).

Milk-Alkali Syndrome. The milk-alkali syndrome occurs as a complication of excessive ingestion of soluble, absorbable alkali (e.g., sodium bicarbonate) and milk. It is characterized by hypercalcemia, precipitation of calcium in the kidney, and progressive renal insufficiency. This syndrome occurs in people taking large amounts of sodium bicarbonate or calcium carbonate, particularly those with preexistent renal insufficiency (8).

Use of calcium salt supplements to delay age- or medication (corticosteroid)-related bone loss or to prevent hypertension has the potential to cause the milk-alkali syndrome (137). The current extensive use of calcium carbonate tablets for osteoporosis and hypertension prevention might therefore increase the prevalence of the syndrome, as happened in peptic ulcer patients when the Sippy diet and antacid treatment were in vogue.

Magnesium Overload. Patients with chronic renal failure who are taking magnesium-containing antacids can develop magnesium intoxication. Signs include nausea, vomiting, flushing, impaired respiratory function, and partial or complete heart block.

Iron Malabsorption. Absorption of iron occurs when it is in the ferrous state, at low pH. The elevated pH induced by antacids may lead to iron aggregate formation and conversion of iron to its ferric form. In addition, aluminum hydroxide gels bind iron and thereby decrease its absorption.

H2 Blockers and Proton Pump Inhibitors

Histamine H₂-receptor antagonists and proton pump inhibitors can profoundly decrease stomach acid secretion. Histamine H₂ blockers give a more inconsistent and variable reduction in acidity than do proton pump inhibitors.

Vitamin B₁₂ Malabsorption.

In a review of the literature on H₂ blockers, Force and Nahata ([138](#)) found evidence for a significant effect of histamine H₂ receptor antagonists on vitamin B₁₂ absorption because stomach acid failed to release the vitamin from dietary protein. The malabsorption may become clinically manifest only 2 or more years after initiation of therapy and is a particular hazard for those who may have low stores of vitamin B₁₂ before the initiation of therapy ([138](#)).

Omeprazole therapy decreases cyanocobalamin absorption in a dose-dependent manner at both 20 and 40 mg daily ([139](#)). This effect of omeprazole may be at least partially counteracted by consuming an acidic drink with meals ([140](#)). The clinical importance of this decrease may only become manifest after prolonged (>4 years) administration ([141](#)).

Sulfasalazine

Folate Malabsorption. Sulfasalazine is a competitive inhibitor of intestinal folate transport. Folate malabsorption in patients with inflammatory bowel disease who are receiving this drug depends not only on drug intake but also on whether they obtain sufficient dietary folate ([142](#)).

Sulfasalazine and other NSAIDs with a carboxylic side-chain inhibit folate-dependent enzymes in vitro, including dihydrofolate reductase and phosphoribosylaminoimidazolecarboxamide formyltransferase. The in vivo significance of this inhibition is unknown, although synthesis of serine from glycine and formate is decreased in vitro in mononuclear cells from persons taking these drugs ([143](#)).

Antituberculous Agents

Vitamin D Metabolism. Two drugs used in the treatment of tuberculosis, rifampin and isoniazid, affect vitamin D metabolism, presumably through their effects on the hepatic P450 enzyme, vitamin D 25-hydroxylase ([144](#), [145](#) and [146](#)). Although short-term studies of these drugs have shown marked alterations in vitamin D metabolism and calcium status in nontuberculous subjects ([146](#), [147](#)), longer-term studies of patients receiving the drugs for tuberculosis have not shown clinically significant effects on vitamin D status and calcium and phosphate metabolism ([148](#), [149](#) and [150](#)). Patients with untreated tuberculosis may have abnormally low levels of vitamin D metabolites, so it may be difficult to distinguish the effects of drugs from the effects of the disease itself

(151).

Hydrazone Formation with Pyridoxine. Isoniazid and other carbonyl compounds combine with pyridoxine to form hydrazones. These compounds are potent inhibitors of pyridoxal kinase and place the person at risk for developing peripheral neuritis. The elderly, diabetic, alcoholic, uremic, or pregnant patient is most susceptible to this side effect. Pyridoxine supplementation can prevent development of this complication of isoniazid therapy (8).

Niacin Deficiency. Isoniazid can induce a secondary niacin deficiency with development of pellagra (152); this problem is rare but has been reported in tuberculous patients who have been on a marginal intake of niacin. The deficiency in these patients is thought to result from inhibition of the enzyme kynureninase, which lies in the pathway of nicotinamide nucleotide synthesis from tryptophan. This enzyme is inhibited as a result of complex formation between isoniazid and pyridoxal phosphate (Schiff base formation). Supplementation with nicotinamide may allow chemotherapy to continue.

Interactions of Pyridoxine with Decarboxylases: Effects on L-Dopa and Hydralazine/Cycloserine

Pyridoxine is an essential coenzyme of aromatic L-amino acid decarboxylase. Hydralazine and cycloserine deplete pyridoxine, which leads to defective dopamine production and neurologic signs in persons treated with these drugs. Pyridoxine supplementation can reverse the defect in dopa decarboxylation (8, 153), but sodium excretion is attenuated, which may not be desirable in persons with hypertension (154).

Anticonvulsants

Calcium and Vitamin D Metabolism. The anticonvulsant drugs phenytoin and phenobarbital can cause hypocalcemia, rickets in children, and high-turnover osteoporosis in adults. Phenytoin acts through three mechanisms: decreased calcium absorption, possibly through inhibition of the synthesis of calcium-binding protein; stimulation of the catabolism of 25-hydroxycholecalciferol, with a possible reduction in 24,25-dihydroxycholecalciferol production; and increased catabolism of vitamin K, with reduction in formation of the vitamin K-dependent proteins involved in calcium handling by osteoblasts, in particular osteocalcin (8). Levels of 1,25-dihydroxycholecalciferol appear to be normal, suggesting that the effects on calcium absorption are probably the major reason for the development of bone disorders with these drugs.

Folate Metabolism. High doses of folic acid may counteract the anticonvulsant effects of phenobarbital, phenytoin, and primidone (155). Patients who develop megaloblastic anemia while taking these drugs may respond to folate supplementation with increased seizure frequency. It may be necessary either to change the drugs the patient is taking or to tolerate a degree of anemia, if a change in drugs is not possible. Note that for phenytoin, part of the mechanism for decreased effectiveness with folate supplementation may lie in increased formation and excretion of hydroxylated

metabolites of the drug.

Vitamin K Catabolism. Phenytoin and phenobarbital, probably through their action on hepatic P450 enzymes, increase hepatic catabolism of vitamin K and decrease production of vitamin K–dependent proteins. Infants born to mothers who have taken these drugs in pregnancy are susceptible to neonatal hemorrhage, which may be counteracted by injection of vitamin K (8).

Mineral Oil

Mineral oil acts as both a physical barrier and a lipid solvent and thereby decreases absorption of fat and fat-soluble vitamins.

Bile Acid Sequestrants

Drugs that bind bile acids (e.g., cholestyramine and aluminum-containing antacids) may lead to malabsorption of fats and hence to malabsorption of fat-soluble vitamins, particularly vitamins A and E. Cholestyramine also binds folic acid (156). Although the clinical significance of cholestyramine-induced malabsorption may not be great, patients taking this drug over long periods of time should be monitored for vitamin A and vitamin E status and prothrombin time and should receive folate supplements (157).

Methotrexate and Other Folate Antagonists

The clinical effectiveness of methotrexate and other folate antagonists (e.g., trimethoprim, trimetrexate) depends on their ability to bind tightly to dihydrofolate reductase, displacing folate (see Chapter 26). Drug polyglutamates are formed, and synthesis of folate polyglutamates is diminished. Thymidylate synthetase is inhibited, which in turn leads to inhibition of the synthesis of DNA, RNA, and protein (8). Methotrexate reduces incorporation of deoxyuridine (dU) into DNA and favors incorporation of thymidine into DNA by the alternate pathway. The dU suppression test is abnormal in those who are receiving methotrexate (158).

Methotrexate is used at low dosages for the treatment of rheumatoid arthritis. In this regimen, the risk of antifolate effects is low. Folic acid supplements can further reduce the risk of these side effects (159). Patients with AIDS who are taking trimethoprim for long periods of time are at particular risk for developing folate deficiency. Because bacterial dihydrofolate reductase is a thousandfold more sensitive to trimethoprim than is the human enzyme (8), folate supplementation may be appropriate for these patients (160). Similarly, patients receiving trimetrexate for *Pneumocystis carinii* infection should also receive leucovorin (161).

Methotrexate has a greater affinity than folate for folate-binding protein at the pH optimum for the radiometric assay for plasma folate. It has therefore been proposed that this assay, which involves competitive protein binding in plasma and erythrocytes, should not be used to measure this vitamin in the plasma or erythrocytes of patients

receiving the drug (162).

Nitrous Oxide

Nitrous oxide, long used as an anesthetic and more recently used in the management of patients after cardiac bypass surgery, is a vitamin B₁₂ antagonist. Megaloblastic erythropoiesis and neurologic disorders have been reported in both man and laboratory animals after exposures to high concentrations of this gas, especially in persons whose vitamin B₁₂ status is marginal (e.g., vegans) (163). Exposure may also present a particular hazard to dentists and others who use this anesthetic in office situations (164).

Nitrous oxide oxidizes vitamin B₁₂ and inhibits methionine synthetase. Inactivation of methionine synthetase displaces cobalamin from the enzyme. Furthermore, there is increased formation of inactive cobalamin analogues. In animals exposed to NO₂, the neuropathy can be partially prevented by feeding methionine (165).

Corticosteroids

Corticosteroids administered chronically increase the need for vitamin B₆, calcium, and vitamin D. Table 99.10 shows the nutritionally significant consequences of long-term corticosteroid use.

Gastrointestinal system
Peptic ulceration
Gastric or intestinal perforation
Pancreatitis
Endocrine system and metabolism
Hyperglycemia
Hyperlipidemia
Weight gain
Altered distribution of fat tissue
Hypertension with renal sodium retention and potassium and zinc loss
Skeletal system
Osteoporosis
Growth failure in children
Spontaneous fractures
Immune system
Immunosuppression with increased risk of infection leading to hypermetabolism

Table 99.10 Nutritionally Significant Consequences of Long-Term Corticosteroid Use

Antibiotics and Coagulation

Effects of Antibiotic Therapy on Intestinal Synthesis of Vitamin K. In humans, intestinal microbes synthesize vitamin K in the form of menaquinones. Thus it is theoretically possible for a person taking broad-spectrum antibiotics to become deficient

in this vitamin. Indeed, menaquinone levels are diminished in the livers of persons who have taken broad-spectrum antibiotics (166). However, the main sources of liver vitamin K are phylloquinones in the diet (167), and phylloquinone levels were unchanged in the livers of persons taking broad-spectrum antibiotics (166). Conversely, bacterial vitamin K cannot compensate for a dietary deficiency in vitamin K (168).

Cephalosporin Antibiotics. Cephalosporin antibiotics with *N*-methylthiotetrazole sidechains can decrease clotting through inhibition of hepatic vitamin K epoxide reductase, with the appearance of PIVKA II (prothrombin induced in vitamin K absence II) (169). This decrease in vitamin K function is only measurable in persons who are otherwise vitamin K deficient (170) and, in fact, may be only a minor cause (if at all) of clotting problems in persons receiving these antibiotics (171). Prevention is accomplished by providing vitamin K injections to persons receiving these drugs.

Doxorubicin Doxorubicin produces a dose-dependent cardiomyopathy when the total cumulative dose exceeds 500 mg/m². In laboratory animals, the histopathologic aspects of the cardiac lesion are similar to those of vitamin E deficiency and appear to be due to free radical reactions that cause peroxidation of membrane lipids. The incidence and severity of the doxorubicin-induced cardiac damage has been reduced by administration of vitamin E to laboratory animals, but this vitamin has not been effective in preventing doxorubicin cardiotoxicity in man (172).

Drugs That Inhibit Riboflavin Absorption and Metabolism

Psyllium hydrophilic mucilloid decreases absorption of pharmacologic doses of riboflavin (173). The clinical importance of this finding is unknown. Phenothiazines, the tricyclic antidepressants, and quinacrine inhibit conversion of riboflavin to FMN flavokinase. Riboflavin supplementation may reverse this effect (8).

Vitamin B₆ Analogues: Hydralazine and Cycloserine

Hydralazine and cycloserine are analogues of pyridoxine. Concomitant administration of pyridoxine supplements may reduce the incidence of neurotoxicity caused by these drugs (8).

Diuretics

Electrolyte Imbalance. Because diuretics act by altering renal excretion of sodium and potassium, they may lead to the development of electrolyte imbalance. Common drugs that cause potassium deficiency include thiazide, loop-type diuretics, and laxatives. The potassium-losing diuretics deliver large amounts of sodium to the distal tubule, where part of the sodium is exchanged for potassium, with loss of potassium. Drugs that cause potassium depletion may damage the renal tubule and thereby cause secondary depletion of magnesium and zinc (174).

Drugs that can cause hyperkalemia include spironolactone, an aldosterone antagonist, and triamterene and amiloride, which appear to block the luminal sodium channels that

drive potassium excretion in the late distal tubule and collecting duct (8). Persons with impaired renal function or those taking a high potassium diet or potassium supplements are particularly prone to develop hyperkalemia when taking these drugs.

Drug-induced mineral depletion is commonly multifactorial. For example, in the elderly, it may result from concurrent use of several drugs that have this side effect, as well as decreased intake of the mineral. Factors predisposing to mineral depletion include prolonged drug intake and renal disorder, including the age-related decline in renal function, and catabolic diseases, including metastatic cancer.

Calcium Status. Thiazide diuretics cause renal calcium retention and can cause hypercalcemia, although this side effect is relatively uncommon and may only be temporary. However, thiazide users do have a greater bone mineral content than age- and sex-matched nonusers. It has been suggested that thiazide drugs might have a therapeutic role in the management of osteoporosis (8).

Nondiuretic Antihypertensive Agents

The antihypertensive agent diazoxide, which increases the proximal tubular reabsorption of sodium, can cause sodium overload (8). Increased serum potassium levels have been reported with use of b-blocking drugs in conjunction with potassium-sparing diuretics (8).

Oral Antiglycemic Agents

The oral antihyperglycemic agent metformin decreases absorption of vitamin B₁₂ and folate, although significant hematologic effects appear to be rare (175).

Low-Molecular-Weight Heparin

Low-molecular-weight heparin is commonly used for prevention and treatment of thromboembolism. Heparin inhibits aldosterone biosynthesis. Treatment with low-molecular-weight heparin increases serum potassium levels, so the potassium status of persons treated with this drug should be monitored (176).

Alcohol

For a discussion of the effects of alcohol on vitamin and mineral status and metabolism, see [Chapter 94](#).

DRUG-FOOD AND DRUG-ALCOHOL INCOMPATIBILITIES

Food and drug incompatibilities usually result from drug-induced inhibition of enzymes required in the catabolism of potentially toxic endogenous metabolites. These are outlined in [Table 99.11](#).

Reaction	Drug	Food	Sign/Symptoms
'Niacin poisoning,' probably due to inhibition of MAO activity of drug'	Isosrelol	Certain kinds of fish, including tuna and sardines ¹	Redness of face, itching of eyes, face and palms, severe headache
Tyramine reactions	MAO inhibitors	Tyramine-containing foods	Hypertensive crisis
Oxalufan reaction	All drugs that are aldehyde dehydrogenase inhibitors ²	Alcohol, in food or in liquor/ other solutions applied to the skin	Flushing, nausea, vomiting, variable degree of chest and/or abdominal pain
Hypoglycemia	Sulfonamides	Alcohol, including sweet or fermented drinks with alcohol	Hypoglycemia, manifested as weakness, mental confusion, irrational behavior, loss of consciousness

¹See text

²See text

¹Including codfish, herring, salmon, mackerel, sardines, and mussels; ²including penicillins, penicillins, and the phthalimide derivatives, sulfonamide, sulfonamide

Table 99.11 Drug-Food and Drug-Alcohol Incompatibilities

EFFECTS OF NONTHERAPEUTIC DRUG COMPONENTS AND NONNUTRITIVE COMPONENTS OF FOODS

Food additives, nonnutritive components of foods, and excipients and preservatives in medications may lead to untoward effects when ingested.

Monosodium Glutamate

Monosodium glutamate (MSG) is added to food to enhance flavor. Although MSG is classically thought of in connection with "Chinese restaurant syndrome," in fact it is found in numerous prepared foods. MSG causes symptoms that mimic those of angina pectoris.

Tartrazine

Tartrazine (Yellow Dye no. 5) is a color additive used in both foods and drugs. Patients may have allergic reactions to this dye, so the Food and Drug Administration requires that its presence be noted on the labels of both foods and drugs.

Sulfites

Sulfites are added to foods, beverages, and drugs as preservatives because of their antioxidant properties. They can cause severe allergic reactions. Sulfites are added as sulfur dioxide, sodium sulfite, sodium and potassium bisulfite, and sodium and potassium metabisulfite.

Licorice

Black licorice contains glycyrrhizic acid, a compound that has mineralocorticoid activity through inhibition of 11- β -hydroxysteroid dehydrogenase (8). It thereby enhances sodium and water retention and increases potassium excretion. Consumption of licorice (as little as “a couple of twists” a day) can counteract the effects of diuretics and increase the mineralocorticoid effects of corticosteroids.

Lactose

Many drugs contain lactose as an excipient. Although the amount per capsule or pill may be small, lactose-intolerant patients taking large amounts of these drugs may experience symptoms, including bloating and diarrhea.

Oxalates

Oxalates are absorbed when they are not bound to calcium or magnesium in the gut. When absorbed, they are excreted by the kidney, where they precipitate as calcium or magnesium salts. Excessive oxalate consumption in situations when calcium or magnesium is unavailable (e.g., with consumption of aluminum hydroxide gels that bind calcium and magnesium) may lead to formation of kidney stones and interstitial renal failure.

Aspartame

Certain drugs contain phenylalanine, usually in the form of aspartame, which may be detrimental to persons with phenylketonuria.

Methylxanthines

Caffeine, other methylxanthines, and theophylline are all metabolized by demethylation and xanthine oxidase activity, although the major pathway for theophylline catabolism involves hydroxylation. Because of the common degradative pathways and the fact that the therapeutic range for theophylline is very narrow, methylxanthine consumption by persons receiving theophylline and its congeners should be kept constant. A person taking theophylline who decreases consumption of methylxanthines (caffeine, theobromine in coffee, teas, chocolate, cola drinks) must receive a higher dose of theophylline to maintain therapeutic blood levels. When methylxanthine consumption is decreased, theophylline is metabolized more rapidly and blood levels of the drug cannot be maintained within a therapeutic range unless the dose is increased. Increased methylxanthine consumption would lead to increased blood levels of theophylline and resultant toxicity.

PROBIOTICS

Probiotics is the term given to live bacteria, often coupled with substances that enhance bacterial growth, which are either components of foods or are added to foods to provide

a pharmacologic effect. These bacteria (usually *Lactobacillus* spp. and *Bifidobacterium* spp.) multiply in the gastrointestinal tract and displace pathogenic bacteria.

Probiotics have been used for the prevention and treatment of antibiotic-associated diarrhea, acute infantile diarrhea, and recurrent *Clostridium difficile* infection (178). There is reason to believe that they may be effective in peptic ulcers associated with *Helicobacter pylori* (180).

The lower gastrointestinal tract is critically dependent on bacterial metabolism for provision of specific nutrients, such as short-chain fatty acids. These bacteria require nutrients derived from enterally delivered food. Antibiotics wipe out these essential bacteria, while TPN does not provide the luminal nutrients they require. With antibiotics or TPN, gut mucosal atrophy can occur, with increased bacterial translocation and sepsis (180). Probiotics also stimulate local immunity and thus may prevent bacterial translocation immunologically as well as through trophic effects on the gut (181).

For probiotics to regenerate the gut flora following treatment with antibiotics, the probiotic bacteria must be antibiotic resistant and adhere readily to the gastrointestinal tract mucosa. Probiotics are usually given in a vehicle that enhances bacterial multiplication. Some vehicles are the actual foods created by bacterial action, such as fermented foods (sour milk, yogurt); some probiotic bacteria are added to foods accompanied by galactooligosaccharides, which serve as substrates for their growth (182).

Complex carbohydrates coupled with surfactant lipids and glutamine are important for maintenance of the probiotic flora. In this respect, oat bran appears especially useful because it is high in glutamine, surfactant lipids, and water-soluble, fermentable b-glucans (183). Elemental enteral formulae, which do not contain proteins or complex carbohydrates, are poor substrates for these bacteria, because the components of the formulae are absorbed in the proximal tract and do not reach the lower intestine in any quantity.

There is evidence that probiotics may have beneficial effects on blood cholesterol levels (184), possibly through action of *Lactobacillus*-derived bile salt hydrolases (185), which may help prevent gastrointestinal carcinogenesis (186).

Despite their overall benign profile, lactobacilli do have pathogenic potential in certain populations (187). They are involved in formation of dental caries and in septicemia, rheumatic vascular disease, and infectious endocarditis. Subjects who are immunocompromised or elderly and who are receiving broad-spectrum antibiotics are particularly susceptible to these complications. It appears that the capacity of the lactobacilli to aggregate platelets and to adhere to collagen (particularly type V collagen, which is associated with sites of damage) is indicative of this pathogenic potential (187). However, in general, the pathogenic potential of probiotics appears to be very low (188).

For a review of the status of probiotics, see Elmer et al. (179).

FOOD-DRUG INTERACTIONS AND THE JOINT COMMISSION ON ACCREDITATION OF HEALTHCARE ORGANIZATIONS (JCAHO)

In its 1996 accreditation standards, the JCAHO cited the issue of food-drug interactions as important in the care of patients (4). The commission particularly emphasized the importance of considering food-drug interactions in the safe use of medication, in provision of nutrition care, and in education. Regulation PF.2.2.3 specifically states that the patient should receive “instruction on potential drug-food interactions and counseling on nutrition intervention and/or modified diets, as appropriate.”

The JCAHO targeted five drugs for specific monitoring, to ensure that both in-hospital and outpatient administration of these drugs is appropriate. These drugs are captopril, sucralfate, prednisone/dexamethasone, and warfarin. These drugs were chosen by a multidisciplinary group consisting of persons in pharmacy, nursing, dietetics, and nutrition, based on (a) the high risk associated with these drugs if they are not prescribed and administered appropriately and (b) their high frequency of use and the chronicity with which they are taken. Extensive standards were developed to implement this monitoring, including standards for staff and patient education and standards for administration of these drugs in conjunction with diet and the timing of meals.

ACKNOWLEDGMENTS

This chapter is dedicated to the memory of Daphne A. Roe, M.D., extraordinary colleague and friend. Some of her text has been included in this chapter.

[Chapter References](#)

Enteral feeding is a method of providing nutrient solutions into the gastrointestinal (GI) tract through a tube. This method is used for nutritional support in patients who cannot ingest or digest sufficient amounts of food but have adequate intestinal absorptive capacity. The increasing popularity of enteral feeding in various clinical states can be attributed to a number of factors:

1. Development of simple, low-risk procedures for placement of tubes in the GI tract, particularly percutaneous endoscopic gastrostomies and jejunostomies
2. Availability of a wide variety of commercial enteral feeding formulas with diverse nutrient components that allow a choice of suitable formulas for patients with limitations in GI function or those who require special nutrition
3. Advantages of enteral feeding over the alternative of parenteral feeding: preservation of the structure and function of the GI tract (absence of nutrients in the intestines is associated with atrophy of the intestinal mucosa and decreased function of the pancreatic-biliary system), more efficient nutrient use, fewer infectious and metabolic complications, greater ease of administration, and lower cost

HISTORY

The history of enteral feeding has been reviewed by Randall (1). The practice of placing nutrients into the GI tract while bypassing the mouth originated in ancient times with the Egyptians, who used nutrient enemas for preservation of general health. Greek physicians used enemas containing wine, whey, milk, and barley broth to treat diarrhea and provide nutrients. In the 19th century, European physicians installed various foods and liquids in patients' rectums, including beef extracts, milk, and whiskey. Rectal feeding was widely used until the beginning of the 20th century, when Einhorn pointed out its inadequacies (2). Capivaccus, a Venetian physician, is considered the first (in 1598) to use a hollow tube attached to an animal's bladder for feeding into the esophagus. The use of a small silver tube passed from the nose to the esophagus was reported in 1617 for feeding patients suffering from tetanus. A major development in provision of nutrition through tubes occurred at the end of the 18th century, when John Hunter, a famous surgeon at the time, proposed that a nasogastric tube be made from eel skin to feed a patient suffering from neurogenic dysphagia. The tube was made and used successfully for 5 weeks, after which the patient regained his ability to swallow. The use of nasogastric tubes both for feeding and for emptying the stomach became widespread in the 19th century.

The concept of early postoperative enteral feeding was introduced by Andresen in 1918 when he started jejunal feeding in a patient following a gastrojejunostomy (3). This practice gained increasing popularity because of the realization that following an operation, small bowel peristalsis is preserved, although the stomach remains nonmotile for a few days. Regular foodstuffs were mixed and ground or blenderized into a fine solution, which was instilled into the stomach through a tube. In 1959, Barron reported on enteral feeding in the postoperative period in a few hundred patients who had undergone various surgical procedures (4). He used natural juices and foods in finely dispersed solutions. He also infused GI secretions collected from drainage from biliary, pancreatic, gastric, and intestinal fistulas; these were introduced through polyethylene tubes passed through the nose.

Specialized enteral feeding formulas appeared in the 1930s with the introduction of casein hydrolysate for use in both enteral and parenteral feeding. Subsequently, crystalline amino acids were used in combination with various amounts of carbohydrates, fats, minerals, and vitamins. The first commercial enteral feeding formula was Nutramigen, introduced to the market in 1942 for treatment of children with intestinal diseases and allergies. A major advance in knowledge and use of chemically defined formulas was achieved through studies sponsored by the National Aeronautics and Space Administration (5). These studies demonstrated that normal volunteers could be maintained in a normal nutritional and physical status while being fed solely with chemically defined solutions during a 6-month period. Based on the results of these studies, Randall and colleagues started a series of studies using commercial chemically defined diets (1) and demonstrated the usefulness of these diets given to patients with a variety of GI diseases.

FEEDING TUBES

Enteral feeding requires administration of the nutrient solutions (or more properly, liquid formulas, because they are rarely true solutions) through a tube into the upper GI tract. (The ancient practice of feeding through the rectum has been abandoned.) At present, enteral feeding devices can be divided into two major categories—those entering the GI tract through the nose (nasogastric or nasoenteral tubes) and those entering through the abdominal wall (gastrostomies, duodenostomies, or jejunostomies). Occasionally, feedings are given through a pharyngostomy or an esophagostomy.

Nasogastric and Nasoenteral Tubes

Numerous types of nasogastric and nasoenteral tubes are available commercially. Most are made of silicone or polyurethane. Tubes used in adults vary in length from 30 to 43 inches, with diameters from 5 to 16 French. The shorter tubes are used for nasogastric feeding and the longer tubes are used for nasoduodenal or nasojejunal feeding, usually in patients who are at an increased risk from aspiration.

Most tubes have tips containing tungsten or silicone to facilitate passage through the GI tract. However, whether a weighted tip is necessary for placement or maintenance of the tube in the GI tract has been questioned, and tubes without weighted tips are now available. The tubes come with a stylet that facilitates insertion through the nose and into the GI tract. Nasogastric tubes are generally used for short-term enteral feeding, mostly in the hospital. They are placed at the bedside by health professionals, and verification of the location of the tip of the tube in the stomach or small intestine is required. This verification can be made by obtaining a radiograph of the abdomen. Listening for airflow over the upper abdomen can provide misleading information and is not recommended. Airflow can be heard over the epigastrium even if the tip of the tube is in the chest (6) and can thus lead to serious complications. Color, pH, and quantity of aspirated fluid are also inadequate for determining the location of the feeding tube tip. Nasojejunal rather than nasogastric tubes should be used whenever there is risk for aspiration or gastric motility is impaired. Advancement of such tubes from the stomach into the small bowel may be facilitated by administering prokinetic drugs: erythromycin, metoclopramide, or Cisapride (7). Placement of the tubes in the duodenum or jejunum can also be assisted by endoscopic (8) or radiographic techniques (9).

Complications related to nasogastric and nasoenteral tubes can be divided into two categories: those resulting from insertion of the tube and those arising thereafter. Insertion-related complications include trauma and bleeding from the nose and upper GI tract, perforation, misplacement of the tube into the respiratory tract (particularly in unconscious patients), respiratory compromise caused by coiling of the tube in the nasopharynx, aspiration pneumonia, and vomiting of gastric contents as a result of pharyngeal irritation. Postinsertion complications include migration of the tube (especially into the esophagus), aspiration of infused solutions, erosion of the GI tract mucosa by the tip of the tube, and ear and nose infections.

Malfunction of nasogastric and nasoenteral tubes occurs commonly because of clogging

with nutrition solutions or medications, kinking, or bursting (secondary to forceful injection of solutions). These malfunctions can be avoided with appropriate care of the tube. Complication rates of feeding tubes vary, depending on the experience of the person inserting the tube and on the care of the tube after it is inserted. The reported complication rate varies between 7.6 and 19% (10, 11). The average time of use of nasogastric and nasoenteral tubes is 10 days (8). A comprehensive review of nasogastric and nasoenteral feeding tubes, techniques, complications, and recommendations for practice has been published recently (12).

Gastrostomy and Jejunostomy Tubes

For long-term enteral feeding (more than 2 weeks), gastrostomy or jejunostomy tubes are advantageous for the following reasons: (a) they have a larger diameter (15–24 French) and thus do not tend to clog, and wider tubes also allow easier and more rapid administration of feeding solution and medications; (b) the risk of aspiration is considerably decreased because they are fixed in the stomach or upper intestines and do not migrate into the esophagus (as may happen with nasogastric tubes; and (c) they are more convenient and aesthetically acceptable to the patient. A recent randomized study demonstrated that feeding patients with acute strokes through a gastrostomy tube was associated with more optimal provision of nutrients, a better nutritional state, and less mortality than feeding through a nasogastric tube (13). The various methods of placement of gastrostomy and jejunostomy tubes have been reviewed extensively (14). In a prospective study comparing nasogastric tube feeding with percutaneous endoscopic gastrostomy (PEG) feeding in patients with neurologic dysphagia, the PEG group received 93% of the prescribed feeding compared with 55% in the nasogastric tube group. Most of the failures in the nasogastric tube group were attributed to tube dislodgement (15).

Gastrostomy and jejunostomy tubes can be placed surgically, endoscopically, or radiologically. For many years only the surgical technique was used. Although the operation is relatively minor, it requires a laparotomy, which has a complication rate of 2.5 to 16% and a mortality rate of 1 to 6% (16, 17 and 18). An alternative surgical technique for placement of gastrostomy and jejunostomy tubes uses the laparoscope for access into the abdomen. Experience with this technique is still limited (19). Radiologic techniques have been developed for placement of percutaneous gastrostomies and jejunostomies (20). The advantage is the more aseptic procedure; however, the radiologically placed tubes are usually of small diameter and tend to clog. The radiologic techniques are also considerably more expensive than the endoscopic techniques (21).

In recent years, the PEG has become the most commonly used method because of the ease of the procedure, its safety, and the ability to perform the procedure on an outpatient basis. The technical aspects of the procedure have been reported (22, 23). In patients with gastric resection and those with increased risk for aspiration, (e.g., gastroparesis, severe reflux, neurologic disorders) jejunal tubes can be placed using a modification of the technique of endoscopic gastrostomy tube placement (24). Such percutaneous endoscopic jejunostomy (PEJ) tubes can be placed directly into a jejunal loop. This technique requires a high level of expertise because of the small diameter of the jejunum compared with that of the stomach. An alternative technique is to place a

wide PEG tube (28 French) through which a small-diameter (usually 8 French) jejunal tube is passed into the stomach and carried into the jejunum by forceps passed through the endoscope. However, the narrow jejunal feeding tube tends to clog and to migrate.

Endoscopic placement of PEG and PEJ tubes is associated with a morbidity rate of 5 to 15% and a mortality rate of 0.3 to 1% ([22](#), [23](#) and [24](#)). The tubes function well in the long term, with few complications ([23](#)). Active patients who require long-term enteral feeding can benefit from a skin-level button gastrostomy or jejunostomy ([25](#)), which is less obtrusive and more convenient than the regular PEG or PEJ tubes.

ENTERAL FEEDING SOLUTIONS

More than 100 commercial solutions are available for enteral feeding. The names and types of various enteral feeding products and the companies that produce them are listed in the Appendix Table VI-A-40-a. The composition of different solutions varies greatly, with some intended for general nutrition and others designed for specific metabolic or clinical conditions. In addition to, or instead of, using commercial products, patients can blenderize regular foods and use them for enteral feeding. Such foods can be easily administered through PEGs and PEJs because of the wide diameter of the tubes.

Solutions used for enteral feeding have been classified according to various criteria. The names given to different classes of solutions have not always been consistent and often overlap, thus leading to lack of clarity and confusion. The general term *medical foods* has been used since 1989 by the United States Food and Drug Administration (FDA) to define enteral nutrition products ([2](#)):

Medical foods (MF) are distinguished from other foods for special dietary purposes or foods which make health claims (e.g., fiber in relation to cancer) by the requirement that they (MF) be used under medical supervision. In general, in order to be considered a MF a product must, at a minimum, meet the following criteria:

- The product is labeled for the dietary management of a medical disorder, disease, or condition.
- The product is labeled for the dietary management of a medical disorder, disease or condition.

The definitions and regulatory aspects of enteral feeding products have been summarized by Talbot ([27](#)).

The term *defined formula diets* was suggested as a general term to indicate that the ingredients (including nutrients processed from foods and/or relatively purified compounds, simple or complex) are prepared commercially by designated procedures so that their composition is established fairly well, although not necessarily with chemical precision ([28](#)).

The term *elemental* has been used mostly to indicate formulas containing predigested

protein. Most of the so-called elemental solutions, however, are not elemental in the chemical sense (see below).

As stated above, solutions for enteral feeding can be classified in different ways. The following classification is based on practical considerations according to the clinical indications for the solution:

Blenderized foods: Natural foods, semiliquified in a blender, which can be used to provide nutrition by the oral route or through a tube

Polymeric solutions: Solutions containing macronutrients in the form of isolates of intact protein, triglycerides, and carbohydrate polymers, which can be used orally or through a tube and provide complete nutrition

Monomeric solutions: Solutions usually containing proteins as peptides and/or amino acids, fat as long-chain triglycerides (LCTs) or a mixture of LCTs and medium-chain triglycerides (MCTs), and carbohydrates as partially hydrolyzed starch maltodextrins and glucose oligosaccharides; these solutions are often used for patients with impaired digestion or absorption, but it is questionable whether they are necessary or more advantageous than polymeric solutions

Solutions for specific metabolic needs: Solutions intended for patients who have unique metabolic requirements—inborn errors of metabolism, renal failure, hepatic failure, etc.

Modular solutions: Nutritional components that can be given by themselves or be mixed with other enteral products to provide solutions that meet special nutritional or metabolic needs of a given patient (e.g., increased calories, increased minerals)

Hydration solutions: Solutions providing minerals, water, and small amounts of carbohydrates.

Natural Foods

Blenderized natural foods are available commercially or can be prepared at home. Commercial blenderized food solutions are prepared from milk, beef, fruits, vegetables, and fiber; hence their nutrient content is not determined precisely. Although they have the advantage of being “natural foods,” they are prepared from a limited number of food items, and thus, their nutritional completeness is not ensured. Commercial blenderized food products are usually more expensive than others. Currently the use of blenderized products is limited. The ranges of the nutrient contents are listed in [Table 100.1](#).

	Energy (kcal)	Protein (g)	Carbohydrate (g)	Fat (g)	Water (g)
Energy	1.0-1.2	1.0-1.2	1.0-1.2	1.0-1.2	1.0-1.2

Table 100.1 Ranges of Nutrient Content of Enteral Feeding Products

Patients who use enteral feeding in the home can prepare blenderized foods from regular foods in the household. If this practice is used, nutritional adequacy of the blenderized foods must be ensured.

Polymeric Solutions

The term *polymeric formulas* refers to those that contain macronutrients in the form of isolates of intact protein, triglycerides, and carbohydrate polymers. A wide variety of polymeric commercial enteral feeding solutions is available. In most of them, protein constitutes 12 to 20% of total calories; carbohydrates, 40 to 60%; and fats, 30 to 40%. In the standard formulas, the ratio of nonprotein calories:nitrogen is about 150 kcal/g nitrogen. In the high-nitrogen polymeric solutions, this ratio can be as low as 75 kcal/g nitrogen.
