Infections caused by fluconazole-resistant organisms, such as *Candida krusei* and *Candida glabrata*, have become all too common, with many centers reporting that more than 50% of their *Candida* isolates are non-*albicans* species that are usually resistant to azoles.¹⁶⁴ Caspofungin was recently shown to be at least as effective as IV amphotericin B in a prospective randomized double-blind trial in patients with deep *Candida* infections, most of whom had candidemia¹⁷⁶; most notably, caspofungin was associated with a greatly reduced rate of study drug withdrawal because of adverse events (2.6% versus 23.2%; $P = 0.003$). Intravenous caspofungin, which has a low incidence of side effects and can be given once daily, can now be considered a first-line drug for initial treatment of deep invasive candidal infection in centers with high rates of infection caused by non-*albicans* species, pending identification and susceptibility of the bloodstream isolate.

Hepatosplenic candidiasis is a more indolent form of visceral candidiasis that typically presents as persistent fever in a cancer patient who is recovering from granulocytopenia.¹⁷⁷ Blood cultures are usually negative; however, imaging with CT demonstrates multiple small nodules in the liver and spleen (Figure 76.8), and occasionally in the lungs, kidneys, or bone as well. Cultures of material obtained by percutaneous aspiration or biopsy can confirm the diagnosis but because of the small size of the infected nodules may be negative. Therefore, most clinicians initiate therapy (see Table 76.11) on the basis of radiographic findings and only proceed to invasive diagnostic procedures when patients remain refractory to treatment.

FIGURE 76.8. Hepatosplenic candidiasis in a patient with acute myelogenous leukemia seen on computed tomography (CT) scan. Multiple nodules can be seen in the liver and spleen. ASPERGILLUS

Aspergillus spp. are ubiquitous environmental organisms, encountered most often in rural areas but also found throughout most hospitals. Invasive infections caused by *Aspergillus* spp. are an increasing problem in many hematology and solid organ transplant centers, with incidence rates of 5% to 24% among patients with acute leukemia.¹⁷⁸ Invasive aspergillosis is most often a complication of severe and prolonged granulocytopenia, and the duration of granulocytopenia is the most powerful predictor of risk of invasive aspergillosis. The median time to onset of disease in patients with severe granulocytopenia is 17 days and, historically, the majority of cases occur within 90 days in patients undergoing BMT,¹⁶³ although recent studies have found an increasing number of patients with invasive aspergillus that developed in 90 days or more.^{179,180} Other risk factors associated with invasive aspergillosis include receipt of OKT3 antibodies, active CMV disease, and renal failure.¹⁶³ The most commonly isolated

species have been *Aspergillus fumigatus* (more than 90% of all proven infections), *Aspergillus flavus*, *Aspergillus niger*, and *Aspergillus terreus*.

Aspergillus can infect any organ, but sinopulmonary disease is the most common manifestation. Infections often present insidiously in patients with granulocytopenia and fever may be the only manifestation. Dull chest pain that may become pleuritic in nature, cough, and sinus congestion are also common. Hemoptysis, although suspicious for invasive pulmonary aspergillosis, is relatively uncommon. Up to half of patients with lung involvement have disseminated disease that can involve the central nervous system, gastrointestinal tract, kidney, liver, or skin.¹⁶³ Less common presentations include isolated skin lesions, often at sites of vascular catheter insertions¹⁸¹ or isolated gastrointestinal involvement,¹⁶³ possibly the result of ingestion of water containing these organisms.¹⁸² Despite advances in diagnosis and treatment, mortality in patients with invasive aspergillosis remains high, 90% in BMT patients and nearly 80% in patients with leukemia.¹⁸³

The diagnosis of invasive *Aspergillus* infection remains a formidable challenge. Chest radiographs are completely normal in 10% of patients with documented infection.¹⁸⁴ Chest CT is read as normal in only 3% of cases, and up to 85% of infected patients have characteristic radiographic findings, such as a "halo"¹⁸⁵ or "crescent"¹⁸⁶ sign. *Aspergillus* species are rarely isolated from expectorated sputum, and cultures of bronchoalveolar lavage (BAL) fluid are positive in only 20% of cases in most series; however, a positive culture for *Aspergillus fumigatus* has a very high positive predictive value for invasive disease in high-risk patients, in excess of 75%.¹⁸⁷ Transbronchial biopsy increases the diagnostic yield to 75%.¹⁸⁴ Molecular diagnostic tests that detect the presence of circulating galactomannan, a fungal cell wall constituent, and PCR techniques to detect ribosomal genetic material conserved across *Aspergillus* species, may eventually abrogate the need for invasive tests.¹⁶³ The sequential use of an ELISA to detect galactomannan was found to have an 87.5% positive predictive value and a 98.4% negative predictive value in a recent prospective trial in neutropenic BMT patients.¹⁸⁸

The treatment of invasive aspergillosis has also undergone evolution. Traditional therapy has relied upon IV amphotericin B deoxycholate in doses of 1 to 1.5 mg/kg/day (Table 76.12); however, at these doses, nephrotoxicity is ubiquitous.

TABLE 76.12. Treatment options for patients with invasive infections caused by *Aspergillus* species.

Drug	Route	Dose	Duration
Amphotericin B deoxycholate	IV	1.0–1.5 mg/kg daily	Until evidence of infection has resolved
Liposomal amphotericin B (Ambisome)	IV	5.0–7.5 mg/kg daily; doses as high as 15 mg/kg daily have been used safely	Same
Amphotericin B lipid complex (ABLCL)	IV	5.0 mg/kg daily	Same
Amphotericin B colloidal dispersion (ABCD)	IV	3–4 mg/kg daily	Same
Caspofungin	IV	70 mg loading dose 50 mg daily	Same
Itraconazole (suspension)	IV PO	6–12 mg/kg daily 200 mg bid	Same Same
Voriconazole	IV PO	6 mg/kg q12 for 2 doses 4 mg/kg bid thereafter IV load as above 200 mg bid thereafter	Same Same
Combination therapy	Investigational		

Despite the use of lipid-based agents, such as liposomal amphotericin B and amphotericin B lipid complex, in daily doses of 5 to 10 mg/kg, treatment-related side effects have remained high, prompting a search for less toxic alternatives. Caspofungin, a member of a new class of drugs that inhibit the synthesis of 1,3- β -glucan, an integral component of the fungal cell wall, was approved for the treatment of invasive aspergillosis refractory to treatment with other agents in 2001.¹⁸⁹ Itraconazole also possesses activity against *Aspergillus* spp. and appeared to be equivalent to amphotericin B deoxycholate in a retrospective analysis¹⁹⁰; however, bias toward treatment of less severely ill patients limits the generalizability of this report, and we do not believe that clinicians should rely upon itraconazole alone for the treatment of invasive aspergillus infections at this time.¹⁹⁰ On the other hand, the newly released triazole, voriconazole, was recently shown to be superior, in terms of fewer side effects and improved clinical response (53% versus 32%) and patient survival (71% versus 58%), compared to amphotericin B deoxycholate in a large multicenter randomized trial.¹⁹¹ As a result, voriconazole is now widely considered the standard of therapy for patients with documented *Aspergillus* infections. The use of antifungal drug combinations for treatment of invasive aspergillosis is currently under investigation, with caspofungin combined with lipid-based amphotericin B or voriconazole showing the most promise.^{192,193}

ZYGOMYCETES

Zycomycosis, known more commonly as mucormycosis, is a devastating infection caused by a variety of filamentous fungi in the order Mucorales. Risk factors for mucormycosis include diabetic ketoacidosis, iron overload, and, increasingly, prolonged granulocytopenia.¹⁹⁴ Rhinocerebral disease is the most common presentation in patients with diabetic ketoacidosis; however, pulmonary involvement, very similar to that seen with invasive aspergillosis, appears to be the most common manifestation of Mucorales infection in patients with cancer.¹⁹⁴ A black eschar may be seen on the nasal mucosa or soft palate in rhinocerebral disease, or on the skin in disseminated disease (Figure 76.9), or at sites of intravascular catheter insertion.¹⁹⁵ Involvement of the central

FIGURE 76.9. Necrotizing rhinocerebral infection with *Rhizopus*. Note the black eschar on the nose. [By permission of Stone DR, Gorbach SL (eds) Atlas of Infectious Diseases. Philadelphia: Saunders, 2000.]

nervous system can occur either as a result of direct extension from the sinuses, with rhinocerebral disease, or hematogenously, in disseminated disease.

Diagnosis of Mucorales infection rests on histopathologic examination or culture of a biopsy specimen, as blood and respiratory tract specimens are almost always culture negative, and the radiographic presentation may not be distinguishable from that seen with invasive pulmonary aspergillosis. It is important to recognize that the newer antifungals, voriconazole and caspofungin, have no activity against zygomycetes. Treatment begins with aggressive debridement whenever possible, combined with the use of conventional (1.0 to 1.5 mg/kg/day) or lipid-based amphotericin B (5 to 7.5 mg/kg/day). Despite treatment, mortality is greater than 75% in cancer patients.¹⁶³

FUSARIUM

Fusarium species are soil saprophytes that have been increasingly implicated as a cause of fatal infection in patients with cancer, primarily patients with acute leukemia or those undergoing BMT.¹⁹⁶ Colonization originating from contaminated hospital water systems has been described,¹⁹⁷ although the significance of this finding has been challenged.¹⁹⁸ Fusariosis may be acquired either as a result of inhalation, with the development of pulmonary disease indistinguishable from invasive pulmonary aspergillosis, or from direct inoculation through the skin or an IVD access site. In all settings, hematogenous dissemination with widespread cutaneous involvement is common, and blood cultures are positive in up to 50% of patients with documented systemic fusariosis.¹⁶³ Recovery from granulocytopenia is critical to patient survival: a recent study found that all patients who had refractory granulocytopenia died of fusarium infection.¹⁹⁹

Fluconazole and itraconazole are inactive against *Fusarium* species, and amphotericin B (1.0 to 1.5 mg/kg/day) is still considered the first line of therapy. Voriconazole possesses activity against *Fusarium* species in vitro, and its clinical use was associated with a complete or partial response in 43% of patients in a recent small trial.¹⁹⁴ Granulocyte infusions may have an important adjunctive role in infected patients with refractory granulocytopenia.¹⁹⁹

OTHER FUNGAL INFECTIONS

A variety of unusual fungal organisms has been increasingly reported in infected patients with cancer.¹⁶³ Infections caused by these rare organisms have recently been reviewed by Walsh and Groll.²⁰⁰ Table 76.13 lists some of the more prevalent emerging fungal pathogens and possible therapeutic options, although it is important to note that the outcome with most of these infections has been poor, and reported successes with treatment modalities have been anecdotal.

Evaluation of the Granulocytopenic Patient with Fever⁶

Infection in the granulocytopenic patient can progress very rapidly; hence, a thorough evaluation of the granulocytopenic patient with fever must be undertaken without delay. Characteristic signs and symptoms of inflammation may be minimal or absent,²⁰¹ and careful examination is necessary to detect subtle findings, especially in the periodontium; the

TABLE 76.13. Emerging fungal pathogens in patients with cancer.

Organism	Treatment
Dematiaceous (dark-walled) fungi	
<i>Alternaria</i>	Amphotericin B + flucytosine, itraconazole
<i>Bipolaris</i>	Itraconazole, voriconazole
<i>Cladosporium</i>	Amphotericin B, itraconazole
<i>Curvularia</i>	Amphotericin B, itraconazole, terbinafine
<i>Scedosporium apiospermum</i> (<i>Pseudallescheria boydii</i>)	Voriconazole, amphotericin B + itraconazole
<i>Wangiella</i> (<i>Exophiala</i>) <i>dermatidis</i>	Amphotericin + itraconazole, itraconazole
Hyaline fungi	
<i>Acremonium</i>	Amphotericin B, voriconazole
<i>Geotrichum</i>	Amphotericin B ± 5-flucytosine, itraconazole
<i>Paecilomyces lilacinus</i>	Amphotericin B, terbinafine
<i>Paecilomyces variotii</i>	Itraconazole or fluconazole
<i>Penicillium</i>	Amphotericin B, fluconazole, itraconazole
<i>Trichophyton</i>	Itraconazole or fluconazole
Yeasts	
<i>Blastoschizomyces capitatus</i>	Fluconazole
<i>Trichosporon beigeli</i>	Amphotericin B

pharynx; the lower esophagus; the lung; the perineum, including the anus; the eye (fundus); and the skin, including bone marrow aspiration sites, vascular catheter access sites, and tissue around the nails.

Bacterial cultures of blood should be obtained, including one drawn through the IVD; if a catheter insertion site has exudate, the material should be also be sent for Gram stain and culture. If the exudate is chronic, the material should also be analyzed for fungi and mycobacteria. A sample for urine microscopy and culture should also be obtained.

The evaluation of infectious diarrhea is based on whether it is community acquired, nosocomial, or chronic. For community-acquired diarrhea, stool specimens should be cultured for *Salmonella*, *Shigella*, *Campylobacter*, and *Escherichia coli* O157:H7. The major cause of nosocomial diarrhea is *Clostridium difficile*, which has been addressed in an earlier section; for diarrhea after 3 or more days of hospitalization, stool cultures for common community-acquired enteric pathogens have very low yield and are rarely necessary.²⁰² Persistent infectious cryptogenic diarrhea may warrant evaluation for giardia and cryptosporidium infection.

New, abnormal skin lesions in granulocytopenic patients often represent invasive bacterial or fungal infection and should be aspirated, or better, biopsied, and a Gram stain, bacterial and fungal culture, and histopathologic examination should be performed.

Chest radiographs should be obtained whenever signs or symptoms point toward a respiratory tract process. Some experts recommend chest radiography for all persons who are to be treated as outpatients, even without clinical evidence of pulmonary infection. A baseline radiograph may be helpful for granulocytopenic patients who subsequently develop respiratory symptoms or evidence of an infiltrate but may not be cost-effective on a routine basis. Of note, high-resolution CT will reveal evidence of pneumonia in more than one-half of febrile granulocytopenic patients who have normal findings on chest radiograph.

Examination of CSF is not recommended as a routine procedure unless the patient has severe headache, meningismus,

or altered mental status. However, in general, a CT scan with and without intravenous contrast should be obtained before performing a lumbar puncture because of the risk of intracranial hemorrhage in patients with drug-induced thrombocytopenia and to rule out central fungal infection.

Complete blood cell counts and determination of the levels of serum creatinine and urea nitrogen are needed to plan supportive care and to monitor antiinfective drug toxicity. These tests should be done at least every 3 days during the course of intensive antiinfective therapy; more frequent monitoring may be required if amphotericin B is also being given.

INITIAL EMPIRIC ANTIMICROBIAL THERAPY

Empiric antimicrobial therapy should be instituted without delay in all granulocytopenic patients with fever, ideally, within 2 hours of the clinical evaluation. Afebrile patients who are granulocytopenic, but who have signs or symptoms suggestive of infection, should also receive empirical antimicrobial therapy, begun in the same manner as for febrile patients. The choice of initial antimicrobial regimens should be based on knowledge of the most common infecting pathogens in that center or patient population and the antibiotic susceptibilities at that institution. The major pathogens causing infection in granulocytopenic patients are shown in Table 76.3. *Because of the ever-present risk of life-threatening infection by Pseudomonas aeruginosa, all initial antimicrobial regimens must include at least one drug with antipseudomonal activity.*

Despite a plethora of randomized trials, no single empiric regimen can be recommended for the treatment of all patients with granulocytopenic fever. Comparing numerous studies is difficult because of differing definitions of disease and criteria used to assess the response to treatment.

The 2002 IDSA Guideline offers three options for initial intravenous antimicrobial therapy that are considered to be of comparable efficacy,⁶ with the caveat that one may be more appropriate for certain patients or in certain institutions than the others: single-drug therapy (monotherapy), two-drug

therapy without a glycopeptide (vancomycin), and therapy with glycopeptide (vancomycin) plus one or two other anti-infective drugs.

MONOTHERAPY

Multiple studies have shown no outcome differences between monotherapy and multidrug combinations for empiric treatment of uncomplicated fever in granulocytopenic patients, that is, those without clinical evidence of local infection or sepsis at the outset. Two recent meta-analyses encompassing more than 4,000 patients, found that patients with uncomplicated granulocytopenic fever treated with a beta-lactam alone, as contrasted with a beta-lactam plus an aminoglycoside found no significant difference in all-cause mortality (RR, 0.85–0.87; $P = 0.057$).^{203,204} Although rates of superinfection in both groups were similar, the frequency of adverse events was higher in patients receiving combination therapy. Another meta-analysis, using clinical failure of antimicrobial therapy as the outcome measure, also found beta-lactam monotherapy to be comparable to aminoglycoside-containing combinations in uncomplicated granulocytopenic fever.²⁰⁵

The antimicrobial agents that have been best studied for monotherapy include a third-generation (ceftazidime) or fourth-generation cephalosporin (cefepime) or a carbapenem (imipenem-cilastatin or meropenem). The emergence of extended-spectrum β -lactamases (ESBL) in *Enterobacteriaceae* has reduced the utility of ceftazidime for monotherapy.²⁰⁶ Imipenem-cilastatin, meropenem, and cefepime, unlike ceftazidime, are active against ESBL-producing *Enterobacteriaceae* and also have excellent activity against viridans streptococci and pneumococci. A prospective double-blind study of 411 patients with cancer showed that the rate of clinical response was higher in febrile granulocytopenic patients treated with meropenem than it was in those treated with ceftazidime.²⁰⁷

It is important to recognize that the spectrum of any of these drugs does not usually encompass coagulase-negative staphylococci, methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci, and some strains of multi-resistant *Streptococcus pneumoniae* or viridans streptococci. Therefore, close monitoring of the clinical response to treatment is important, and anti-infective therapy may need to be adapted to institutional susceptibilities, and modified, based on the susceptibilities of the organisms recovered in culture.

Current evidence to support the use of fluoroquinolones as monotherapy is limited and the results of the few studies have been conflicting.²⁰⁸ The widespread use of fluoroquinolones for prophylaxis in granulocytopenic patients also limits their utility for initial empiric therapy, and this class of drugs cannot be recommended for initial monotherapy in patients with granulocytopenia and fever. Treatment with aminoglycosides alone is also suboptimal and not recommended.

TWO-DRUG COMBINATION THERAPY

Two-drug combination therapy most often comprises an aminoglycoside (gentamicin, tobramycin, or amikacin) plus an antipseudomonal penicillin (ticarcillin-clavulanate or piperacillin-tazobactam) or an antipseudomonal cephalosporin (cefepime or ceftazidime), or an aminoglycoside plus

a carbapenem (imipenem-cilastatin or meropenem). These regimens have been shown to have comparable efficacy in numerous trials.²⁰⁴ Because of intrinsic and growing acquired resistance in many species of gram-negative bacteria causing serious infections,²⁰⁹ and the high mortality associated with these infections, combination antimicrobial therapy, most commonly with two drugs, is intuitively appealing. However, as noted, the studies to date have not shown combination therapy to be superior to monotherapy *if there is no clinical obvious source of infection at the time therapy is begun*.^{31,204} Moreover, there are disadvantages to using combination anti-infective therapy, including increased toxicity and cost and, possibly, an increased likelihood of a superinfection with even more resistant bacteria or fungi.

Although the combination of ciprofloxacin with piperacillin-tazobactam was found to have efficacy comparable to tobramycin and piperacillin-tazobactam in a large multicenter randomized trial,²¹⁰ in our opinion, fluoroquinolones in initial empiric regimens should not be used *if the patient has had heavy exposure to this class of drugs in the past, such as for prophylaxis or treatment of a recent infection*.

VANCOMYCIN-CONTAINING REGIMENS

There has been much controversy regarding the inclusion of vancomycin in the initial empiric regimen for the febrile granulocytopenic patient to provide a drug active against methicillin-resistant staphylococci, enterococci, and *Corynebacterium* species. Comparative trials have found that inclusion of vancomycin in the initial regimen does reduce the frequency of secondary nosocomial BSIs with these organisms during therapy²¹¹; however, these studies have not shown reduced morbidity and mortality. A recent prospective trial randomized 165 granulocytopenic patients with persistent fever despite piperacillin/tazobactam to the addition of vancomycin or placebo; no statistically significant differences were noted regarding time to defervescence or additional episodes of gram-positive bacteremia.²¹²

In general, heavy use of vancomycin in the absence of a clear clinical indication is undesirable because of the risk of promoting vancomycin resistance in enterococci or *S. aureus*. Thus, routine use of vancomycin in the initial antimicrobial regimen for the febrile granulocytopenic patient is not recommended unless (1) the hospital has a high rate of nosocomial infection with MRSA or the patient is known to have previously been colonized or infected by MRSA, (2) there are reasons to suspect overwhelming alpha-hemolytic viridans streptococcal bacteremia, that is, shock with respiratory distress, (3) the patient shows evidence of infection at the exit site or tunnel of a CVC, or (4) the patient is at risk for endocarditis, that is, has a prosthetic heart valve.²¹³

For microbiologically confirmed infections with coagulase-negative staphylococci or other resistant gram-positive organisms, vancomycin should be added to the initial regimen. Linezolid, the first U.S. Food and Drug Administration (FDA)-approved oxazolidinone, offers promise for treatment of resistant gram-positive bacterial infections, including those caused by VRE, although reversible drug-related myelosuppression can be seen, mainly with prolonged courses. Quinupristin-dalfopristin, another drug that has recently been approved by the FDA, is also effective against vancomycin-resistant *E. faecium* (but not *E. faecalis*) and other gram-positive bacteria.²¹⁴ However, further studies are needed

before recommendations can be made for the use of these drugs in initial empiric regimens in patients with cancer.

ORAL ANTIMICROBIAL THERAPY

Until recently, the accepted standard of care for the cancer patient with granulocytopenic fever, has been immediate hospitalization for parenteral administration of antibiotics, with close monitoring for complications and response to therapy.²¹⁵ As a result, there has been a dramatic decrease in mortality among febrile granulocytopenic patients. Recent investigations have shown that granulocytopenic patients with fever are a heterogeneous population, with varying risks relative to the response to therapy, the occurrence of serious medical complications, and mortality.^{216,217}

Over the past decade, subsets of febrile granulocytopenic patients at low risk for complications have been identified, which have impelled studies of using oral antimicrobials, entirely in the outpatient setting or in the hospital, usually following a brief course of parenteral broad-spectrum anti-infective therapy. Table 76.14 summarizes the randomized controlled trials that have been undertaken to examine the efficacy and safety of oral antimicrobial therapy for low-risk patients with granulocytopenic fever.

These trials should be interpreted within the context of their limitations. Assessment of risk of infection, antimicrobial regimens used, and location of antimicrobial therapy (inpatient or outpatient) varied widely. Moreover, the outcome "success of therapy" was not uniformly defined. Nonetheless, the results of these important studies show

TABLE 76.14. Randomized controlled trials assessing the efficacy of oral antibiotic therapy in granulocytopenic patients with fever.

<i>Author</i>	<i>Patient population</i>	<i>Location of group treated orally</i>	<i>Antimicrobial regimen Oral treatment</i>	<i>Resolution of infection Inpatient parenteral</i>	<i>Oral treatment parenteral</i>	<i>RR Inpatient</i>	<i>Relative risk</i>

^a Parenteral regimen was provided on an outpatient basis.

that, in general, the outcomes for low-risk patients treated with oral antimicrobial therapy are generally equivalent to those for similar-risk patients treated with intravenously administered therapy. Oral therapy has the advantages of reduced cost, the potential for outpatient management, and avoidance of intravenous access, thereby obviating the risk of IVDR BSI. The oral regimens that have been most thoroughly evaluated are ofloxacin alone, ciprofloxacin alone, and ciprofloxacin plus amoxicillin-clavulanate.

Pivotal to the success of this approach in clinical practice is to accurately identify patients at low risk. Clinical prediction rules have been developed for this purpose. The hypothesis of Talcott et al. that granulocytopenic patients with controlled cancer and no serious comorbidity who developed fever in an outpatient setting are at low risk and can safely be treated as outpatients, was validated in a prospective study.²¹⁷ Klustersky et al. developed a Multinational Association for Supportive Care in Cancer risk index; a score of more than 21 identified low-risk patients with a positive predictive value of 91%, specificity of 68%, and sensitivity of 71%.²¹⁸ The variables comprising this index are summarized in Table 76.15.

SUMMARY RECOMMENDATIONS FOR INITIAL EMPIRIC THERAPY

Figure 76.10 summarizes the IDSA 2002 Guideline Recommendations for Initial Empiric Antimicrobial Therapy in Granulocytopenic Patients with Fever.⁶ The first step is to determine whether the patient is at low or high risk for serious life-threatening infection, on the basis of the criteria observed at the time of presentation (see Table 76.15). If the risk is high, IV antimicrobials must be used; if risk is low, the patient may be treated with either intravenous or oral drugs. Second, decide whether the patient qualifies for vancomycin therapy. If the patient qualifies, begin treatment with a two- or three-drug combination, with vancomycin plus cefepime, ceftazidime, or a carbapenem, with or without an aminoglycoside. If vancomycin is not indicated, begin monotherapy with a cephalosporin (cefepime or ceftazidime) or a carbapenem (meropenem or imipenem-cilastatin), administered

TABLE 76.15. Scoring index for identification of low-risk febrile granulocytopenic patients at time of presentation with fever.^a

Characteristic	Score
Extent of illness ^b	
No symptoms	5
Mild symptoms	5
Moderate symptoms	3
No hypotension	5
No chronic obstructive pulmonary disease	4
Solid tumor or no fungal infection	4
No dehydration	3
Outpatient at onset of fever	3
Age less than 60 years	2

^aDoes not apply to patients 16 years of age or less. Initial monocyte count of 100 cells/mm³ or more, no comorbidity, and normal chest radiograph findings indicate children at low risk for significant bacterial infections.

^bChoose one item only. Highest theoretical score is 26. A risk index score of 21 or more indicates that the patient is likely to be at low risk for complications and morbidity.

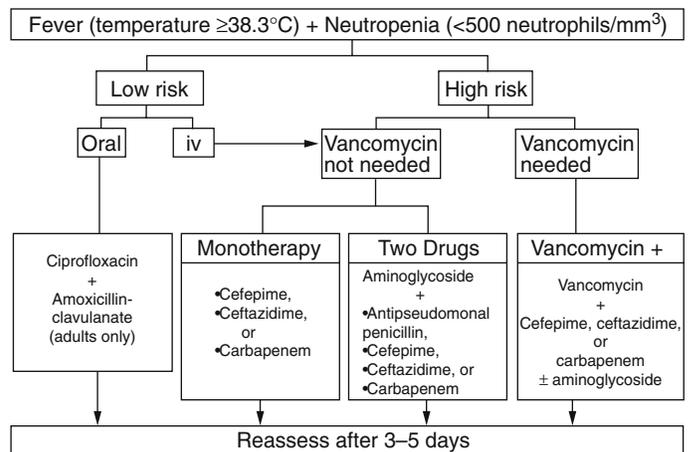

FIGURE 76.10. Algorithm for initial management of febrile granulocytopenic patients. (From Hughes et al.,⁶ by permission of *Clinical Infectious Diseases*.)

intravenously for uncomplicated cases. Two-drug combinations are recommended for management of complicated cases or if antimicrobial resistance is strongly suspected.

Adults selected for oral therapy may receive ciprofloxacin plus amoxicillin-clavulanate. Selection of patients for outpatient therapy must be done carefully from the low-risk group, depending on the capabilities of the medical center and the feasibility of close follow-up. Initial therapy with oral antimicrobials alone in the outpatient setting is not recommended for children because of a lack of sufficient evidence.

MODIFICATION OF EMPIRIC THERAPY

The majority of patients with febrile granulocytopenia will not have a microbiologically documented infection. Therefore, duration of therapy usually cannot be guided by monitoring clinical resolution of a local infection or clearance of bacteremia. Scientific evidence to answer this important question is scant and does not permit definitive conclusions. The evidence-based 2002 IDSA Guideline for the management of granulocytopenic fever stratifies patients by duration of fever and, for patients who become afebrile by day 3, recommends discontinuation of antiinfective therapy if the patient's granulocyte count is 500 cells/mm³ or higher for 2 consecutive days, there is no definite site of infection, and cultures remain negative. If the patient's granulocyte count is still less than 500 cells/mm³ by day 7, but the patient was initially at low risk and there are no subsequent complications, therapy may be stopped when the patient is afebrile for 5 to 7 days. However, if the patient was initially considered to be high risk, antiinfective therapy should be continued (Figure 76.11).⁶

Patients with persistent fever for more than 3 days after initial therapy, for whom no infected site of organism has been identified, pose the greatest challenge. Persistent fever suggests that the patient has a nonbacterial, especially fungal, infection, a bacterial infection resistant to or slow to respond to the drug or drugs being given, the emergence of a superinfection, inadequate serum and tissue levels of the antibiotic(s), drug fever, or need for source control (e.g., an abscess or infected IVD). Although some patients with microbiologically defined bacterial infections, even when appropriately

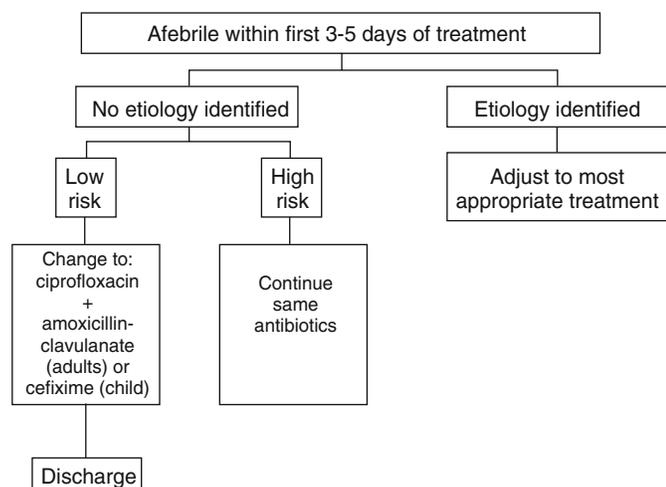

FIGURE 76.11. Guide for management of patients who become afebrile in the first 3 to 5 days of initial antibiotic therapy. See Table 7.15 for rating patients at low risk. (From Hughes et al.,⁶ by permission of *Clinical Infectious Diseases*.)

treated, may require 5 days of therapy before defervescence occurs, a comprehensive reassessment should be undertaken if the patient fails to respond to initial therapy within 3 days, to include a review of all culture results, physical examination, chest radiograph, culturing of additional blood samples, and samples from clinically suspected sites of infection, and diagnostic imaging of any deep organ suspected of harboring infection. Ultrasonography or high-resolution CT are especially helpful for patients with suspected pneumonia, sinusitis, or typhlitis.

If fever persists after 5 days of antimicrobial therapy and reassessment does not yield a cause, there are three possible approaches (Figure 76.12): (1) continue treatment with the initial antibiotics, (2) modify the initial regimen, or (3) add an antifungal agent to the regimen, with or without modification of the antibacterial regimen.

If no discernible improvement in the patient's condition has occurred (i.e., the patient remains febrile but stable) during the first 4 to 5 days of initial antimicrobial therapy, and if reevaluation yields no new information to the contrary,

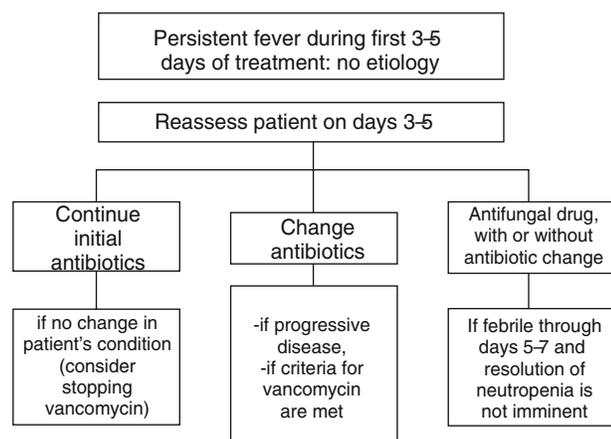

FIGURE 76.12. Guide to treatment of patients who have persistent fever after 3 to 5 days of treatment and for whom the cause of the fever is not found. (From Hughes et al.,⁶ by permission of *Clinical Infectious Diseases*.)

the initial regimen can be continued. This decision will be strengthened if the granulocytopenia can be expected to resolve within the ensuing 5 days.

If evidence suggests clinical deterioration or a complication (such as the onset of abdominal pain from enterocolitis or typhlitis, new or worsening mucosal lesions, or drainage from an IVD exit site or pulmonary infiltrates) during the initial antimicrobial course, consideration should be given to adding appropriate antibiotics or changing to a different regimen.

If the initial regimen is monotherapy or two drugs without vancomycin, vancomycin may be considered if any of the criteria for use of vancomycin previously mentioned has been met. If a blood- or site-specific pathogen is isolated, the most appropriate antibiotic should be used while continuing broad-spectrum coverage.

The third decision to consider is the addition of empiric antifungal therapy. Amphotericin B is usually the drug of first choice (see Figure 76.12). Studies in 1982²¹⁹ and 1989²²⁰ suggested that up to one-third of febrile granulocytopenic patients who do not respond to a 1-week course of empiric antimicrobial therapy have a systemic fungal infection that, in most cases, is caused by *Candida* or *Aspergillus* species. The empiric use of IV amphotericin B deoxycholate in patients with prolonged febrile granulocytopenia, was shown to reduce the incidence of invasive fungal infection and improve patient survival.^{221,222} Although clinicians disagree when amphotericin B therapy should be initiated empirically, most believe that the patient who remains febrile and profoundly granulocytopenic for 5 days, despite administration of antimicrobial therapy in adequate doses, is a candidate for antifungal therapy.⁶ However, every effort should be made to determine whether systemic fungal infection exists, by biopsy of suspicious lesions, radiographs of chest and sinuses, nasal endoscopy to investigate sinusitis, and CT of the abdomen and chest, before amphotericin B therapy is started.

Comparative trials show that lipid formulations of amphotericin B can be used as alternatives to amphotericin B deoxycholate for empiric therapy. Although they do not appear to be any more effective therapeutically,²²³ lipid formulations of amphotericin are associated with much less infusion-related toxicity and, especially, nephrotoxicity.^{224,225}

The use of azoles—fluconazole, itraconazole, or voriconazole—in patients with febrile granulocytopenia has been less well studied. Small trials have demonstrated equivalency between amphotericin B deoxycholate and fluconazole²²⁶ or itraconazole²²⁷; however, both these studies were performed in populations with low rates of filamentous fungal infection.

The new triazole, voriconazole, has also been compared to liposomal amphotericin B in a large randomized multicenter study.²²⁸ The use of voriconazole was associated with a reduced incidence of documented invasive fungal infections; however, voriconazole was found to be inferior to liposomal amphotericin, based on a five-part composite primary endpoint. As a result, voriconazole has not been licensed by the FDA for the empiric therapy of febrile granulocytopenia.²²⁹

DURATION OF ANTIMICROBIAL THERAPY

The most important guides to successful discontinuation of antibiotics are the granulocyte count and defervescence

TABLE 76.16. Recommendations for duration of empiric antimicrobial therapy for patients with granulocytopenic fever.

<i>Duration</i>	<i>Recommendation</i>
Afebrile by day 3–5	
ANC >500 per 2 consecutive days	Stop antibiotics 48 hours after afebrile and ANC >500
ANC <500 by day 7	
Initially considered low-risk patient and clinically well	Stop antibiotics when afebrile for 5–7 days
Initially considered high risk, or profoundly granulocytopenic, or with mucositis or clinically unstable	Continue antibiotics
Persistent fever without identifiable source or pathogen	
ANC >500	Stop antibiotics 4–5 days after ANC >500 and reassess
ANC <500	Continue antibiotics for 2 weeks; reassess and stop if no disease is found

Source: Adapted from Hughes et al.,⁶ by permission of *Clinical Infectious Diseases*.

(Table 76.16). As noted earlier, if no infection is identified, if the granulocyte count is 500 cells/mm³ or more for 2 consecutive days, and the patient is afebrile for 48 hours or more, empiric antimicrobial therapy may be stopped at that time.

If the patient becomes afebrile but remains granulocytopenic, the best course is less well defined and no consensus exists. Some authorities recommend continuation of antibiotics, given intravenously or orally, until granulocytopenia has resolved; others suggest that for granulocytopenic patients who appear healthy clinically, who are in a low-risk category at onset of treatment, and who have no radiographic or laboratory evidence of infection may have systemic antimicrobial therapy stopped after 5 to 7 afebrile days, or sooner with hematologic recovery.²³⁰ If antibiotics are stopped while the patient has granulocytopenia, the patient must be monitored very closely and intravenous antibiotics resumed immediately with the recurrence of fever or other evidence of bacterial infection.²³¹ *In general, antibiotic therapy should be continued throughout the granulocytopenic period in patients with profound granulocytopenia (less than 100 cells/mm³), mucous membrane lesions of the mouth or gastrointestinal tract, unstable vital signs, or other identified risk factors.*

In patients with prolonged granulocytopenia in whom hematologic recovery cannot be anticipated, one can consider stopping antibiotic therapy after 2 weeks if no site of infection has been identified and the patient can be observed carefully (see Table 76.16).

The duration of amphotericin B therapy differs. If a systemic fungal infection has been identified, the course of antifungal therapy will be determined by the causative agent, the extent of the disease, and the clinical and microbiologic response. However, if no fungal infection is found, it is less clear how long empiric amphotericin B or other antifungal drugs should be continued. Experience is limited predominantly to amphotericin B. When granulocytopenia has resolved, the patient is clinically well, and CT of the abdomen

and chest reveal no suspicious lesions, amphotericin B may be discontinued.²³² For clinically well patients with prolonged granulocytopenia, it is suggested that, after 2 weeks of daily doses of amphotericin B, if no discernible lesions can be found by clinical evaluation, chest radiography (or CT of the chest), and CT of the intraabdominal organs,²³³ the drug can be stopped. In the patient who appears ill or is at high risk, one should consider continuation of therapy with antibiotics and amphotericin B throughout the period of granulocytopenia, assuming that hematologic recovery can be anticipated.

PREDICTORS OF RESPONSE TO ANTIMICROBIAL THERAPY

Elting et al. assessed predictors of outcome in 909 episodes of bacteremia selected from 10 randomized clinical trials of antimicrobial therapy for infection in patients with cancer and granulocytopenia.²³⁴ Extensive tissue infection significantly compromised response to initial therapy (74% versus 38%; *P* less than 0.0001), ultimate outcome of infection (94% versus 73%; *P* less than 0.0001), and survival (94% versus 75%; *P* less than 0.0001). Log regression showed that shock (OR, 18.0; *P* less than 0.0001) and bacteremia caused by *P. aeruginosa* species (OR, 7.0; *P* = 0.03), *Clostridium* species (OR, 9.0; *P* = 0.006), or a pathogen resistant to antibiotics used for initial therapy (OR, 3.0; *P* less than 0.0001), were each independently associated with a poor outcome. Recovery of the granulocyte count predicted a favorable outcome (OR, 0.4; *P* less than 0.0001). Although the overall mortality rate was not significantly increased when patients with bacteremia caused by gram-negative organisms initially received monotherapy or when patients with bacteremia due to gram-positive organisms received delayed vancomycin therapy, these strategies increased the duration of therapy by 25%. Patients with bacteremia caused by alpha-hemolytic streptococcus were more likely to die if vancomycin was not included in the initial empirical regimen (*P* = 0.004).

HEMATOPOIETIC GROWTH FACTORS

Hematopoietic growth factors have been studied as an adjunct to antimicrobial therapy for granulocytopenic fever in several randomized trials. Although the duration of granulocytopenia was consistently shorter in these studies, it did not translate into clinically relevant improved outcomes. In a meta-analysis of 13 randomized, controlled trials comparing antibiotics and granulocyte colony-stimulating factor (G-CSF) with antibiotics alone for granulocytopenic fever, Clark et al. found a decrease in length of hospitalization [RR, 0.63; 95% confidence interval (CI), 0.40–0.82; *P* less than 0.001] and a shorter time to granulocyte recovery (RR, 0.32; 95% CI, 0.23–0.46; *P* less than 0.001); however, no effect on either overall mortality (OR, 0.68; 95% CI, 0.43–1.08; *P* = 0.05) or infection-related mortality (OR, 0.85; 95% CI, 0.33–2.20; *P* = 0.7) was observed.²³⁵ Based on the available evidence, recent guidelines^{6,236} that have addressed the use of G-CSF and granulocyte macrophage colony-stimulating factors (GM-CSF) in patients with cancer recommend against the routine use of hematopoietic growth factors. However, under certain conditions, with a worsening of the course and expected delay in marrow recovery, use of these agents may be appropriate with pneumonia, hypotension, or shock, severe cellulitis or sinusitis, systemic fungal infections, or multiorgan dysfunction secondary to sepsis.⁶ Therapy with colony-stimulating factors

could also be considered for patients who remain severely granulocytopenic and have documented infections that have failed to respond to appropriate antimicrobial therapy, such as gram-negative cellulitis.

GRANULOCYTE TRANSFUSIONS

Existing evidence does not support the routine use of granulocyte transfusions in patients with granulocytopenic fever. The major indication for granulocyte transfusion support at the present time is the patient with profound granulocytopenia and overwhelming gram-negative bacillary infection, especially major soft tissue infection that is unresponsive to antiinfective therapy.²³⁷

Supportive Therapy

Treatment of infection, especially associated with sepsis or early multiple organ dysfunction (MODS) syndrome, does not stop with source control and antiinfective therapy but demands the highest skills of the clinician to keep the patient alive until the infection can be controlled.

Circulatory Support

The importance of very early and aggressive circulatory support of the septic patient with large volumes of fluids, with or without cardiovascular pressor drugs, cannot be overemphasized.²³⁸ The most experienced clinician cannot by physical examination alone reliably assess a critically ill patient's cardiac performance vis-à-vis ventricular filling pressures or cardiac output. Thus, if an infected patient exhibits hypoxemia or hypotension refractory to initial fluid resuscitation, a flow-directed, balloon-tipped, pulmonary artery catheter (PAC) can be helpful to guide fluid therapy and decisions on choice of pressors and inotropic drugs, with the physiologic goal of optimizing oxygen delivery and uptake. Recent fear, based on a retrospective study, that PACs increase mortality in critically ill patients²³⁹ has been dispelled by a large, multicenter randomized trial in older adult surgical patients showing that PACs can be used safely without increased mortality.²⁴⁰

There are no data to indicate that colloid solutions, such as albumin, plasma protein fraction, or hydroxyethyl starch (hetastarch) are superior to crystalloids, such as 0.9% normal saline or Ringer's lactate, for support of the failing circulation in the patient with septic shock. Crystalloids should be the IV fluid of choice for treatment of sepsis and in the patient with shock and should be given aggressively in the first 4 to 6 hours, guided by the central venous pressure, to minimize mortality.²³⁸

Novel Adjunctive Therapies

For nearly 40 years, despite advances in antiinfective therapy and in ICU care, the mortality of septic shock has declined only marginally, pointing up the need to modulate the severe systemic inflammatory response syndrome that underlies shock, multiorgan dysfunction, and death.²¹³

Patients who have been receiving long-term corticosteroid therapy who develop sepsis need supplemental stress doses of corticosteroids, hydrocortisone 50 to 75 mg IV every

6 hours, to prevent acute adrenal crisis. However, there is growing evidence to suggest that these doses of hydrocortisone will improve survival in patients with severe sepsis. A recent multicenter, double-blind randomized trial in France found, in patients with severe sepsis or septic shock, that adjunctive therapy with hydrocortisone 50 mg IV every 6 hours and fludrocortisone 5 µg per day orally reduced mortality 30%.²⁴¹

It has long been recognized that most patients with septic shock have low levels of the essential physiologic anticoagulant, protein C. A recent international, multicenter trial was undertaken to assess the therapeutic effect of repleting protein C with a recombinant activated form (rhAPC) in patients with severe sepsis, 75% with shock.²⁴² The choice of protein C was influenced by knowledge of its capacity to modulate inflammation through inhibition of monocyte production of tumor necrosis factor- α (TNF- α) and interleukin (IL)-1b, inhibition of neutrophil activation, and downregulation of endothelial expression molecules, intercellular adhesion molecule ICAM-1, E-selectin, and VCAM-1. In the double-blind trial in 1,640 patients, a continuous infusion of rhAPC 24 µg/kg/min, begun within 24 hours of the onset of severe sepsis and continued for 96 hours, was associated with a 19% reduction in 28-day all-cause mortality ($P = 0.005$). There was a slight increase in bleeding complications in recipients of rhAPC (serious bleeding, 3.5% versus 2.0%; $P = 0.06$); however, rhAPC was well tolerated, considering the critical illness of most of the recipients.²⁴² The major contraindications to adjuvant use of rhAPC in cancer patients are active bleeding, severe thrombocytopenia (less than 30,000), or chronic renal or hepatic failure.

Prevention of Infection in the Patient with Cancer²¹³

Protective Isolation

Profound and prolonged granulocytopenia, whether caused by the primary hematologic malignancy or its therapy, puts the patient at great risk for severe infection. Approximately 70% of deaths from acute nonlymphoblastic leukemia (ANLL) are ascribed to infection, the risk of which is inversely related to the absolute granulocyte count. Prevention of infection may allow patients to receive more intensive chemotherapy and thereby increase the rates of remission and overall survival. Concerted efforts have been made to protect the granulocytopenic patient from nosocomial infection during chemotherapy or bone marrow transplantation. Randomized trials have prospectively evaluated various procedures for protection of the granulocytopenic patient, including protective environments, the use of prophylactic nonabsorbable antibiotics, or both.²⁴³

Most programs have been based on elaborate protocols for protection against both extrinsic and endogenous pathogens, typically isolating the patient in a room or tent with filtered ultraclean air and requiring persons entering the room to wear sterile overgarments, gloves, shoe covers, and masks. Such protocols have been supplemented by regular applications of cutaneous and orificial disinfectants, use of food and water low in microbial content, and continuous administration of prophylactic oral nonabsorbable antibiotics. Because the

expense of such complex programs is prohibitive for most hospitals, simple protective isolation (or reverse precautions) requiring that the person entering the room wear a clean gown, gloves, and mask is widely used as an alternative means to protect the granulocytopenic patient from infection. A prospective, randomized unblinded study to assess the efficacy of protective isolation in 37 granulocytopenic patients with 43 episodes of infection found no statistically significant differences in the overall incidence of infection, time to onset of first infection, or days with fever.²⁴⁴ Neither response to antileukemic therapy nor survival was improved with isolation.

These randomized trials are difficult to compare because of differing isolation protocols, different antileukemic or antibiotic regimens; moreover, criteria of infection have not been consistently defined. In general, however, comparative studies have shown that patients in whom some method or protection was used, either a protective environment or antibiotics alone or in combination, had fewer infections, fewer days of fever, and often reduced mortality from infection. However, more importantly, these measures have failed to find improvement in rates of leukemic remission or overall survival.

Prevention of Nosocomial Transmission of Resistant Organisms

Isolation of infected and colonized patients is widely regarded as the most important measure to prevent spread of resistant pathogens through the healthcare institution.^{245,246} The most recent CDC Guideline categorizes isolation precautions: (1) standard precautions and (2) transmission-based precautions.²⁴⁷ Standard precautions specify the use of gloves for any anticipated contact with blood, any body fluid, secretions or excretions (except sweat), nonintact, skin or mucous membranes. Gowns are recommended if patient care activities are likely to generate splashes of blood, body fluids, and secretions. Hand hygiene is expected after removing gloves and between patients. Standard precautions apply to *all* patients, without regard to clinical diagnosis.

Transmission-based precautions include contact, droplet, and airborne precautions, each based on the mode of transmission of the infectious agent within the healthcare setting. Acknowledging that multiresistant nosocomial pathogens, particularly MRSA and VRE, are spread primarily by direct (and indirect) contact with healthcare workers, the Guideline specifies that patients known to be colonized or infected by resistant bacteria are to be placed in contact isolation, which requires a private room for the patient (or pairing the patient in a semiprivate room with another patient who is also colonized or infected by the same organism). Healthcare workers are expected to wear gloves on entry to the room, and gowns as well if substantial contact with the patient or the environment is anticipated. Gloves and gowns should be removed and hands treated with a medicated hand hygiene product while still in the isolation room. Noncritical patient care items should be dedicated; if reused, they must be disinfected between patients.

Unfortunately, the existent paradigm for preventing spread of resistant organisms in the hospital—waiting until colonization or infection by MRSA, VRE, or some other resis-

tant organism is serendipitously identified by the clinical laboratory, following which the patient is placed in isolation, usually in a single room, requiring gloves, with or without a gown, for all contacts with the patient—is failing dismally, viewing the inexorable growth in antimicrobial resistance.^{49,248,249}

A recent Guideline from the Society for Healthcare Epidemiology of America²⁵⁰ recommends that surveillance cultures to detect silent VRE or MRSA carriage be performed in roommates of VRE- or MRSA-colonized or -infected patients and other high-risk patients, at the discretion of infection control staff; patients found to be colonized must *also* be placed in contact isolation.²⁵⁰ If these measures fail to contain spread, efforts should be intensified in the highest risk areas, such as the ICU. Grouping of staff and screening of staff for carriage, if epidemiologic data point to a link, is recommended. Verification that environmental disinfection procedures are effective, by environmental surveillance cultures before and after cleaning areas containing VRE- or MRSA-colonized or -infected patients, is also recommended.

Strategies designed to proactively identify the reservoir of asymptomatic colonized patients by routine surveillance cultures of patients at high risk for MRSA or VRE carriage, rather than relying solely on clinical cultures driven by suspicion of infection, followed by isolation only if cultures indicate the presence of a resistant organism,^{251,252} have had variable results; most before-and-after studies have shown that this strategy has been useful in containing institutional spread of multiresistant organisms,^{251,253,254} but others have found limited benefit.^{255–257} It is notable that no randomized trial has yet been undertaken to assess the effectiveness of prospective microbiologic surveillance beyond the outbreak setting.

Eradication of VRE or MRSA from the hospital is most likely to succeed when the rate of colonization or infection is still low or confined to a single unit.^{258,259} A comprehensive multifaceted infection control program, consisting of contact isolation (gowns, gloves) for patients found to be colonized in weekly screening of all patients, handwashing, dedicated use of noncritical equipment, and intensive education, was highly successful in reducing the prevalence of VRE colonization from 2.2% to 0.5% in the Siouxland region of Iowa, Nebraska, and South Dakota, where VRE was only recently detected for the first time.²⁵⁸ Once hyperendemicity has occurred, eradication is very difficult and costly. The continued reintroduction of new multiresistant strains into the institution from interinstitutional transfers of unrecognized colonized patients has fueled the continued spread of multiresistant nosocomial organisms. Infection control policies must find ways to prevent both intra- and interinstitutional spread.

The majority of patients admitted to ICUs have multiple risk factors for colonization or infection by resistant organisms,²³ which mandates screening a very large proportion of the patients or, better, all of them. Weekly surveillance cultures, as performed in the majority of studies that have used this approach, requires substantial microbiologic support and is labor intensive.²⁶⁰ By the time the results of surveillance cultures showing colonization by a resistant organism become available, and isolation precautions can be implemented, precious time has passed, providing opportunities for further spread of the organism. Moreover, targeted screening for only one nosocomial pathogen, such as VRE,

ignores the possibility that the patient might be colonized by nosocomial pathogens other than VRE, such as MRSA, resistant gram-negative bacteria, or *Clostridium difficile*, which obviously facilitates their spread.

We believe that a simpler strategy for preventing spread of all types of multiresistant bacteria, is the preemptive use of barrier isolation precautions (gowns and gloves) and dedicated patient care items, such as stethoscopes and sphygmomanometers, in all high-risk patients from the time of admission, to prevent healthcare workers from acquiring hand contamination by multiresistant organisms when having contact with patients with unrecognized colonization or infection, and thus, to block transmission to other, as yet uncolonized, patients. Numerous studies have shown that the preemptive use of barrier precautions, also called "protective isolation," can effectively prevent the spread of multiresistant organisms, such as MRSA or VRE, in an epidemic setting,^{261,262} and other studies have shown the effectiveness of protective isolation in high-risk populations, such as patients in an ICU, for prevention of endemic nosocomial infection, including spread by multiresistant organisms.^{256,263-267} Three prospective randomized trials have been conducted to assess the efficacy of preemptive barrier precautions^{263,264,268}; two showed benefit with a reduction in all nosocomial infections in ICU patients (relative risk reduction, 52% to 81%).^{263,264}

Antimicrobial Prophylaxis

Prophylactic antimicrobials during granulocytopenia have been shown to reduce the frequency of febrile episodes; however, enthusiasm for the use of prophylactic antimicrobials has been damped by the adverse consequences of such a strategy, particularly emergence of multiresistant bacteria, superinfection by fungi, and toxicity from the antimicrobials used.

Combinations of nonabsorbable drugs, such as aminoglycosides, polymyxins, and vancomycin, have been used for infection prophylaxis in the past. However, recent prospective, randomized trials have consistently found that trimethoprim-sulfamethoxazole (TMP-SMZ) and fluoroquinolones are more effective and better tolerated.^{269,270}

A recent meta-analysis of nine prospective, randomized trials (1,202 patients) to assess the benefit of adding an agent for gram-positive coverage (vancomycin, penicillin, amoxicillin, roxithromycin, or rifampin) to prophylactic fluoroquinolones found that although the frequency of infections caused by gram-positive bacteria (coagulase-negative staphylococci and streptococci) was reduced, overall mortality attributable to infection was similar in both groups.²⁷¹ Side effects occurred twice as frequently in the group receiving additional prophylaxis against gram-positive bacteria. As such, the routine use of prophylactic antibiotics for prevention of infection in patients with cancer and granulocytopenia is not recommended.

Invasive fungal infection is associated with considerable morbidity and mortality especially in patients with hematologic malignancy. Because these infections are difficult to diagnose and have high mortality, prophylaxis against fungal infections is an attractive approach for patients expected to have prolonged granulocytopenia. Numerous randomized

trials assessing the efficacy of antifungal agents, most often fluconazole, itraconazole, or amphotericin have been undertaken. The results are difficult to compare because of differing patient populations, myelosuppressive regimens, drug dosage and routes of administration, varying durations of prophylaxis, and lack of uniform case definitions. Nonetheless, most trials have found benefit for prevention of invasive fungal infections; however, a survival benefit was not consistently demonstrated.^{272,273}

The risk of developing a potentially fatal invasive fungal infection increases in patients with hematologic (rather than solid organ) malignancy, duration of granulocytopenia, prolonged corticosteroid therapy, allogeneic and autologous bone marrow and stem cell transplantation, graft-versus-host disease, and concomitant viral infections.^{274,275} Therefore, the best studies of antifungal prophylaxis have focused on these high-risk groups. Fluconazole has been the most widely studied agent for prophylaxis in doses ranging from 50 to 400 mg daily. Goodman et al. found that 400mg/day of fluconazole was superior to placebo in reducing both the incidence of invasive fungal infection and attributable mortality.²⁷⁶ In the second trial, performed in pediatric and adult bone marrow transplant recipients, fluconazole, given for 100 days posttransplantation, reduced the incidence of invasive fungal infection when compared with clotrimazole troches.²⁷⁷

Based on results from these and other studies that reported similar results, 400mg/day fluconazole is recommended for patients undergoing allogeneic bone marrow or stem cell transplantation.

Fluconazole has dose-dependent activity against *Candida glabrata* and no activity against *Candida krusei* and *Aspergillus* species. An azole with a broader spectrum, itraconazole, has been studied in several trials. The oral suspension has superior bioavailability than capsules and has been shown to be more efficacious. The results of randomized trials indicate a reduction in the incidence of fungal infection; however, a mortality benefit was not consistently demonstrated. A recent meta-analysis of 13 randomized trials (3,597 patients) found that prophylaxis with itraconazole reduced the incidence of invasive fungal infection (RR, 40%; $P = 0.002$) and mortality from invasive fungal infection; however, no impact on overall mortality was observed.²⁷⁸ As yet, the benefit of prophylaxis with itraconazole remains controversial, and it cannot be recommended universally.

Amphotericin B deoxycholate and lipid-based amphotericin B have each been studied in a limited number of trials, most of which employed historical controls or a small number of subjects.^{279,280} Infusion-related toxicity with amphotericin B and the high cost of lipid-associated amphotericin B have limited the prophylactic use of these agents.

Two new antifungal agents, voriconazole and caspofungin, have recently become available for treatment of fungal infection; however, data on prophylaxis are as yet too limited to draw conclusions.²⁸¹ Recent recommendations regarding the use of antifungal prophylaxis have been published by the German Society of Hematology and Oncology²⁸² and are summarized in Table 76.17.

TABLE 76.17. Summary of recommendations for antifungal prophylaxis in patients with malignancy.

Patient population	Drug	Dosage	Level of evidence
Conventional chemotherapy	Fluconazole	50–400 mg/day	C-I
	Itraconazole oral suspension	≤5 mg/kg/day	C-I
	Itraconazole capsules parenteral	Any dose	C-I
	amphotericin B deoxycholate parenteral	0.5–1.0 mg/kg every 48 hours	C-II
	amphotericin B deoxycholate	<0.5 mg/kg every 48 hours	C-II
Allogeneic transplant	Fluconazole	400 mg/day	A-I
	Fluconazole	50–200 mg/day	C-I
	Itraconazole	400 mg/day oral solution	C-I
	Liposomal amphotericin B	1.0 mg/kg/day	C-I
Solid tumors	Any antifungal	Any dose	C-I

Acute Toxicities of Therapy: Pulmonary Complications

Scott E. Evans and Andrew H. Limper

Surveillance data indicate that adverse drug reactions result in between 3.5% and 32.9% of hospitalizations.¹⁻³ Of the more than 350 medications known or suspected of causing pulmonary complications, a substantial number are chemotherapeutic agents.

Twenty percent of patients receiving cytotoxic chemotherapeutic agents (10% or less for noncytotoxic drugs) develop symptoms of untoward pulmonary reactions.^{4,5} Up to 3% of patients on some cytotoxic regimens will succumb to pulmonary-related mortality.^{6,7} An estimated 5% to 30% of pulmonary disorders in cancer patients are directly attributed to chemotherapy.⁸ Further, a Mayo Clinic study of lung biopsies from immunocompromised patients with diffuse lung disease, implicated chemotherapeutic agents as causative 21% of the time.⁹

Despite the prevalence of chemotherapy-associated pulmonary toxicity (CAPT), the assessment of these effects remains difficult. The myriad presentations of CAPT are often nonspecific and vary both by drug and by individual patient.^{4,10} Further, although unrecognized CAPT may be fatal, so too are the conditions from which it must most often be differentiated: progression or metastasis of the underlying malignancy and pulmonary infections in the immunocompromised cancer patient. Unfortunately, neither blood tests nor even biopsy can alone confirm the diagnosis of CAPT,^{9,11} and, accordingly, the diagnosis of CAPT is sometimes a diagnosis of exclusion.^{11,12}

Typical Presentations

The first indications of CAPT often arise weeks to years after the initial administration of chemotherapeutic drugs. The most consistently described symptoms in CAPT are dyspnea, nonproductive cough, and, notably, fever. Chills are typically absent. Although the physical examination varies with the underlying process, the most common finding in CAPT is the presence of fine crackles.

With the possible exception of methotrexate pneumonitis-related hilar lymphadenopathy, specific X-ray presentations cannot be reliably used to predict the offending chemotherapeutic agent.¹³ The most frequently described chest X-ray findings are diffuse interstitial changes,^{13,14} and a

diffuse mixed alveolar-interstitial pattern may also be observed in some forms of CAPT (Figure 77.1).

High-resolution computed tomography (HRCT) of the chest may help exclude common CAPT mimics, such as some lower respiratory tract infection, radiation pneumonitis, or progression of malignancy.¹⁵ Although nonspecific, identification of suggestive HRCT findings may aid in the diagnosis of CAPT.¹⁶⁻¹⁸ The most common findings in CAPT are diffuse or multifocal ground-glass opacities, patchy areas of consolidation, interlobular septal thickening, centrilobular nodules, pleural effusion, and pulmonary nodules.^{13,14,18}

Gallium (⁶⁷Ga) uptake is elevated in most chemotherapy-induced pulmonary reactions.⁹ One study also prospectively showed that technetium (^{99m}Tc) pentetic acid (DTPA) scintigraphy can discriminate patients with methotrexate pneumonitis from those not receiving methotrexate.¹⁹

Routine pulmonary function testing is often recommended for patients managed with agents known to have pulmonary toxicities, particularly, bleomycin. Plethysmographic testing of lung volumes in CAPT can reveal evidence of restrictive lung disease, although spirometry does not generally demonstrate airflow obstruction.⁹ Probably the most sensitive pulmonary function parameter for identifying pre-clinical CAPT is the carbon monoxide diffusing capacity (D_{Lco}). Decrements in the D_{Lco} have been prospectively noted days to weeks before symptoms or radiographic changes of CAPT are evident,²⁰ and may offer an opportunity to minimize disease progression through drug withdrawal. Conflicting data exist, however, and some authors argue that isolated D_{Lco} decreases rarely progress to clinically relevant disease and improve after completion of therapy.²¹

Fiberoptic bronchoscopy with bronchoalveolar lavage and/or transbronchial biopsy is commonly performed in cases of suspected CAPT. The utility of this approach remains unproved in a prospective manner, although valuable information may be gained.⁵ In particular, the presence of lower respiratory tract infections may be excluded by either bronchoalveolar lavage or transbronchial biopsy with a reasonably strong negative predictive value. Either test may reveal alternate pulmonary diagnoses, and transbronchial biopsy may identify lymphangitic tumor spread. Although sampling error is always a concern with transbronchial biopsy, it has also been reported that lymphocytic alveolitis identified in a bronchoscopically obtained sample may be suggestive of CAPT.²²

The determination for open versus thoracoscopic biopsy must be made on a case-by-case basis, determined by features, such as clinical stability, location of infiltrates, and coagulopathies.²³

Largely as a result of differing mechanisms of injury and interindividual variations, no single histologic pattern has been identified to conclusively prove CAPT. In this respect, the most informative element of pathologic reports is often the exclusion of alternate conditions when CAPT is suspected.²⁴

Several classic histologic patterns have been described in CAPT. Most commonly described are “bizarre” changes of type II pneumocytes with marked cellular atypia and hyperplasia, but no changes suggestive of malignancy, and a reduction in the type I pneumocyte population. The simple presence of cytological atypia cannot by itself definitively establish chemotherapy-associated lung injury.

Interstitial inflammation is also frequently reported during CAPT and can be associated with septal thickening caused by fibrin and collagen deposition. Such extracellular matrix deposition can eventually progress to severe fibrosis, such as occurs during long-term bleomycin therapy (Figure 77.2). Other forms of CAPT, including that associated with cytosine arabinoside, demonstrate a pattern of diffuse alveolar damage. In addition, bronchiolitis obliterans-organizing pneumonia has also been described with chemotherapeutic agents. Because of the limited number of toxic responses the lung is capable of generating, many biopsy specimens in CAPT can be characterized no more precisely than interstitial pneumonia.²⁴

Also complicating the pathologic assessment of patients with CAPT, is incomplete understanding of the correlation between histologic changes and clinical disease. More precisely, the relevance of atypical epithelial cells recovered from bronchial washings or sputum samples remains unclear. Even when classic type II pneumocyte changes are observed, the rate of progression to symptomatic CAPT is unknown.

An understanding of the typical timing of various CAPT syndromes often facilitates determination of the significance of radiographic and pathologic findings. The majority of patients who develop CAPT present more than 2 months after the completion of therapy. Hypersensitivity pneumonitis and hypersensitivity-like inflammatory interstitial pneumonias, however, are most often reported in the early days to weeks of therapy and are most commonly described with methotrexate, procarbazine, carmustine (BCNU), paclitaxel, and bleomycin.²⁵ These patients present with features typical of hypersensitivity of other causes, including nonproductive cough, exertional dyspnea, fine crackles on examination, interstitial or mixed interstitial-alveolar infiltrates on radiographs, and often with peripheral and parenchymal eosinophilia. As with many other CAPT presentations, they also tend to have low-grade fevers. Another commonly problematic early-onset presentation of CAPT, is noncardiogenic pulmonary edema, with chemotherapy-induced endothelial inflammation leading to vascular leak. Cytosine arabinoside (ara-C), interleukin-2, all-*trans*-retinoic acid (ATRA), and bleomycin, are the most common culprits in this type of reaction.²⁵ Other well-characterized early presentations include bronchospasm (vinblastine, methotrexate), pleural effusion

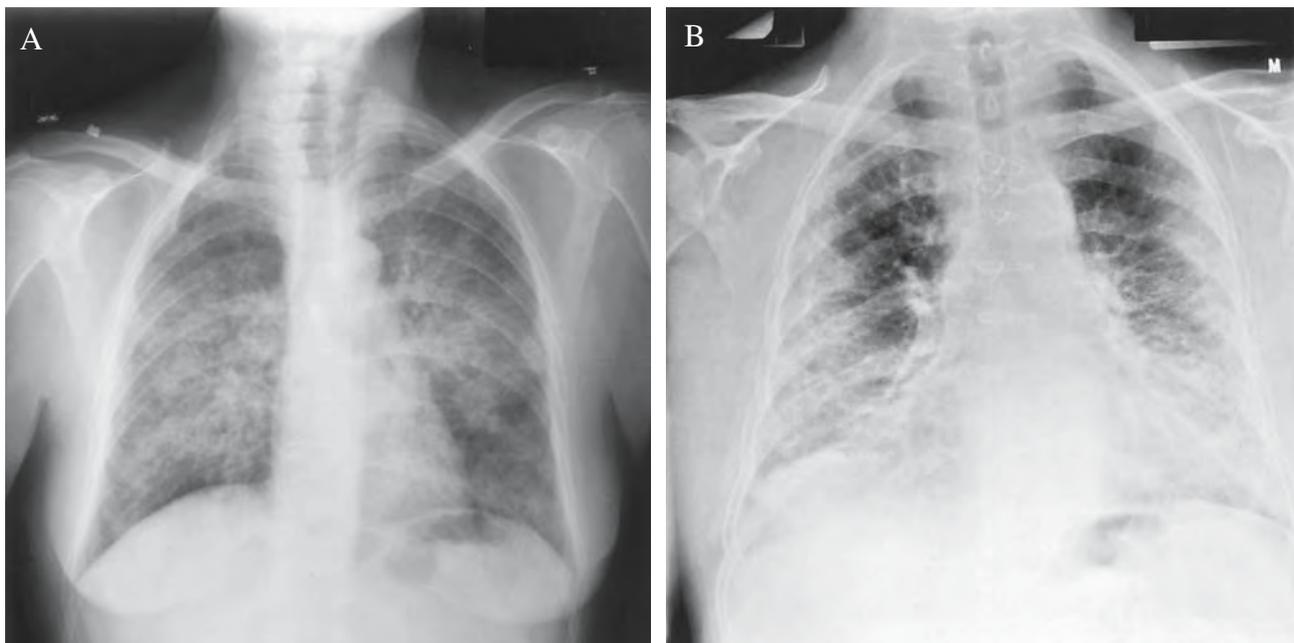

FIGURE 77.1. Radiographic patterns of chemotherapy-associated pulmonary toxicity. (A) Chest radiograph of a patient receiving busulfan therapy. The X-ray demonstrates diffuse mixed alveolar and inter-

stitial infiltrates. (B) Chest radiograph shows chronic interstitial fibrotic infiltrates in patient receiving long-term chlorambucil therapy.

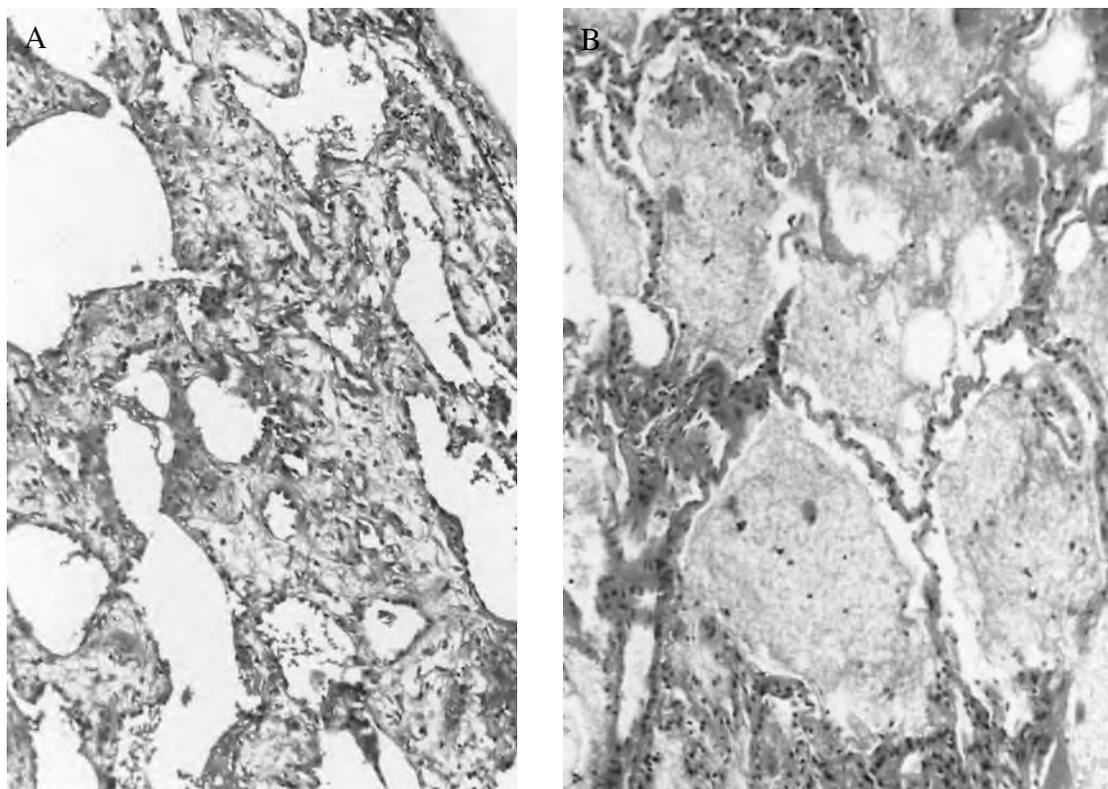

FIGURE 77.2. Histologic manifestations of chemotherapy-associated pulmonary toxicity (CAPT). (A) Bleomycin typically produces a pattern of chronic interstitial fibrosis remarkably similar to idi-

opathic usual interstitial pneumonia. (B) Certain types of CAPT, such as associated with high-dose cytosine arabinoside (ARA-C), produce a histologic pattern of diffuse alveolar damage.

(methotrexate, ATRA, mitomycin-C), and early-onset pulmonary fibrosis (ATRA, rarely bleomycin).

The norm is CAPT presentation months to years after initiation of therapy.^{9,25} Interstitial fibrosis is undoubtedly the most common manifestation of late-stage CAPT, with bleomycin, BCNU, busulfan, and mitomycin-C the biggest offenders.^{4,26} Although the radiographic distribution may be somewhat atypical, the histologic features of CAPT-induced fibrosis are generally identical to those in idiopathic pulmonary fibrosis. In addition to interstitial fibrosis, both pleural thickening and pulmonary nodules have been described with late-stage extracellular matrix deposition and bronchiolitis obliterans-organizing pneumonia. Intriguingly, cytotoxic chemotherapeutic agents have also been associated with exacerbations of previously established radiation pneumonitis with fibrosis, so-called radiation recall effects.⁶ And, conversely, patients with cytotoxic agent-induced fibrosis have been shown to display accelerated collagen deposition following exposure to high inspired oxygen concentrations for at least 6 months after completion of therapy.⁶

Regardless of the specific agent, the central tenets of CAPT management are cessation of exposure to the drug and supportive care. Oxygen supplementation, mechanical ventilation, diuresis, and even lung transplantation have been used when clinically necessary. Corticosteroid therapy is also widely advocated for many severe reactions, although data are lacking to show proof of effect for most CAPT reactions.^{9,10,12,26}

Specific Agents

Antibiotics

BLEOMYCIN

With reports of 20% to 46%⁶ of treated patients demonstrating clinically relevant CAPT and 1% to 3% mortality,^{7,27} bleomycin is both the most common cause of CAPT and the prototypical example. Although other uncommon presentations abound, pulmonary fibrosis is the characteristic manifestation of bleomycin toxicity (Table 77.1).

Bleomycin toxicity appears to result from direct cellular damage by the drug.⁶ The predilection for bleomycin to affect lung and skin, results from relatively low levels of the inactivating enzyme bleomycin hydrolase in these cells,⁶ and allows for drug accumulation and DNA fragmentation in pneumocytes. Type I pneumocytes are typically affected first, but because type II cells proliferate to replace injured type I cells, they are affected as well. The cell-cycle-dependent manner of type II cell injury results in increased risk of type II cell injury with repeated dosing. The fibroblast proliferation in bleomycin-induced fibrosis occurs both by direct stimulation of fibroblasts by the drug and as a secondary consequence of pneumocyte depletion. An additional component of free radical-related injury almost certainly exists and likely accounts for subsequent sensitivity to oxygen therapy.

TABLE 77.1. Reported manifestations of bleomycin-induced pulmonary toxicity.

Chronic interstitial pneumonia/chronic fibrosis
Acute interstitial pneumonia/acute fibrosis
Bronchiolitis obliterans-organizing pneumonia
Hypersensitivity pneumonitis
Single or multiple pulmonary nodules
Chest pain
"Radiation recall"/exacerbation of prior radiation fibrosis
Chronic eosinophilic pneumonia
Pneumothorax (rare)

Many studies have been undertaken to identify those most at risk for bleomycin-induced disease, and cumulative dose is among the most convincing risk factors. Although toxicity has been described with as little as 20 units, most bleomycin-induced fibrosis occurs in patients who have received more than 450 units.²⁷ At doses greater than 550 units, the mortality rates can exceed 10%. Age also appears to affect the likelihood of bleomycin-induced lung disease. Bleomycin-treated patients over 70 years of age demonstrate a significant increase in the incidence of fibrosis.⁶ Conversely, children also may be at elevated risk, with up to 70% of patients treated for rhabdomyosarcomas developing some fibrosis.²⁵ Human studies predict risk factors based on polymorphisms of the tumor necrosis factor- α_2 domain,²⁸ and animal investigations have implicated numerous foci in bleomycin susceptibility, including p53.²⁹

In addition to the direct effects of the drug, bleomycin is uniquely prone to synergistic effects with other pulmonary toxic agents.^{9,25,26} As already described, pneumonitis related to prior or concomitant radiotherapy can be exacerbated, or even induced, by bleomycin. Inspiring high oxygen concentrations during or after bleomycin treatment can foster progression of bleomycin injury,⁶ often encountered during surgery or during episodes of acute respiratory failure. The durability of this effect is unclear, but this oxygen sensitivity has been clearly noted for months to years after therapy with bleomycin. Further, a host of other chemotherapeutic agents are reported to have enhanced pulmonary toxicities when coadministered with bleomycin. Implicated drugs include cyclophosphamide, vincristine, doxorubicin, methotrexate, and possibly, granulocyte colony-stimulating factor (G-CSF).²⁵

Although prospective evidence of benefit is lacking, many clinicians advocate frequent monitoring of the diffusing capacity to predict the development of clinically apparent bleomycin toxicity. Drug withdrawal is generally recommended when there is a progressive fall in $D_{L_{CO}}$. Studies have failed to conclusively link subtle gas exchange abnormalities with dose-limiting toxicity, with some authors arguing that changes in the vital capacity and pulmonary capillary blood volume are better predictors of impending CAPT.²¹ CT scanning appears somewhat helpful in the diagnosis of subclinical bleomycin fibrosis, with one series showing 38% abnormal CT scans but only 15% abnormal chest X-rays.⁶ This finding bears unclear relevance, as up to 20% of patients with findings indicative of bleomycin toxicity are asymptomatic.³⁰

After discontinuation of the drug, any additional therapy for bleomycin-induced fibrosis is strictly empiric. Expert,

mostly anecdotal, opinion suggests dosing prednisone equivalents of approximately 60 mg per day for worsening fibrosis. Outcomes data following corticosteroid therapy are widely variable.

In addition to the characteristic fibrosis, bleomycin toxicity manifests in many other, less common presentations. Numerous radiographic patterns are described, including acute interstitial changes and rare pneumothoraces. Among the most troublesome presentations, is the development of single or multiple pulmonary nodules. Because the primary diagnosis from which this must be differentiated is the progression of malignancy, essentially all suspected bleomycin-induced nodules must be biopsied. Most nodules that prove nonmalignant demonstrate histologic features of bronchiolitis obliterans-organizing pneumonia. Hypersensitivity pneumonitis and chronic eosinophilic pneumonia have also been rarely reported during bleomycin therapy, with abrupt onset symptoms, cough, fever, exertional dyspnea, and eosinophilia.³¹

MITOMYCIN C

Mitomycin C-related CAPT has been estimated to occur in the range of 8% to 39% of treated patients.^{25,26} In many ways, mitomycin-induced changes are similar to those of bleomycin, with toxicity commonly evident as an interstitial pneumonitis with fibrosis that occurs 3 to 12 months after completion of therapy. As with bleomycin, mitomycin-treated patients appear more likely to develop significant toxicities when exposed to high inspired oxygen concentrations or radiation therapy. Additionally, prior or concomitant therapy with bleomycin, cisplatin, cyclophosphamide, doxorubicin, or vinca alkaloids is a risk factor for mitomycin-induced fibrosis. As with bleomycin, the $D_{L_{CO}}$ often falls before the development of fibrosis-related symptoms. However, the development of symptoms after a decline in the $D_{L_{CO}}$ is less common than with bleomycin (in one series, 28% of treated patients had a reduction in the $D_{L_{CO}}$, but only 5% developed symptoms).³² Suggested therapy for mitomycin-induced fibrosis is identical to that of bleomycin: drug discontinuation, avoidance of high oxygen tensions, and supportive care. Corticosteroids are reported to be somewhat more beneficial in mitomycin toxicity than with bleomycin.

Unique to mitomycin toxicity are accumulating case reports of a microangiopathic hemolytic anemia; this is associated with renal failure and noncardiogenic pulmonary edema, with perhaps half of these patients progressing to acute respiratory distress syndrome. Pathologic review demonstrates arteriolar intimal hyperplasia, capillary cellular atypia, and fibrin thrombi in the kidneys and lungs. Risk factors for this syndrome appear to include fluorouracil therapy and blood transfusions.³³

OTHER ANTIBIOTICS

Actinomycin D appears particularly prone to radiation recall effects, even when the drug is given long after completion of radiation therapy.^{25,26} It otherwise behaves similarly to the other antineoplastic antibiotics. Mitoxantrone occasionally induces interstitial pneumonia.²⁶ Phase I trials of the mitomycin C analog KW-2149 have also induced dose-limiting CAPT that was not prevented by prophylactic corticosteroid administration.³⁴

Alkylating Agents

BUSULFAN

First identified in 1961, busulfan was the first chemotherapeutic agent linked to pulmonary toxicity. Although the alkylating agents often demonstrate less CAPT when used as monotherapy than many other agents, prediction of patients who will develop busulfan toxicity remains very difficult. No risk factors have been convincingly identified,¹¹ and no relationship to cumulative dose has been demonstrated. Further, symptom development averages 3.5 years after completion of therapy and is reported as much as a decade later. Even more troubling is the fact that mortality rates from busulfan CAPT are exceedingly high (estimated 80%), and no therapies are known to improve this.²⁵

Busulfan toxicity probably occurs in about 4% to 6% of patients (reported range, 2.5% to 43%).³⁵ In general, the clinical findings are similar to those of bleomycin toxicity, with progressive fibrosis. These patients may have a greater predilection for mixed alveolar-interstitial patterns on radiographs. Accordingly, histologic findings often demonstrate lymphocytic and plasma cell infiltration, in addition to fibrosis and type II pneumocyte hyperplasia with atypia. Alveolar proteinosis is also occasionally described with busulfan toxicity. By report, the proteinosis is more refractory to lavage therapy than primary alveolar lipoproteinosis. No data exist regarding corticosteroid therapy in busulfan-induced alveolar proteinosis.⁹

CYCLOPHOSPHAMIDE

Although some experts have suggested that the incidence of cyclophosphamide-induced pulmonary toxicity is underestimated, current estimates indicate that less than 1% of patients develop fibrosis with therapy.²⁵ A review of 20 years experience at the Mayo Clinic identified only six cases in which cyclophosphamide was the only factor contributing to pulmonary toxicity.³⁶

Cyclophosphamide toxicity typically presents as one of two temporally distinct variants.³⁶ Both present with dyspnea, fever, nonproductive cough, and new parenchymal infiltrates. The early-onset variety (6 months or less of initiation of therapy) is often mistaken for an infectious pneumonia because of its rapidity of onset. This variety responds well to drug withdrawal alone and may resolve entirely without additional intervention. The late-onset form (months to years after initiating therapy) displays less encouraging outcomes. The interstitial radiographic changes in late-onset cyclophosphamide toxicity include marked, progressive fibrosis, often with honeycombing, and may be associated with bilateral pleural thickening. On histologic section, the fibrosis in cyclophosphamide toxicity is associated with lymphocytic and plasma cell infiltrates and organizing pneumonia. In this form of toxicity, the pulmonary-related mortality approaches 60% despite drug withdrawal and corticosteroids.³⁶

It appears that cumulative dosing of greater than 150 to 250mg may be associated with CAPT, although this association is not universally accepted. The risk of cyclophosphamide toxicity is likely elevated when used in conjunction with carmustine (BCNU) for conditioning before bone marrow transplantation, but no other drugs have been implicated in inducing cyclophosphamide toxicity. For additionally

unclear reasons, some patients with a history of resolved cyclophosphamide toxicity can be rechallenged with the drug and not redevelop the syndrome. For safety reasons, this practice is not recommended. As previously noted, cyclophosphamide may exacerbate bleomycin toxicity.

IFOSEAMIDE

Ifosfamide has rarely been reported to cause pulmonary toxicity. These occasional reports describe fibrosis similar to that seen in cyclophosphamide, as might be expected given the chemical similarities of the two agents.

VINBLASTINE

Aside from anecdotal reports of noncardiogenic pulmonary edema,³⁷ vinblastine has not historically been associated with significant pulmonary toxicities, despite many years of use. In recent years, however, combination therapies that include vinblastine have resulted in increased reports of CAPT. Approximately 2% of patients treated with concurrent vinblastine and mitomycin C present with noncardiogenic pulmonary edema, interstitial fibrosis, or bronchospasm.³⁷

CHLORAMBUCIL

Chlorambucil occasionally induces an interstitial pneumonitis similar to that seen with busulfan and cyclophosphamide. Peak timing for this complication occurs in the range of 6 to 12 months after initiating therapy; this generally occurs with doses between 2 and 7.5g and is associated with high mortality rates.^{25,26}

MELPHALAN

Rare cases of pulmonary toxicity have been described with high-dose (200mg/m² or more) melphalan use.³⁸ Some experts have argued that the incidence is underestimated, although given the chronicity of use for many melphalan-treated diseases, this seems unlikely. Similar to chlorambucil, when present, melphalan toxicity is associated with high mortality rates.

Antimetabolites

METHOTREXATE

Methotrexate pneumonitis has been confirmed in several hundred cases⁸ but represents a quite unusual phenomenon.^{39,40} Further, methotrexate pneumonitis-related fatalities are reported in less than 10% of affected patients.^{26,39}

The CAPT associated with methotrexate is unique in many aspects. The timing of symptoms is earlier than with most chemotherapeutic agents. Most patients who eventually experience cough, dyspnea, and nonproductive cough, do so in the first days to weeks of therapy, and only rarely in subsequent weeks or months. The histologic features on biopsy are usually more consistent with hypersensitivity pneumonitis than with fibrosis. More than half of affected patients have a peripheral eosinophilia, also supporting a hypersensitivity state. The radiographic presentation of methotrexate pneumonitis is usually homogeneous interstitial infiltrates, although methotrexate is also uniquely prone to causing pleural effusions or hilar lymphadenopathy.

Most cases of methotrexate pneumonitis resolve with drug withdrawal alone. In the rare cases of acute fibrotic reactions, corticosteroid therapy is thought to reduce sequelae and to improve mortality.³⁹ The development of methotrexate pneumonitis does not appear to be dose related, and fatalities have been described following intrathecal as well as oral administration. Fatal noncardiogenic pulmonary edema has also been seen after intrathecal administration.³⁷ As with a handful of other chemotherapeutic drugs, patients with confirmed cases of methotrexate pneumonitis have been later rechallenged without redevelopment of the toxicity. In general, we do not, however, recommend rechallenge with methotrexate or any other agent causing CAPT.

CYTOSINE ARABINOSIDE (ARA-C)

Noncardiogenic pulmonary edema is the respiratory complication most frequently reported with ara-C therapy and has a high mortality.⁴¹ Pathologic review typically demonstrates proteinaceous material filling alveolar airspaces but not the pneumocyte atypia or inflammatory infiltrates described with most other chemotherapeutic agents. An estimated 13% to 28% of patients develop respiratory complaints during administration of ara-C, and more than 40% develop symptoms within 1 month. Clinical management relies on oxygen supplementation and mechanical ventilation, if needed. Diuretics may be beneficial, and some have suggested that clearance is enhanced by corticosteroids.⁴¹

GEMCITABINE

Although often regarded as minimally toxic to the lungs, gemcitabine has also been associated with fatal noncardiogenic pulmonary edema.^{37,42} This event results from a vascular leak syndrome, comparable to that seen with chemically similar ara-C.⁴¹ Gemcitabine therapy induces severe dyspnea in 3% to 5% of treated patients,⁴¹ and pulmonary edema affects 0.1% to 7%, usually after multiple doses.⁴³ Pulmonary edema may occur more frequently when gemcitabine is combined with docetaxel.³⁷ The early introduction of corticosteroids has been advised for gemcitabine-related pulmonary edema.⁴¹ Interstitial pneumonitis has been rarely reported with gemcitabine and also appears to improve with steroid therapy.⁴⁴

OTHER ANTIMETABOLITES

Azathioprine and its metabolite 6-mercaptopurine have both been occasionally reported to cause interstitial pneumonias, although many cases are confounded by the coadministration of other drugs that may have similar toxicities. Most cases of azathioprine-associated pulmonary fibrosis have been reported following solid organ transplants.²⁶ Similarly, fludarabine has rarely been reported to cause chronic interstitial fibrosis, acute eosinophilic pneumonia, and hypersensitivity pneumonitis, with apparent corticosteroid benefit.⁴⁵⁻⁴⁷

Nitrosoureas

CARMUSTINE (BCNU)

BCNU has been associated with several distinct CAPT syndromes, with an overall incidence estimated between 1.5%

and 20% of treated patients. Some patients experience an early-onset alveolitis and fibrosis, as can be seen with bleomycin. This phenomenon appears dose related, likely at dosages greater than 1,400 mg/m²,⁴⁸ although this has clearly occurred among patients receiving much lower doses.⁴⁹ Some experts note that fever is less prominent with BCNU than in other CAPT syndromes.

BCNU also results in late-phase pulmonary fibrosis, 6 months to 3 years after completion of therapy. All the nitrosoureas have been reported to cause fibrosis, but BCNU has been most often described to produce this effect. It is also uniquely predisposed to cause upper lobe predominant fibrosis. In fact, one small long-term series suggested the incidence of upper lobe fibrosis might surpass 70% if patients are followed long enough. In general, patients with BCNU-related fibrosis experience clinical courses similar to that seen with bleomycin-related fibrosis, although the response to corticosteroids is reportedly more robust.⁴⁹

Another unique feature of BCNU-related CAPT is the occurrence of drug-induced pneumothoraces, which is seldom described with any other chemotherapeutic agent; this may be related to the upper lobe fibrobullous changes induced by this agent.

BCNU synergistically induces pulmonary toxicity with other antineoplastic interventions, including cyclophosphamide and radiation therapy, as mentioned previously. BCNU-containing regimens also exacerbate bone marrow transplant-related pulmonary toxicity, with up to 40% incidence.²⁶ Underlying lung diseases, especially chronic obstructive pulmonary disease and certain pneumoconioses, also place patients at higher risk of BCNU toxicity.

OTHER NITROSOUREAS

Occasional reports of inflammatory pneumonitis and chronic fibrosis have been associated with lomustine (CCNU), semustine (methyl-CCNU), fotemustine (CENU), and chlorozotocin. Rare reports of pneumothoraces have also surfaced with these agents. Their pulmonary toxicities are expected to be closely aligned with those of BCNU, given their chemical similarities.

Interleukin 2 (IL-2)

Most patients receiving IL-2 develop some manifestation of pulmonary toxicity, primarily because of its induction of severe vascular leakage. Early experience with IL-2 resulted in pulmonary radiologic infiltrates in up to 80% of patients and pleural effusions in more than half. More recent data place the risk of severe vascular effects in the range of 3% to 20% of treated patients. Risk factors for development of the vascular phenomenon include reduction in pretreatment airflows, previous chemotherapy, and bolus infusion of IL-2.

The noncardiogenic pulmonary edema resulting from IL-2-induced vascular leak can lead to acute respiratory distress syndrome. Complicating the management of NCPE/ARDS is the potential for IL-2 to cause cardiac toxicity, thereby inducing cardiogenic pulmonary edema. Fortunately, even in the case of severe toxicity, the process resolves in most patients within days of cessation of therapy.³⁷ There may be a role for prostaglandins or cyclooxygenase-2 inhibitors in manage-

ment of this toxicity, although clinicians are increasingly aware that it may often be avoided through careful patient selection.³⁷

IL-2 is also responsible for inducing hypersensitivity pneumonitis, as well as bronchospasm in patients without preexisting asthma. Both conditions tend to resolve with discontinuation of therapy.

Gefitinib

Considerable recent attention has been paid to the pulmonary toxicity of gefitinib, the selective epidermal growth factor receptor-tyrosine kinase inhibitor recently approved in the United States for management of salvage therapy of non-small cell lung carcinoma. By mid-2003, nearly 200 deaths had been reported as a result of respiratory failure among more than 10,000 patients in Japan.^{50,51} The best characterized series reports 4 patients among 18 gefitinib-treated patients who developed severe acute interstitial pneumonia. All 4 patients had undergone previous thoracic radiation and/or had a low performance score; 2 subsequently improved with corticosteroids, and 2 patients died.⁵² Although this agent is restricted in use to patients who have failed platinum-based therapy, post-marketing experience will certainly enhance the understanding of its CAPT.

Miscellaneous Chemotherapeutic Agents with Pulmonary Toxicities

Procarbazine infrequently causes CAPT, usually after the third or fourth dose. The characteristic toxicity seen with procarbazine is hypersensitivity pneumonitis, with marked eosinophilia. In most cases, this syndrome resolves following discontinuation of procarbazine therapy. Reports of procarbazine-induced fibrosis are exceedingly rare.⁵³

Zinostatin is described to occasionally result in an interstitial pneumonia, particularly among patients receiving long-term therapy. One histologic feature distinguishing zinostatin-related CAPT from that of other drugs, is its propensity to induce endothelial hypertrophy in the pulmonary vasculature.⁹

Case reports implicate etoposide (VP-16) as having pulmonary toxic effects.⁵⁴ However, its frequent use in the management of small cell lung cancer (especially in combination with known pulmonary toxic agents, such as methotrexate and cyclophosphamide) has confounded the comprehensive evaluation of its pulmonary toxicity.

The pulmonary effects of tumor necrosis factor- α in anti-neoplastic therapy remain unclear. One small study prospectively showed statistically significant reductions in the D_{LCO} in all patients studied but did not identify other physiologic manifestations of CAPT.⁵⁵

Roughly one-quarter of patients receiving all-*trans* retinoic acid (ATRA) for acute promyelocytic leukemia develop a vascular leak syndrome similar to that seen with IL-2; this is believed to result from the sudden differentiation of blasts into mature granulocytes that then adhere to the pulmonary endothelium. Absolute blast count is the only identified risk factor for this syndrome, although a specific number below which ATRA is safe remains unidentified. ATRA can also induce acute pulmonary fibrosis in a smaller

percentage of patients. In addition to drug withdrawal, steroids appear beneficial if started early.³⁷

The taxanes paclitaxel and docetaxel have both been reported to cause noncardiogenic pulmonary edema,^{25,37} and numerous radiographic patterns have been described for treated patients.¹⁴ Hypersensitivity pneumonitis occurs in 3% to 5% of paclitaxel treated patients,⁵⁶ although some of the reported patients were likely hypersensitive to the suspension vehicle (Cremophor EL) rather than the antineoplastic agent.²⁶ The concurrent use of thoracic radiation has been shown to exacerbate the pulmonary toxicity of paclitaxel.⁵⁷

Monotherapy with granulocyte colony-stimulating factor (G-CSF) occasionally induces noncardiogenic pulmonary edema.³⁷ More frequently, however, it exacerbates preexisting lung injury, whether caused by CAPT or acute lung injury associated with previous critical illness.^{58,59} This effect likely occurs by a neutrophil-dependent mechanism, and it responds well to corticosteroids in most cases.⁶⁰ Further understanding of G-CSF-induced toxicities is hindered by the rarity with which it is used as monotherapy.⁶⁰

When used in combination with radiation therapy, irinotecan (CPT-11) results in more respiratory symptoms than are seen among patients receiving radiotherapy alone. This finding is notable, given the already high incidence (17.4% to 22%) of cough and dyspnea with CPT-11 therapy.⁶¹ A wide range of radiographic patterns accompany the respiratory symptoms, including very rare pleural effusions.¹⁴ Fatal respiratory insufficiency has been reported with CPT-11 treatment.⁶¹

Hormone therapy is generally regarded as having little pulmonary toxicity. However, one well-characterized case report describes severe pulmonary fibrosis following therapy with nilutamide and buserelin.⁶²

Combination Therapies

Many specific combinations of chemotherapeutic agents are reported to induce pulmonary toxicities at rates greater than expected from their additive effects. Several are described in the foregoing chapter. Additionally, Table 77.2 describes several additional combinations of agents with their reported toxicities.

Radiation Effects

The acute effects of radiation can produce tissue changes that mimic cytotoxic lung responses and may on occasion involve areas of lung outside the port of radiation. The process is generally initiated with fever beginning 3 to 8 weeks after initiation of radiation therapy and may progress rapidly to a respiratory failure despite corticosteroid therapy. The disease may improve spontaneously but usually progresses to chronic radiation effects. Bronchoalveolar lavage predominantly demonstrates lymphocytes, not only in the involved lung but also in the opposite lung.⁶³ The chronic effects of radiation are well known: they begin 3 to 6 months or later after radiation therapy, and their primary effect is vascular obliteration and fibrosis.⁶⁴ Recently, a form of radiation pneumonitis has been observed outside the treatment fields, usually in patients with breast cancer.⁶⁵ Tissue examination has revealed bronchiolitis obliterans with organizing pneumonitis in these cases.⁶⁵

TABLE 77.2. Chemotherapeutic combinations reported to induce pulmonary toxicity.

<i>Combination</i>	<i>Toxicity</i>
Adriamycin, bleomycin, vincristine, dexamethasone (ABVD)	Interstitial fibrosis
Cyclophosphamide, cisplatin, carmustine (CPB)	Interstitial fibrosis
Mitoxantrone, methotrexate, mitomycin C (3M)	Radiation sensitivity
Carmustine, etoposide, melphalan (BEM)	Acute interstitial pneumonia
Carmustine, etoposide, cyclophosphamide (BVC, CBV)	Acute interstitial pneumonia
Doxorubicin, cyclophosphamide, 5-fluorouracil (CAF)	Interstitial fibrosis
Fludarabine, cytarabine, idarubicin, G-CSF (FLAG-ida)	Interstitial fibrosis
Cyclophosphamide, dexamethasone, etoposide, cisplatin (CDEP)	Acute interstitial pneumonia
Cyclophosphamide, methotrexate, etoposide	Acute interstitial pneumonia
Docetaxel, gemcitabine	Pulmonary edema
Docetaxel, estramustine	Acute interstitial pneumonia
Paclitaxel, carboplatin	Interstitial fibrosis
Doxorubicin, G-CSF	Acute interstitial pneumonia
Doxorubicin, vindesine	Acute interstitial pneumonia
Vinblastine, mitomycin C	Pulmonary edema

Listed are combinations of agents with toxicities reported to occur with greater frequency than would be anticipated from the summative effects of the components, along with their described effects.

Conclusions

Uniformity in reporting untoward pulmonary effects of chemotherapy, thereby enhancing our collective ability to diagnose and manage CAPT, is essential in advancing our understanding of these processes. One system proposed by the authors is outlined in Table 77.3. The goal of this approach is to standardize the commonly used clinical criteria for diagnosis of drug-induced lung disease, including drug exposure, usual clinical symptoms, and time course consistent with the suspected drug, exclusion of competing diagnoses, and beneficial response to withdrawal of the agent. Widespread use of such a system would promote a more uniform approach to reporting CAPT and enhance critical appraisal of the available literature. In addition to better defining CAPT, authors must also be challenged to describe its severity. This practice will help evaluate the success of interventions and provide data by which one can weigh the risks and benefits of a therapeutic regimen. Such a scoring system has been endorsed for studies of radiation-induced lung toxicity⁶⁶ but has not been defined for CAPT.

State-of-the-art management for CAPT relies on early recognition of consistent syndromes and prompt drug withdrawal when necessary. Supportive care and empiric anti-inflammatory therapies are utilized when removal of the offending agent is insufficient. As CAPT is better defined, the systematic assessment of risk factors will certainly assist clinicians to avoid the induction of CAPT syndromes before they develop.

TABLE 77.3. Clinical criteria for diagnosis of chemotherapy-associated pulmonary toxicity (CAPT).

Symptom complex consistent with suspect drug
The time course (acute, subacute, chronic, delayed) is compatible with that suspect drug
Reasonable competing diagnoses have been excluded
Objective improvement after drug D/C'ed
BAL and tissue compatible
Occurs after rechallenge: the latter is NOT recommended

Definite CAPT requires five criteria are met; probable CAPT requires four criteria are met; suspected CAPT requires three criteria are met.

Cardiac Complications

Maged I. Gharib and Alan K. Burnett

Cardiac toxicity is a well-recognized serious side effect of chemotherapy. Since early reports of heart failure in children treated with doxorubicin,¹ anthracyclines remain the best known chemotherapeutic agents clearly linked to cardiotoxicity. There are, however, a number of other chemotherapeutic agents that cause cardiotoxicity which are still not so well recognized in clinical practice.

Cardiac toxicity may occur acutely, during, or up to 1 week following the administration of chemotherapy, usually as mild transient blood pressure and/or electrocardiographic (ECG) changes. More serious acute cardiotoxicity, such as arrhythmias, myocarditis, pericarditis, or myocardial infarction occur less commonly. The most clinically significant, however, is the anthracycline-induced chronic progressive cardiomyopathy, which may end in left ventricular failure (LVF) or congestive heart failure (CHF).

Cytotoxic Antibiotics (Anthracyclines and Mitoxantrone)

Anthracyclines

The cytotoxic antibiotics daunorubicin and doxorubicin were originally extracted from fungi belonging to the species *Streptomyces*. They are very efficacious broad-spectrum antineoplastic agents that demonstrate a clear dose-response relationship in several curative chemotherapeutic regimens.^{2,3} Their cardiotoxicity, however, remains the major limiting factor for their use at high doses that could substantially improve the cure rates of various cancers. Two distinct subtypes of cardiotoxicity could follow anthracycline use.

ACUTE/SUBACUTE CARDIOTOXICITY

This form of cardiotoxicity occurs within a week of anthracycline administration. Although rare, it may occur after only one dose. It seldom leads to serious clinical consequences. Transient electrophysiologic abnormalities detected as ECG changes may be seen in 20% to 30% of the patients as non-specific ST- and T-wave changes, T-wave flattening, decreased QRS voltage, and/or prolongation of the QT interval. Arrhythmias, including ventricular, supraventricular, and junctional tachycardias, are seen in 0.5% to 3% of patients with an overall incidence of 0.7%.⁴ More serious arrhythmias, such as atrial flutter or atrial fibrillation, are rare. Subacute cardiotoxicity has resulted in acute left ventricular failure, peri-

carditis, or a fatal pericarditis-myocarditis syndrome in some rare cases.⁵ No clear risk factors have been linked to this form of cardiotoxicity, and it does not appear to be related to the chronic progressive form.⁶

CHRONIC PROGRESSIVE CARDIOTOXICITY

Chronic progressive cardiotoxicity is the more recognized and clinically significant subtype of cardiotoxicity. Authors used to subdivide chronic anthracycline-induced cardiomyopathy into early-onset⁷ and late-onset subtypes.^{6,8} This designation originated from the earliest work published on this subject by Von Hoff and associates,⁷ who reported that heart failure as a result of anthracycline-induced cardiomyopathy occurred 0 to 231 days after the completion of therapy. They retrospectively analyzed 4,018 records of patients treated with anthracyclines; their endpoint was "clinically manifest" congestive heart failure as "recorded" by the treating clinician. With accumulation of data over the years, it became apparent that cardiotoxicity remained subclinical but progressed over time only to become "clinically manifest" years after completion of the treatment. Steinherz and coworkers have shown that the both the incidence and severity of systolic ventricular dysfunction increased with the length of follow-up.⁹ It therefore seems logical not to use this artificial classification.

PATHOGENESIS

The exact mechanism through which anthracyclines cause cardiac damage is still debatable and is probably multifactorial. There is a general consensus that doxorubicin undergoes redox cycling to generate free radicals that are responsible for mediating the myocyte damage. The quinone form of doxorubicin is reduced to the free radical semiquinone form by cytochrome P-450 reductase, particularly in myocardial cells with a high level of flavin-centered reductases.⁶ The subcellular targets continue to be debated, however. Anthracyclines have been shown to alter transcription of myocellular proteins.¹⁰

INCIDENCE

Because of the variability of treatment protocols (doses, rates of administration, and combination with other chemotherapeutic agents and/or mediastinal irradiation), parameters used for the assessment of cardiac functions and endpoints in different reports (clinically manifest or subclinical echocardiographic finding), age at exposure, and the time lapsed since exposure, it is not surprising to see a lack of consensus on the reported incidence of this complication.⁹⁻²⁵ An incidence of

65% of increased afterload or decreased contractility has been reported with cumulative doxorubicin doses as low as 228 mg/m² in children treated for leukemia 15 years after treatment.¹¹ In the majority of cases, this effect remains subclinical. The incidence of symptomatic heart failure during or within the first year of completing anthracycline therapy is less than 3%.^{7,9,12} It should be emphasized, however, that early-onset cardiotoxicity (occurring during or within 1 year of anthracycline therapy) is the largest predictor of the deterioration over time.^{9,11,13,14} At 15 years after treatment, up to 5% of children treated with anthracyclines at cumulative dose higher than 300 mg/m² develop heart failure.²⁵

RISK FACTORS

Risk factors for anthracycline-related chronic progressive cardiotoxicity include the following:

- Total cumulative dose^{7,9,10,25}; this, by far, is the most important risk factor
- Age at anthracycline administration^{7,11,13,20}
- Rate of administration^{7,15–20}
- Female gender^{13,21}
- Preexisting heart disease and hypertension⁷
- Mediastinal irradiation^{22–24}
- Interval since anthracycline chemotherapy should also be considered as a risk factor, particularly in those who received the drug in their childhood^{9,11,13,14}

The incidence of CHF secondary to doxorubicin-induced cardiomyopathy is strongly linked to the cumulative dose of the drug.^{7,8,9,11–14} In adults, with a cumulative dose of less than 400 mg/m², the incidence of *early* CHF was 0.14%, compared with 7% at a dose of more than 550 mg/m² and to 18% at a dose of more than 700 mg/m².⁷ This rapid increase in the clinical cardiotoxicity at doses greater than 550 mg/m² has made it a common empirical maximum allowable cumulative dose in clinical practice. There appears to be great individual variability in the tolerable anthracycline dose in both adults and children. Five patients in Von Hoff's series (3,941 patients) received more than 1,000 mg/m²; none of them sustained early CHF.⁷ A cumulative dose of anthracycline guaranteed not to lead to cardiomyopathy has not been established.¹⁴

Children appear to be at higher risk of developing anthracycline-induced cardiotoxicity.^{11,13,20} Age less than 4 years at the time of exposure has been shown to be a significant risk factor for abnormal cardiac function; it was mainly predictive of increased afterload caused by reduced ventricular wall thickness.¹¹ Anthracyclines have been shown to alter transcription of myocellular proteins.¹⁰ The inappropriate reduction in the left ventricular wall thickness found in children previously treated with anthracyclines^{11,14} could be the result of such an effect. In adults, an increasing risk of doxorubicin-induced CHF with increasing patient age has been observed ($P = 0.0027$).⁷ Previous cardiac disease and hypertension may also potentially increase the risk of doxorubicin-induced CHF ($P = 0.08$).⁷

Anthracycline-induced cardiotoxicity seems to be related to the peak plasma drug concentration. The antineoplastic activity seems, however, to be dependent on the total systemic exposure or the tissue concentration over time and not the peak plasma concentration.¹⁵ Doxorubicin appears to be less cardiotoxic when administered as a prolonged, continu-

ous intravenous infusion over more than 48 to 96 hours.¹⁵ A 2.81-fold-greater risk of developing cardiomyopathy after a maximum single dose of 50 mg/m²/dose has been reported as compared with lower dosing schedules,²⁰ which is probably why anthracycline regimens given as weekly injections instead of a single bolus injection every 3 weeks were found to be less cardiotoxic.^{16–19} Also, female patients appear to be more vulnerable to the cardiotoxic effects of anthracyclines.^{13,21}

Radiotherapy is frequently used in combination with multidrug chemotherapy protocols in patients with various hematologic and solid neoplasms. Mediastinal irradiation is believed to increase anthracycline-induced cardiotoxicity.^{22–24} Severity of histopathologic changes evaluated by endomyocardial biopsy were significantly higher (P less than 0.01) in patients pretreated with mediastinal irradiation before anthracycline compared with those who did not receive radiation therapy.²³

A relatively recently published study on a cohort of 607 children with long-term follow-up (mean, 6.3 years) has shown the only independent risk factor is a cumulative dose greater than 300 mg/m². The other possible risk factors (i.e., female sex, younger age at diagnosis, radiotherapy involving the heart, and ifosfamide or cyclophosphamide treatment) were not associated with increased risk in this cohort.²⁵

MANAGEMENT

Monitoring and Prevention In clinical practice, regular monitoring of the cardiac functions to stop further exposure, once evidence of deterioration starts to appear, is still the only management action. Theoretically, the following measures could prevent (or minimize) cardiotoxicity:

- Identifying individuals at risk before commencing anthracycline chemotherapy to modify the dose, formulation (e.g., liposomal encapsulated daunorubicin), and administration rate and schedule.
- Regular patient monitoring during and following completion of anthracycline therapy.
- Anthracycline modification:
 - Use of anthracycline analogues of less cardiotoxicity
 - Use of cardioprotective drugs (dexrazoxane)
 - Liposomal encapsulation (this is likely to supersede the previous two)

Identifying patients at risk of cardiotoxicity is the first and crucial step for prophylaxis. The difficulty starts as early as this because there appears to be a great variation in the individual sensitivity to anthracyclines. Histopathologic changes consistent with anthracycline-induced cardiotoxicity have been noted at doses as low as 183 mg/m² (less than one-third of what is considered the allowable maximum cumulative dose),²⁶ whereas doses greater than 1,000 mg/m² have been tolerated by others.^{7,27} There is so far no test to detect those at high risk. Monitoring still depends on signs of early (subclinical) reduction of left ventricular systolic function aiming at early discontinuation of anthracyclines.

Noninvasive echocardiographic measurement of left ventricular ejection fraction (LVEF) and fractional shorting (FS) is by far the most commonly used method in most centers. Complete recovery of echocardiographic LVEF and FS may occur if anthracycline therapy is discontinued at an early

stage,²⁸ although this does not necessarily exclude long-term reductions in functional reserve.²⁹ Radionuclide angiocardiology is also widely used in monitoring for early anthracycline-induced cardiotoxicity. Schwartz et al. proposed guidelines for prophylaxis against anthracycline-induced heart failure based on serial radionuclide measurement of LVEF.³⁰ Patients with a baseline LVEF of 30% or less should not receive anthracycline therapy. Those with LVEF greater than 30%, but less than 50%, can receive doxorubicin, but measures should be repeated before each dose. For patients with LVEF of 50% or more, evaluations should be repeated after a cumulative dose of 250 to 300 mg/m², and thereafter at 450 mg/m² if they have no risk factors. Doxorubicin therapy should be stopped if there is a 10% or greater absolute decrease in the EF, with decrease of the LVEF to 50% or less in patients with baseline LVEF of 50% or more, and to 30% or less in those with a baseline LVEF less than 50% but more than 30%. Multivariate analysis demonstrated a fourfold reduction in the incidence of CHF in those patients whose management was concordant with the proposed guideline criteria.³⁰ Unfortunately, resting LVEF obtained by radionuclide angiocardiology is relatively insensitive in detecting early anthracycline cardiotoxicity. Both LVEF and FS are load-dependent indices that give an estimate of the overall left ventricular systolic performance rather than the absolute contractility. Sensitivity could be increased by using load-independent contractility indices, for example, the stress velocity index. Exercise radionuclide studies may also increase the chance of detecting subclinical anthracycline-induced cardiotoxicity.^{22,31} Failure to increase the ejection fraction by 5% over the resting value has been suggested to be a marker of high risk for developing anthracycline-induced ventricular dysfunction.³² Serial testing is, however, required to improve the low specificity of a single test, and maximal exercise is often difficult for patients receiving chemotherapy, because most of them are debilitated.

Measuring diastolic parameters has been found useful in early detection of anthracycline-induced cardiomyopathy. Results have been inconsistent as to whether this precedes systolic dysfunction.³³⁻⁴⁰ This inconsistency probably reflects the fact that in some patients, anthracyclines cause extensive endocardial fibrous thickening, which gives a restrictive cardiomyopathic picture.⁴¹

Endomyocardial biopsy is a fairly sensitive indicator of chronic anthracycline-induced cardiotoxicity. A semiquantitative histologic scoring system that correlated well with the cumulative anthracycline dose has been available since 1984.⁴² Such a monitoring strategy did not find its way to clinical practice for clear reasons, being invasive with concerns about safety of its repetition, particularly in children.⁴³ Moreover, underestimation of cardiac damage with right ventricular biopsy may occur because of scattered cardiomyopathic changes⁴⁴ or the predominance of left ventricular injury.⁴¹ Finally, expertise in obtaining and interpreting biopsy specimens is not widely available.

PROSPECTS FOR IDEAL MONITORING

No ideal screening or monitoring technique has yet been found. One would speculate that this might aim at detection of susceptible genotype(s), probably by using one of the recent molecular techniques or a biochemical marker. The former

might explain the great individual tolerability variation, and so define individuals in whom anthracyclines should be avoided. The latter, on the other hand, aims at reliable prediction of early irreversible myocardiocyte damage in a way very similar to the elevation of liver enzymes many years before the cirrhosis in chronic active hepatitis. Natriuretic peptides could be useful in this respect, as shown by preliminary studies.⁴⁵⁻⁴⁸ These studies are, however, of small size and of short-term follow-up. A relatively recent study, on the other hand, suggested that serial natriuretic peptide measurements cannot be used in predicting the impairment of left ventricular function. It was found that the decrease in LVEF started very early and could already be seen after the cumulative doxorubicin dose of 200 mg/m², whereas the increase in plasma natriuretic peptides was not evident until the cumulative doxorubicin dose of 400 mg/m².⁴⁹

Endothelin 1 could also be a potential predictor. In a single small-scale study so far, progressive elevation of its plasma levels occurred before deterioration of LVEF in patients who subsequently developed CHF.^{50,51} Cardiac troponins also warrant further investigation to evaluate their potential use for monitoring patients during and after anthracycline therapy.^{52,53}

ANTHRACYCLINE SEMISYNTHETIC ANALOGUES

Epirubicin is an epimer of doxorubicin with comparable antitumor activity and less cardiotoxicity.⁵⁴⁻⁵⁶ Cardiotoxicity appears to occur at a higher cumulative dose greater than 900 mg/m².

Idarubicin is a lipophilic semisynthetic derivative of daunorubicin that can be orally administered.⁶ It was shown to be less cardiotoxic than doxorubicin.^{57,58}

CARDIOPROTECTIVE AGENTS

Dexrazoxane is a derivative of ethylenediaminetetraacetic acid (EDTA) that readily penetrates cell membranes and acts as an intracellular chelating agent.⁶ Its proposed mechanism of cardioprotection is through the chelation of intracellular iron, which may decrease anthracycline-induced free radical generation. Dexrazoxane (ICRF-187) has been shown to decrease the incidence of clinical CHF in patients treated with anthracyclines.^{59,60} Neither the normal antioxidant mechanisms nor the pharmacokinetics of doxorubicin or its metabolites is affected by dexrazoxane.⁶¹ It is given via slow IV push or rapid infusion not more than 30 minutes before doxorubicin administration. The recommended dose is 10 times that of the scheduled doxorubicin dose. It is generally well tolerated, but side effects include enhanced myelosuppression and pain on injection.⁶⁰

Concerns, however, exist concerning possible interference of dexrazoxane with the efficacy of the anthracycline antitumor effect.^{60,62} It is therefore *not routinely recommended with anthracycline therapy*, at least at the present time. Recent guidelines by the American Society of Clinical Oncology advised that dexrazoxane *may only be considered for patients with metastatic breast cancer* who have received a cumulative doxorubicin dose 300 mg/m² or more in the metastatic setting and who may benefit from further anthracycline therapy. Patients receiving dexrazoxane should continue to be monitored for anthracycline-induced cardiotoxicity.⁶³

LIPOSOMAL ANTHRACYCLINES

Liposomal encapsulation of daunorubicin improves its pharmacokinetic properties. Encapsulation reduces its volume of distribution, the total body clearance, and interindividual variability.^{64,65} Experimentally, it has been shown that liposomal encapsulation reduces the intracellular accumulation speed of daunorubicin, and therefore, diminishes free radical generation, ATP depletion, and necrotic (but not apoptotic) cell death⁶⁶; however, this does not affect its efficacy on tumor cells. Both free and encapsulated forms induce activation of caspases 9 and 3. The sensitivity of leukemic cells correlates with caspase activation and reduction of mitochondrial membrane potential but not depletion of ATP and the generation of free radicals.⁶⁶ In fact, experimentally, liposomal encapsulation overcomes resistance to the free drug in certain resistant breast (MCF7ADR), ovarian (SKOV3), and small-cell lung (H69VP) carcinoma cell lines, probably by escaping the membrane pumps, such as P-glycoprotein.⁶⁷ Early clinical studies suggest that liposomal daunorubicin is safer with much less early cardiotoxicity. These results are encouraging, but as mentioned earlier, cardiomyopathy can appear years after exposure, and therefore, long-term follow-up for larger number of patients is essential to give a better profile of its cardiac safety.

Mitoxantrone

This non-cell-cycle-specific anthraquinone derivative was developed to provide broad-spectrum antitumor activity, similar to anthracyclines, without cardiotoxicity. Although initial animal studies revealed a lack of cardiotoxicity,^{68,69} its cardiotoxicity soon became evident in clinical trials. It has been shown to have an anthracycline-like spectrum of cardiotoxicity. Prior doxorubicin therapy and mitoxantrone cumulative dose are the main risk factors.⁷⁰ The incidence of CHF significantly increases (more than 5%) beyond a cumulative dose of 160mg/m², even in the absence of previous doxorubicin exposure.⁷¹

Prophylaxis should follow the same lines of anthracyclines therapy, and mitoxantrone therapy to a patient previously treated with an anthracycline, should be based on the risk-to-benefit balance for each individual case and the awareness of the heart failure risk prediction curves⁶⁰ for anthracyclines and mitoxantrone.

Alkylating Agents

Cyclophosphamide

Cyclophosphamide is a non-cell-cycle-specific alkylating agent that is a mainstay of most pretransplant conditioning regimens. High-dose cyclophosphamide can cause an acute form of cardiotoxicity within 10 days of its administration.⁷²⁻⁷⁴ Cyclophosphamide-induced cardiotoxicity presents as a combination of symptoms and signs of myopericarditis, which could lead to fatal complications (e.g., CHF, arrhythmias, cardiac tamponade).^{72,74,75} The total dose of cyclophosphamide per course is so far the only reproducible risk factor.⁷³ The incidence of symptomatic cyclophosphamide-induced cardiotoxicity in two series,^{75,76} when combined, was 22% (16/72), and that of fatal cardiotoxicity was 11%. A total

dose greater than 170 to 180mg/kg per course (over 4 to 7 days) was the risk factor. Goldberg et al. found that doses based on body surface area, rather than body weight, correlate well with incidence of cyclophosphamide-induced cardiotoxicity.⁷² The incidence of symptomatic cyclophosphamide-induced cardiotoxicity in a group of patients who never had prior anthracycline therapy was 25% (13/52), with 12% (6/52) mortality when cyclophosphamide dose exceeded 1.55mg/m²/day. Those who received less than 1.55 mg/m²/day had 3% (1/32) symptomatic cardiotoxicity with no mortality.⁷² The fact that young children have a relatively higher body surface area probably explains the lower incidence and severity of cyclophosphamide-induced effects in them compared with adolescent and adult cardiotoxicity.^{67,72} Cyclophosphamide-induced cardiotoxicity may last from 1 to 6 days and, despite the relatively high mortality, there are no long-term sequelae or late cardiotoxicity in patients who survive the initial acute event.⁷⁵ So far, there is no evidence of cumulative cyclophosphamide cardiotoxicity.

PREVENTION

Ideal prevention would depend on the avoidance of exceeding a certain critical dose, beyond which the incidence and severity of cardiotoxicity becomes unacceptably high. Identification of this critical dose warrants further large-scale studies, but it is likely to be around 1.55g/m²/day, as shown by the Goldberg group.⁷⁷ We, therefore, recommend that hematopoietic stem cell transplant protocols should be modified to use cyclophosphamide doses calculated per body surface area/day to limit the daily dose to less than 1.55g/m². The current evidence shows that this will significantly reduce this potentially fatal cardiotoxicity without affecting engraftment success.⁷⁷

Secondary prevention of cyclophosphamide-induced cardiotoxicity necessitates awareness by the clinicians of this potential complication. They should keep it in mind when looking after patients who received high-dose cyclophosphamide within the past 2 weeks.

Ifosfamide

Ifosfamide, structurally similar to cyclophosphamide, seems to have a similar cardiotoxicity pattern with a 30% incidence of cardiotoxicity with doses beyond 20g/m².⁷⁸ Further studies are needed to confirm the critical dose that should not be exceeded, as this will be the efficient route of prophylaxis.

Mitomycin

There is strong evidence that mitomycin (MMC) enhances doxorubicin-induced cardiomyopathy when administered in combination with or following such agent.^{79,80} MMC-related cardiotoxicity is dose dependent, occurring at cumulative dose levels of 30mg/m², mainly in patients treated, previously or simultaneously, with doxorubicin.⁸¹ Careful monitoring of left ventricular function is therefore essential as with anthracycline chemotherapy.

Miscellaneous Agents

The previously mentioned chemotherapeutic agents are the most significant as far as cardiotoxicity in clinical practice is concerned. It is worth mentioning, however, that many other

chemotherapeutic agents could sometimes cause transient cardiotoxicity, such as transient ECG change, arrhythmias, or blood pressure changes. Although these are rarely of clinical significance, clinicians should be aware of them.

Fluorouracil (5-FU)

Care should be taken with this synthetic pyrimidine antimetabolite as it can cause myocardial ischemia.⁸² Although rare (1.6%), the possibility must be taken into account in practice, particularly in those patients already affected with cardiac diseases, as cases of massive myocardial infarctions have occurred.⁸²⁻⁸⁴ 5-FU cardiotoxicity is more common following high-dose continuous infusion than after IV bolus administration.⁸⁵ Prophylaxis starts with identifying those with ischemic heart disease in whom the agent should be avoided. Using IV bolus administration rather than continuous administration is advisable based on the current available evidence. Taking this potential cardiotoxicity into account in practice should be of prophylactic benefit.

Taxanes (Paclitaxel and Docetaxel)

This is a group of antimicrotubule agents originally extracted from the bark of the western yew tree, *Taxus brevifolia*. Paclitaxel has been linked to cardiotoxicity in two ways: early arrhythmias during or soon after administration and possible aggravation of anthracycline-induced cardiomyopathy when given in combination. Both ways warrant closer scientific examination.

As regards arrhythmias, critical evaluation of reports show that in early Phase I studies, paclitaxel was associated with a high incidence of serious hypersensitivity reactions.^{7,86} Premedication with antihistamines, and a slower rate of infusion, reduced the frequency and severity of this side effect, but it also led to routine continuous cardiac monitoring during paclitaxel administration in Phase II studies in an attempt to evaluate hypersensitivity reactions more efficiently. This approach had led to unintentional overreporting of cardiac *arrhythmias* in patients receiving paclitaxel, with "asymptomatic sinus bradycardia" being the most frequently reported cardiac event.⁸⁷ Paclitaxel-associated cardiac rhythm disturbances described in the literature, included nearly every known arrhythmia, but seldom led to clinically significant sequelae, and the reported incidence of life-threatening ventricular arrhythmias (fibrillation or tachycardia) is only 0.26%.⁸⁸ Ventricular arrhythmias could occur at any time during the drug infusion. It can occur during first-dose infusion although it is most often seen during second and subsequent doses.⁸⁸ Patients revert to normal sinus rhythm after discontinuation of paclitaxel, but some patients may continue to exhibit infrequent, brief episodes of supraventricular tachycardia or rare ventricular premature beats up to 10 days after discontinuation of paclitaxel. As mentioned previously, paclitaxel-induced arrhythmias seldom led to clinically significant sequelae.

Paclitaxel and doxorubicin is a highly effective combination in advanced breast cancer. The unexpectedly high incidence of CHF reported in two of the early trials caused some concern. It is likely that a pharmacokinetic interaction between doxorubicin and paclitaxel is responsible for the higher than expected incidence of congestive heart failure

observed in these studies, as paclitaxel decreases the clearance of doxorubicin by approximately 30% when the two drugs are administered in close succession.⁸⁹ A recent review of results from 10 studies (657 patients) was, however, reassuring that the use of combination doxorubicin and paclitaxel is safe up to a cumulative doxorubicin dose of 340 to 380 mg/m².⁹⁰

The paclitaxel closely related antimicrotubule, docetaxel, does not seem to induce arrhythmias.⁹¹ No concerns were raised to its use in combination with anthracyclines.

Neurologic Complications of Therapy

Kristin Bradley and H. Ian Robins

The etiology of neurotoxicity following treatment with chemotherapy and/or radiation therapy is not always obvious. Neurologic complications can be difficult to identify, diagnose appropriately, and measure. In addition, neurotoxicity may be delayed and patients may experience tumor-related mortality before the diagnosis of treatment-related complications. Furthermore, the signs and symptoms of neurotoxicity may resemble those of disease progression. Finally, underlying diseases, such as diabetes mellitus, infections, hypertension, paraneoplastic syndromes, age-related dementia, seizures, concomitant medications, such as anti-epileptic agents, and metabolic disorders can be confounding factors.

Neurotoxicity following treatment spans a spectrum from acute to chronic, and from reversible to irreversible; neurotoxicity may involve the central nervous system (CNS), the peripheral nervous system (PNS), or both. The complications can range in grade from subclinical to severe. In the following sections, we discuss the neurotoxicities of chemotherapy and radiation therapy individually, as well as the neurologic complications of combined chemoradiation. In specific areas, the limited information regarding prophylaxis and/or treatment of therapy-related neurotoxicity is similarly presented.

In the text to follow, an attempt is made to critically summarize an extensive literature. In this regard, many of the available data pertaining to this significant treatment-limiting morbidity are observational. In spite of this, a substantial database has been accrued by investigators. Thus, it is the intention of this review to provide a synopsis to reinforce early clinical recognition of these toxicities. It was further envisioned that this review might serve to stimulate further laboratory and controlled clinical research.

Chemotherapy-Induced Neurotoxicity

Vinca Alkaloids

Vincristine was the first chemotherapeutic agent described as having neurotoxicity,¹ which, it is dose-limiting for this drug. Other *Vinca* alkaloids, for example, vinblastine and vinorelbine, share this same predisposition, but to a lesser extent.² Such neurotoxicity can involve the peripheral, autonomic, or central nervous system.¹⁻⁷ Toxicity can be dose related and/or

cumulative. Peripheral neuropathy is well recognized by clinicians, and it tends to be reversible over the course of years.⁷ Severe constipation and bladder atony are not uncommonly observed. Rarely, cranial nerves can be affected, resulting in ophthalmoplegia and facial palsies; laryngeal nerve paralysis and cortical blindness have also been reported.^{5,6} Although many physicians treat these complications with vitamin therapy (including the B group), there are no data to support this practice. The use of metoclopramide has been used and reported for gastrointestinal (GI) motility dysfunction.⁸

5-Fluorouracil

Historically, 5-fluorouracil (5-FU) was also an early chemotherapy drug for which neurotoxicity became readily apparent,⁹⁻¹⁷ with an incidence up to 5%. Clinically, patients can experience loss of coordination, ataxia of the trunk and extremities, slurred speech, nystagmus, optic neuropathy, and hypotonia. Peripheral neuropathy and acute encephalopathy have also been reported.^{12,13} It has been postulated that the use of 5-FU in conjunction with levamisole or leucovorin (both of which can be neurotoxins^{18,19}) may add to the neurotoxic potential of 5-FU.¹⁶ The neurotoxicity observed is not necessarily dose or schedule dependent, and it is often reversible on drug cessation. It has also been postulated²⁰ that 5-FU toxicity may relate to 5-FU-induced thiamine deficiency (observed in a series of 35 patients²¹); this may be particularly relevant to the syndrome of 5-FU-cerebellar ataxia. Pathologically, some toxic events can be correlated with multifocal cerebral demyelination. In extreme cases, patients can become encephalopathic.¹² This life-threatening complication may be associated with dihydropyrimidine dehydrogenase deficiency. This enzyme deficiency, which may exist in up to 3% of the population, affects 5-FU metabolism and places patients at extreme risk for any and all 5-FU complications.²² Takimoto et al.²³ reported such a case in which a comatose state was reversible with infusional thymidine.

Platinum Agents

With the introduction of cisplatin more than two decades ago, its neurotoxic potential was immediately recognized. The toxicity of this heavy metal is generally dose related and in

part, may be related to segmental demyelination of sensory nerves.²⁴ Neurologic complications in addition to peripheral sensory loss, with paresthesias severe enough to result in loss of fine motor skills, include loss of motor reflexes; foot drop; leg cramping; neuropathic pain (as an extension of the sensory neuropathy); Lhermitte's sign (also induced by radiation); auditory and visual cranial nerve injury; and autonomic neuropathy.²⁴⁻³² Although cisplatin-induced hypomagnesemia is correlated with increased risk for neurotoxicity,²⁹ it is not clear that diligent magnesium repletion prevents progression of peripheral neuropathy. Hearing deficits begin the majority of the time with reversible tinnitus, progress to asymptomatic loss of high-frequency tones, and finally to symptomatic permanent mid-frequency loss. Vision compromise can range from color alteration to retinal inflammation and/or damage, transient blindness, and papilledema. The sensory neuropathy can result in severe gait disturbances. These observations taken collectively, often necessitate the modification or discontinuation of the drug, particularly in patients not being treated with curative intent. Consideration of a less neurotoxic analogue, that is, carboplatin, represents an alternative option. Amifostine, primarily used as a renal protectant, provides limited neuropathy protection relative to cisplatin,³³ but its use is limited by the amifostine-related side effects. Most recently, a new platinum analogue, oxaliplatin, has entered clinical practice. It too has sensory neuropathy and cramping, but also can produce pharyngolaryngeal dysesthesias.^{34,35} The appearance of the pharyngolaryngeal dysesthesias is often acute, as is the appearance of cold intolerance. Extending the period of oxaliplatin infusion can minimize the toxicities. The sensory neuropathy is late, cumulative, and dose dependent, but often reverses to some extent at approximately 6 months. Some clinicians believe that calcium and magnesium supplementation is beneficial in palliating and preventing this complication.

Taxanes

At this point in the discussion, it is appropriate to highlight that the combined use of two neurotoxic agents produces enhancement of neurotoxicity. Examples include doublets of platinum agents, *Vinca* alkaloids, and/or taxanes.^{2,36-43} Relative to the taxanes as a class, the two approved analogues, paclitaxel and docetaxel, also have treatment-limiting peripheral neuropathy much the same as the platinum-based drugs and the *Vinca* alkaloids.⁴⁴⁻⁵⁰ Taxane-related neuropathy is cumulative and dose dependent. In general, neurosensory and neuromuscular effects are less severe and less frequent with docetaxel than with paclitaxel. The toxicity relates in part to axonal degeneration and demyelination related to a direct effect on microtubules.⁵¹ Motor myopathy also has been associated with the taxanes. It is difficult, however, to differentiate this sequela of therapy from the effect of corticosteroids usually given with the taxanes to prevent allergic reactions. Rare reports of visual disturbances and encephalopathy also exist.^{52,53} There is some controversy as to whether preexisting conditions, such as diabetes mellitus, can predispose patients to increased neuropathy.⁴⁴ As in the case of the previously discussed peripheral neuropathies, no intervention to date has been demonstrated to be efficacious in alleviating symptoms, although the empiric use of amitriptyline is popular. Early work has reported that glutamine may be

beneficial in reducing neuropathy associated with paclitaxel administration.⁵⁴ These early results, however, need to be confirmed by a placebo-controlled trial. Occasionally, symptoms may reverse several months after drug cessation. In contrast to cisplatin, amifostine is not effective for taxane-induced neuropathy.⁵⁵

Cytosine Arabinoside

Cytosine arabinoside (Ara-C), given systemically or intrathecally (IT), can cause an acute dose-dependent cerebellar neuropathy defined by specific pathologic changes.⁵⁶⁻⁶¹ Although this toxicity is reversible with drug cessation, permanent truncal and gait ataxia can develop. The neurotoxicity of Ara-C is dose and schedule dependent, and is related to the cumulative dose of the drug. Early clinical signs include nystagmus, dysarthria, tremors, and dysmetria. Mental status changes including encephalopathy and seizures may follow. Additionally, spinal myopathy, basal ganglia necrosis, and pseudobulbar palsy have been reported.⁶⁰ If the need for drug cessation is not recognized early in the patient's clinical course, any of these complications can progress to death.

Methotrexate

Methotrexate (MTX), which can also be given intravenously (IV) or IT, also can produce significant neurologic symptoms (both acute and late), ranging from meningeal irritation and/or transient paraparesis to encephalopathy.⁶²⁻⁶⁵ Such complications typically are only seen with IV use at high doses and probably are directly related to levels in the cerebrospinal fluid. The physician treating a CNS manifestation of malignancy with MTX (as is also the case with ara-C) must be careful not to mistake drug toxicity for disease progression, as the symptoms (e.g., seizures, somnolence, nuchal rigidity, nausea and vomiting, headache) may overlap. Aminophylline has been reported to reverse MTX neurotoxicity.⁶⁶ In general, the major neurologic complications encountered with MTX relate to its use (high-dose IV or IT) in combination with ionizing irradiation.^{67,68} Leukoencephalopathy is a well-recognized complication following combined modality therapy. In this regard, children may be at increased risk for such toxicity.⁶⁹

Alkylating Agents

The alkylating agent ifosfamide can produce an array of neurologic complications, probably as a result of degradation metabolites.⁷⁰ Acute clinical manifestations can include hallucinations, confusion, seizures, hemiparesis, lethargy, coma, personality changes, cerebellar and cranial nerve deficits, peripheral neuropathy, and extrapyramidal problems.⁷¹⁻⁷⁵ Although cumulative dose neurotoxic effects have not been reported, rechallenge with the drug can again precipitate acute neurotoxicity. Reversal of such CNS toxicity has been achieved with the use of IV methylene blue.^{70,71} Altretramine, another alkylating agent, predominantly produces peripheral neuropathy-related toxicity, but central effects similar to ifosfamide, including parkinsonian tremors, have been reported.⁷⁶

Radiation Therapy Toxicities

Central Nervous System Toxicity

The neurotoxicities of radiation therapy, similar to those from chemotherapy, can be broadly classified as acute (within the first 3 months), subacute (from 3 months to 1 year), and chronic (years after irradiation).

A person may suffer from headache, nausea, vomiting, lethargy, fever, and occasionally, exacerbation of their neurologic symptoms within 2 weeks of finishing radiation therapy. This acute phenomenon is broadly attributed to breakdown of the blood–brain barrier with subsequent development of increased intracranial pressure caused by edema. Experimental models in large animals support the hypothesis of radiation-induced breakdown of the blood–brain barrier with accumulation of vasogenic edema; in humans, large fraction radiation, as seen with radiosurgery, supports this observation.^{77,78} Rarely, early neurologic toxicity may be more severe in patients with multiple metastases, a large posterior fossa tumor, or with large radiation fraction sizes.⁷⁹

Subacute CNS toxicity generally manifests between 1 to 6 months after radiation therapy and is not limited to a single clinical presentation; both the brain and the spinal cord can be affected. In the spinal cord, Lhermitte's sign, in which neck flexion triggers fleeting, electrical shocklike paresthesias radiating from the neck to the extremities, typifies the onset of radiation myelopathy. Believed to be caused by transient demyelination, the syndrome is self-limiting, gradually improves over 2 to 9 months, and does not predict for the development of later, irreversible myelopathy.^{80,81}

Early-delayed brain injury following cranial irradiation is marked by a somnolence syndrome and is most prominent in children. Up to three-quarters of children receiving prophylactic or therapeutic CNS irradiation for acute lymphoblastic leukemia, may develop a somnolence syndrome characterized by hypersomnia, irritability, anorexia, headache, and fever.^{82,83} Adults rarely experience the somnolence syndrome.⁸⁴ The pathogenesis of the somnolence syndrome is believed to be due to oligodendroglial cell injury and altered capillary permeability resulting in transient demyelination.^{80,81,85} The syndrome may go undiagnosed, with the patient improving spontaneously over weeks or months. Rarely, subacute CNS toxicity following irradiation may be severe, or even fatal.⁸¹

The manifestations of late-delayed radiation-induced CNS toxicity can appear months to years after irradiation.⁸⁶ Radiation necrosis is one of the most serious delayed CNS complications. It typically presents 1 to 2 years following external-beam radiation therapy and 6 to 9 months after interstitial brachytherapy or radiosurgery.⁸⁷ The reappearance of prior neurologic deficits, as well as the emergence of new focal neurologic problems, can simulate tumor recurrence. The use of positron emission tomography (PET) scanning and/or magnetic resonance imaging (MRI) spectroscopy can be useful in distinguishing recurrent or progressive disease from necrosis. Radiation necrosis tends to be progressive and may be irreversible, with prominent edema and mass effect caused by coagulative necrosis of cerebral white matter.⁸⁸ Another delayed neurotoxicity following irradiation is leukoencephalopathic cognitive dysfunction without necrosis.^{89,90} Some reports have estimated that there is a 10% to 15% risk of leukoencephalopathy following whole-brain radiotherapy.

Children whose brains are still developing are at particularly high risk of developing profound neurocognitive sequelae; the risk is greatest for children irradiated before 3 to 4 years of age, the age when CNS myelination is complete.^{91,92} Radiation-induced neurocognitive dysfunction ranges from mild changes in attention span, short-term memory, and problem-solving ability that do not affect overall performance status, to more profound functional deficits. Severe decline and alterations of IQ, memory, response times, problem-solving ability, emotional state, balance, and gait trend toward progressive deterioration, with death 1 to 48 months after the onset of symptoms.⁸⁷ The pathophysiology of late cognitive and intellectual decline following cranial irradiation is not fully understood, but clinical, radiographic, and neuropathologic findings incriminate white matter changes.^{87,93–95}

Spinal cord radiation myelopathy, another delayed neurotoxicity, has a median latency of 20 months after irradiation, but this varies with radiation dose, region and length of spinal cord irradiated, patient age, and prior treatment.^{81,96} Clinically, delayed myelopathy may be gradual or sudden and may result in partial or complete functional deficits, but is generally progressive and irreversible, often resulting in bowel and bladder dysfunction, paraplegia or quadriplegia, paresthesias, partial Brown–Séquard syndrome, and lower motor neuron dysfunction.^{81,97} As many as one-half of patients die of secondary complications, including infection, pulmonary embolism, and respiratory compromise.⁹⁸

Other chronic radiation-induced CNS toxicities may include hypothalamic-pituitary axis (HPA) dysfunction with endocrinopathies, cranial nerve injuries, vascular abnormalities, and second malignancies.

Peripheral Nervous System Toxicity

Shortly after receiving radiotherapy, patients may note paresthesias following irradiation of peripheral nerves. More significant, however, are the early- and late-delayed complications of PNS irradiation. Fortunately, reports of peripheral nerve injury have decreased as a result of the use of three-dimensional, computer-based planning and improved quality control.⁹⁹ Brachial plexopathy following radiotherapy for locally advanced breast cancer manifests as paresthesias, pain, and weakness in the distribution of the brachial plexus nerve roots. The injury may be transient or may develop into an irreversible, progressive brachial plexopathy, typically a year or more after receiving 60Gy or greater. Lumbosacral plexopathy, presenting as unilateral or bilateral lower extremity sensory or motor deficits following pelvic irradiation, has been reported less frequently than brachial plexus injury. Paresthesias and pain may or may not accompany muscle atrophy and weakness.⁹⁹ Identifying the etiology of plexopathies can be a challenge for the treating physician because the findings of treatment-induced injury may resemble those of tumor recurrence.

Toxicities of Combined Chemotherapy and Radiation Therapy

Neurotoxicity, in particular CNS toxicity, following combined treatment with chemotherapy and radiation therapy, is a challenging problem for the oncologist. Although

chemotherapy and radiation have their own independent toxicities, overlapping toxicities make it difficult to clearly identify the offending modality. Complications of other illnesses, such as diabetes and hypertension, as well as neurotoxicity resulting from disease recurrence or progression, must be eliminated before ascribing a complication to chemoradiotherapy. The neurotoxicities of two important drug–radiation interactions are discussed in detail next.

Methotrexate and Cranial Irradiation

There are three widely recognized late syndromes following the combined use of methotrexate (MTX) and cranial irradiation: necrotizing leukoencephalopathy, mineralizing microangiopathy, and cognitive impairment.¹⁰⁰ Necrotizing leukoencephalopathy results from white matter necrosis with sparing of grey matter and is generally without an inflammatory response. The risk of its development appears to be greatest if MTX is given concurrently with or after radiation therapy. Usually occurring within 1 year of treatment, it manifests as a change in personality, dementia, seizures, ataxia, hemiparesis or quadriparesis, and pseudobulbar palsy. The clinical course may stabilize, or rarely, improve, but for the majority of patients, it is severe, progressive, and potentially fatal. Leukoencephalopathy following treatment with MTX and cranial radiation has been extensively reported in children receiving CNS treatment or prophylaxis for acute lymphoblastic leukemia (ALL).^{101–103} The dose of radiation and intravenous MTX, rather than intrathecal MTX, is correlated with the risk of its development.¹⁰³

In contrast to necrotizing leukoencephalopathy, mineralizing microangiopathy generally has longer latency periods and usually produces milder neurologic dysfunction.¹⁰¹ Its course may be subclinical, or it may produce headaches, incoordination, and seizures. Similar to most neurologic sequelae of chemoradiation, younger children are at greater risk. Grey matter changes are seen, resulting from the mineral deposition in the walls of the small vessels of grey matter.¹⁰⁴

A third syndrome seen following the combined use of MTX and cranial irradiation is cognitive impairment.^{105–109} In adults, the use of high-dose MTX, along with whole-brain radiotherapy for primary CNS lymphoma, has resulted in a 15% to 32% overall incidence of late neurotoxicity.^{108,109} In the recently reported Radiation Therapy Oncology Group (RTOG) study (93-10), a neurotoxicity rate of 15% was seen.¹⁰⁹ In children treated with chemoradiation for ALL, medulloblastoma, or other intracranial tumors, neurocognitive toxicity typically manifests as a decline in IQ with impaired school performance resulting from learning disabilities.^{92,105–107} In children 3 to 7 years of age treated for medulloblastoma, a 20- to 30-point decline in IQ score over a 3- to 4-year period has been reported.⁹² A debate continues about whether cranial irradiation or intrathecal MTX is the primary causative factor.^{110,111}

Cisplatin and Cranial Irradiation

As discussed in a previous section, cisplatin alone can result in neurotoxicity. One of the most recognized neurotoxicities of cisplatin is ototoxicity, a high-frequency hearing loss resulting from hair cell damage. When cranial irradiation is combined with cisplatin, either sequentially or concurrently,

the risk of severe ototoxicity increases significantly.^{112,113} As the sensorineural hearing loss progresses from high frequencies to frequencies required for speech perception and recognition, a child's ability to understand and learn is impaired. In an attempt to decrease the audiototoxicity of combined cisplatin and irradiation, intensity-modulated radiation therapy (IMRT), which provides for more conformal radiation delivery, has been employed to decrease radiation dose to the auditory apparatus.¹¹⁴ A retrospective comparison of patients with medulloblastoma who received either conventional radiotherapy or IMRT showed that IMRT delivered 32% less radiation dose to the auditory apparatus while delivering full doses to the target volume. Children treated with IMRT experienced lower ototoxicity: 13% of the IMRT patients had grade 3 or 4 hearing loss compared with 64% of the conventional radiotherapy patients.¹¹⁴

Management of Neurotoxicity Following Chemotherapy and Radiation Therapy

The first and most important step in the management of neurotoxicity related to chemotherapy and/or radiation therapy is to recognize its existence and, subsequently, to make attempts at prophylaxis. Prevention begins with the elucidation of factors that predict such toxicity, including age; medical comorbidities; use of concomitant chemoradiotherapy; and the specifics of dose, dose-per-fraction, and volume treated. Whenever possible, an attempt should be made to mitigate these risk factors.

Symptomatic Management

Corticosteroids are commonly used in the symptomatic management of treatment-related, and particularly radiation-induced, neurotoxicity. They are employed to decrease the edema seen after radiation.¹¹⁵ Although beneficial in decreasing vasogenic edema, dexamethasone is less effective for treatment-related brain necrosis. Animal and human studies have shown, at best, only a minor delay in the development of radiation necrosis with dexamethasone.^{116,117} Similarly, following spinal cord irradiation, some studies have demonstrated that corticosteroids can temporarily delay the progression of radiation myelitis but do not prevent or successfully treat it.^{85,118} Other pharmacologic agents, including deferoxamine, anticoagulants, lipid peroxidase inhibitors, and antioxidants, have been investigated with mixed results.^{119–121}

Management of Radiation Necrosis

Because corticosteroids have a limited role in the symptomatic management of brain necrosis following chemoradiation, other strategies have been explored as treatment options. Resection of the necrotic tissue may or may not lead to recovery of impaired neurologic functions. Surgical resection is more successful for discrete areas of necrosis than for areas of diffuse necrosis.^{122,123} Hyperbaric oxygen (HBO) therapy also has been used to treat complications of radiation therapy. By increasing tissue oxygenation concentration, HBO stimulates angiogenesis and improves capillary function.^{124,125} Small reports have detailed improvement of radia-

tion myelitis and cerebral radiation necrosis with HBO therapy.¹²⁶⁻¹²⁸ Additional study of the application of HBO therapy in adults and children suffering from nervous system necrosis after chemoradiation is required before a conclusion can be reached about its effectiveness. Controlled clinical trials of innovative therapeutic interventions for radiation necrosis are difficult to design and execute. Nevertheless, such studies are now being designed by the RTOG.

Amifostine

In considering the collective neurotoxicities of chemotherapy, it is the peripheral neurotoxicities that represent the major clinical problem, as they are often dose limiting. Many attempts have been made to develop strategies for treatment and prevention. Amifostine (WR 2721) has been explored as a neuroprotective agent. Amifostine is a thiol compound that requires endothelial dephosphorylation to be activated. Because normal endothelium dephosphorylates the drug more efficiently than tumor endothelium, amifostine may exert a preferential protective effect in normal tissue.^{129,130} However, the intracranial permeability and localization of amifostine in normal brain are very limited; hence its value as a radioprotector for the CNS is limited. Amifostine provides some protection against cisplatin-related peripheral neurotoxicity, but its utility is limited by vomiting and significant hypotension.^{33,38}

Conclusions

Neurotoxicity can occur following chemotherapy, radiation therapy, or the combined use of both therapeutic modalities. Neurologic complications can develop during the course of therapy, weeks to months after finishing therapy, and even years following treatment. Similarly, their severity covers a wide range, with a reported spectrum of mild to function impairing to potentially fatal. The clinical and radiographic signs and symptoms of neurotoxicity often are not unique to the etiology. As a consequence, distinguishing treatment-related toxicities from recurrent tumor or from complications of other medical illnesses can be difficult. Currently, management of the neurotoxicities of chemotherapy and radiation therapy is mostly symptomatic, with initial efforts being undertaken at prevention and prophylaxis. Further elucidation of the mechanisms of these toxicities (via preclinical and controlled clinical studies), coupled to the investigation of patient- and treatment-related factors that predict for or increase the risk of their development, are needed. Only when these mechanisms and predictive factors are better understood will significant success at prevention and prophylaxis be achieved. The elucidation of both mechanistic and predictive factors should provide a foundation for future research encompassing prevention, prophylaxis, and treatment.

Issues in Vascular Access with Special Emphasis on the Cancer Patient

Paul F. Mansfield and David L. Smith

Vascular Access in the Cancer Patient

The management of the cancer patient is often complex and involves multiple disciplines. The complexity of the care that is required often necessitates venous access for the administration of myriad therapies and the acquisition of blood samples. Reliable venous access is critical for the optimal management of the many aspects of care of a patient with cancer. Although the exact number of catheters inserted annually in the United States for care of cancer patients is unknown, it is likely that it represents a significant percentage of the more than 5 million central venous catheters placed.¹

Many chemotherapeutic agents require prolonged venous access for continuous infusion, which may last several days, and a full course of treatment may last a year or more. Critically ill patients may require monitoring of central venous pressure or central access for administration of vasoactive agents. In addition, maintaining adequate nutrition in the cancer patient is often a difficult issue. Although the use of total parenteral nutrition (TPN) in the cancer patient may be controversial, we generally believe it is a reasonable option in the patient actively undergoing therapy. Although the alimentary tract is always the preferred route of feeding in patients, in the cancer patient, TPN is often necessary, because the gastrointestinal side effects of chemotherapeutic agents can be severe, and complications of surgery may render the gastrointestinal tract unusable for various periods of time. The selection of patients for the use of TPN is a complex one that requires careful consideration of the patient's treatment, the response of the malignancy to therapy and physical factors, and in some rare circumstances, such as appendiceal cancer, a patient may live for several years on TPN. TPN, vesicant or protracted infusion chemotherapy, or central pressure monitoring and resuscitation, all require consistent and durable access to the central venous system.

Peripheral venous access is not often reliable or available for long in cancer patients. Some patients simply have very poor peripheral veins to start with, whereas others lose their venous access from repeated use and caustic agents. The multiple episodes of venipuncture for blood draws and administration of medications and fluids often result in sclerosis of the vessels. In a randomized trial between peripherally inserted central catheters (PICC) and peripheral IVs for the

postoperative management of pediatric patients, Schwengel et al. found, not surprisingly, that there were fewer venipunctures in the PICC group and that both patient and parent satisfaction were higher in the PICC group (P less than 0.05).² Major complications were rare in both groups but minor ones were common in the IV group. The authors advocated the use of PICC lines whenever postoperative hospitalization was anticipated to last 4 or more days.

In general, the choice of peripheral venous access versus central venous access is determined by the following factors: the nature of the planned therapy, the length of time of administration, the number of agents and the nature of their compatibilities, the patients' desire for a particular type of access, which may be based on lifestyle, and the status of the patients' peripheral venous system versus their central venous system. Patients with multiple prior central venous catheters may require investigation of the patency of the central vasculature as a part of their assessment. Peripheral access is certainly appropriate in a patient with excellent peripheral veins requiring a short-term course of therapy or a weekly infusion with nonsclerosing agents.

Catheter Types

We initially globally review some of the various issues of access and then examine studies that address the major issues which apply to all access approaches, specifically, those related to the insertion, and then the complications of thrombosis and infection. There are many venous access devices available, which have been designed to fit pediatric and adult patients with various body types and various clinical scenarios. The catheters are also designed to accommodate infusions at different rates, allow for blood draws, accommodate patients' daily activities, and, more recently, to withstand the pressures of bolus infusions for radiographic imaging. The types of central venous catheters can be divided in several different ways:

- External versus implanted
- Tunneled versus nontunneled
- Peripheral versus central
- Single lumen versus multilumen
- Untreated versus antibiotic-coated or antibiotic-impregnated

Each of these choices has specific benefits and downsides, and there are also some unusual situations that can arise in the patient who has lost the use of the major venous branches feeding into the superior vena cava. The common approaches to central access are via the subclavian, jugular, or femoral approaches. In addition, some of the most difficult access cases may require direct inferior vena cava (IVC) puncture through a translumbar or a transhepatic approach, or through the azygous system or directly into the right atrium (RA) via thoracotomy.

Devices that have an external component have a higher risk of infection than totally implanted ones but can be inserted or exchanged more easily. This higher rate of infection comes from two potential sources: first, from the repeated manipulation and accessing of the hub of the catheter, and second, from the area where the catheter transits the skin. Implanted ports require flushing with heparin for thrombosis prevention only once a month, whereas external devices generally are flushed once a day. The implanted port has a silicon diaphragm that can sustain repeated penetrations by an offset (Huber) needle. One should never use a standard needle for accessing these devices. For an active person who likes to participate in water sports, an implanted port may be better. However, if a patient is facing a bone marrow or stem cell transplant, a percutaneous catheter may be a better choice, as one can exchange the catheter over a wire and not lose access if a catheter-related bloodstream infection (CRBSI) is suspected. Implanted ports are usually placed in the operating room, and patients may require a trip back to the operating room for removal, both with obviously added expense. If frequent, repeated, and prolonged instrumentation of the port is anticipated, this may increase the risk of infection. There has never been a prospective randomized trial of implanted ports versus percutaneous catheters, and thus, the decisions are often based on patient and local clinical practice patterns.

External catheters may be tunneled (usually with a cuff) or percutaneous. Cuffed catheters are designed to be tunneled, with the cuff in a subcutaneous position. The cuff encourages significant fibrosis in the surrounding tissue. This fibrotic rim of tissues provides a mechanical barrier to pathogens, which can gain access via the external components of the device. In a small prospective randomized trial of cuffed versus non-cuffed catheters, Flowers et al. found a significant reduction in both the rate of colonization (34.5% to 7.7%) and that of CRBSI (13.8% to 0%).³ One of the major problems with this study is that most of the infections were fungal, as an antibacterial (not fungicidal) ointment was used for dressings. Tunneled catheters may have a lower rate of infection than percutaneous catheters, but in patient populations where intense education and training in catheter care are performed, the rates are similar. One area where this may not be accurate was revealed in a randomized trial of tunneled versus nontunneled femoral catheters by Timsit et al.⁴ In a study of 336 evaluable intensive care unit (ICU) patients, they found probable systemic catheter-related sepsis occurred in 15 of 168 nontunneled catheters and 5 of 168 tunneled catheters (P less than 0.025). The relative risk of actual CRBSI in the tunneled group was 0.28 [confidence interval (CI), 0.03 to 0.72; P = 0.005]. Whether this approach would also benefit sites with lower general risk of infection, such as the subclavian approach, is unknown. Cuffed, tunneled catheters are usually

placed in the operating room or interventional radiology, whereas percutaneous ones may be placed at the patient bedside. It should be noted that both implanted catheters and implanted ports should be placed with fluoroscopic guidance. Similar to implanted ports, if a catheter-related infection is suspected, a cuffed or tunneled catheter generally cannot be exchanged over a wire as can a percutaneous catheter, as we do for suspected CRBSI. This approach was endorsed in a small prospective (and partially randomized) trial by Michel et al., in which they found fewer insertion problems in the exchange group, when compared with the new insertion group and no difference in infection rates.⁵

Peripherally inserted catheters generally eliminate the risk of puncture of the lung, or arterial or nerve structures, during insertion, but carry a 15% incidence of thrombophlebitis. In our experience, in 3% of patients this is severe enough to necessitate removal. Centrally inserted catheters also have the risk of puncture (or less frequently, laceration) of the subclavian artery or injury to nerves (brachial plexus, phrenic, and vagus have all been reported) or the thoracic duct. These concerns are discussed in more detail next.

Single-lumen catheters are used for the simplest of therapies, such as antibiotic therapy or single-agent chemotherapy. Multilumen catheters (two or three) are used for more complex therapies, particularly when there are problems of compatibility. When there is a choice about the number of lumens that will be necessary, it is generally considered best to use the fewest lumens (which is generally a reflection of catheter diameter and has been associated with increased risk of thrombosis).⁶ Farkas et al. conducted a randomized trial of single- versus triple-lumen catheters.⁷ They found it was much more likely that patients with a single-lumen catheter would need additional peripheral access (25/68 versus 1/61, respectively; P less than 0.001). However, they found no difference in the incidence of catheter-related sepsis. In contrast, Clark-Christoff et al. randomized 204 patients to either a single- or double-lumen catheter, and found a substantial increase in the incidence of catheter-related sepsis when using the triple-lumen catheter, compared with a single-lumen catheter [2/78 (3%) versus 13/99 (13%); P less than 0.01].⁸ Ma et al. found no difference among single-, double-, and triple-lumen catheters used to administer TPN.⁹ Implanted ports and tunneled catheters also come as single- or double-lumen constructions. In this chapter, we examine the common complications of central venous catheters and ways to prevent or treat them or minimize their risk: these include (1) risks of insertion, (2) infection, and (3) thrombosis.

Site Selection

The first issue with central venous access is to determine the site of placement. We find the subclavian approach to be the best for long-term access; however, other sites may have specific advantages and disadvantages. Ruesch et al. conducted a systematic review of internal jugular (IJ) versus subclavian approaches in 17 prospective randomized trials (comprising more than 4,500 patients).¹⁰ They found there were more arterial punctures in the IJ group (3.0% versus 0.5%) but more malpositioned catheters with the subclavian approach (5.3% versus 9.3%). In our own experience, from a prospective trial of more than 800 subclavian catheters alone, the risk of arte-

rial puncture occurred in approximately 3% of patients and the risk of malposition was about 4%.¹¹ The authors found the risk of CRBSI was roughly twice as high with the IJ approach compared to the subclavian (8.3% versus 4.0%). Curiously, in this study the risk of hemothorax or pneumothorax was nearly the same, at 1.3% versus 1.5%, whereas the rate of pneumothorax is generally assumed to be lower with the jugular approach. Martin et al. conducted a comparative, nonrandomized trial of IJ compared with subclavian catheters, and found no difference in a series of 141 patient (catheter-related infection, 8.1% for subclavian and 7.6 for IJ, respectively).¹² Merrer et al. conducted a randomized trial of femoral and subclavian approaches for central access in eight ICUs across France.¹³ They examined mechanical, infectious, and thrombotic complications in 289 patients. Overall infection rates were 19.8% in the femoral group and 4.5% in the subclavian group (P less than 0.001); however, the risk of sepsis was 4.4% versus 1.5% ($P = 0.07$). The risk of thrombotic complications was 21.5% and 1.9%, respectively. Complete thrombosis of the vessel occurred in 6% of the femoral approach and none of the subclavian group ($P = 0.01$). Although this study underscores the increased thrombotic and infectious risks with the femoral approach, there are still occasions (such as the coagulopathic patient) where this approach is necessary. As in all of medicine, it is a weighing of the relative risks and benefits.

Insertion Technique

Once a decision is made to place a central venous catheter, there are some specific and general considerations. In general, implanted ports and catheters (tunneled) should be placed in the operating room (for maximal sterility) with fluoroscopic assistance. Several authors have examined the role of sterile barriers. Hu et al. conducted a systematic review of the use of maximal sterile barriers and found three primary research studies.¹⁴ Although each study seemed to support the use of the barriers and gowns, the authors seemed lukewarm in their endorsement of the approach. In a prospective randomized trial from our institution, Raad et al. found a significant reduction in catheter-related infections when using the barriers, and following patients for up to 3 months (4/176 test group versus 12/167 in the control group; $P = 0.03$).¹⁵ This was

a controlled population of cancer patients; however, anyone who has placed a central venous catheter recognizes the ease with which the wire may easily brush against a forearm or nonsterile sheet if the whole site is not protected. Different institutions handle patient education in different ways, from minimal or none to extensive programs. For external devices, intensive training of patients and their caregivers can dramatically decrease the incidence of infection. In preparation for placement of the venous access device, the patient and a caregiver should be instructed on the placement and long-term care of the device. This procedure allows the patient an opportunity to determine what lifestyle changes may be necessary as well as which device would be best suited to the patient. At University of Texas M.D. Anderson Cancer Center, the patients are shown a detailed video regarding implantation and care of the device. Patients and their caregivers (typically the spouse or other family member) also receive personal detailed instruction in the care of the catheter and must even pass a test, demonstrating competency.

Before arriving for line placement, patients should be assessed for the appropriate form of access to be used. This assessment includes an evaluation of the coagulation profile [prothrombin time (PT) and platelet count] as well as the intended use of the catheter. Table 81.1 is a copy of the guidelines used at M.D. Anderson Cancer Center for the management of various coagulation situations one may encounter. These may seem a bit liberal for some but have proved to be quite safe in a setting where more than 6,000 subclavian insertions are performed annually. If a patient's coagulation profile cannot be corrected, a safer alternative, such as a jugular or femoral approach, where pressure can be applied directly, may be used. After a detailed history, including number of previous catheters or attempts and prior operations, such as axillary or neck dissection, has been obtained, a physical examination is performed and a suitable site is selected. The factors important in this decision include anatomic factors, such as evidence of occlusion (prominent collaterals) or location of tumor or open wounds or irritated skin, whether the patient is left- or right-handed, as well as preferences of the healthcare provider placing the device. In the case of central venous catheter placements, a chest radiograph is also obtained to confirm the absence of any anatomic abnormalities that might alter the side of placement (bony abnormali-

TABLE 81.1. Coagulation profile and platelet count guidelines for insertion of central venous catheters (CVCs) procedure.

Platelet count	PT less than or equal to 16 s	PT greater than 16 s
More than 50K	Place line	Give 2 units of FFP (or vitamin K if indicated) If PT remains greater than 16 s, consider femoral or jugular line
More than 20K but less than 50K	Place line while 6 units of platelets are infusing	Give 4–6 units of platelets If platelet count and/or PT improve, then reassess If PT remains more than 16 s, consider femoral jugular line Then 4–6 more units of platelets should be infused while line is placed
Less than 20K	Give 4–6 units of platelets If platelet counts remain less than 20,000, primary medical team should contact surgical team for line placement; then 4–6 units of platelets should be infused while line being placed	Give 4–6 units of platelets and 2 units of FFP If platelet count and PT remain out of range, then femoral or jugular line may be placed with additional 4–6 units of platelets

Large-bore subclavian and jugular catheters have more risk and require platelet transfusion when necessary. Large-bore catheter placement in patients with abnormal coagulation carries increased risk, to be weighed against the need for access.
PT, prothrombin time; FFP, fresh frozen plasma.

ties or pleural effusions). Patient anxiety level and the ability to tolerate only local anesthesia also may determine the need for sedation during the planned procedure. Over the past few years, we have significantly increased the availability of conscious sedation for patients undergoing this procedure. Patients should also be instructed to be off any antiplatelet therapy for several days before insertion.

Several factors have been found to increase the risk of complications or failure during insertion: these include the experience of the inserter as well as patient factors, including previous catheters, prior radiation, surgery at the site, or a body mass index greater than 30 or less than 20.^{1,11}

Technique for Specific Sites

SUBCLAVIAN VEIN

All patients for elective line placement are encouraged to hydrate themselves well the night before the procedure and to not eat or drink for at least 8 hours before if they are to receive sedation. Although most surgeons are trained to place a rolled towel between the shoulder blades, Jessep et al. performed a magnetic resonance imaging (MRI) and cadaver dissection study, and found that such practice actually distorted the regional anatomy and would make the risk of failure or malposition greater.¹⁶ Boyd et al. conducted a prospective randomized trial by a single house staff officer of placing a shoulder roll (bump); of 105 randomized patients, 93 had a successful outcome (98% in the bump group and 83% in the no-bump group; P less than 0.04).¹⁷ The limitations of a single practitioner study cannot be overemphasized, although the results are intriguing. Fortune and Feustel examined five different patient positions with ultrasound in healthy volunteers, and found that the Trendelenburg's position with the shoulders flat and head neutral maximized the diameter of the subclavian vein at the level of the clavicle, whereas arching the back (roll or bump) caused the vein to be closer to the clavicle.¹⁸ We prefer to use a neutral position. The patient's chest is prepped and draped in a sterile fashion with the patient in the supine position. Minimal draping and only sterile gloves for the person inserting the catheter should be discouraged. Parienti et al. conducted a randomized trial of

alcoholic 5% povidone-iodine solution with aqueous 10% povidone-iodine solution.¹⁹ This study, which was conducted over a 2-year period, randomized two different ICUs and alternated therapy by unit every 3 months to achieve randomization. Catheter colonization and catheter-related infection were both less in the alcohol group [relative risk (RR), 0.38 (P less than 0.001) and 0.34 (P less than 0.04)], respectively. Catheter-related bacteremia was similar in both arms of the study, however. For the reasons already mentioned, we generally do not use a shoulder roll and keep the head in the neutral position. The patient's bed is then placed in Trendelenburg's position to facilitate distension of the subclavian vein. Although the vein is technically fixed as it courses between the clavicle and first rib, some distension does occur, as noted in the study by Fortune and Feustel.¹⁸ Using local anesthesia, the area of the chest wall at the site of the bend in the clavicle, as well as the periosteum of the clavicle is anesthetized. If the patient is not too obese, we often try to find the vein with the 1.5-in. local anesthetic needle; this will provide information about the location depth and angle of entry to the vein while minimizing any risk should an arterial puncture or puncture of the lung occur. The introducer needle with syringe attached is then inserted under the clavicle, entering the skin 2 cm from the inferior edge of the clavicle, in the direction of the suprasternal notch (Figure 81.1).

Once under the clavicle with negative pressure applied to the syringe, the subclavian vein is punctured. Upon obtaining good venous blood flow, the syringe is removed and the guidewire is inserted into the subclavian vein. The color and nature (pressure or flow) of the blood return must be carefully noted to make sure that it is not arterial. The needle is then withdrawn over the guidewire and a small incision is made in the skin at the site of entry of the guidewire. Ectopy is generally considered evidence that the wire is in the correct location. A dilator is passed over the guidewire with gentle pressure to avoid penetrating the back wall of the vein while keeping the wire straight to prevent kinking of the wire in the subcutaneous tissues. The dilator is removed and the catheter is inserted over the guidewire to the predetermined length. Several studies have looked at ways to confirm the best location of the tip of the catheter. The system we use was developed by a nurse in our infusion therapy unit and is

reproduced as Table 81.2. Using these lengths, based on patient height and site of insertion, in a series of 382 insertions, 373 (97%) were correctly placed.²⁰ Several studies have shown that the optimal location of the catheter tip is in the distal superior vena cava (SVC) or at the junction of the SVC and RA; tip placement outside this area leads to much higher risk of thrombosis. If an implanted port or tunneled catheter is being placed, this should always be done with fluoroscopic guidance to confirm the position of the tip of the catheter, as it cannot easily be corrected after final placement.

INTERNAL JUGULAR VEIN

The neck is palpated and examined before the insertion. Attention must be addressed to the location of the carotid artery and the heads of the sternocleidomastoid muscle. The patient's head is turned to face the direction away from the site of insertion. The area is prepped and draped in sterile fashion and the patient's bed is placed in Trendelenburg's position.

With the operator standing at the head of the bed, the carotid artery is palpated. The area is anesthetized, and the internal jugular vein is accessed with a small-gauge needle by directing the venipuncture lateral to the location of the carotid artery in a direction toward the ipsilateral nipple. A larger-gauge needle mounted on a syringe is then used to access the internal jugular vein. Once adequate blood flow is obtained, Seldinger's technique is once again used to pass the guidewire and subsequently place the catheter. As with the subclavian vein placement, fluoroscopy can be used to determine catheter location, although this is only truly necessary for tunneled catheters. At this time, the exit area for a tunneled device is determined. The subcutaneous pocket or the exit site for external devices that are tunneled is situated on the midanterior chest wall within 5 to 10 cm of the midclavicle area. This area is anesthetized, as well as the tract of the tunnel between the planned exit site of the device or the subcutaneous pocket for the port. The subcutaneous tunnel is created by passing the tunneling device from the site of insertion of the guidewire to the planned exit site or the subcutaneous pocket. The catheter is attached to the tunneling

device, which is then withdrawn, bringing the catheter to the site of insertion of the guidewire. The catheter is then passed over the guidewire and secured as previously described.

Complications

Insertion Related

Several factors are associated with an increased risk of complications. For jugular catheters, a short neck or obese patient makes the insertion more difficult and the risk of complications (principally arterial puncture) greater. For subclavian venipuncture, the most common complications include pneumothorax, arterial puncture, hemothorax, malposition of the catheter, and injury to the regional nerves (including brachial plexus, vagus, and phrenic nerves). Although injury to the nerves is extremely rare (approximately 1:20,000–1:30,000 procedures), injuries can happen and typically are associated with less experienced practitioners or persistence beyond a reasonable chance of success. As mentioned previously, factors that are associated with an increased risk of complications, include a very thin patient, prior surgery or radiotherapy in the area, and an inexperienced practitioner. The incidence of insertion-related pneumothorax, which is continuously monitored on an ongoing basis at M.D. Anderson Cancer Center (MDACC), is between 1% and 1.5%. Most pneumothoraces are asymptomatic and a postprocedure chest X-ray (CXR) is mandatory. Although most of these CXRs are negative, it is important to confirm the location of the tip of the catheter. A malpositioned catheter can oftentimes be corrected by either patient positioning or a power flush.²¹ Sometimes a partial withdrawal over a wire or fluoroscopic correction is needed. In a study by Laronga et al. from our institution, 100 pneumothoraces were detected in a consecutive series of 9,637 patients (1.04%), suggesting that the yield of routine CXR to be very low for pneumothorax in the asymptomatic patient.²² If one were able to confirm catheter tip by another means, this could then lead to a challenge of the practice of obtaining routine CXR following central

venous access placement. However, we have not yet reached that state. CXR performed in patients with symptoms appears to be a more pertinent approach, and in fact, both the patient and clinician must be aware of the risk of delayed pneumothorax, which we find comprises about 10% of our pneumothoraces. If the line is inserted as an outpatient procedure, the patient may not develop the symptoms of pneumothorax for 12 to 24 hours. It is imperative that such patients seek medical attention urgently. Laronga et al. also developed a treatment algorithm for the management of postcentral venous catheter (post-CVC) pneumothorax, whereby some patients, based on size of pneumothorax, presence of symptoms, difficulty of insertion, and prior history of a CVC, may safely be observed with follow-up CXR²² (Figure 81.2).

Hemorrhage is another potential complication of central venous access placement. As with pneumothorax, this occurs infrequently, and although most are self-limited, the outcome of this complication can be fatal. Hemorrhage can be a consequence of either accidental arterial puncture or result from a venous puncture. Major vessel injury can occur during placement of the introducer sheath. As mentioned in the Insertion section, the introducer sheath should be placed with gentle pressure. When this placement occurs too vigorously the sheath can accidentally penetrate the back wall of the vessel. The loss of blood into the chest cavity may also go unrecognized before the patient develops symptoms. In roughly 1 of 10,000 procedures, the artery may be injured in such a fashion as to become an emergency requiring either surgical, or in some cases, interventional radiology, correction.

The proximity of the brachial plexus to both the subclavian and internal jugular veins, places these nerves at risk for laceration by the introducer needle, although fortunately, this risk is quite low. Another mode of injury can occur as a result of compression by a hematoma. This effect is usually associated with neuropraxia as opposed to paralysis. The symptoms associated with nerve injury from compression are usually self-limiting and usually resolve without any sequelae.

An unusual, and more annoying than life-threatening complication of central venous access, is that of a chyle leak. This complication can be encountered while accessing the left subclavian vein or the left internal jugular vein. Perforation of the thoracic duct results in leakage of chyle, which tracks back out around the catheter. Chyle leaks are treated with direct pressure dressing, and if this fails, the catheter may need to be removed and a new stick performed. Only on the rarest of occasions may surgical exploration with ligation of the thoracic duct become necessary.

Numerous efforts have been undertaken in an attempt to minimize the risks of central venous catheter placement. Most often these attempts have involved the use of imaging guidance of the insertion attempt. Although some have found the use of ultrasound beneficial, this advantage may be site dependent. In a randomized trial of more than 800 patients, we found that ultrasound localization (but not real-time guidance) was of no benefit for subclavian catheter placement.¹¹ Other investigators have found varying results. In a randomized study, in which a single clinician inserted the catheters, Lefrant et al. found only modest benefit from ultrasound guidance.²³ Although the overall risk of complications was decreased by using ultrasound guidance from 16.8% to 5.6% (P less than 0.01), most of this benefit was actually for malpositioned catheters (7.7% to 0.7%; P less than 0.01). In fact, failures, immediate complications, and total number of skin punctures were similar in the two arms, whereas the Doppler ultrasound arm took six times as long for insertion (300 versus 27 seconds). Bold et al. conducted a randomized trial of Doppler-guided placement of subclavian catheters in approximately 500 patients, and found no benefit to the technology.²⁴ Clinicians inserting the catheters were either highly efficient with and without the technology or they were not. This is one of the problems with applying technology across the board; there is significant operator variation. Conversely, Teichgraber et al., in a randomized trial of 100 patients undergoing IJ venipuncture, found that ultrasound markedly decreased time of insertion, failure rate, and complications.²⁵

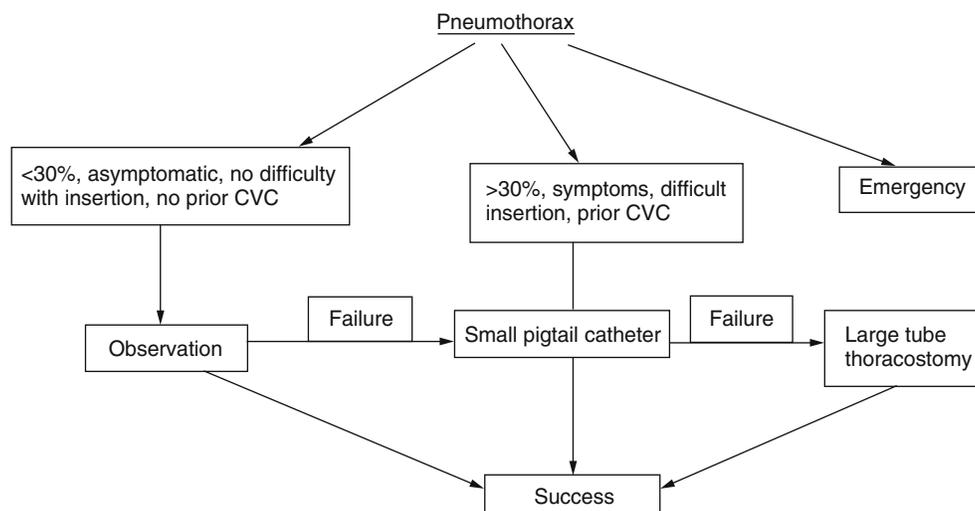

FIGURE 81.2. Algorithm for management of pneumothorax occurring secondary to central venous catheter (CVC) placement. (From Laronga et al.,²² by permission of *American Journal of Surgery*.)

Randolph et al. performed a meta-analysis of real-time ultrasound guidance for both subclavian and IJ catheter placement and found improvements in failure rate (RR, 0.32; 95% confidence interval, 0.18–0.55) and complications (RR, 0.22; 95% confidence interval, 0.10–0.45).²⁶

Catheter Related

The two main considerations here, are CRBSI and venous thrombosis, although there is some overlap between the two. We examine first the issue of thrombosis and then move to infection.

THROMBOSIS

Venous thrombosis is a serious and relatively common catheter-related complication. Although studies have examined the use of various anticoagulants to prevent thrombosis, perhaps one of the most important interventions to prevent them is to make sure the catheter tip is in the correct position (distal superior vena cava to junction of superior vena cava and right atrium).²⁷ In patients with central venous access, this may present with upper extremity swelling or difficulty withdrawing blood from the device. One must differentiate between an occluded catheter and an occluded vein or determine if both are present, with the latter causing the former. The evaluation of this would include either a nuclear or contrast venogram, although duplex Doppler can also be helpful. Once the diagnosis is made, the decision on how to treat is heavily influenced by the need of the patient for the device. If it is suspected that a clot or a fibrin sheath obstructs the catheter, tissue plasminogen activator (tPA) may be instilled in the device with a high success rate.²⁸ Recombinant urokinase has also been shown to be better than placebo at restoring catheter patency.²⁹ If the thrombosis involves the subclavian vein, anticoagulation with heparin, followed by warfarin therapy, may be necessary as these clots can also lead to pulmonary embolism. If one has an aggressive interventional radiology unit, and the patient is anticipated to have long-term needs for venous access and loss of this vessel would be extremely detrimental to that care, a peripheral catheter can be inserted and tPA used to lyse the clot and the patient is then placed on long-term anticoagulation.

Several efforts have been made to prevent the formation of clots. It is helpful to know how frequent the problem is before trying to prevent it. In a prospective study by Martin et al., it was found that 47% of patients developed a fibrin sheath and that partial vein occlusion occurred in 8% of patients.³⁰ An additional 3% of patients developed evidence of a radiographic complete occlusion. In addition, the authors examined the duration of catheter presence and found that catheters in place less than 2 weeks were unlikely to develop thrombosis. Abdelkefi et al. examined the use of continuous-infusion low-dose heparin (compared with saline) to prevent catheter-related thrombosis in patients with hematologic malignancies.³¹ They found, in 128 randomized patients, that catheter-related thrombosis occurred in 1.5% of the heparin group and 12.6% of the control group ($P = 0.03$). There was no difference in bleeding complications (2 in the heparin group and 3 in the control group). Massicotte et al. conducted a randomized trial of low molecular weight heparin for pre-

vention of CVC-related thrombosis.³² This study, conducted in children, was closed early for slow accrual; no difference was found in the rate of venous thromboembolism between standard care and reviparin-sodium (12.5% and 14.1%, respectively, in 80 and 78 patients), and there was also no difference in bleeding complications.

INFECTION

There are several components to the issue of catheter-related infections. Some of these, including skin preparation and draping the patient, we have already discussed. Contrary to the suggestion in the study by Ma et al. mentioned earlier, regarding the risk of infection and TPN, Tokars et al. evaluated risk factors for infection in catheters maintained in an outpatient setting.³³ Of 988 catheters maintained in 827 patients, they found five factors associated with an increased risk of infection, including (1) recent bone marrow transplant (RR, 5.8), (2) TPN (RR, 4.1), (3) receipt of therapy outside the home (such as at a physician's office) (RR, 3.6), (4) use of a multilumen catheter (RR, 2.8), and (5) history of a previous bloodstream infection (RR, 2.5). Patients who had three or more of these risk factors had an approximately 40-fold-increased risk of infection when compared with those with none of these risk factors. In addition, catheter maintenance (including the site and connections), the various uses of the catheter, prophylactic antibiotics, routine catheter exchange, antimicrobial flushes, and use of catheters impregnated or coated with various antimicrobial agents, all may have roles. This section examines these issues.

Prophylactic Antibiotics

Bock et al. conducted a prospective randomized trial of preinsertion intravenous antibiotics compared with placebo or routine catheter exchange in 92 patients undergoing therapy with interleukin 2 (IL-2).³⁴ They found a significant decrease in catheter-related sepsis in the oxacillin group ($P = 0.05$), as well as a decrease in bacterial colonization (P less than 0.001) when compared with the other two arms.

Catheter Exchange

Bonawitz et al. randomized 85 patients with 159 catheters to have a replacement at 3 or 7 days and whether or not a cuffed catheter was used.³⁵ They found no benefit to either the earlier exchange or the use of the cuff, although the size of the study may have been limiting. Nevertheless, there was certainly no obvious benefit to routine exchange. Cobb et al. also examined the role of routine catheter exchange in a four-arm randomized trial.³⁶ Patients were randomized to either having the catheter exchanged or replaced every 3 days or when clinically indicated. They found that there was no decrease in infections with replacement or exchange every 3 days. Exchange over a wire was associated with an increase in infections, and new placement every 3 days was associated with an increased risk of complications of insertion. Eyer et al. conducted a prospective randomized trial among every-7-days over-wire exchange, every-7-days new catheter placement, and change based only on clinical need in 112 patients.³⁷ Although there was no difference in catheter-

related infections, the size of the study does limit conclusions to some degree.

Catheter Dressings, Connections, and Tubing

As noted earlier in the study of catheter cuffs by Flowers et al., in fact the topical antimicrobial may have been responsible for fungal infections.³ Other investigators have examined various aspects of the local care of catheters. Conly et al. randomized 115 patients between a transparent or gauze dressing, and found that colonization was far less in the gauze group ($P = 0.009$).³⁸ Local catheter-related infection and catheter-related bacteremia were both significantly more common in the transparent group ($P = 0.002$ and $P = 0.15$, respectively). Maki et al. randomized 442 patients to one of three local dressing approaches: (1) sterile gauze and tape replaced every 2 days, (2) conventional polyurethane dressing replaced every 5 days, or (3) a highly permeable polyurethane dressing replaced every 5 days.³⁹ Although they found no difference in catheter colonization or CRBSI, bacterial colonization under the dressing was greatest with the standard polyurethane dressing, and least with the gauze dressing (P less than 0.001). Laura et al. compared two different time intervals for CVC dressing changes in a bone marrow transplant population.⁴⁰ This multiinstitutional study evaluated 399 patients with either a tunneled or nontunneled catheter. The randomized times were different for the two types of catheters (5 or 10 days for the tunneled and 2 or 5 for the nontunneled). They found no difference in local infection rates based on duration of dressing, but did find more local skin reactions in the every-2-day group. Crawford et al. conducted a cost-benefit analysis based on randomized controlled trial data of chlorhexidine dressings when compared with standard dressings.⁴¹ Considering averted cost of treatment of both local infections and CRBSI at all Philadelphia area hospitals, they calculated that the standard use of a chlorhexidine gluconate dressing would result in potential savings of \$275 million to \$1.97 billion, with 329 to 3,906 lives saved annually across the United States. Rickard et al. examined the practice of routine changing of the intravenous administration sets on colonization or infection of CVCs.⁴² In this study, 251 patients with 404 catheters were randomized to have their IV administration sets changed at 4 days or not. There were 10 colonized CVCs in the change group and 19 in the no-change group, the difference not being statistically different (P less than 0.1). All lines were removed by day 7. One of the major considerations of trying to extrapolate from these data, is that all the patients had chlorhexidine gluconate and silver sulfadiazine-coated catheters. Henrickson et al. conducted a three-arm randomized trial in 126 pediatric patients comparing the impact of flushing the catheter with vancomycin, heparin, and ciprofloxacin (VHC), with vancomycin and heparin (VH), and heparin alone.⁴³ Both the VHC and VH groups had substantially fewer CRBSIs than the heparin-alone group (heparin, 31; VH, 3; VHC, 6). Interestingly, there were significantly fewer episodes of occlusion in the VHC group when compared with the heparin-alone group (P less than 0.001). Two reports of the use of needle-less connectors found somewhat divergent results. Cookson et al. found a significant increase in the risk of BSIs in patients after the introduction of a needle-less system (9.4 versus 5.0/1,000 CVC days).⁴⁴ The authors conjectured that much of the increase

was likely the result of nurses' unfamiliarity with the devices and departure from manufacturers' recommendations. Casey et al. conducted a randomized trial of needle-less versus standard cap in 77 cardiac patients.⁴⁵ After 72 hours, the caps/connectors were cultured; 55 of 306 (18%) of the standard Luer group were contaminated, whereas 18 of 274 (6.6%) of the needle-less group were contaminated (P less than 0.001). The authors also randomized patients to receive various disinfectants for the external surfaces and found the combination of chlorhexidine and alcohol was far superior to alcohol alone (30.8% versus 69.2%, respectively; P less than 0.001).

At M.D. Anderson, line care is done according to very specific treatment guidelines to minimize site infections and prolong catheter life. However, site problems will occur, and these are managed at our institution according to the algorithm shown in Figure 81.3, based on the severity of the site problem.

Impregnated or Coated Catheters

In what seems to be the pinnacle of attempts to prevent CRBSI, several investigators have either coated or impregnated catheters with various agents to prevent the development of the biofilm that coats catheters and serves as a nidus for infections, as well as to prevent the severe toxicity of CRBSI. A summary of reported trials with at least 100 randomized patients is included in Table 81.3. Maki et al. conducted a randomized trial of a chlorhexidine/silver sulfadiazine-impregnated polyurethane catheter with a standard polyurethane catheter⁴⁶ that studied 403 catheters in 158 adult patients. Catheter colonization, bloodstream infection, and CRBSI were all significantly less common in the treated-catheter group. There were in fact no instances of CRBSI in the treatment group, whereas 8 occurred in the control group ($P = 0.003$). Carrasco et al. performed a randomized trial between a heparin-coated catheter and a chlorhexidine/silver sulfadiazine-coated one in 180 patients requiring a triple-lumen catheter.⁴⁷ Of the 132 heparin catheters, 29 were colonized, whereas 13 of the 128 chlorhexidine/silver sulfadiazine catheters were ($P = 0.03$). The incidence of CRBSI was similar in the two arms, 3.24 per 1,000 catheter-days and 2.6 per 1,000 catheter-days, respectively. Corral et al. evaluated a silver central venous catheter in 206 patients randomized to receive a standard catheter or the silver one.⁴⁸ Colonization was less in the silver group, with 30 of 103 compared with 45 of 103, respectively ($P = 0.04$), whereas the rates of CRBSI were 0.8 and 2.8 per 1,000 catheter-days (P less than 0.001). Darouiche et al. conducted a multiinstitutional randomized trial comparing minocycline/rifampin (MR)-impregnated catheters with those impregnated with chlorhexidine/silver sulfadiazine (CSS),⁴⁹ in which 865 catheters were inserted and 85% were evaluable. Colonization occurred in 28 of 356 (7.9%) MR catheters and 87 of 382 (22.8%) in the CSS group (P less than 0.001). Most importantly, CRBSI occurred in only 1 of 356 (0.3%) MR catheters and 13 of 382 (3.4%) of the CSS catheters (P less than 0.002). All these studies utilized polyurethane catheters, which are generally associated with a greater risk of thrombosis and generally have a much shorter functional life than silicone catheters. Hanna et al. randomized 370 patients to receive either a standard silicone catheter or one impregnated with minocycline and rifampin.⁵⁰ There were

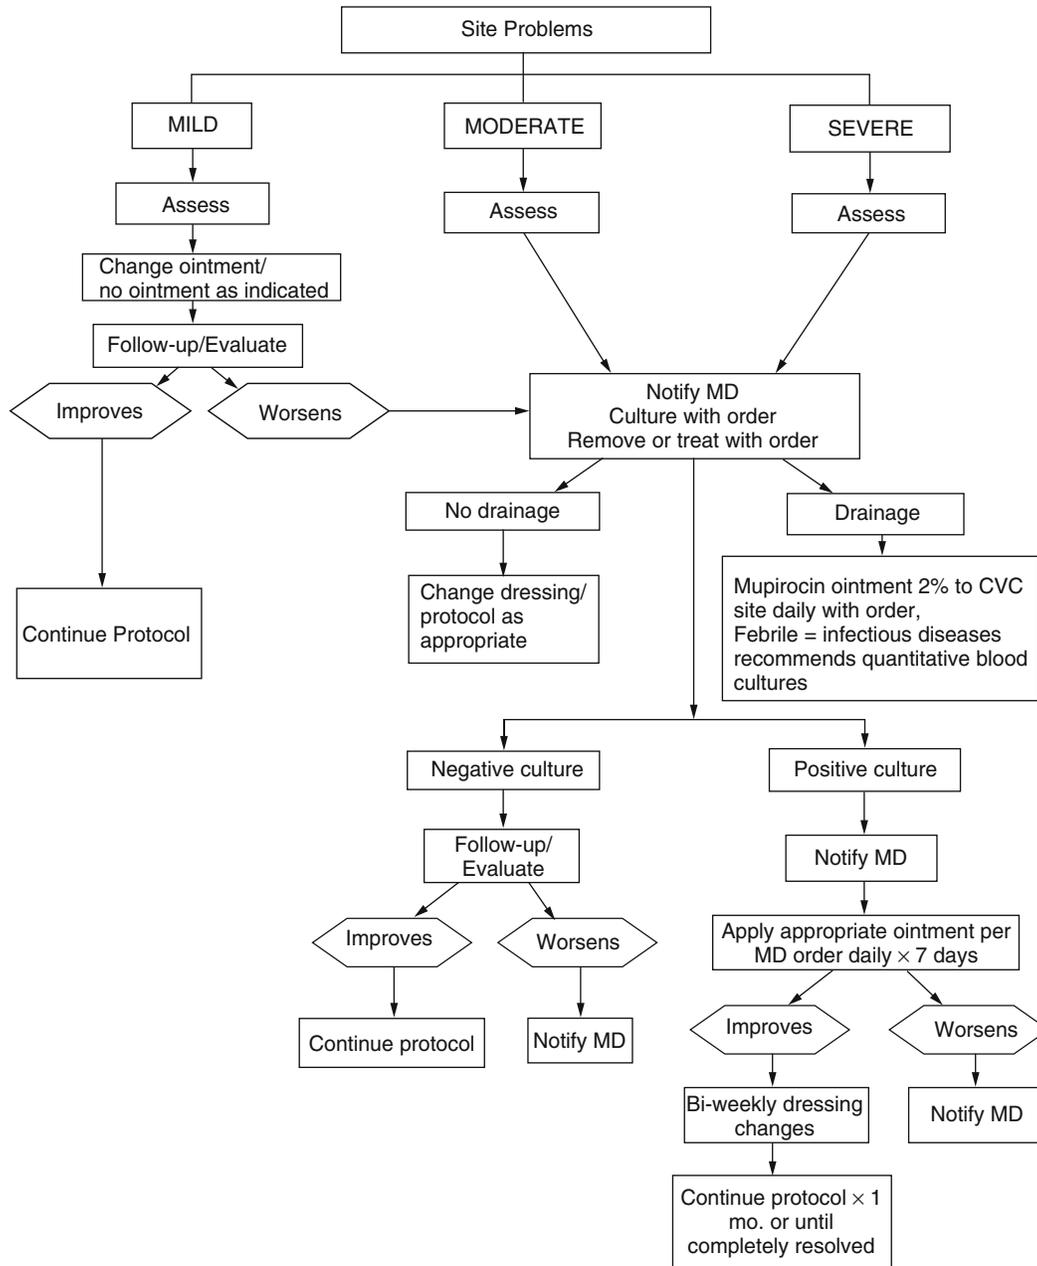

FIGURE 81.3. Algorithm for management of CVC site problems. (By permission of Raad IL. *Guidelines for Managing VAD Site Complications*. Infusion Therapy Team, The University of Texas M.D. Anderson Cancer Center, June 25, 1996.)

356 evaluable catheters in 355 patients. In this study, the mean duration was more than 2 months in both groups, and the risk of CRBSI was substantially less in the impregnated catheters than the standard ones (0.25 and 1.28/1,000 catheter-days; $P = 0.003$). The importance of these results should not be minimized as silicone catheters generally have a much longer duration of use than polyurethane ones. At M.D. Anderson, we generally restrict their use to patients receiving a marrow or stem cell transplant or IL-2-based therapy; those who are having a catheter exchanged for suspected infection; long-term ICU patients; and those patients who are known to have poor access options and have had catheter-related infections in the past.

General Infection Recommendations

Based on some of the data presented here, in 2002, the Centers for Disease Control and Prevention (CDC), issued guidelines for the prevention of catheter-related infections.⁵¹ Their major points were (1) education and training of those placing and maintaining the catheters, (2) use of maximal sterile barrier at time of insertion, (3) use of a 2% chlorhexidine skin preparation, (4) avoidance of routine catheter replacement, and (5) use of antiseptic/antibiotic-impregnated catheters if the rate of infection is high despite the other interventions.

TABLE 81.3. Summary of randomized trials of 100 or more patients using impregnated or coated catheters.

Author	No. of patients randomized	Year	No. of catheters total	Control arm	Treatment arm	No. of lumens of catheters	Catheter material	Median catheter duration, Tx/Cont	Coated (C) vs. impregnated (I)	Catheter colonization (%treatment over %control)	CRBSI/1,000 catheter days (or %CRBSI) treatment/control
Brun-Buisson ⁵²	363	2004	363	Noncoated	Chlorhexidine/silber sulfadiazine (CSS)	1 or 2	Polyurethane	10.5/12.0	C	3.7/13.1 (P = 0.01)	2/5.2 (P = 0.1)
Carrasco ⁴⁷	180	2004	260	Heparin coated	CSS	3	Polyurethane	9.5/9.0	C	10.1/22.0 (P = 0.03)	2.6/3.24 (P = 0.79)
Jaeger ⁵³	106	2005	106	Uncoated triple lumen	CSS	3	Polyurethane	14.3/16.6	I	9.8/16.4 (P + 0.035)	2.0% vs. 14.5% (P = 0.02)
Hanna ⁵⁰	356	2004	356	Uncoated silicone	Minocycline-rifampin (MR)	1 or 2	Silicone	66.2/63.0	I	Not specified	0.25/1.28 (P = 0.003)
Leon ⁵⁴	465	2004	465	Nonimpregnated	MR	3	Polyurethane	10.3/10.4	I	10.4/24 (RR, 0.43; CI, 0.26-0.73)	3.1/5.9 (RR, 0.53; CI, 0.2-1.44)
Darouiche ⁴⁹	698	1999	738	CSS	MR	3	Polyurethane	6.0/7.0	I	7.9%/22.8% (P < 0.001)	0.3% vs. 3.4% (P < 0.002)
Logghe ⁵⁵	538	1997	680	Nonimpregnated	CSS	>1	Polyurethane	19/19	I	Not specified	5% vs. 4.4% (P = NS)
Maki ⁴⁶	158	1997	403	Standard	CSS	3	Polyurethane	6.0/6.0	I	13.5%/24.1% (P = 0.005)	1.6/7.6 (RR, 0.21; CI, 0.03-0.95)
Heard ⁵⁶	251	1998	308	Uncoated	CSS	3	Polyurethane	8.5/9.0	C	40%/52% (P < 0.05)	3.3% vs. 3.8% (P = NS)
Tennenberg ⁵⁷	282	1997	282	Uncoated	CSS	>1	Polyurethane	5.2/7.8	C	28% vs. 49% (P < 0.001)	3.8% vs. 6.4% (P = NS)

Thornton ⁵⁹	110	1996	176	Nonbonded	Vancomycin	3	Not specified	Not specified	C	62% vs. 80% (P = 0.01)	

Tx., treatment; Cont, control; RR, relative risk; CI, confidence interval.

Conclusions

With all the progress that has been made, issues that remain of concern for venous access in patients with cancer are the optimal way to minimize the risk of thrombosis, the best way to minimize the risks of insertion, and balancing the competing concerns of minimizing complications and the costs of these interventions, particularly in those populations which may be at lower risk. Although there are many efforts to increase the use of oral agents in the treatment of the cancer patient, it is unlikely that the need for central venous access will diminish during our lifetime.

Management of Cancer Pain

Donald P. Lawrence, Leonidas C. Goudas,
Andrew J. Lipman, Joseph Lau,
Rina M. Bloch, and Daniel B. Carr

Enormous advances have occurred in the past two decades in our understanding of cancer pain and in our capacity to relieve it in most cases. Progress has been made in our understanding of the pathogenesis of nociception, the epidemiology of cancer pain, the validation of effective treatment algorithms, and the evaluation of novel pharmacologic and nonpharmacologic approaches to ameliorate pain. Paralleling these developments in research,¹ pain management has emerged as a priority in healthcare policy and medical education.²

Despite these advances, pain remains the aspect of cancer perhaps most feared by patients. Substantial barriers to optimal pain management persist, including the expense of appropriate medications or lack of access to them, healthcare disparities based on age, gender, and race,³ inadequate awareness or expertise on the part of practitioners, and the stigma still attached to opioid analgesics.⁴

This chapter is an updated synopsis of two recently published comprehensive evidence reports focusing on three broad areas of cancer pain: occurrence (i.e., prevalence and incidence), methods of assessment, and treatment.

Cancer Pain: Definitions

Cancer pain may be a manifestation of the disease itself, or may result from treatments, including surgery, radiotherapy, and chemotherapy. Acute pain, chronic pain, tumor-specific pain, and treatment-related pain may exist simultaneously or sequentially.

The experience of pain is profoundly influenced by cultural⁵ and psychologic factors,⁶ and therefore a distinction can be made between pain and the distress and suffering that may result from it.⁷⁻⁹ In cancer, pain may be a reminder of mortality and carries profound personal, social, cultural, and religious implications.^{10,11}

Cancer pain shares mechanisms with both acute and chronic noncancer pain. Traditional definitions of chronic pain require duration of 3 to 6 months.¹²⁻¹⁵ Yet, current pain research¹⁶ confirms that every physiologic feature considered essential for chronic pain—central sensitization, hyperalgesia, novel gene expression, synaptic remodeling (“plasticity”), “pain memory” formation, and behavioral adjustment—is triggered within days of acute, ongoing tissue injury.¹⁷ Thus,

pain of relatively brief duration has the potential to provoke the physiologic responses associated with chronic pain. Furthermore, when a new painful stimulus occurs in a patient with cancer, the intensity of the pain and its response to analgesics may be modulated by a nervous system sensitized by prior nociception.

Tumors cause pain by the local release of inflammatory mediators and by exerting pressure on surrounding tissues, including nerves.^{18,19} Inflammatory mediators associated with cancer include prostaglandins, cytokines, such as tumor necrosis factor,²⁰ growth factors, and other tumor-derived products, such as endothelin,²¹ each of which can excite nociceptors.²² Some cancers induce the production of autoantibodies that are implicated in painful paraneoplastic syndromes.^{23,24} Animal models of bone cancer pain have suggested a distinctive neurochemical and histologic “signature” in afferent nerves and their spinal cord connections.²⁵

Cancer pain frequently has neuropathic components, in which damage to the nervous system causes pain,²⁶ as well as nociceptive components, in which injury to nonneural tissue is conveyed through an intact nervous system. Common causes of neuropathic pain in cancer patients include nerve entrapment syndromes, postprocedural pain, and neuropathies due to chemotherapy and radiation therapy.

Current therapeutic options for cancer pain relief overlap substantially with those for noncancer pain. However, there is increasing evidence to support the use of modalities that are specific for cancer pain. The palliative benefit of external-beam radiation for cancer pain is well established. The use of bisphosphonates, radiofrequency tumor ablation, and systemic radionuclides has been shown to improve pain in specific cancer types. Improved pain control also has been demonstrated in clinical trials of chemotherapy and hormonal therapy for certain advanced cancers.

Methodology of Finding, Retrieving, and Evaluating the Evidence on Cancer-Related Pain

A comprehensive, systematic review of cancer pain is beyond the scope of this chapter. The material presented represents a summary and selective update of two recent evidence

reports on cancer pain prepared for the Agency for Healthcare Research and Quality (AHRQ) at the request of the American Pain Society²⁷ and, subsequently, the National Cancer Institute.²⁸ The purpose of the evidence reports was to provide a comprehensive overview of published studies on the occurrence, assessment, and treatment of cancer pain. In preparing the evidence reports, a sensitive search strategy was applied to the Medline and CancerLit databases and the Cochrane Controlled Trials Registry. This strategy yielded 24,822 reports published in English. Studies selected for inclusion in the evidence reports met all the following criteria: (a) all or part of the population studied suffered from cancer, (b) pain was a measured primary or secondary outcome, and (c) pain was attributed to the cancer itself or to cancer treatment. Studies with the primary purpose of assessing the prevalence or incidence of cancer pain, were used to obtain information about the occurrence of cancer pain. Both retrospective and prospective studies were used to obtain information about the methods of assessment of cancer pain. Randomized controlled trials were used to assess the efficacy of interventions. The characteristics of the retrieved studies were analyzed with respect to population and disease characteristics, patient demographics, treatment comparisons, outcome measures, and methodological features. The methodological quality, the applicability of the reported findings, and the magnitude of treatment effects of randomized controlled trials (RCTs) were assessed. For the purposes of this text, a selective review of the evidence included in these two evidence reports is provided, and more recent studies of particular importance are highlighted.

Occurrence of Cancer-Related Pain

Twenty-nine studies were identified reporting the prevalence and/or incidence of cancer-related pain²⁹⁻⁵⁷ (Table 82.1). More than half the studies were conducted in the United States. The majority of the remaining studies were conducted in Europe; 2 were from Asia and 1 was from South Africa. Two studies focused on pain in pediatric cancer patients.^{32,33} In two studies, the prevalence of pain in patients with recently diagnosed cancers was reported.^{44,52} Three studies focused on hospice or end-of-life care.^{35,43,55} We identified only 2 studies that provided a quantitative estimate of the prevalence of pain in minority groups (African-Americans, Hispanics, Asians, and American Indians)^{42,51} and 1 study that reported the prevalence of pain in elderly cancer patients.⁵¹

The patient populations were heterogeneous in the majority of studies, representing a mixture of demographics, cancer types, stages of disease, and mechanisms of pain. Two studies focused on the occurrence of a specific pain syndrome, pain after surgery for breast cancer.^{46,49} Four studies focused on specific malignancies: one on patients with colon or lung cancer,³⁸ and one each on ovarian cancer,⁴¹ lung cancer,⁴³ and pancreatic cancer.⁴⁴

The large majority of the studies involved selected cohorts, ranging from 60 to 2,266 subjects, from hospitals, clinics, pain services, and hospices. The largest study by far (and the only one that could be considered population based) was a national survey from Japan of 35,683 hospitalized patients with cancer.³⁷ In this study, the incidence of pain was defined as the percentage of patients receiving analgesics (32.6%), a definition that excludes untreated pain and there-

fore, almost certainly represents an underestimate of the true incidence.

By any measure, pain is extremely common among cancer patients, and a large majority experience pain during the course of their illness. None of the studies identified a pain prevalence rate less than 14% of the patients surveyed, and rates of up to 100% were found in selected populations. As might be expected, pain appears to be more common in metastatic than in localized cancer. It is difficult, however, to determine other reliable correlations between the prevalence or incidence of pain and patient factors, disease characteristics, the setting in which care is provided (e.g., primary care or specialized oncology or pain treatment clinics), or specific treatments directed toward the underlying disease. Various methods were used to assess pain, and therefore the reported rates in different studies are not readily comparable.

The total number of patients surveyed in studies on the occurrence of cancer pain is a minuscule fraction of those affected, a much lower fraction than has been studied in other conditions of comparable frequency and impact. Few of the studies were longitudinal and none focused on cancer survivors. Only one study was population based; the others were cohort studies. Studies of selected cohorts may underestimate the true burden of pain because patients with the most intense pain may have been too symptomatic to participate or perhaps less likely to receive their care in the academic referral centers where the majority of the studies were conducted. Although much has been learned about the prevalence of cancer pain, the picture remains far from complete. Little is known about the variations in the prevalence, severity, and course of cancer pain with respect to patient factors (age, gender, race, socioeconomic status, ethnicity), disease characteristics (type, stage, and phenotypic or genotypic classifications), treatment modalities, provider attributes, and the setting in which care is provided.

Assessment of Cancer-Related Pain

Simple patient self-report instruments, such as numeric, verbal, or pictorial scales and brief questionnaires have proven to be a rapid, reliable way to assess cancer pain. The U.S. Joint Commission on Accreditation of Healthcare Organizations includes the assessment of pain using such methods among its standards for accreditation of hospitals. The Brief Pain Inventory (BPI) has been validated in at least 18 languages and is perhaps the most widely used multiple-item pain assessment instrument. Despite the availability of reliable methods of assessment and the mandate for their use as a matter of healthcare policy, it remains uncertain how effectively and consistently cancer pain is assessed in various practice settings. A number of studies have suggested that inadequate assessment is a major contributing factor to the undertreatment of cancer pain, particularly in children, the elderly, and minorities (see following).^{42,51,58}

In clinical practice, regular evaluation of pain is the foundation of effective treatment.^{12,59,60} Patients with cancer may experience acute or chronic pain related to their primary diagnosis, from treatment, or from unrelated, even preexisting disorders. The initial evaluation of a patient with cancer pain should include assessment of the pain intensity by patient self-report, using a numerical, verbal, or pictorial scale. Assessment of cancer pain intensity serially, using a standard,

TABLE 82.1. Summary of studies reporting the prevalence and/or incidence of cancer pain.

Author	Setting	Population	Aim of the study	Type of cancer	Incidence or prevalence of pain, etiology, characteristics (comments)
Daut 1982 ²⁹	Country: USA Setting: hospital clinic (inpatients and outpatients) Specialty: oncology, urology, and gynecology	N = 667 Age: 19–88 years Symptoms: pain Sx duration: 9 months Source of data: questionnaire, charts	To evaluate the incidence of pain at the time of diagnosis and in progression of disease. Also evaluated were intensity, location, and perceived cause, treatment, and efficacy, interference with life.	Breast (289/667 = 43.3%) Prostate (48/667 = 7.2%) Colon/rectal (127/667 = 19.0%) Cervix (91/667 = 13.6%) Uterine (27/667 = 4.0%) Ovary (85/667 = 12.0%)	Met Non-met Breast 64% 40% Prostate 75% 30% Colon/rectal 47% 40% Cervix ND 35% Uterine 40% 14% Ovary 59% 39% Total (pain due directly to tumor): 33% 6% 6%–7% pain due to other etiologies
Ahles 1984 ³⁰	Country: USA Setting: clinic outpatients Specialty: oncology	N = 208 Age: 17–86 years Symptoms: pain Sx duration: 7 months Source of data: questionnaire, charts	To determine prevalence of pain and relation of pain to cancer, treatment of cancer, or other. The study also evaluated the incidence of pain according to the stage (local, regional, metastatic).	Breast (62/208 = 29.8%) Lung (26/208 = 12.5%) Lymphoma (22/208 = 10.6%) Colon (19/208 = 9.1%) Other (79/208 = 38.0%)	33.5% pain due to cancer 6.7% cancer-related procedures 11.0% non-cancer-related pain commonly associated with metastatic disease.
Gilbert 1986 ³¹	Country: USA Setting: clinic inpatients Specialty: oncology	N = 162 Age: >18 years Symptoms: neurologic Sx duration: 3 months Source of data: questionnaire, charts	To determine the incidence and nature of pain and other major neurologic problems (e.g., disorientation) in cancer patients.	Non-Hodgkin's lymphoma (26/162 = 16.0%) Breast (17/162 = 10.5%) Hepatoma (15/162 = 9.2%) Small-cell lung (13/162 = 8.0%) Multiple myeloma (13/162 = 8.0%) Colon (10/162 = 6.1%) (All others <10)	34/162 21% overall
Miser 1987 ³²	Country: USA Setting: hospital, clinic (in- and outpatients) Specialty: pediatric oncology	N = 139 161 inpatient days, 195 outpatient clinic visits (in- and outpatients) Age: >7 years Symptoms: pain Sx duration: 6 months Source of data: questionnaires	To investigate the prevalence and nature of pain in children and young adults with malignancy.	Leukemia (44/139 = 31%) Soft tissue sarcoma (33/139 = 23.7%) Ewing's sarcoma (28/139 = 20.1%) Osteosarcoma (20/139 = 14.4%) Lymphoma (12/139 = 8.6%) Other (2/139 = 1.4%)	In 356 patient visits, pain present in 54% of total inpatient population and 26% of outpatient population: 46% pain due to tumor alone, 14% pain due to both tumor and therapy 40% pain due to cancer Tx Only tumor-related pain was due to bone invasion 68%, cord compression 5%, and multiple causes 11%. Pain was associated with lower functional status (Karnofsky score).

TABLE 82.1. (continued)

Author	Setting	Population	Aim of the study	Type of cancer	Incidence or prevalence of pain, etiology, characteristics (comments)
Miser 1987 ³³	Country: USA Setting: hospital, clinic (in- and outpatients) Specialty: pediatric oncology	N = 92 Age: children and young adults (age not stated) Symptoms: pain Sx duration: 26 months Source of data: questionnaires	To investigate the incidence of pain in children and young adults presenting with newly diagnosed malignancy.	Soft tissue sarcoma (23/92 = 25%) Ewing's sarcoma (21/92 = 22.8%) Osteosarcoma (14/92 = 15.2%) Leukemia (12/92 = 13%) Lymphoma (10/92 = 10.9%) Neuroblastoma (1/92 = 1.0%) Other (11)	Soft tissue sarcoma 52.2% Ewing's sarcoma 60.0% Osteosarcoma 78.3% Leukemia 100% Lymphoma 100% Neuroblastoma 100% On initial evaluation 72 of 92 patients were experiencing pain that had been present for median 74 days (3–21 days, range); 42 had experienced sleep disturbances due to pain. Pain was associated with lower functional status (Karnofsky score).
Greenwald 1987 ³⁴	Country: USA Setting: hospital (outpatients) Specialty: anesthesiology and pain management	N = 536 Age: 20–80 years Symptoms: neurologic Sx duration: 18 months Source of data: Cancer Surveillance System registry, graphic rating scales, McGill Pain Questionnaire	To determine the prevalence and characteristics of pain in four types of primary cancer restricted to recently diagnosed patients (within 3 months of the survey).	Lung (260/536 = 48.5%) Prostate (201/536 = 37.5%) Uterine/cervix (50/536 = 9.3%) Pancreas (25/536 = 4.7%)	Lung 50.7% Prostate 38.3% Uterine/cervix 38.0% Pancreas 60.0% % of patients reporting moderate to very bad pain in past week by cancer site; % by stage also reported.
Coyle 1990 ³⁵	Country: USA Setting: pain service (outpatients) Specialty: neurology	N = 90 (40M, 50F) Median age: 59 (23–82) years Symptoms: pain Sx duration: 6 years (retrospective) Source of data: retrospective/patient charts	To retrospectively evaluate the prevalence of pain by intensity, type, analgesic consumption, and suicidal ideation in cancer patients during the 4 weeks preceding death.	Lung (23/90 = 25.6%) Colon (18/90 = 20.0%) Breast (18/90 = 20.0%) Head/neck (9/90 = 10.0%) Gynecologic (6/90 = 6.7%) (All others <5%)	For all sites: 100% had pain 80% mild to moderate 20% moderate to severe 67% more than one type of pain (40% somatic and neuropathic)
Portenoy 1990 ³⁶	Country: USA Setting: pain service Specialty: neurology	N = 63, 41 (64% with breakthrough pain episodes (19M, 22F) Median age: 51 (15–81) years Symptoms: breakthrough pain Sx duration: 3 months Source of data: prospective survey	To evaluate prevalence and characteristics of breakthrough pain.	Genitourinary (11/41 = 26.8%) Head/neck (5/41 = 12.2%) GI (4/41 = 9.8%) Lung (3/41 = 7.3%) Sarcoma (3/41 = 7.3%) Other (13)	Patients with breakthrough pain, 1 type (32), 2 distinct types (8), and 3 types (1). Characteristics: (median 4 pains/day; range 1–3,600) 22 (43%) had rapid onset (<3 min) Duration: (median 30 min; range 1–240) 21 (41%) both paroxysmal and brief 15 (29%) began or worsened at end of a fixed opioid dose interval Type of pain: somatic 17 (33%) visceral 10 (20%) neuropathic 14 (27%) mixed 10 (20%)
Hiraga 1991 ³⁷	Country: Japan Setting: nationwide hospitals (inpatients) Specialty: all	N = 35,683 (31.6% of all hospitalized patients at the time of survey) Age: not reported Symptoms: pain Sx duration: not reported Source of data: nationwide questionnaire by nurses	To determine the incidence of pain in different stages of illness, analgesic methods, and rate of pain relief in cancer patients in Japan (incidence was defined as the percentage of patients receiving pain medication).	Stomach (5,882/35,683 = 16.4%) Liver/biliary/pancreas (4,578/35,683 = 12.8%) Lung (4,428/35,683 = 12.4%) Colon/rectal (3,332/35,683 = 9.3%) Oral/pharynx/larynx (2,966/35,683 = 8.3%) Ovary/cervix/corpus (2,765/35,683 = 7.7%)	32.6%

TABLE 82.1. Summary of studies reporting the prevalence and/or incidence of cancer pain. (continued)

Author	Setting	Population	Aim of the study	Type of cancer	Incidence or prevalence of pain, etiology, characteristics (comments)
Portenoy 1992 ³⁸	Country: USA Setting: three physicians' outpatient practices Specialty: oncology, two specialists in lung cancer and one in colon cancer	N = 398 patients with lung or colon cancer Age: 57 ± 10.4 years (average for 91 patients who reported pain during the 2 previous weeks and consented to an interview) Symptoms: pain, mood (0–100 mm VAS for pain intensity, pain relief, and mood and 8-point categorical scale for pain intensity) Sx duration: 9 months Source of data: prospective survey with face-to-face interviews	To evaluate the prevalence and characteristics of pain in ambulatory patients with colon and lung cancer during active antitumor therapy. A prospective survey using face-to-face and telephone interviews by trained quality assurance analysts.	Genitourinary (2,746/35,683 = 7.7%) Lymphoma/leukemia (2,686/35,683 = 7.5%) Breast (1,925/35,683 = 5.4%) Other (9675) Lung (185/398 = 46.4%) Colon (213/398 = 55.6%)	“Persistent or frequent pain” during the previous 2 weeks was reported by: 57/145(39.3%) with lung cancer and 52/181(28.7%) with colon cancer. 91 of the above patients (47 lung, 44 colon) were interviewed in detail. There were no significant differences in pain with the exception of pain location between the two tumor types. One-third of patients had more than one discrete pain. Median pain duration was 4 weeks (range, less than 1 week-468 weeks), and average pain intensity was moderate. Approximately 90% of patients experienced pain more than 25% of the time. Regarding pain treatment: 56/91(61.5%) were prescribed no medication; 4/91(4.4%) were prescribed nonopioid medication; 31/91(34.1%) were given opioids. Of patients reporting that pain in general was moderate or greater, 57.8% were prescribed no pain medications and 37.3% received opioids.
Brescia 1992 ³⁹	Country: USA Setting: a 200-bed “specialty hospital for advanced cancer” Specialty: terminal care	N = 1,103 patients admitted during the survey period, and 1,017 patients who died within 6 months of the end of the survey Age: mean, 68; range, 24–94 years; 62% of patients were older than 65. Symptoms: pain intensity (none, mild, or severe) Severe pain was defined as recorded pain of moderate or greater intensity that occurred with regularity throughout the day. Mild pain was noted when the record stated that pain was relieved without the use of analgesics, by nonopioid agents, or by the “weak” opioids such as	To develop a clinical database for advanced cancer patients and to survey data to determine (1) pain severity at admission, (2) opioid use at admission, (3) change in opioid use during the hospital stay, and (4) survival in the hospital. Data were collected prospectively within 72 h after admission and soon after death or discharge.	Primary sites: Lung 19% Breast 13% Colon 10% Colon-rectum 6% Other sites 33%–55% Bone metastases: (pain-producing) in 38% Other sites of metastases: Lung 24% Liver 28% Brain 17%	73% of patients had pain at admission. Severe pain was inversely related to age; patients younger than 55 were twice as likely to have severe pain as older patients. Frequency of severe pain by type of cancer: cervix (68%, prostate 57%, colon-rectum 49%); severe pain was noted by nearly one-half (49%) of the patients with bone metastases. At baseline, 25% of patients were receiving morphine, 18% codeine, 6% hydromorphone, and 3% methadone or levorphanol. Most (71.7%) patients had a stable dosing pattern; only 4.2% required opioid dose increases of 10% or more per day.

TABLE 82.1. (continued)

Author	Setting	Population	Aim of the study	Type of cancer	Incidence or prevalence of pain, etiology, characteristics (comments)
		codeine. No pain was recorded when the record stated explicitly that the patient offered no complaint of pain or was comfortable. Sx duration: 12 months Source of data: prospective chart review at baseline (72h after admission) and again "soon after the patient's death or discharge."			
Vuorinen 1993 ⁴⁰	Country: Finland Setting: pain clinic (outpatients) Specialty: anesthesiology	N = 378 (240 evaluable, 40% M, 60% F) Median age: 64 (27–89) years Symptoms: pain Sx duration: 9 months. Source of data: questionnaire	To investigate the prevalence and causes of pain at the early stages of cancer (0–6 months from diagnosis).	Genitourinary (73/240 = 31%) GI (38/240 = 16%) Breast (63/240 = 26%) Hematologic (26/240 = 11%) Lung (14/240 = 6%) Skin (13/240 = 5%) Other (13/240 = 5%)	66/240 (28%) at time of questionnaire; 42/240 (24%) as first sign of cancer. Cause: 46% direct tumor growth 67% conditions secondary to cancer 18% unrelated to cancer
Portenoy 1994 ⁴¹	Country: USA Setting: hospital clinic (inpatients and outpatients) Specialty: neurology, pain	N = 151 (111 inpatients, 40 outpatients) Median age: 55 (23–86) years Symptoms: pain Sx duration: 18 months. Source of data: questionnaires	To investigate the prevalence, characteristics, and impact of pain in ovarian cancer patients.	Ovarian cancer	62% had pain before diagnosis 42% had pain during last 2 weeks. Most patients had pain-related interference with function.
Cleeland 1994 ⁴²	Country: USA Setting: outpatients in 54 oncology clinics Specialty: medical research, neurology	N = 1,308 (376 M, 495 F) 871 with pain or taking analgesics during week before to study Median age: 62 (19–90) years Symptoms: pain Sx duration: 12 months Source of data: questionnaire	To assess adequacy of analgesic drug prescribing according to WHO guidelines, factors that influence whether analgesia was adequate, and the effects of inadequate analgesia on patients' perception of pain relief and function status.	Breast (270/871 = 60%) GI (148/871 = 58%) Lung (124/871 = 63%) genitourinary (86/871 = 66%) Lymphoma (55/871 = 71%) Gyn (23/871 = 63%) [% of patients by site (see prior column) with substantial pain; pooled figure = 67%]	Physicians commonly underestimated the severity of pain; 42% of patients with pain were not given adequate analgesic therapy according to WHO guidelines. Independent risk factors for inadequate pain management included pain not attributed to cancer, better performance status, age 70 or older, female sex, and minority status. Underrated pain impaired function.
Mercadante 1994 ⁴³	Country: Italy Setting: palliative care service (outpatients) Specialty: pain management	N = 60 (52 evaluable, 44 M, 8 F) Age: 64.2 ± 2 (42–82) years Symptoms: pain Sx duration: unclear, 51.3 ± 9.4 days observation period Source of data: questionnaires	To obtain the prevalence, characteristics, and localization of pain in lung cancer and also to determine response to treatment by WHO analgesic ladder.	Lung	46 of 52 (88.4%) experienced pain. Pain was localized in: Chest 26/52 Legs/lumbar 1/52 Abdomen/arms 8/52 Head 6/52 The type of pain was: Somatic 85.7% Visceral 42.8% Neuropathic 30.9% Incident 23.8%
Kelsen 1995 ⁴⁴	Country: USA Setting: oncology and palliative care service, in- and outpatients	N = 189 (130 evaluable, 79 M, 51 F, total screened 277) Patients were divided into two groups, those who	To evaluate the prevalence of pain and depression, their correlation and their effect on quality of life in	Adenocarcinoma of the pancreas	At study entrance: 37% no pain 34% mild or minimal pain; 29% moderate to severe pain. Of patients who reported pain at entry, its duration ranged

Author	Setting	Population	Aim of the study	Type of cancer	Incidence or prevalence of pain, etiology, characteristics (comments)
	Specialty: neurology and medicine	underwent surgery (83/130) and those who received chemotherapy (47/130). Median age: 63 years Symptoms: pain Sx duration: unclear Source of data: questionnaires	patients with recently diagnosed adenocarcinoma of the pancreas.		from 1 to >5 months, 67% described a diffuse abdominal pain. Chemotherapy patients had more intense pain than preoperative patients. Patients with moderate or greater pain had more impairment of functional activity than patients with mild or no pain. Significant correlations between increasing pain and depression, and between pain/depressive symptoms and quality of life.
Larue 1995 ⁴⁵	Country: France Setting: 20 cancer treatment services, in- and outpatients Specialty: not specified	N = 605 (601 evaluable, 252 M, 347 F, ?2) Mean age: 57.8 ± 14 SD Symptoms: pain Sx duration: unclear Source of data: questionnaires by patients and physicians	To describe the treatment of cancer pain in France and to evaluate the predictive factors for inadequate management.	Breast (211/605 = 34.8%) GI (108/605 = 17.9%) Genitourinary (80/605 = 13.2%) Lung (77/605 = 12.7%) Head/neck (57/605 = 9.4%) Lymphoma (26/605 = 4.2%) Other (46/605 = 7.6%)	57% (340/601) reported pain due to their disease. 69% (224/325) of those with pain rated their worst pain at a level that impaired their ability to function. 30% (84/279) were not receiving pain medication. 51% (137/200) of those receiving pain medication found relief was inadequate. Doctors' pain ratings were consistently less than patients'.
Stevens 1995 ⁴⁶	Country: USA Setting: 16 ambulatory care services Specialty: nursing	N = 95 (435 oncology patients screened) Mean age: 49.16 ± 13 SD and 52.6 ± 12.4 SD (with and without pain, respectively) Symptoms: postmastectomy pain Sx duration: unclear Source of data: medical records, questionnaires	To investigate prevalence, characteristics, and impact of postmastectomy pain.	Breast (postmastectomy)	65% reported no pain 15% reported pain of somatic or visceral type associated with the tumor 20% postmastectomy pain. All with pain reported interference with work or home activities. All with pain reported exacerbation on movement. Patients used weak, nonopioid analgesics (25%) or none (75%). 85% used nonpharmacologic pain control.
Vainio 1996 ⁴⁷	Country: Switzerland (data from UK, Switzerland, Finland, USA, and Australia) Setting: 7 hospices, in- and outpatients Specialty: multiple	N = 1640 Age: ≥18 years Symptoms: pain and other symptoms Sx duration: 3 months to 3 years Source of data: questionnaire by nurse or doctor	To estimate the prevalence of pain and eight other common symptoms in a large population of patients with advanced cancer from different palliative care centers.	Lung (343/1,640 = 21%) Breast (174/1,640 = 11%) Colorectal (121/1,640 = 7%) Head/neck (92/1,640 = 6%) Stomach (86/1,640 = 5%) Prostate (76/1,640 = 5%) Gynecologic (83/1,640 = 5%) Lympho-hematologic (60/1,640 = 4%) Esophagus (36/1,640 = 2%) Other, unknown (569/1,640 = 35%)	The prevalence of moderate to severe pain was 51%, ranging from 43% (stomach) to 80% (gynecologic). Wide intercenter differences (e.g., 10%–50% with severe pain).
Grond 1996 ⁴⁸	Country: Germany Setting: pain service Specialty: anesthesiology; unclear if	N = 2266 (53% M, 47% F) Mean age: 59 ± 13 SD Symptoms: pain Sx duration: 9 years (1983–1992)	To evaluate the localization, etiologies, and pathophysiologic mechanisms of cancer-related pain syndromes.	GI (663/2,266 = 29%) Genitourinary (379/2,266 = 17%) Head/neck (377/2,266 = 17%) Breast (227/2,266 = 10%)	30% 1 pain location 39% 2 pain location 31% 3 pain location Etiology: cancer 85% antineoplastic Tx 17% Type of pain: bone 35% soft tissue 45%

Author	Setting	Population	Aim of the study	Type of cancer	Incidence or prevalence of pain, etiology, characteristics (comments)
	inpatient or outpatient	Source of data: questionnaire by nurse or doctor		Lung (218/2,266 = 10%) Lymphatic-hematopoietic (114/2,266 = 5%) Skin, bone, connective (121/2,266 = 5%) Others or multiple (167/2,266 = 7%)	visceral 33% neuropathic 34% Localization: lower back 36%; abdominal 27%; thorax 23%; legs 21% head 17%; pelvis 15%
Tasmuth 1996 ⁴⁹	Country: Finland Setting: university hospital, surgical outpatient clinic Specialty: anesthesiology	N = 93 (105 screened) Median age: 59 (29–85) and 57 (40–86) years [two groups, mastectomy, resection] Symptoms: pain Sx duration: 1 year (1993–1994) Source of data: questionnaire by nurse or doctor	To assess pain, neurologic symptoms, edema of the ipsilateral arm, depression, and anxiety in women treated with mastectomy or limited resection (plus axillary dissection for either), and the impact of these symptoms in daily life.	Breast (postmastectomy)	Incidence of pain before surgery: 36% (mastectomy) 23% (resection) After surgery: 26%, 15%, and 17% (1 month, 6 months, and 1 year postmastectomy) 28%, 33%, and 33% (postresection at same times)
Higginson 1997 ⁵⁰	Country: UK, Ireland Setting: multi-disciplinary palliative care centers (6 in England, 5 in London), in- and outpatients Specialty: palliative medicine and oncology (nursing with special training)	N = 695 (55% M, 45% F [Irl], 54% M, 46% F [UK]) Median age: 67 (5–95) years UK and 67 (32–90) years Irl [two ethnic groups] Symptoms: pain Sx duration: not reported Source of data: questionnaire by nurse	To investigate the prevalence and intensity of pain in advanced cancer patients.	Lung/ENT (110/418 = 16.3% & 73/277 = 26%) GI (144/418 = 34% & 84/277 = 30%) Genitourinary (58/418 = 13.8% & 44/277 = 15.8%) Breast/bone (48/418 = 11.4% & 26/277 = 9.4%) Lymph/hematopoietic (13/418 = 3.1% & 10/277 = 3.6%) Other (45/418 = 10.8% & 40/277 = 14%)	UK Ireland Lung/ENT 69% GI 74% GI 68% GI 68% Genitourinary 66% 84% Breast/bone 71% 85% Lymph/hemato 62% 90% Other 62% 63% Overall prevalence of pain at referral in the two settings was 68% and 74% (similar figures for home hospice patients as for hospitalized cancer patients).
Bernabei 1998 ⁵¹	Country: USA Setting: 1492 nursing homes Specialty: multiple	N = 13,625 Age: >65 (65–74 years, 45% M) 65–84 years (44% M) >85 years (40% M) Symptoms: pain Sx duration: 1992–1995 Source of data: systematic assessment of geriatric drug use via epidemiology database	To evaluate the adequacy of pain management in elderly and minority cancer patients admitted to nursing homes.	Not provided	4,003/13,625 (27.38%) reported daily pain. Age, gender, race, marital status, physical function, depression, and cognitive status were all independently associated with presence of pain. 26% of those in pain received no analgesic agent. Predictors for not receiving any analgesic agent despite daily pain were age >85, minority race, impaired cognition, and receiving multiple medications concurrently.

TABLE 82.1. Summary of studies reporting the prevalence and/or incidence of cancer pain. (continued)

Author	Setting	Population	Aim of the study	Type of cancer	Incidence or prevalence of pain, etiology, characteristics (comments)
Ger 1998 ⁵²	Country: Taiwan Setting: three outpatient oncology clinics Specialty: anesthesiology	N = 296 (194 M, 66%, 102 F, 34%) 69% interviewed within 14 days from cancer diagnosis. Age: 56.4 ± 16 SD (10–80) years Symptoms: pain Sx duration: 18 months Source of data: questionnaire	To evaluate the prevalence and severity of cancer pain in newly diagnosed cancer patients.	Lung (63/296 = 21%) Upper GI (58/296 = 20%) Colorectal (36/296 = 12%) Head/neck (29/296 = 10%) Other (76/296 = 36%)	113/296 (38%) had pain Of those, 92% cancer related, 5% treatment related, 3% both cancer and treatment related. Ethnic minority status, lower-grade insurance status, excellent prior pain tolerance, impaired function status (ECOG scale), and distant spread of disease each separately predicted the presence of pain.
Petzke 1999 ⁵³	Part I Country: Germany Setting: 1 Outpatient clinic Specialty: Anesthesiology	N = 243 (39% of 613 consecutive cancer pts with pain; 270 M, 361 F) Age: 59.2 ± 13.8 (16–97) years Symptoms: Transitory exacerbations of pain Duration: Within past week Source of data: Patient interview	To identify and evaluate the incidence of transitory pain in cancer pain patients	GI 26%, GU 17%, Head/neck 16%, Breast 12%, Other 29%	Location of cancer, tumor stage, presence/absence of metastasis, and type of therapy were not significantly different in patients with or without transitory pain. The intensity of baseline pain was higher in pts without transitory pain: 68% reported severe-maximal pain vs 54%. However, the intensity in those with transitory pain was rated severe to maximal in 92% of pts.
	Part II Country: Germany Setting: Clinic as above Specialty: Anesthesiology	N = 55 (68% of 81 pts, 33 M, 22 F) reported transitory pain on admission. Age: 59 ± 12.1 (30–85) years Symptoms: Pain similar in frequency, duration, and intensity to those in Part I.	To further describe and quantify transitory pain experienced by these patients.	Comparable to those in Part I.	Transitory pain was characterized by rapid onset (within 3 min) in 47% of pts; 58% of these pts reported a duration of less than 15 min. 97% of these pts had either neuropathic (35%) or nociceptive pain (62%). 40% of patients identified no precipitating event, while movements or timing of analgesic regimen were named as known triggers for 2/3 of the others. Additional or regular medication was effective in relieving transitory pain in 75% of patient. Analgesic preparations with novel delivery mechanisms—i.e., oral transmucosal have recently been found effective for breakthrough pain.
Chang 2000 ⁵⁴	Country: USA Setting: VA Medical Center, NJ Specialty: Medical oncology	N = 240 (232 M, 8 F): 100 consecutive outpatients, 140 consecutive inpatients who reported pain symptoms. Age: Median 68 (27–89) years; Symptoms: median of 8	To assess symptom prevalence, symptom intensity and their relationship to QOL in this population.	Solid tumors: 201 (139 metastatic); Hematologic disease: 39	Symptom assessment: MSAS found median number of symptoms/pt to be 8. Fatigue/lack of energy and pain were most prevalent symptoms: 62% and 52%, respectively. Number of symptoms, intensity, and resulting level of distress were correlated with extent of disease. Lower Karnofsky scores indicated a likelihood of intense and/or distressing symptoms. Authors noted that pain was never a solitary symptom, and should be considered a marker for presence of other symptoms.

TABLE 82.1. (continued)

Author	Setting	Population	Aim of the study	Type of cancer	Incidence or prevalence of pain, etiology, characteristics (comments)
Zepetella 2000 ⁵⁵	Country: UK Setting: Hospice Specialty: Palliative medicine	N = 245 (59% of 414 consecutive cancer admissions; 185 M, 229 F) Age: 71(33–100) years Symptoms: Chronic pain of variable duration	To examine the prevalence and characteristics of breakthrough pain in terminally ill pts admitted to hospice. Satisfaction with treatment was also assessed.	Lung 27%, Breast, Prostate, and Unknown Primary 9% each. Most breakthrough pain was tumor related; 38% rated as severe-excruciating, and related to patient dissatisfaction, underlining the value of ongoing assessment.	Of the 245 participants, 89% had breakthrough pain, most of which was frequent and short-lasting, suggesting that effective treatment would include medications that are fast-acting, readily and quickly absorbed
Meuser 2001 ⁵⁶	Country: Germany Setting: Academic Medical Center Specialty: Anesthesiology pain service	N = 593 (all patients treated by the service between August 1992 and July 1994; 46.8% M, 43.2% F). Age: 59 ± 14 years Symptoms: Pain + at least one other symptom	To survey symptom prevalence, etiology, and severity, taking all possibilities of symptom relief into consideration.	Percentages: GI 24.6, Respiratory 19.8, GU 18.9, Head/neck 16.9 most prevalent. 98.3% of patients referred suffered pain and at least one other symptom.	Nonopioid analgesics were used most frequently—initially by 94.3% of pts, finally by 78.3%. WHO step guidelines were used throughout, plus other palliative treatment in 50% of pts: chemo, hormonal therapy, radiation, and surgery in 15.5%, 21.4%, 26.9%, and 8/9%, respectively. Efficacy was good in 70%, satisfactory in 16% of pts and inadequate in 14%, and all caused a significant reduction in other symptoms, demonstrating that pain relief can be achieved without increasing most symptoms.
Beck 2001 ⁵⁷	Country: South Africa Setting: Inpatient and outpatient areas of two healthcare facilities in Pretoria: a 120 bed private hospital, a 1000 bed public hospital Specialty: Medical oncology	Phase I: N = 263 (98.5% of 267 pts seen during study period; 103 M, 160 F; 75% white) Age: mean 55 (18–87) years Symptoms: Pain Sx Duration: Not stated Source of Data: Survey of Cancer Pain in South Africa (BPI translated into five local languages) Phase II: N = 479 were eligible; 426 completed the questionnaire (163 M, 251 F), 46% white, 42% black, 12% colored or Asian Age: mean 56.7 (18–90) years Symptoms: Pain	To document the prevalence of pain among cancer patients in inpatient and outpatient settings To describe patterns of cancer pain and pain management in South Africa	All types represented in patients of the two participating facilities In male pts, prostate, lung, head/neck, and esophagus accounted for 50.5%, in females, breast and cervix alone accounted for 53.3%; lymphoma, colorectal, and esophageal afflicted most of the rest in both.	Cancer type and pain prevalence were determined. Of cancer in males (105) top distribution was as follows: lymphoma 14, head/neck and prostate each 11, lung and melanoma each 10, colorectal 9. In females (158) distribution was breast 86, ovary 14, uterus 13, lymphoma 12, head/neck 6, lung 3. 57.4% of pts experienced pain 7 d/wk; 23.6% were in pain 24 h/day. Ratings of 'worst pain' were highest in community-based pts (38.1%), lowest in hospices (23.6%). Almost twice as many pts were in moderate or severe 'pain now' in public (39%) vs. private (20%) settings. Of nonwhites (black/colored/Asian), 81% experienced 'worst pain' of moderate-severe intensity vs. 65% of whites (P < 0.0001).

Met, metastatic; Non-met, nonmetastatic; GI, gastrointestinal; Sx, symptoms; Tx, therapy; WHO, World Health Organization.

validated measure is essential to judge the efficacy of treatment.^{61–63} Recent studies suggest that patients identify a decline in pain intensity of about 30% as the threshold for clinical pain relief.^{1,64,65}

The reduction of pain to a single parameter (intensity) is pragmatic, perhaps essential, for purposes of assessment and treatment, but intensity should be simply a starting point in pain assessment. The characteristics of the pain (location, intensity, quality, temporal characteristics, exacerbating and relieving factors, and responses to prior treatments) should be assessed, together with a review of treatment, psychosocial assessment, physical examination, and appropriate diagnostic studies.^{66,67} Efforts should be made to determine the etiology of the pain, and in particular, to determine whether it represents an emergency, such as spinal cord compression or an impeding or existing bone fracture. Psychosocial assessment should address the mood of the patient, his or her coping skills, family support structure, signs and symptoms of anxiety or depression, expectations regarding pain management, risk factors for undertreatment of pain, and the meaning of the pain for the patient and family.

The majority of clinical trials evaluating treatments for cancer pain have employed single-variable pain intensity scales. The diverse mechanisms of pain, its quality and time course, and its impact on quality of life were not reported in most treatment trials. Furthermore, the instruments used to capture information about pain are sufficiently heterogeneous to preclude merging of results.²⁸

Figure 82.1 depicts the contribution of various patient- and disease-related factors to the occurrence of cancer symptoms. Fundamental to this model is the fact that the methods of assessment affect the observed prevalence rate of any symptom. Evaluating the clinical evidence on cancer pain is complicated by the heterogeneity of instruments or scales used to assess pain. This problem is of more than academic interest. In a cohort study of 313 cancer patients with pain, the proportion of patients whose pain was inadequately treated varied very widely, from 16% to 91%, depending on which of four different assessment measures was used. This variability was entirely due to the choice of measure, rather than the approach to treatment of the pain.⁶⁸

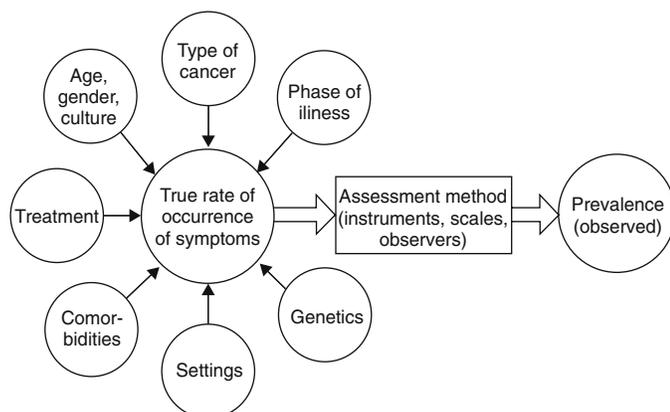

FIGURE 82.1. Relationship among factors that contribute to the occurrence of cancer symptoms, methods of assessment, and prevalence of symptoms.

Treatment of Cancer Pain

Systemic analgesic therapy is the foundation for treating cancer pain because of its relative low risk and cost, dependability, and ease of administration.^{66,69} Nonpharmacologic measures, such as patient education and cognitive-behavioral strategies, are also important components of treatment. Because patients differ in their acceptance of, and responses to, specific analgesics and to different behavioral strategies, it is essential that treatment be individualized.^{70,71}

The three principal families of drugs used to manage cancer pain are nonsteroidal antiinflammatory drugs (NSAIDs; acetaminophen is usually included in this category although it is not an NSAID), opioid analgesics, and adjuvant medications. Adjuvants treat concurrent symptoms that exacerbate pain (e.g., insomnia), enhance the analgesic efficacy of opioids, or provide analgesia for specific types of pain (e.g., antidepressants and anticonvulsants for neuropathic pain). Medicines to prevent or treat the adverse effects of opioids, such as constipation and nausea, also have a critical role.

Clinical consensus and common sense dictate initial use of the least invasive delivery method and simplest dosing regimen.⁷² Oral administration of drugs is effective for most cancer pain, but may be problematic for reasons of dysphagia, odynophagia, nausea from chemotherapy or radiation therapy, malabsorption from gastrointestinal dysfunction, or the need to swallow an unwieldy number of tablets. The rectal, transdermal,⁷³ sublingual, transmucosal,^{74–76} and pulmonary routes are other relatively noninvasive options for the delivery of systemic analgesics. Some of these routes are not influenced by first-pass hepatic metabolism, so, for example, an oral dose of a drug is not expected to be equianalgesic with the same dose administered rectally.

Systemic Opioids

Few studies have evaluated systemic opioids for cancer pain using a randomized, placebo-controlled trial design.^{76–78} Placebo-controlled studies involving people in pain are ethically problematic, unless a rescue medication is provided. Furthermore, the effective palliation of pain with opioids has a strong historical record of efficacy of several millennia, thus obviating the need for placebo-controlled assessment.

Numerous opioids with various pharmacologic features are available; however, no one opioid has consistently been demonstrated to provide either a superior toxicity profile or superior efficacy. A heterogeneous group of 10 trials compared the efficacy and adverse effects of different opioids administered by the same route within each study.^{77,79–87} The applicability of these studies is generally low, and therefore, there is little evidence to support the use of one opioid over another. Exceptions exist to this generalization. Meperidine is generally considered inferior to other opioids for cancer pain because of the potential for accumulation of toxic metabolites with repeated dosing. In patients with renal failure who are treated with morphine, metabolites of the drug (particularly morphine-6-glucuronide) may accumulate, leading to hyperalgesia and central nervous system (CNS) toxicity, so other opioids, such as hydromorphone may be preferable in that setting.

There do not appear to be any advantages for sustained-release formulations of opioids over immediate-release for-

mulations, except possibly for convenience, patient preference, and, by extension, patient adherence. Eight studies have been performed comparing controlled-release morphine with immediate-release oral morphine.⁸⁸⁻⁹⁵ No significant differences were observed between the two formulations with respect to analgesic efficacy (reduction of pain intensity or increased pain relief). The studies also found no difference with respect to adverse effects or other outcomes. Three hundred seventeen patients, with a wide range of cancer types as well as pain types, were enrolled in these trials, of which 244 were evaluated (78.7%). The foregoing studies all addressed the same study question; therefore, a meta-analysis could be performed using pain intensity as the outcome of interest. All eight studies provided numerical data on mean pain intensities and standard errors or confidence intervals. Differences in average pain intensity between the two study arms (over 4 to 14 days), measured on a continuous visual analogue scale (VAS) (0–100mm), were combined using a random effects model. No significant difference in average pain intensity was found between controlled-release morphine and morphine sulfate solution [1.18mm; 95% confidence interval (CI), –1.62 to 3.98mm]. More extended sustained-release formulations of oral morphine, administered once daily, provide analgesia that is comparable to twice-daily sustained-release formulations but may be preferred by patients.^{96,97}

Transdermal fentanyl was compared with oral controlled-release morphine in two studies, neither of which demonstrated a significant difference in pain intensity.^{98,99} In one of the studies, more patients expressed a preference for the fentanyl patch, which was associated with less constipation and daytime drowsiness, but greater sleep disturbance and shorter sleep duration. There were no differences in quality of life measures.

In a given patient, the analgesic effect and adverse effects of the different opioids may vary substantially, even when given at theoretically equianalgesic doses.¹⁰⁰ Although the pharmacologic basis of these observations is not well understood, they have led to the empiric practice of drug rotation to improve analgesia or ameliorate adverse effects. If unacceptable side effects occur before an effective dose of an opioid is reached, another one can often be substituted with good effect.¹⁰¹ Elucidation of genetic variability in the analgesic response to opioids, and in their pharmacokinetics, could potentially give rise to pain treatment that is targeted to the individual patient, rather than be strictly empiric.

Equianalgesic dosing of different opioids is not necessarily straightforward. In the 1960s and 1970s, the relative analgesic potency of single doses of a variety of opioid analgesics (morphine, profadol, oxymorphone, codeine, methotrimeprazine, and oxycodone) was evaluated in patients with cancer.¹⁰²⁻¹⁰⁷ Reproducible estimates were generated for the relative potency of opioids in this context, which provide part of the basis for equianalgesic dosing. Several issues complicate the interpretation of these studies. Baseline pain intensity and information about the pathophysiologic substrate of pain were not reported. Thus, relative potency ratios of opioid analgesics are assumed to apply in the whole range of baseline pain (mild, moderate, and severe) and pathophysiologic mechanisms (nociceptive or neuropathic). The majority of patients in these studies had been exposed to opioid analgesics before enrollment, sug-

gesting potential tolerance to opioid test drugs. However, the existence or precise influence of tolerance on the results cannot be estimated because the duration of previous exposure and type of opioids used were not reported.

Adverse effects that limit opioid dosing include constipation, nausea, sedation, confusion, urinary retention, pruritus, myoclonus, dysphoria, sleep disturbance, and respiratory depression. Persistent respiratory depression is rare in opioid-tolerant individuals. Treatment of these adverse effects was the subject of a recent systematic review.¹⁰¹ Nine uncontrolled studies of at least 180 subjects reported on adverse events of oral opioids.¹⁰⁸⁻¹¹⁶ Seven were prospective cohort studies, each examining one to five oral opioids used for treatment of cancer pain. Pain relief and quality of life were the primary outcomes in seven of the studies. Two studies primarily examined adverse events: constipation and laxative use¹⁰⁸ and emesis.¹⁰⁹ A total of seven opioids were evaluated at a wide range of average daily dosages (for example, from approximately 19 to 60mg/day oxycodone and from approximately 80 to 380mg/day morphine). Subjects were followed from a minimum of 3 days to a maximum of 4 months. In these studies, reported rates of nausea were 7% to 25%; vomiting, 6% to 40%; constipation, 11% to 73%; and sedation, 2% to 54%. The extreme variability of these rates probably reflects the heterogeneous study designs and methods of assessment.

Seven uncontrolled studies of at least 50 subjects reported on adverse events of parenteral opioids.¹¹⁷⁻¹²³ Five were prospective cohort studies. One studied subcutaneous oxycodone¹²¹; the rest studied morphine and/or hydromorphone given subcutaneously or intravenously at a wide range of doses. All the studies examined pain relief or quality of life as primary outcomes. Few studies provided explicit definitions for the symptoms that were being reported. The studies that included both morphine and hydromorphone, or subcutaneous or intravenous injections, did not report different adverse event rates for the different drugs or routes. Six studies reported on nausea and/or vomiting. Nausea (including vomiting) occurred in 0% to 15% percent of subjects; vomiting, when reported separately from nausea, occurred in 0% to 1% percent of subjects. Constipation occurred in 0% to 70% of subjects in five studies. The large range of rates of constipation is likely due to unreported differences in definitions for constipation and different laxative regimens. Fatigue occurred in 17% of subjects and mild sedation in 51% of subjects; otherwise, uncharacterized sedation occurred in 0% to 12% of subjects, and severe sedation in 4% to 6% of subjects. Adverse effects occurring in less than 10% of subjects included local skin irritation or bleeding, skin infections, myoclonus, confusion, dizziness, and seizures. Depending on the methods of assessment and reporting, hallucinations, mental clouding, dry mouth, and sweating ranged from very rare (0% to 6%) to common (15% to 32%). Respiratory depression occurred in 0% to 2% of the subjects in studies evaluating subcutaneous opioids and in 18% of the subjects receiving intravenous morphine.

Tolerance and physical dependence are common, and to some extent, even predictable during chronic opioid administration.¹²⁴ These terms are often confused with psychologic dependence ("addiction"), which causes drug abuse or drug-seeking behavior. However, tolerance simply refers to the requirement for escalating and/or more frequent doses of an

agent to sustain therapeutic effectiveness during chronic administration. Physical dependence indicates that, for certain chronically administered drugs (e.g., benzodiazepines or opioids), sudden discontinuation or the administration of an antagonist drug will precipitate an abstinence syndrome. Addiction rarely occurs in patients with cancer or other medical illness in the absence of a history of substance abuse.

Nonsteroidal Antiinflammatory Drugs

Eighteen studies were identified addressing the question of relative efficacy of one NSAID in comparison to another or to placebo.^{27,28} A total of 1,302 patients were enrolled in these studies (range, 18 to 145), and 15 different NSAIDs were evaluated. The applicability of these studies to the everyday care of patients with cancer is generally low. One study examined the administration of a single dose of the study drug; the duration of treatment in the remaining studies was 7 to 14 days. NSAIDs were consistently found to be superior to placebo. However, only one study suggested a difference in efficacy between different NSAIDs.¹²⁵

Adverse effects of NSAIDs include gastrointestinal distress, ulceration, and bleeding, renal insufficiency or failure, interference with platelet function, and less commonly, allergic reactions, impaired hepatic function, fluid retention, and central nervous system dysfunction. The incidence of adverse effects caused by NSAIDs was generally found to be low in trials of brief duration, but there are limited data on the toxicity of extended use of NSAIDs. Valentini et al. compared misoprostol to ranitidine for prevention of gastrointestinal toxicity in cancer patients receiving high-dose diclofenac.¹²⁶ After 4 weeks, gastric ulcers developed in 7 of 49 evaluable patients; 6 of 7 patients with ulcers were asymptomatic. Ulceration was associated with older age and higher doses of diclofenac. Misoprostol was more effective than ranitidine in preventing gastroduodenal lesions (8.7% versus 38.5%, *P* less than 0.02). The overall 14% incidence of (mostly asymptomatic) gastric ulcers is of concern and suggests that serious gastrointestinal toxicity from NSAIDs may be more common in this population than the rates reported in short-term studies.

Studies comparing NSAIDs with combinations of NSAIDs plus weak opioids, or with opioids alone, are heterogeneous with respect to design characteristics, agents used, route of administration, and type of pain. A meta-analysis of studies to evaluate the relative efficacy of NSAIDs and combinations of opioids was possible with only 3 of the 29 studies assessed.¹²⁷⁻¹²⁹ The treatment arms included in these studies were diclofenac, naproxen or dipyrene (NSAID arm), and diclofenac plus codeine, controlled-release morphine, and morphine (NSAIDs plus weak opioid, or strong opioid). The evaluated outcome was pain intensity differences between NSAIDs and NSAIDs plus weak opioids or opioids alone, expressed on a VAS scale (0–100 mm). Outcomes were combined using a random effects model. No difference was found between NSAIDs and NSAIDs plus weak opioids or opioids alone, 3.8 mm (95% CI, –4.7 to 12.4 mm). These results are in agreement with the findings of other meta-analyses on this topic.^{130,131}

What is the evidence for an opioid-sparing effect, improved analgesia, or a reduction in opioid-related adverse effects as a result of the coadministration of an NSAID with

an opioid? The combination of an NSAID and an opioid is recommended by the World Health Organization (WHO) guidelines for cancer pain. In the large, prospective cohort studies that validated the efficacy of the WHO strategy (see following), however, the specific contribution of NSAIDs and adjunctive analgesics could not be determined. Few randomized studies have addressed these questions. The most convincing evidence for an opioid-sparing effect from an NSAID is based on a study of 156 patients with cancer pain, who, after 1 week of stabilization with opioids, were randomized to continued opioid escalation based on their clinical needs, with or without oral ketorolac. The ketorolac group was found to have significantly better analgesia after 1 week, with slower opioid escalation, and required lower doses of opioids. Gastric discomfort was more common in the group receiving ketorolac and morphine, whereas constipation was more common in the group receiving morphine only. Dropout was substantial in this study, with only 47 of the original 156 patients assessable for the main endpoints.¹³²

The World Health Organization Analgesic Ladder

A simple, widely applied approach to managing cancer pain, developed by the World Health Organization (WHO), is the “three-step analgesic ladder” (Figure 82.2).¹³³ The first tier, for mild to moderate pain, consists of an NSAID or acetaminophen with or without adjuvant medications. As pain escalates or persists, treatment progresses to the second tier, in which a “weak” opioid, such as codeine or hydrocodone, is added to the NSAID, with or without an adjuvant drug. If pain still persists, treatment progresses to the third tier, substitution of a “strong” opioid (i.e., one more readily titrated to doses with greater analgesic efficacy) for the “weak” opioid; the “strong” opioid category includes morphine, hydromorphone, methadone, fentanyl, and levorphanol. The WHO approach to managing cancer pain emphasizes by-the-clock rather than as-needed dosing and therapy individualized to each patient.

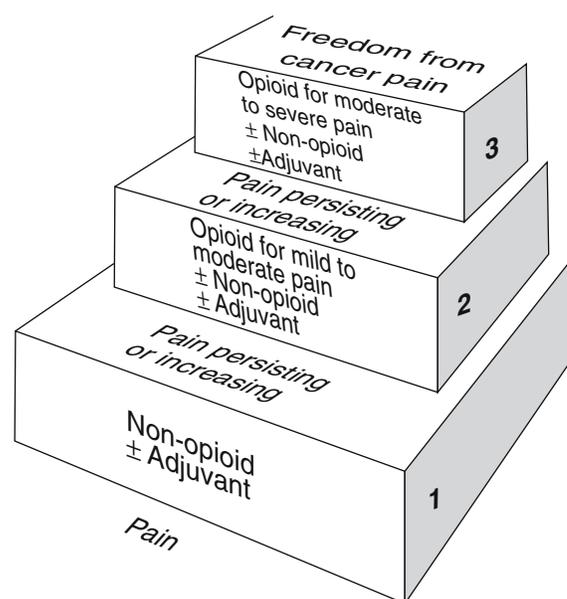

FIGURE 82.2. The World Health Organization analgesic ladder. (From World Health Organization,¹³³ by permission of the World Health Organization.)

In several large case series, the WHO method yielded satisfactory pain relief in a majority (80% to 90%) of patients with cancer pain. However, validation trials of the specific choice of agents and the sequence of their application within the WHO ladder have been limited.^{131,134,135} The common clinical impressions that NSAIDs are particularly beneficial for bone pain, or that opioids are of little benefit for neuropathic pain, are either unconfirmed in systematic literature reviews¹³¹ or are unsupported by direct clinical trials of mechanism-based drug selection.¹³⁶

Mercadante reported results of implementing the WHO guidelines in 3,678 consecutive cancer patients referred to a home palliative care program.¹³⁷ Pain intensity improved rapidly, and the improvement was sustained until death for most patients; 89% of patients achieved adequate pain control (a score of less than 4 on a visual analogue scale, VAS) by week 2. In another large cohort study, 2,118 patients referred to a pain service in a university hospital were treated according to the WHO guidelines over 140,478 treatment days.¹³⁸ Pain reduction was highly significant within the first week; at the time of enrollment, 78% had severe, very severe, or maximal pain. At the first follow-up evaluation (an average of 6 days later), the proportion with severe, very severe, or maximal pain had declined to 13%. The benefits were sustained with an average follow-up of 66 days, and in a smaller cohort that was followed until death, 84% rated their pain as moderate or less in the final days of life. Over the entire treatment period, pain control was reported to be good in 76% of patients, satisfactory in 12%, and inadequate in 12%.

Nausea and vomiting were reported in 6% to 22% of subjects in these studies, more commonly in subjects in step 3 than in step 2 and in step 2 than in step 1. Constipation occurred among 3% to 36% of subjects and sedation occurred in 14% to 46%.

Summary of the Evidence on Adjuvant Medications

Twenty-two RCTs evaluated the efficacy of various adjuvant medications for cancer pain, including anticonvulsants, antidepressants, local anesthetics, calcium channel blockers, psychostimulants, alpha-adrenergic agonists, and *N*-methyl-D-aspartate (NMDA) antagonists.

Stimulant medications have generated interest as adjuvants to opioids because of their potential to ameliorate sedation, as well as suggestions that they may potentiate analgesia. Three double-blind, cross over studies have been performed comparing adjuvant administration of the stimulant methylphenidate to placebo in patients receiving systemic opioids for cancer pain.¹³⁹⁻¹⁴¹ These studies were small (20 to 43 subjects) and the populations heterogeneous. In one of these studies, pain intensity, activity, drowsiness, and the average number of rescue doses of analgesics all improved with methylphenidate compared with placebo. Interestingly, placebo alone significantly decreased pain intensity. Patients and investigators (all blinded) preferred methylphenidate to placebo.¹³⁹ Another study by the same group found that methylphenidate improved cognitive function and decreased drowsiness and confusion but did not alter pain intensity, nausea, or activity. Again, significantly more investigators and patients preferred methylphenidate to placebo.¹⁴⁰ In a third study, however, no statistically significant benefit for

methylphenidate was observed in terms of pain intensity, appetite, anxiety/agitation, drowsiness, well-being/mood, sleep, pain medication use, or patient preference for drug or placebo.¹⁴¹

The anticonvulsant gabapentin appears to be effective for neuropathic pain in patients with diabetic neuropathy and spinal cord injury based on randomized, controlled trials, but the evidence for its use in cancer pain is limited. Two studies have evaluated gabapentin for acute pain after breast cancer surgery. In one, 70 patients were randomized to a single dose of oral gabapentin (1,200 mg) or placebo 1 hour before radical mastectomy. Patients then received patient-controlled analgesia (PCA) morphine postoperatively. The group receiving gabapentin required significantly less morphine and had lower scores on a visual analogue scale of pain during movement at 2 and 4 hours after surgery. There was no difference in pain at rest or in adverse effects.¹⁴² Gabapentin, 1,200 mg/day for 10 days, was compared to mexilitine, 600 mg/day, or placebo in a randomized study of 75 patients undergoing surgery for breast cancer. Both drugs were associated with a reduction in the consumption of codeine and acetaminophen, and with a reduction in pain on the third postoperative day, compared to placebo. The prevalence and intensity of chronic pain 3 months later was similar in the three groups.¹⁴³

Phenytoin (100 mg orally twice daily) was compared with buprenorphine (0.2 mg sublingually twice daily) and the combination of phenytoin and buprenorphine (50 mg orally plus 0.1 mg sublingually, respectively, twice daily) in a double-blind study of 75 patients with moderate to severe cancer pain. The combination of buprenorphine and phenytoin appeared to provide better pain relief than buprenorphine alone.¹⁴⁴

The NMDA antagonist ketamine has shown promising analgesic efficacy in small studies. Ketamine (0.25 or 0.50 mg/kg intravenously) was evaluated in 10 cancer patients whose pain was unrelieved by morphine in a randomized, double-blind, crossover, double-dose study. Ketamine, but not saline solution, significantly reduced the pain intensity in almost all the patients at both doses. Ketamine caused mental status changes that were reversible with diazepam.¹⁴⁵ Oral ketamine has been compared to a transdermal nitroglycerin polymer, the NSAID dipyron, or escalating doses of morphine in 60 patients with cancer pain who had been stabilized on morphine. The VAS pain intensity scores after the test drug was introduced were similar among the groups; however, both oral ketamine and transdermal nitroglycerine appeared to be associated with a morphine-sparing effect.^{146,147} Intranasal ketamine has also been found to be efficacious for "malignant breakthrough pain" in a small ($n = 20$) randomized, double-blind cross over trial of patients with either cancer-related or other types of pain.¹⁴⁸

Ventafriida et al.¹⁴⁹ compared trazodone (225 mg) with amitriptyline (75 mg) in a randomized, double-blind trial in 45 patients with neuropathic pain from cancer ($n = 27$) and non-cancer causes ($n = 18$). Ninety-five percent were receiving NSAIDs, alone or with weak or strong opioids. The integrated pain score decreased significantly from baseline in both groups.

Two small, placebo-controlled trials of the calcium channel blocker nimodipine have been performed in patients with cancer pain. In one study, nimodipine limited escalation of morphine dosages in more patients than did placebo (four

versus nine). Daily morphine consumption declined significantly more with nimodipine than placebo.¹⁵⁰ The second study reported no benefit in pain intensity or relief with nimodipine compared to placebo.¹⁵¹

In small trials, no benefit has been observed for cancer pain with a number of other potential adjuvants, including the somatostatin analogue octreotide,¹⁵² the cholecystokinin antagonist proglumide,¹⁵³ intravenous lidocaine,¹⁵⁴ and oral cocaine.¹⁵⁵

Complementary Approaches for Cancer Pain

Five RCTs examined the effects of hypnosis and cognitive behavioral interventions on various types of cancer pain.¹⁵⁶⁻¹⁶⁰ These studies, although small, provide preliminary indications that these techniques may ameliorate acute procedural pain and pain related to mucositis.

Auricular acupuncture was shown to reduce pain intensity by 36% over a 2-month period and was statistically superior to two placebo treatments in a cohort of 90 patients.¹⁶¹ Acupuncture may also improve postoperative mobility and pain in breast cancer patients.¹⁶² The effects of Chinese herbs, ear acupuncture, and epidural morphine on postoperative pain were evaluated in 16 men with liver cancer. Any combination that included at least one of the three treatments provided better pain relief than placebo.¹⁶³

Neuraxial Drug Delivery

For the minority of cancer patients whose pain is refractory to systemic opioids and adjuvants, or in whom adverse effects are intolerable, neuraxial (epidural or intrathecal) drug delivery can provide effective pain control.¹⁶⁴⁻¹⁶⁶ Considerations as to whether to employ central routes for drug delivery include the site(s), nature, and character of pain; life expectancy; therapeutic preferences of the patient and family; ability of the infrastructure to manage the device and catheter; and stage of the underlying disease.¹⁶⁷

Numerous nonrandomized studies support the efficacy of intrathecal or epidural opioids, with or without adjuvants. We reviewed the eight studies with the largest sample sizes (at least 100) that reported on adverse events of spinal opioids.¹⁶⁸⁻¹⁷⁵ Six studies examined pain relief or quality of life as primary outcomes. Two reported primarily on complications of spinal opioid treatment. Only three studies described collection of information about adverse events in a prospective manner. Most studies followed subjects for a mean of 3 to 5 months. The definition of adverse events varied across studies. Catheter-related infections occurred in 0% to 9% of subjects and meningitis in 0% to 4%. In the four studies that reported removal of catheters and discontinuation of spinal opioids due to adverse events, the rates ranged from 0.3% to 10%. Few studies explicitly defined symptoms. Four studies reported on nausea and/or vomiting, which occurred in 9% to 40% of subjects. Three studies reported on constipation, which occurred in 17% to 34% of subjects. Variable rates were reported for pruritus or skin inflammation (1% to 38%), urinary retention (4% to 73%), and headache (3% to 18%). Sedation was reported in only two studies, at rates of 1% and 2%, and respiratory depression was also uncommon.

Smith et al. reported the results of the only RCT to date evaluating intrathecal opioids in patients with unrelieved

cancer pain.¹⁷⁶ Patients were eligible if they had pain scores of 5/10 or more on a VAS on two occasions within a week of randomization, despite 200 mg/day oral morphine or its equivalent, or if they had refractory adverse effects from systemic opioids. They were randomly assigned to "comprehensive medical management" (CMM), with or without intrathecal analgesia via an implantable drug delivery system (IDDS); 202 patients were enrolled, 200 were analyzed, and 148 were evaluable after 4 weeks. The majority had pain that was characterized as a mixture of neuropathic and nociceptive. CMM was provided according to guidelines published by the Agency for Health Care Policy and Research.⁶⁶ The IDDS patients received intrathecal morphine (94%) or hydromorphone (6%); 29% also received intrathecal bupivacaine. The primary endpoint was the proportion of patients with a reduction in their VAS score of 20% or more regardless of increased toxicity or an equal VAS score with a 20% or greater reduction in toxicity; 84.5% in the IDDS and 70.8% in the CMM group achieved this endpoint ($P = 0.05$). The IDDS group had a greater reduction in VAS pain scores (3.90 ± 3.42 versus 3.05 ± 3.16 , $P = 0.055$). All common opioid adverse effects, except impotence and pruritis, were reduced to a greater degree in the IDDS group, with statistically significant advantages in fatigue, depressed level of consciousness, and an aggregate score of opioid toxicity compared to CMM alone. Six-month survival was found to favor IDDS (53.9% versus 37.2%, $P = 0.06$). This finding must be interpreted cautiously because survival was not a prospectively defined endpoint of this study.

Several issues complicate the interpretation of this important study. Among 101 patients randomized to IDDS, only 51 actually had a drug delivery device implanted. Five patients assigned to CMM eventually crossed over and received an implanted device. Sixteen serious adverse events associated with the devices were reported in the 56 patients who received them. Key results were reported as a percentage of those for whom data were available at 4 weeks, not on an intent-to-treat basis. Despite the questions raised by these issues, this study may lead to greater acceptance of interventional approaches for cancer pain in the 5% to 15% of patients whose pain responds inadequately to medical management or who are intolerant of opioids.

A number of adjuvants administered by the intrathecal or epidural route have been evaluated in small, randomized studies. When combined with morphine, epidural infusion of the alpha-2-adrenergic agonist clonidine at 10 µg/h was found to be superior to placebo in providing successful analgesia, particularly in pain that was characterized as neuropathic.¹⁷⁷ Intrathecal bupivacaine has been reported to provide an opioid-sparing effect.¹⁷⁸ Epidural morphine, combined with low doses of ketamine, neostigmine, or midazolam, was evaluated in a randomized double-blind study of 48 terminal cancer patients.¹⁷⁹ Pain was initially treated with epidural morphine to maintain the VAS score below 4/10. Thereafter, pain escalation was treated by the addition of the epidural study drug (morphine, 2 mg; ketamine, 0.2 mg/kg, neostigmine 100 µg, or midazolam, 500 µg) on a daily basis. Only the patients in the ketamine group had lower VAS pain scores compared to the morphine group ($P = 0.018$). Those receiving ketamine required less epidural morphine during the 25-day period of study ($P = 0.003$). Based on findings such as these, clinical practice in patients treated with neuraxial drug infu-

sions for otherwise intractable pain is evolving toward the administration of several agents simultaneously.^{180,181}

Neurolytic Approaches

Nondestructive analgesia generally precedes tissue-damaging forms of palliation, such as neurolytic blocks and other anesthetic techniques or neurosurgical division of afferent pathways. Among the consensus exceptions, supported by randomized trials, is celiac block for patients with pancreatic or other retroperitoneal tumors who have moderate to severe pain.¹⁸²⁻¹⁸⁷ The decision to employ neurolytic blocks normally follows inadequate pain control with more conservative therapy, lack of other efficacious options, access to medical and social support systems afterward, and a favorable result from a test block using local anesthetic.^{165,188} The evidence for other ablative procedures, such as cordotomy, myelotomy, and rhizotomy, is based on uncontrolled cohort studies.

Treatments for Neuropathic Cancer Pain

Few studies have focused specifically on cancer patients suffering from neuropathic pain. We identified three RCTs reporting on analgesic effects of amantadine, amitriptyline, and capsaicin for the treatment of surgical or postmastectomy neuropathic pain.¹⁸⁹⁻¹⁹¹ All three agents were reported to be significantly superior to placebo; however, the numbers of subjects involved were small and the results must be considered preliminary. Clinical trials¹⁹² and systematic reviews^{193,194} have documented the efficacy of antidepressants and anticonvulsants for a spectrum of neuropathic pain, but not specifically in cancer patients. Anticonvulsant medications have been shown to be effective in the management of postherpetic neuralgia. A multicenter, placebo-controlled RCT in 229 patients demonstrated a significant reduction in pain intensity in those receiving gabapentin versus placebo for 8 weeks.¹⁹⁵ There is as yet no evidence from RCTs that cancer patients with painful neuropathies caused by chemotherapy, radiotherapy, surgery, or nerve entrapment benefit from gabapentin.

Oral Mucositis-Related Pain

The incidence of oral mucositis ranges from 40% in patients undergoing chemotherapy treatment to more than 80% in patients receiving radiation treatment to the head and neck.¹⁹⁶ The treatment and prevention of mucositis have been the subject of recent systematic reviews.¹⁹⁷⁻¹⁹⁹

Treatments that have been evaluated for the prevention of oral mucositis include chlorhexidine,²⁰⁰⁻²⁰³ ice chips,^{204,205} prostaglandins,^{206,207} glutamine,^{208,209} sucralfate,²¹⁰ recombinant human granulocyte macrophage colony-stimulating factor (GM-CSF),²¹¹ chamomile,²¹² and allupurinol mouthwash.²¹³ The conclusion of a Cochrane Review¹⁹⁹ was that there is some evidence that oral ice chips may have a beneficial effect for the prevention of mucositis. However, this conclusion is based on two studies involving 117 subjects who were not blinded to treatment. More recently, recombinant human keratinocyte growth factor (KGF) was evaluated for prevention of mucositis and its symptoms in a randomized Phase I study of 81 patients receiving 5-fluorouracil and leucovorin.²¹⁴ The rates of grade two to four mucositis were 43%

with KGF and 67% with placebo ($P = 0.06$). However, cutaneous toxicity was dose limiting in 3 patients. This trial, although not designed to be definitive, should stimulate further research on the use of KGF for mucositis.

A systematic review and meta-analysis of prophylaxis for oral mucositis in irradiated head and neck cancer included 15 randomized, controlled trials involving a total of 1,022 patients.¹⁹⁷ Nine studies assessed direct cytoprotectants. Of these, 5 evaluated the barrier sucralfate and 4 evaluated protectants that are thought to stimulate epithelial response (1 trial each of prostaglandin, beta-carotene, hydrogen peroxide, and laser therapy). One assessed indirect cytoprotectants (benzylamine) and 5 trials considered antibacterials. Of those, 3 studied broad-spectrum antibacterials and 2 evaluated narrow-spectrum antibiotic lozenges. In the meta-analysis, the odds ratio (OR) favored antibacterial agents over placebo (OR 0.47; 95% CI, 0.25, 0.92), and within this grouping, the only significant effect was for the narrow-spectrum antibacterials, and only when assessed by the physician (OR 0.45; 95% CI, 0.23, 0.86). Based on patient self-assessments, none of the agents was found to provide effective prophylaxis. Furthermore, a subsequent RCT of 137 patients undergoing radiotherapy for head and neck cancer found no benefit for an antimicrobial lozenge compared with placebo.²¹⁵ Amifostine, a thiophosphate cytoprotective agent, has been found to ameliorate acute and chronic xerostomia associated with radiotherapy but does not prevent mucositis.²¹⁶

Treatment of established oral mucositis, and the pain associated with it, has also been the subject of a separate Cochrane Systematic Review¹⁹⁸; 25 RCTs involving 1,292 patients were reviewed. Allopurinol, immunoglobulin, and human placental extract were found (in a single trial of each) to ameliorate mucositis, but 2 of these studies were judged to be at moderate risk for bias and one at high risk. Mucositis was found to heal significantly more quickly with allopurinol compared to placebo and with GM-CSF compared to povidone iodine. In head and neck cancer patients with severe, painful mucositis resulting from concurrent chemotherapy and radiotherapy, a morphine mouthwash was found to reduce significantly the intensity and duration of oral pain, and the duration of functional impairment, compared to a mouthwash containing lidocaine, diphenhydramine, and magnesium aluminum hydroxide ("magic mouthwash").²¹⁷ This trial, although small (26 patients), focused on a highly symptomatic cohort and provides perhaps the best evidence to support a specific treatment for pain due to mucositis.

The Roles of Systemic Chemotherapy and Hormonal Therapy in Treating Cancer Pain

For patients with cancers that can potentially be cured by chemotherapy, the optimal approach to cancer pain may be prompt and aggressive treatment of the underlying disease with the most effective systemic therapy. The number of tumors that fall into this category is, unfortunately, small (e.g., germ cell tumors, choriocarcinoma, non-Hodgkin's lymphoma, Hodgkin's disease). For many common cancers, however, such as non-small cell lung cancer, colorectal cancer, and hormone-refractory prostate cancer (HRPC), the response rates for chemotherapy are generally less than 30%, and complete or durable responses are rare. Despite relatively

low objective response rates, a number of recent studies have demonstrated the potential for chemotherapy to ameliorate cancer pain. In a clinical trial of chemotherapy for metastatic breast cancer, 73.7% of those who responded to treatment experienced an improvement in pain (although it should be noted that, even among patients with disease progression on treatment, 22.7% had improvement in pain, suggesting either a placebo effect for chemotherapy or an improvement in patients' analgesic regimens).²¹⁸

Three RCTs have evaluated the impact of the chemotherapeutic agent mitoxantrone on pain in HRPC.²¹⁹⁻²²¹ Tannock et al. randomized 161 patients to prednisone with or without mitoxantrone.²¹⁹ The primary response variable was pain and analgesic use. Pain declined in 29% of patients receiving combination therapy and in 12% of those receiving prednisone alone ($P = 0.01$). An additional 7 patients in each group reduced analgesic consumption by at least 50% without an increase in pain. The response to combination therapy lasted 15 weeks, twice as long as that to prednisone alone (P less than 0.001). Possible cardiac toxicity was reported in 5 of 130 patients in the mitoxantrone group. In another study of 242 patients with HRPC, there was an indication that health-related quality of life (HRQOL) was better with mitoxantrone and hydrocortisone versus hydrocortisone alone, particularly with respect to pain control.²²⁰ In a third randomized trial comparing mitoxantrone plus prednisone to prednisone alone in HRPC, patients taking prednisone showed no improvement in HRQOL scores after 6 weeks, whereas those taking mitoxantrone plus prednisone showed significant and durable improvement in global quality of life, four functioning domains, and nine symptoms, including pain. The addition of mitoxantrone to prednisone after failure of prednisone alone was associated with improvement in pain, pain impact, pain relief, and global quality of life.²²¹ These three studies present consistent evidence for better relief of pain when using mitoxantrone plus a corticosteroid compared to a corticosteroid alone in selected patients with advanced HRPC. More recently, two large randomized studies suggested that docetaxel is superior to mitoxantrone in HRPC in terms of both pain control and survival.^{222,223}

Advanced pancreatic cancer is notoriously refractory to treatment, rapidly progressive, and often associated with a multiplicity of symptoms. In this context, the results of a study by Burris et al., comparing two chemotherapy regimens, is very striking and has certainly changed the standard of care for this disease.²²⁴ In this study, 126 patients with advanced, symptomatic pancreatic cancer were randomized to treatment with weekly intravenous fluorouracil (5-FU) or intravenous gemcitabine given weekly for 7 of the first 8 weeks and then weekly for 3 weeks of every 4. The primary endpoint was "clinical benefit," a composite measure of pain, analgesic consumption, Karnofsky performance status, and weight. The criterion for clinical benefit was an improvement in any of these parameters for at least 4 weeks, without worsening in the other parameters; 23.8% of patients in the gemcitabine arm had a clinical benefit, compared to 4.8% in the 5-FU arm ($P = 0.0022$). There was also a survival benefit associated with gemcitabine, with 18% of patients alive at 12 months compared to 2% of those treated with 5-FU.

Despite these promising indications that chemotherapy can ameliorate cancer pain under certain circumstances, the number of trials specifically addressing this question is

limited, and other published studies reported negative findings.^{224,225} The potential palliative impact of chemotherapy on pain is only one variable that must be weighed in the decision to pursue such treatment. The decision depends on a multitude of other factors including the patient's wishes, his or her underlying medical condition, and the likelihood of an impact on survival and on overall quality of life.

Less controversial is the role of hormonal therapy in breast and prostate cancer. Androgen deprivation has been recognized to be an effective, albeit palliative, treatment for advanced prostate cancer for more than 60 years. Only a handful of studies have compared the relative efficacy of different types of hormonal therapy for pain caused by prostate cancer.²²⁶⁻²²⁹ Based on the available data, there is no clear advantage for luteinizing hormone-releasing hormone (LHRH) analogues compared to surgical orchiectomy in achieving castrate levels of testosterone, and thus, the choice of method can be made on the basis of patient preference, cost, and convenience. The addition of a nonsteroidal antiandrogen can lead to more rapid resolution of bone pain and can prevent pain and other complications resulting from the tumor flare phenomenon that may accompany the initiation of therapy with LHRH analogues. In men who progress symptomatically after medical or surgical androgen ablation, low-dose prednisone appears to provide better pain relief than the antiandrogen flutamide, with similar time to progression and overall survival.²³⁰ In advanced breast cancer, hormonal therapy is usually the treatment of choice for patients whose tumors express the estrogen receptor, with responses to first-line treatment in the 50% to 60% range and generally favorable toxicity profiles. In patients who respond to it, hormonal therapy for metastatic breast cancer may provide excellent palliation of pain and other symptoms.

External-Beam Radiation and Systemic Radionuclides in Treating Cancer Pain

Fourteen trials involving a total of 3,859 patients compared various fractional dosing schedules of palliative radiotherapy, most often given for painful bone metastases.²³¹⁻²⁴⁴ High rates of pain relief were reported. Meta-analysis is problematic due to the heterogeneity of the dosing schedules, the variability in the anatomic sites and fields involved, and the outcomes assessed. Short courses of treatment with moderate doses appear to yield results similar to longer courses and seem preferable for convenience. Some studies suggest the possibility that a single dose may be sufficient. In one small study, the addition of a corticosteroid to radiotherapy did not improve pain control.²⁴⁵

Few studies have focused specifically on the incidence of pain resulting from radiation therapy. The effect of breast irradiation on HRQOL, including pain and cosmetic outcome, was evaluated in a clinical trial in which 416 patients were randomly allocated to radiation therapy and 421 to no further treatment.²⁴⁶ A modified version of the Breast Cancer Chemotherapy Questionnaire was administered at baseline, 4 weeks, and 8 weeks after randomization. Irritation of the skin of the breast, breast pain, and appearance of the breast to the patient were also assessed every 3 months for the first 2 years of the study. Breast irradiation therapy had a negative effect on quality of life during treatment. After treatment,

irradiated patients reported increased breast symptoms compared with controls. However, no difference was detected between groups after 2 years in the rates of skin irritation, breast pain, and being upset by the appearance of the breast.

Systemic Radionuclide Therapy

Porter et al. evaluated the efficacy of external-beam radiation with or without systemic ^{89}Sr in reducing pain among men with HRPC.²⁴⁷ Pain was assessed by analgesic use and by the Radiation Therapy Oncology Group analgesic and pain scoring system. At 6 months, the ^{89}Sr group had better pain scores, although the difference between groups was not significant. However, the ^{89}Sr group had significantly fewer new pain sites and did not require further radiotherapy for a mean of 35 weeks compared with 20 weeks for the radiotherapy-alone group. The ^{89}Sr group also had significantly higher rates of hematologic toxicity.

Samarium-153 ethylenediaminetetramethylene phosphonate (^{153}Sm EDTMP) was evaluated in 118 patients, most with breast or prostate cancer, who had painful bone metastases.²⁴⁸ They were randomized in a blinded fashion to receive a single dose of placebo or 0.5 or 1.0 mCi/kg of the active drug. Those on the placebo arm who did not respond by week 4 were eligible to cross over to treatment at 1.0 mCi/kg. There was a benefit in integrated pain scores and opioid analgesic use at 4 weeks in patients receiving the higher dose of ^{153}Sm EDTMP. Only 30% of patients completed the 16-week follow-up period. In another study of a single dose of ^{153}Sm EDTMP (either 37 or 18.5 MBq/kg) in patients with painful bone metastases, 58 of 70 patients in the high-dose group, and 30 of 35 in the low-dose group, had a reduction in pain, and Karnofsky indices improved at both doses. Of 72 patients who had been receiving analgesics, 63 reduced their consumption.²⁴⁹

Bisphosphonates in the Treatment and Prevention of Pain Caused by Bone Metastases

Bisphosphonates, inhibitors of bone resorption by osteoclasts, have been evaluated extensively in patients with (primarily osteolytic) bone metastases. Many of the larger and more recent studies have focused on the impact of these agents on skeletal complications, including pathologic fractures, spinal cord compression, and the need for surgery or radiation therapy. Pain was most often reported as a secondary endpoint, without providing detailed information. The main role of bisphosphonates appears to be the prevention of skeletal morbidity in patients with bone involvement from breast cancer and multiple myeloma. Their role in other cancers is not as well established.

A recent Cochrane Systematic Review identified eight RCTs of bisphosphonates involving 1,962 women with breast cancer metastatic to bone.²⁵⁰ Bisphosphonates reduced the risk of a skeletal event by 14% (P less than 0.00001). Compared to placebo or no bisphosphonate, pain was improved significantly in four studies.

The combined results of two prospective, multicenter, randomized, double-blind, placebo-controlled trials of pamidronate, involving 751 evaluable patients, strongly

support a protective effect in women with breast cancer and bone metastases receiving hormonal therapy or chemotherapy.²⁵¹ Skeletal complications occurred in 51% of those receiving pamidronate, 90 mg, intravenously every 3 to 4 weeks and 64% of the placebo group (P less than 0.001). Pain and analgesic requirements were also significantly worse in the placebo groups at 24 months and at the last study visit compared with the pamidronate groups.

A randomized, placebo-controlled, multicenter study in Sweden and Norway evaluated the efficacy of 60 mg pamidronate in 404 women with advanced breast cancer with skeletal metastases.²⁵² Pain scores, using a VAS, and analgesic consumption were recorded every third month. There was a significantly increased time to progression of pain (P less than 0.01) in favor for the pamidronate group; this group also fared better with respect to performance status (P less than 0.05). There was a lower consumption of opioid analgesics in the pamidronate group, but this was not statistically significant ($P = 0.14$).

A Cochrane Review focusing on bisphosphonates in multiple myeloma identified 11 RCTs.²⁵³ In aggregate, there was a highly statistically significant amelioration of pain (as well as skeletal events) associated with bisphosphonates in patients with multiple myeloma. The odds ratio for pain was 0.59 (95% CI, 0.46–0.76); however, the authors of the review stated that the data on pain were heterogeneous and should be interpreted with caution.

The higher-potency bisphosphonate zoledronic acid was shown to be as effective as pamidronate in reducing skeletal complications in a large RCT of patients with breast cancer or multiple myeloma, but its impact on pain is less well documented.²⁵⁴

Because of the tropism of prostate cancer for bone, bisphosphonates have been extensively evaluated for their potential to reduce morbidity from osseous metastases in that disease. In contrast to breast cancer and multiple myeloma, however, the data on the efficacy of these agents in prostate cancer are mixed; this may be because the bone metastases produced by prostate cancer are predominantly blastic rather than lytic. Also, the evaluation of pain or analgesic use as an outcome for bisphosphonate therapy may be confounded by many factors, such as the concurrent use of chemotherapy, hormonal therapy, radiotherapy, and conventional analgesics.

Despite some early promising results, several recent large RCTs have failed to support a role for bisphosphonates in prostate cancer, other than perhaps to slow the progression of osteopenia. Oral clodronate was evaluated in 311 patients on hormonal therapy for bone metastases from prostate cancer.²⁵⁵ There were no significant differences in symptomatic bone progression-free survival (absence of increase in analgesic use, treatment with radiotherapy, change in hormonal therapy, pathologic fracture, or spinal cord compression) associated with clodronate compared to placebo. Similarly, when combined with mitoxantrone and prednisone, intravenous clodronate was no more effective than placebo in reducing pain intensity in an RCT of 209 patients with metastatic hormone-refractory prostate cancer.²⁵⁶ A pooled analysis was performed of two clinical trials in which 378 patients were randomly assigned to 90 mg pamidronate or placebo every 3 weeks for 27 weeks.²⁵⁷ All patients had pain due to metastatic prostate cancer that had progressed on first-line hormonal therapy, and reduction in pain was the primary

endpoint of the studies. No sustained differences were observed between the pamidronate and placebo groups in scores on the Brief Pain Inventory, analgesic consumption, or adverse skeletal events.

The best evidence (albeit equivocal) for a benefit from a bisphosphonate in prostate cancer comes from an RCT evaluating zoledronic acid in subjects with bone metastases and a rising prostate-specific antigen level while on hormonal therapy.²⁵⁸ Those requiring “strong narcotic therapy” were excluded. Six hundred forty-three patients were randomly assigned to receive 8 mg zoledronic acid (subsequently reduced to 4 mg due to renal toxicity), 4 mg zoledronic acid, or placebo, given intravenously every 3 weeks for 15 months. The primary outcome variable was the proportion of patients with at least one skeletal event (pathologic bone fracture, spinal cord compression, surgery or radiotherapy to bone, or a change in antineoplastic therapy to treat bone pain). A smaller proportion of patients in both zoledronic acid arms experienced skeletal events, but the difference was only statistically significant in those on the 4-mg arm (33.2% versus 44.2% for placebo; $P = 0.021$). Pain, as assessed by the Brief Pain Inventory every 6 weeks, increased in all three groups. The mean increase from the baseline pain score after 15 months was less in both active treatment groups than the placebo group, but, unlike the primary outcome, the difference was statistically significant only in the group initially assigned to receive the 8-mg dose of zoledronic acid and subsequently reduced to 4 mg. The observation of significantly fewer skeletal events only in the 4-mg arm, but significantly smaller increments in pain only in the arm initially assigned to receive 8 mg, remains unexplained. There were no significant differences in analgesic use or quality of life among the three groups.

Given the inconsistencies in the data, and the fact that bisphosphonates are not without toxicity (adverse effects include myalgias, fevers, nausea, and renal insufficiency), this class of drugs cannot be considered part of standard care in metastatic prostate cancer. Limited evidence supports a possible benefit in reducing skeletal morbidity, rather than an analgesic or opioid-sparing effect. Few studies have evaluated bisphosphonates in cancers other than breast, prostate, and multiple myeloma, and the results are not definitive.²⁵⁹

Undertreatment of Cancer Pain

Despite the prospect of achieving control of cancer pain in the great majority of patients, cancer pain remains undertreated even in oncology specialty clinics within wealthy, industrialized nations.⁴² A substantial body of research indicates that undertreatment is multifactorial. Inadequacy of clinicians’ knowledge of effective pain assessment and management, negative attitudes of patients and clinicians toward the use of drugs (particularly opioids) for pain relief,^{260–262} and problems of access, cost, and reimbursement,^{263,264} each contribute. Issues of culture and ethnicity^{265–267} have considerable importance for cancer pain assessment and management but have until recently received little attention in clinical trials. The elderly, women, children, and members of racial minorities are at increased risk for unsatisfactory pain relief.^{51,58,268–272} A finding of considerable concern was that, among nursing home patients with cancer in the United States, 26% of

those with daily pain received no analgesics.⁵¹ The predictors for undertreatment or nontreatment of pain included age greater than 85, impaired cognitive status, and minority race. This study and others indicate that disparities exist in pain assessment and treatment based on demographic factors, such as age and race.³ In addition, pilot studies suggest clinically relevant gender^{273–275} and genetic^{276,277} differences in the efficacy and adverse effects of opioid analgesics.

The Role of Patient Education

Lack of adherence with prescribed analgesic regimens represents a significant barrier to effective management of cancer pain.²⁷⁸ The reasons for patients’ lack of adherence are complex, including issues of access and cost, the narrow therapeutic index of opioids, and the fear and misperceptions attached to them. In light of these barriers, educating cancer patients about their pain and its treatment is an essential component of effective management.

The impact of pain education programs has been evaluated in a small number of RCTs. In a study of 313 cancer patients with chronic pain, the educational intervention consisted of verbal, written, and audiotaped instruction on pain management and a pain diary. Among the 67% of patients not receiving home nursing care, there was a statistically significant decrease in pain intensity associated with patient education.²⁷⁹ Miaskowski et al.²⁸⁰ randomized 174 patients with cancer pain to standard care or to a “PRO-SELF” intervention in which patients received individualized counseling by specially trained nurses and written instructions on the management of pain and the adverse effects of their medicines. The patients kept pain diaries and were taught to use a pill box and to communicate effectively with their caregivers about unrelieved pain. Pain intensity scores (worst, average, and least pain) declined significantly in the PRO-SELF group but not in those receiving standard care. “Standard care” in this study consisted of providing subjects with the patient version of the Cancer Pain Guidelines,⁶⁶ instructing them in the maintenance of a daily pain diary, and providing home visits and telephone contacts from a nurse on the same schedule as the PRO-SELF group. As the control group received educational support superior to that provided in most practice settings, the positive results achieved with the PRO-SELF intervention are even more striking.

Conclusion

The studies reviewed here provide unequivocal evidence that cancer pain is highly prevalent yet can be ameliorated in the large majority of people who suffer from it. In the face of this evidence, neglect and therapeutic nihilism are not justifiable. Straightforward algorithms for assessing pain have been validated. Treatment according to the WHO analgesic ladder provides effective pain relief in 80% to 90% of cases. Neuraxial drug delivery and other invasive techniques may be options for the minority of patients who have inadequate relief or intolerable adverse effects with systemic opioid therapy, NSAIDs, and adjuvants. For selected subsets of patients, radiotherapy, chemotherapy, hormonal therapy, and bisphosphonates may provide relief from pain or prevent its escalation.

Further progress in cancer pain depends on dissemination and implementation of methods of assessment and treatment that are known to be effective. The evidence suggests that pain is inadequately assessed and undertreated in many practice settings, and that women, children, the elderly, and minorities are less likely to receive effective pain management. Education of caregivers is needed to address these disparities. Educational support for patients and their families has been shown to play an important role in optimal pain management.

Investigations of the mechanisms of pain have led to an increasingly detailed understanding of its pathogenesis, yet treatment remains largely empiric rather than mechanism based. Various routes of drug administration have been explored, but no new, generally effective agents have been added to the traditional pharmacopeia of opioids, acetaminophen, NSAIDs, and adjuvants. Variations in individual responses to the different agents in these classes are poorly understood, leading to empiric rotation of drugs. There is little evidence to support specific, "targeted" therapies for defined pain syndromes, such as postmastectomy or postthoracotomy pain. The narrow therapeutic index of opioids means that, for many patients, pain relief comes at the cost of opioid-related adverse effects including sedation, constipation, and nausea, which themselves require treatment.

The development of new drugs and other treatment modalities for cancer pain, and the more efficacious use of existing modalities, depend on their evaluation in well-designed, adequately powered clinical trials. The performance of such trials presents several challenges, including the heterogeneity of cancer pain, difficulties in accruing symptomatic patients, the ethical problems associated with placebo controls in patients with pain, high dropout rates, and the choice of appropriate assessment measures and endpoints. Researchers concerned with improving symptoms in cancer patients have already demonstrated the capacity to surmount these and other obstacles. They have provided a strong evidence base for daily clinical care and a foundation for continued progress against cancer pain.

Nausea and Vomiting in the Cancer Patient

Paula Gill, Axel Grothey,
and Charles Loprinzi

Nausea and vomiting are two of the most feared cancer treatment-related side effects for cancer patients and their families. In 1983, Coates et al. found that patients receiving chemotherapy ranked nausea and vomiting as the first and second most severe side effects, respectively.¹ Up to 20% of patients receiving highly emetogenic agents in this era postponed, or even refused, potentially curable treatments.² Despite the availability of more than 20 different antiemetics, nausea and vomiting in cancer patients remain problematic and continue to pose tremendous challenges to practicing oncologists.

The broad scope of this problem and the vast number of ways to intervene may seem overwhelming to the busy oncologist whose patient is in the examination room waiting for a solution. This is a reason to take an evidence-based approach when tackling this problem. This chapter presents options based on data and experience gathered over the past several decades in different clinical settings and discusses the importance of using cost-effective antiemetic regimens.

Chemotherapy-Induced Nausea and Vomiting Syndromes

Investigations into the control of chemotherapy-related nausea and vomiting have led to the description of three distinct, widely accepted, emetic syndromes: acute, delayed, and anticipatory.^{3,4} Despite many theories and hypotheses, the exact pathophysiology behind each syndrome is not known (Figure 83.1).

Acute

Acute nausea and vomiting has been, for no convincing pathophysiologic reason, considered as that which occurs within the first 24 hours of chemotherapy initiation. It has been hypothesized that the chemostimulated release of serotonin binds to 5-hydroxytryptamine 3 (5-HT₃) receptors on gut vagal afferent neurons and initiates the emetic reflex arch.^{3,4} Within 18 hours postinfusion, the serum serotonin concentration returns to "normal," that is, prechemotherapy levels.⁵

Several factors have been identified for predicting chemotherapy-induced nausea and vomiting (CINV). The most important factor is the emetogenicity of the chemother-

apeutic agents being used. In 1997, Hesketh et al. proposed a classification for the acute emetogenicity of cancer chemotherapy, both single agents and combination chemotherapy.⁶ They proposed that the emetogenic potential of chemotherapy, without the use of antiemetics, be divided into five levels based on frequency (Table 83.1).⁶ An algorithm for the emetogenic potential of combined regimens was also outlined (Table 83.2). Part of the problem with utilizing this emetogenic classification system, particularly with newer chemotherapy agents, is that antiemetics are given to patients as a standard of care; this makes it difficult to know the true emetogenic potential of individual cytotoxic agents. In 1998, the Anti-emetic Subcommittee of the Multinational Association of Supportive Care in Cancer held a consensus conference, whereby the foregoing classification was reviewed.⁷ Although the use of the classification was encouraged by the panel, the lack of evidence regarding the emetogenicity of specific agents or chemotherapy combinations rendered them unable to come to a consensus.^{8,9}

There are also well-described patient factors, predisposing for more or less emetic trouble with specific chemotherapy regimens, that have been supported in multiple studies. Factors predicting for more emetic troubles include poor emetic control with prior chemotherapy,¹⁰ female gender, low alcohol intake (current or chronic, less than 100g EtOH/day),¹¹⁻¹³ younger age (less than 50 to 65 years),¹¹⁻¹⁴ and, although less consistent, low social functioning or high fatigue scores.¹² CINV increases almost fourfold in those with any four of six risk factors they described (female, prechemotherapy nausea, highly emetogenic chemotherapy, lack of maintenance antiemetics, low social functioning, history of low alcohol use).

Delayed

Delayed nausea and vomiting is arbitrarily defined as occurring more than 24 hours after chemotherapy. As little as we know about the pathophysiology of acute CINV, we know even less about that of delayed.¹⁵ The neurokinin substance P, however, has recently been implicated in the pathogenesis of acute and delayed CINV. Neurokinins (NK) are a family of peptides found in mammals that share a common carboxy-terminal amino acid sequence (Phe-X-Gly-Leu-Met•NH₂). Three neurokinins have been identified to date (substance P, neurokinin A, and neurokinin B), along with three NK recep-

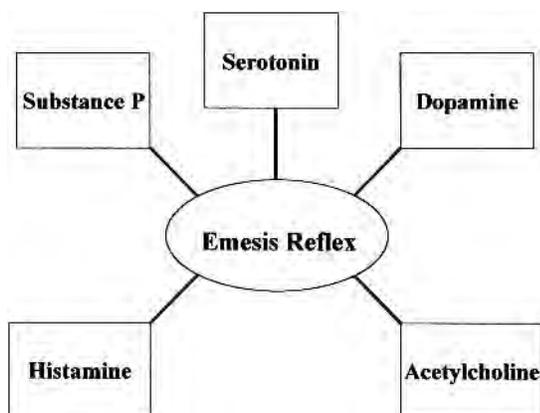

FIGURE 83.1. Proposed endogenous mediators of chemotherapy-induced nausea and vomiting (CINV).

tors (NK1, NK2, NK3). NK1 receptors are found throughout the central nervous system, peripheral nervous system, and gut, with a very high density located in the chemoreceptor trigger zone (CTZ) of the medulla oblongata.¹⁶ NK1-receptor antagonists have been shown to be helpful in the treatment of both acute and delayed CINV (discussed next).

As with acute CINV, the emetogenic potential of chemotherapy regimens and certain patient characteristics can help oncologists predict which patients are at risk for developing delayed CINV. Delayed CINV is well described in patients receiving cisplatin chemotherapy. Only recently has this risk been formally assessed with moderately emetogenic agents, such as cyclophosphamide (750–1,500 mg/m²).¹⁷

In some models, one patient characteristic that predicts for an increased risk of delayed CINV is poor control of acute CINV.^{3,8,11} Those who experience acute nausea and/or emesis with chemotherapy are much more likely to develop these complications 24 hours or more after treatment. It makes sense, therefore, that patient characteristics that increase the risk of acute CINV (poor emetic control with prior chemotherapy, female gender, low alcohol intake, younger age) will also increase their risk of delayed CINV.

Anticipatory

Anticipatory nausea and/or vomiting is a conditioned response that has a tendency to occur when nausea and vomiting have been poorly controlled with previous cycles of chemotherapy.^{7,18,19} Previously neutral stimuli become conditioned stimuli and can thereby elicit anticipatory nausea and/or vomiting. This event can occur before, during, or after chemotherapy and can be brought on by sights (the clinic, the oncologist), smells (smell of the hospital), or environments (the chemotherapy suite).

Several studies have shown acute or delayed CINV with previous cycles, highly emetogenic drugs, and a patient receiving chemotherapy over an extended period of time (i.e., several months) are associated with a higher incidence of anticipatory nausea and/or vomiting.⁴ Some studies have shown that younger patients (less than 50 years old), as well as those with a history of anxiety or depression, have more difficulty with anticipatory nausea and/or vomiting.¹⁸ One of the most well supported predictors is a history of motion sick-

TABLE 83.2. Algorithm for estimation of emetogenic potential of combination chemotherapy regimens.

1. Use Table 83.1 to assign emetic level to each agent in the regimen.
2. Identify most emetogenic agent.
3. When considering the other components of the regimen, use the following rules:
 - a. Level 1 agents do not contribute to emetogenicity.
 - b. Adding level 3 or 4 agents increases emetogenicity by one level/agent.
 - c. Adding level 2 agents (regardless of number) increases emetogenicity by one level greater than the most emetogenic agent.

Source: From Hesketh et al.,⁶ by permission of *Journal of Clinical Oncology*.

ness.^{19,20} It is important to realize that anticipatory nausea and/or vomiting is not a sign of underlying psychopathology but is a classically conditioned, Pavlovian-type response that may be avoided if nausea and/or vomiting does not occur with previous cycles of chemotherapy.

Treatment of Chemotherapy-Induced Nausea and Vomiting

Treatment of Acute Nausea and Vomiting (Table 83.3)

SEROTONIN RECEPTOR ANTAGONISTS

5-HT3, 5-hydroxytryptamine 3.

plastic agents, such as cisplatin and ifosfamide, led to their increased use worldwide. As stated previously, despite higher cure rates with these effective antineoplastic agents, a drawback was their association with a marked increase in chemotherapy-related nausea and vomiting. Clinicians responded by raising the dose of metoclopramide (2–3 mg/kg IV), a potent antagonist of type 2 dopamine receptors and very weak inhibitor of serotonin receptors.²¹ In response to the intolerable extrapyramidal side effects that occurred at high doses of metoclopramide,²² investigators searched for more selective 5-HT₃ receptor antagonists.²³ The successful discovery of selective receptor antagonists led to clinical trials, which then proved their efficacy and safety. As of 2004, five such 5-HT₃ receptor-selective antagonists had found their way into clinical practice: granisetron, ondansetron, tropisetron, dolasetron, and, most recently, palonosetron. Granisetron, ondansetron, tropisetron, and dolasetron share similar low side effect profiles, which include headache, transient asymptomatic elevation in transaminases, and constipation.¹¹ Therefore, toxicity criteria do not help the practicing physician decide which serotonin receptor antagonist to use. Multiple large, randomized, well-controlled studies compared these agents to each other.^{24–31} The overall conclusion is that their efficacy is relatively equivalent.

Following initial trials that supported comparable effectiveness of the agents in this class, subsequent studies were conducted to address the issues of route (po or IV), dose, and schedule. Serotonin receptor antagonists have excellent oral bioavailability. In a multicenter, double-blind, randomized parallel study, Perez et al. showed that a single oral dose of granisetron (2 mg) was equivalent to a single IV dose of ondansetron (32 mg) for the prevention of acute CINV with moderately emetogenic chemotherapy (cyclophosphamide 500–1,200 mg/m² or carboplatin).¹³ Gralla et al. reported similar results when comparing the same antiemetic regimens [granisetron 2 mg po versus ondansetron 32 mg IV] for highly emetogenic cisplatin-based chemotherapy.²⁴ Multiple studies were also done comparing oral ondansetron (16–24 mg po) to an intravenous dose (32 mg IV) of the same agent.^{31–33} Again, equal effectiveness was shown. Given the comparable efficacy of oral and intravenous routes, current recommendations are based upon ease of administration and cost-effectiveness, concluding that the oral use of these 5-HT₃ receptor-selective antagonists is preferred above intravenous administration, unless the patient is unable to tolerate oral medications. Part of the rationale for this preference relates to medication cost. At the time that these studies were reported (1998), a single dose of oral granisetron (2 mg) was US \$62 whereas a dose of IV ondansetron was US \$129.^{8,21} Although the specific prices may have changed over time, a similar gap between the oral and intravenous costs remains.

The optimal dose of serotonin receptor antagonists has been investigated as well. Many studies have shown that it is possible to give too little of a particular 5-HT₃ antagonist, resulting in poor emetic control.^{34–37} On the other hand, given the physiology of serotonin receptor antagonists, most experts concur that there is likely a threshold effect, meaning that once all receptors are saturated, higher doses will not increase antiemetic activity. An illustration of this phenomenon is provided in Figure 83.2. The threshold dose of each serotonin receptor antagonist may vary based on the emetogenicity of a particular chemotherapy treatment regimen; this

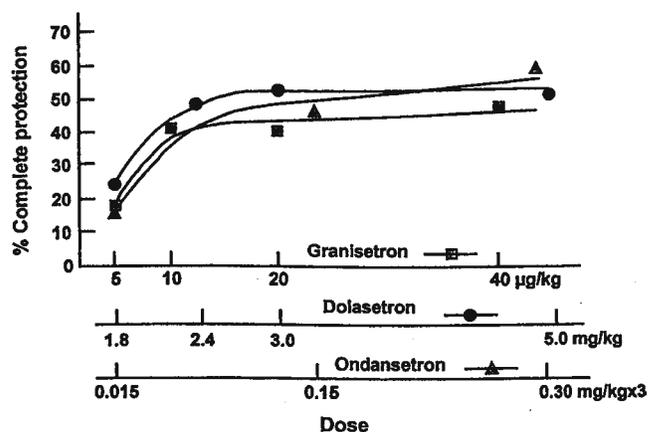

FIGURE 83.2. Protection from cisplatin-induced emesis by various 5HT₃ antagonists. (From Grunberg et al.,³⁷ by permission of *Cancer Chemotherapy and Pharmacology*.)

has led to the current recommendation that the lowest fully effective dose of each agent should be used for CINV.^{8,11,27}

Several large, randomized trials have been conducted to study whether serotonin receptor antagonists are best given in a single daily dose versus dividing the total daily dose and administering as multiple doses. Beck et al. compared IV ondansetron, given as a single 32 mg dose, to ondansetron dosed at 0.15 mg/m² every 4 hours, in a stratified, randomized, double-blind, multicenter study.³⁵ The single IV dose regimen was as effective as the multiple dose regimen. Once the equivalent efficacy of oral 5-HT₃ antagonists was established, similar studies were performed to examine dosing schedules. Ettinger et al. compared a single, 2 mg oral dose of granisetron to two divided doses (1 mg 1 hour before chemotherapy, 1 mg 12 hours after chemotherapy).³⁸ Both regimens were equally effective in controlling CINV. Harman et al. looked at the same question, single dose versus divided dose, with dolasetron.³⁹ Once again, both dosing schedules appeared equivalent. Current guidelines for the use of 5-HT₃ antagonists for acute CINV, taking the aforementioned factors (lowest effective dose, ease of administration, and cost-effectiveness) into consideration, are outlined in Tables 83.2, 83.3, and 83.4. Although there are many similarities between the recommendations of

TABLE 83.4. Levels of evidence.

Level	Type of evidence
I	Evidence is obtained from meta-analysis of multiple, well-designed, controlled studies. Randomized trials have low false-positive and low false-negative errors (high power).
II	Evidence is obtained from at least one well-designed experimental study. Randomized trials have high false-positive and/or false-negative errors (low power).
III	Evidence is obtained from well-designed, quasi-experimental studies, such as nonrandomized, controlled, single-group, prepost, cohort, time, or matched case-control series.
IV	Evidence is from well-designed, nonexperimental studies, such as comparative and correlational descriptive and case studies.
V	Evidence is from case reports and clinical examples.

the American Society for Clinical Oncology, the National Comprehensive Cancer Network (NCCN), and the American Society of Health-System Pharmacists, there are also some notable differences. For example, the NCCN guidelines include aprepitant, an NK-1 antagonist further discussed next, for prevention of acute and delayed CINV.^{8,11,40}

Palonosetron is a new antiemetic agent, approved by the U.S. Food and Drug Administration (FDA) in the fall of 2003, that shows high selectivity and strong binding affinity for 5-HT₃ receptor sites. Of particular significance, compared to other serotonin receptor antagonists, is its substantially higher binding capacity to the targeted serotonin receptor and its extended plasma half-life of approximately 40 hours, which presumably contributes to its prolonged antiemetic effects. Phase III studies have shown that palonosetron is safe and effective in treating both acute and delayed CINV.^{41,42} Palonosetron decreases both acute and delayed nausea and emesis with a single intravenous dose, given before chemotherapy. In one trial, it appeared to be better than dolasetron (100 mg orally) for diminishing both acute and delayed nausea/vomiting, although this trial did not utilize corticosteroids.^{41,42} Beneficial effects remained through multiple cycles of chemotherapy. The most common adverse effect was headache, with a frequency similar to other 5-HT₃ antagonists. The eventual role of palonosetron in relationship to the other available serotonin receptor antagonists is yet to be determined.

CORTICOSTEROIDS

Corticosteroids are among the most frequently used antiemetics because of their efficacy, low cost, and wide availability.^{7,8} Dexamethasone and methylprednisolone are the most thoroughly studied. Dexamethasone is used most often due to its wide availability and its variety of dosage formulations. The efficacy of oral and IV corticosteroids appears to be equivalent, so oral formulations are recommended based on ease of use and cost.

Recently, a meta-analysis was performed to identify randomized evidence of the efficacy of dexamethasone in protecting against acute and delayed nausea and vomiting in patients who received highly or moderately emetic chemotherapy. Data were collected from a search of the medical literature. All randomized studies that compared dexamethasone to placebo, no treatment, or other antiemetic therapy, qualified for inclusion in this analysis. A search of 1,200 citations revealed 32 studies that included 42 pertinent comparisons involving a total population of 5,613 patients. Results of the meta-analysis revealed that dexamethasone was superior to placebo or to no treatment for complete protection from acute and delayed emesis and nausea.⁴³

To determine the optimal dose of dexamethasone for control of nausea and vomiting associated with highly emetogenic chemotherapy, a double-blind dose-finding study was undertaken. A total of 531 patients were randomized to receive either 4, 8, 12, or 20 mg dexamethasone, administered by IV infusion, along with 8 mg ondansetron.⁴⁴ The 4 mg and 8-mg doses of dexamethasone provided complete control of acute vomiting in 69% of patients and complete control of acute nausea in 61%. For patients receiving the 12-mg dose, complete control rates were 79% for vomiting and 67% for nausea. The 20-mg dose provided the highest control rates of

83% for vomiting and 71% for nausea. Complete protection from vomiting was substantially significantly better for patients receiving 20 mg dexamethasone compared to those receiving 4 or 8 mg (*P* less than 0.005) and somewhat better, but not statistically significant, than results for patients receiving 12 mg dexamethasone. There was no difference between groups in the frequency of side effects. Treatment guidelines currently recommend dexamethasone 10 to 20 mg po/IV or methylprednisolone 40 to 125 mg administered once, before chemotherapy, to control acute emesis.^{7-9,11,40} When the NK1 receptor antagonist aprepitant (discussed next) is given, the corticosteroid dose should be cut in half, as aprepitant decreases dexamethasone metabolism.^{45,46}

COMBINED REGIMENS

Given that both corticosteroids and 5-HT₃ antagonists are effective in reducing acute CINV, the obvious question arises as to whether combining the two classes of antiemetics would be more efficacious than either alone. Several well-designed randomized studies were performed to address this question. A meta-analysis evaluated 30 randomized studies comparing 5-HT₃ antagonists with conventional antiemetics in patients receiving moderately and highly emetogenic chemotherapy. In 11 of these trials, 5-HT₃ antagonists used as single agents were compared to combination therapy with 5-HT₃ antagonists plus dexamethasone. Combination therapy with dexamethasone was superior to treatment with a 5-HT₃ antagonist alone in 10 of 11 trials.³¹ Current recommendations, therefore, suggest the use of 5-HT₃ antagonists and dexamethasone for emetic prophylaxis when using highly or moderately emetogenic chemotherapy regimens.^{7,8,11,40}

OTHER AGENTS

Other antiemetic classes, such as benzamides, phenothiazines, butyrophenones, and cannabinoids, have a lower therapeutic index and are only recommended for use with highly emetogenic treatments in patients who are refractory to, or intolerant of, 5-HT₃ receptor antagonists or corticosteroids for the treatment of acute CINV. Chemotherapy regimens that have a lower risk of inducing nausea or vomiting do not require as aggressive prophylaxis. The minimal benefit that may exist with using serotonin receptor antagonists in this situation has not been shown to be cost-effective.⁹ In fact, for treatments with level 1 and 2 emetogenicity, most guidelines suggest that antiemetics should be used on an as-needed basis.

BENZAMIDES

Metoclopramide is the most commonly used drug in this class. Since the advent of serotonin receptor antagonists, the use of high-dose metoclopramide has become almost obsolete. Metoclopramide blocks type 2 dopamine receptors in the chemoreceptor trigger zone (CTZ), increases lower esophageal sphincter tone, and enhances bowel and gastric motility. At lower doses (20–40 mg po q 4–6 h), metoclopramide may be a useful tool for treating less severe CINV.

PHENOTHIAZINES

Phenothiazines, such as prochlorperazine, thiethylperazine, and promethazine, are widely prescribed antiemetic agents.

They act on dopamine receptors centrally and peripherally, and, similar to the benzamides, are useful in treating mild CINV. Side effects include extrapyramidal symptoms (EPS; acute dystonia, akathisia, dyskinesias), anticholinergic effects (dry mouth, drowsiness, urinary retention, tachycardia), and sedation. As with metoclopramide, diphenhydramine or hydroxyzine may be used prophylactically or therapeutically to antagonize extrapyramidal system receptors. Intravenous prochlorperazine can cause marked hypotension if administered too rapidly. Phenothiazines can be given IV, IM, po, or rectally, making them very useful in patients who are having trouble with oral intake or who have difficult IV access.

BUTYROPHENONES

The two drugs in this class, droperidol and haloperidol, are type 2 dopamine receptor antagonists. Their side effect profile is similar to the phenothiazines, including extrapyramidal reactions, sedation, and hypotension. Although they have stronger antiemetic effects than the phenothiazines, the incidence of EPS is higher. Droperidol can be given IM or IV, and haloperidol can be administered orally as well.

CANNABINOIDS

Despite the controversy that surrounds the use of cannabinoids for CINV, several studies have shown them to be effective antiemetics alone or in combination with other agents.^{11,47,48} However, cannabinoids have not been proven effective as prophylaxis against highly emetogenic chemotherapies. Drugs in this class are available as plant extracts (dronabinol) and semisynthetic substances (nabilone, levonantradol). Side effects include dizziness, sedation, hypotension, and dysphoria, which are more pronounced in older patients. As with the other agents having a lower therapeutic index, cannabinoids are only recommended for the treatment of acute CINV as an adjunct to serotonin receptor antagonists and corticosteroids, or in those who are intolerant of more standard antiemetics.

NEUROKININ 1 ANTAGONISTS

As discussed earlier in this chapter, the neurokinin substance P has been implicated in the pathogenesis of acute and delayed CINV.¹⁶ This discovery has led to the development of a novel NK-1 antagonist, such as aprepitant, which has recently been approved by the FDA for use in preventing acute and delayed CINV related to highly emetogenic chemotherapy. The rationale for the use of NK-1 antagonists is discussed in the next section.

Treatment of Delayed Nausea and Vomiting

CORTICOSTEROIDS

In 1985, D'Olimpio et al. demonstrated that dexamethasone is better than placebo when used as single agent for preventing delayed CINV.⁴⁹ In a randomized, double-blind trial, 64 patients receiving cisplatin-based chemotherapy were given either high-dose intravenous dexamethasone (20 mg IV pre-cisplatin and 20 mg IV at 3, 6, and 9 hours postcisplatin) or an intravenous placebo. Although there was no clinically sig-

nificant difference in episodes of emesis between the two arms, those receiving dexamethasone experienced much less nausea, and had it for a shorter duration, than the patients in the placebo group (25% for 30 minutes versus 53% for 3.5 hours, respectively).

Current treatment guidelines recommend the use of oral corticosteroids to reduce or prevent delayed emesis (Tables 83.5, 83.6, and 83.7). Optimal dosing regimens need further study, but typical regimens currently include 8 mg administered twice daily for 2 to 3 days, with the continued use of 4 mg bid for 1 or 2 more days, as needed. Long-term use of corticosteroids may cause adrenal insufficiency, but the short duration of corticosteroids for antiemetic therapy does not result in this side effect. However, adrenal insufficiency can occur in patients receiving dexamethasone in multiple daily chemotherapy regimens. In addition, corticosteroid use may cause hyperglycemia and insomnia.

Clinical studies have shown that dexamethasone provides improved control of delayed emesis when used alone, but improved efficacy may occur when it is used in combination with another antiemetic agent.^{27,43,50,51}

METOCLOPRAMIDE

Metoclopramide (20 mg po q 6 h days 2–5) added to dexamethasone (8 mg po bid days 2–3, 4 mg po bid days 4–5) has been reported to be better than dexamethasone alone.^{52,53} Two large, randomized trials showed complete protection from delayed vomiting in 52% and 70% of patients treated with metoclopramide and dexamethasone, after receiving cisplatin chemotherapy, compared to only 35% and 44% of patients treated with dexamethasone alone.⁵⁴ Nonetheless, the toxicities of metoclopramide, as already discussed, can be quite problematic in some patients.⁹

SEROTONIN RECEPTOR ANTAGONISTS

Given that delayed CINV was successfully preempted only 50% to 70% of the time with corticosteroids, the role of serotonin receptor antagonists in this setting has also been investigated. Initially, ondansetron and granisetron were compared to placebo. Although they did provide some symptom improvement in patients receiving highly emetogenic chemotherapy, this benefit was only modest. Further studies compared 5-HT₃ antagonists plus dexamethasone to dexamethasone alone. Large, randomized, double-blind trials, however, were unable to demonstrate an improvement in control of delayed CINV with the addition of serotonin receptor antagonists.⁵⁴ In 1997, the Italian Group for Antiemetic Research compared dexamethasone plus metoclopramide versus dexamethasone plus ondansetron (8 mg po bid days 2–4) in a randomized, double-blind study of 322 patients receiving cisplatin.²⁷ The two treatment regimens offered similar protection from delayed CINV associated with highly emetogenic chemotherapy.

The only study to compare antiemetic regimens, in patients receiving moderately emetogenic treatments, comes, again, from the Italian Group for Antiemetic Research: 705 patients were divided into two groups 24 hours after moderately emetogenic chemotherapy.⁵⁵ The low-risk group, defined as those who had no vomiting and only minimal nausea, included 618 patients. The high-risk group, those who had either emesis or moderate to severe nausea, numbered

TABLE 83.5. Summary of American Society of Clinical Oncology (ASCO) antiemetic guidelines.

-
- I. Chemotherapy-Induced Emesis**
- A. Acute Emesis (vomiting occurring 0 to 24 hours after chemotherapy)**
1. Antiemetic Agents: Highest Therapeutic Index
 - a. Serotonin Receptor Antagonists
 - i. Agent equivalence: At equivalent doses, serotonin receptor antagonists have equivalent safety and efficacy and can be used interchangeably based on convenience, availability, and cost.
 - ii. Drug dosage: Established, proven doses of all agents are recommended.
 - iii. Drug schedule: Single doses of antiemetics are effective and preferred for convenience and cost.
 - iv. Route of administration: At biologically equivalent doses, oral agents are equally effective and are as safe as intravenous antiemetics. In most settings, oral agents are less costly and more convenient; for these reasons, they are recommended over intravenous therapy.
 - b. Corticosteroids
 - i. Agent equivalence and route of administration: At equivalent doses, corticosteroids have equivalent safety and efficacy and can be used interchangeably.
 - ii. Drug dose and schedule: Single doses of corticosteroids are recommended.
 2. Antiemetic Agents: Lower Therapeutic Index—Dopamine Antagonists, Butyrophenones, Phenothiazines, and Cannabinoids: For chemotherapy with a high risk of emesis, selective serotonin antagonists (with dexamethasone) are recommended.
 3. Antiemetic Agents: Adjunctive Drugs—Benzodiazepines and Antihistamines: Benzodiazepines and antihistamines are useful adjuncts to antiemetic drugs but are not recommended as single agents.
 4. Antiemetic Agents: Combinations of Antiemetics: It is recommended that serotonin antagonists be given with corticosteroids.
 5. Risk Factors for Acute Emesis
 - a. Patient Characteristics
 - b. Chemotherapeutic Agents
 - c. Guidelines
 - i(a). High risk: Cisplatin: The combination of a 5-HT₃ antagonist plus a corticosteroid is recommended before chemotherapy.
 - i(b). High risk: Noncisplatin: The combination of a 5-HT₃ antagonist plus a corticosteroid is recommended before chemotherapy.
 - ii. Intermediate risk: A corticosteroid is suggested for patients being treated with agents of intermediate emetic risk.
 - iii. Low risk: It is suggested that, for patients being treated with agents of low emetic risk, no antiemetic be routinely administered before chemotherapy.
 - iv. Combination chemotherapy: It is suggested that, when combination chemotherapy is given, the patient be given antiemetics appropriate for the chemotherapeutic agent of greatest emetic risk.
 - v. Multiple consecutive days of chemotherapy: It is suggested that antiemetics appropriate for the risk class of the chemotherapy, as outlined above, be administered for each day of the chemotherapy.
- B. Delayed Emesis (vomiting occurring >24 hours after chemotherapy)**
1. Antiemetic Agents
 - a. Single Agents
 - i. Corticosteroids
 - ii. Metoclopramide and serotonin receptor antagonists
 - c. Guidelines
 - i(a). High risk: Cisplatin
For all patients receiving cisplatin, a corticosteroid plus metoclopramide or plus a 5-HT₃ antagonist is recommended for the prevention of delayed emesis.
 - i(b). High risk: Noncisplatin
A prophylactic corticosteroid as a single agent, a prophylactic corticosteroid plus metoclopramide, and a prophylactic corticosteroid plus a 5-HT₃ antagonist are regimens suggested for the prevention of delayed emesis.
 - ii. Intermediate—low risk
No regular preventive use of antiemetics for patients receiving these chemotherapeutic agents or delayed emesis is suggested for patients.
- C. Anticipatory Emesis**
1. Prevention: Use of the most active antiemetic regimens appropriate for the chemotherapy being given to prevent acute or delayed emesis is suggested. Such regimens must be used with the initial chemotherapy, rather than after assessment of the patient's emetic response to less effective treatment.
 2. Treatment: If anticipatory emesis occurs, behavioral therapy with systematic desensitization is effective and is suggested.
- II. Radiation-Induced Emesis**
- A. Risk Factors for Radiation-Induced Emesis**
1. Guidelines
 - a. High Risk: Total-Body Irradiation
A serotonin receptor antagonist should be given with or without a corticosteroid before each fraction and for at least 24 hours after.
 - b. Intermediate Risk: Hemibody Irradiation, Upper Abdomen, Abdominal-Pelvic, Mantle, Cranial Radiosurgery, and Craniospinal Radiotherapy
A serotonin receptor antagonist or a dopamine receptor antagonist should be given before each fraction.
 - c. Low Risk: Radiation of the Cranium Only, Breast, Head and Neck, Extremities, Pelvis, and Thorax
Treatment should be given on an as-needed basis only. Dopamine or serotonin receptor antagonists are advised. Antiemetics should be continued prophylactically for each remaining radiation treatment day.
-

TABLE 83.6. Summary of American Society of Health-System Pharmacists (ASHP) antiemetic recommendations.

1. The emetic potential of the chemotherapeutic agent is the primary factor to consider when deciding whether to administer pharmacologic prophylaxis and which antiemetic(s) to select.
2. Adult and pediatric patients receiving chemotherapeutic agent(s) with emetic potential classified as level 2 through 5 should receive pharmacologic prophylaxis against nausea and vomiting each day on which chemotherapy is given. Antiemetic prophylaxis is not required when the level of emetogenicity is 1.
 - (a) Adult and pediatric patients receiving level 2 chemotherapeutic regimens can receive dexamethasone or methylprednisolone alone for prophylaxis of nausea and vomiting. Prochlorperazine is also an option for adults.
 - (b) Adult and pediatric patients receiving chemotherapeutic agent(s) with emetic potential of level 3 through 5 should receive a corticosteroid (dexamethasone or methylprednisolone) in combination with a 5-HT₃ receptor antagonist.
 - (c) Orally and intravenously administered antiemetics are generally equivalent in efficacy and safety for both adult and pediatric patients. The decision as to which formulation to use should be based on patient-specific factors and cost.
 - (d) The decision as to which 5-HT₃ receptor antagonist to use should be based on the acquisition cost of comparable doses. Dosage recommendations for adult and pediatric patients differ.
3. All patients receiving chemotherapy should have antiemetics available on an as-needed basis for rescue for breakthrough nausea and vomiting. Patients should be educated about the appropriate administration of and expectations for therapy and should be reassured that every effort is being made to prevent symptoms. In adults, lorazepam, methylprednisolone, prochlorperazine, metoclopramide, dexamethasone, haloperidol, and dronabinol are effective. In pediatric patients, chlorpromazine, lorazepam, or methylprednisolone (or dexamethasone) is recommended. The choice of agent should be based on patient-specific factors (e.g., anticipated adverse effects, past success) and cost.
4. For the prevention of delayed emesis after cisplatin therapy in adults, dexamethasone with metoclopramide or a 5-HT₃ receptor antagonist is recommended. The choice of agent should be based on patient-specific factors and cost. For delayed emesis after cyclophosphamide, doxorubicin, or carboplatin therapy, a 5-HT₃ receptor antagonist with dexamethasone is recommended. Prochlorperazine in combination with dexamethasone has also been used and is available in extended-release and rectal dosage forms, but the evidence to support this combination is limited. In pediatric patients, chlorpromazine, lorazepam, or a 5-HT₃ receptor antagonist can be used in combination with a corticosteroid.
5. Patients receiving total or hemibody irradiation (with or without concomitant chemotherapeutic agents) or single-exposure, high-dose radiation therapy to the upper abdomen should receive preventive therapy for nausea and vomiting with each day of therapy. A 5-HT₃ receptor antagonist should be used both in adults and in pediatric patients. Oral therapy should be encouraged; however, IV therapy is an acceptable option. There is no evidence to support the use of 5-HT₃ receptor antagonists 24 hours beyond the last dose of radiation.
6. If an agent is needed to treat established radiation therapy-induced emesis in adults, prochlorperazine, metoclopramide, or thiethylperazine is recommended. 5-HT₃ receptor antagonists are also an option. Chlorpromazine and lorazepam can be used in pediatric patients.
7. When patients do not respond to initial therapy with an antiemetic agent, it is recommended that an agent from another pharmacologic class be added, that the dose of the antiemetic be increased to the maximum within an accepted range, or that a combination of both approaches be used.

TABLE 83.7. Summary of National Comprehensive Cancer Network (NCCN) antiemetic guidelines.

1. **Highly emetogenic chemotherapy (level 5)**
 - Aprepitant (NK-1 antagonist) pre- and postchemotherapy **AND**
 - Dexamethasone pre- and postchemotherapy **AND**
 - 5-HT₃ inhibitor pre- and postchemotherapy
 - ± Benzodiazepine if needed
2. **Moderately emetogenic chemotherapy (level 3–4)**

Day 1

 - Dexamethasone **AND**
 - 5-HT₃ inhibitor **OR**
 - 5-HT₃ inhibitor
 - ± Benzodiazepine if needed
 - ± Aprepitant if needed

Days 2–4

 - Dexamethasone **OR**
 - 5-HT₃ inhibitor pre- and postchemotherapy **OR**
 - Metoclopramide ± diphenhydramine **OR**
 - Aprepitant **AND** dexamethasone
 - ± Benzodiazepine if needed
3. **Low emetogenic potential chemotherapy (level 2)**
 - a. Dexamethasone prechemotherapy **OR**
 - b. Phenothiazine as needed **OR**
 - c. Metoclopramide + diphenhydramine as needed
 - d. ± Benzodiazepine as needed
4. **Minimal emetogenic potential chemotherapy (level 1)**
 - a. No prechemotherapy emesis prevention
 - b. Use phenothiazines/metoclopramide/benzodiazepines as needed

Source: NCCN Antiemesis Practice Guidelines in Oncology. Version 1.2004, 03-30-04. National Comprehensive Cancer Network; 2004. Available at <http://www.nccn.org>. Accessed April 10, 2004.

87 patients. Patients in the low-risk group were randomly assigned to receive placebo, dexamethasone (4 mg po bid), or ondansetron (8 mg po bid) plus dexamethasone on days 2 to 5 after chemotherapy. The high-risk patients were randomly assigned to receive oral dexamethasone only or dexamethasone plus ondansetron at the same doses given in the low-risk group. In the low-risk group, 92% of those receiving combined treatment (dexamethasone and ondansetron) had complete protection from significant delayed CINV; 87% of those who received dexamethasone only, and 77% of the placebo group, achieved complete protection. For the patients in the high-risk group, 41% of those treated with ondansetron and dexamethasone achieved complete protection, whereas only 23% using dexamethasone alone had complete protection. Nonetheless, the results in the high-risk group were not statistically significant. What this study suggested, above all else, is that the best way to prevent delayed CINV with moderately emetogenic chemotherapy regimens is to control acute CINV.

PALONOSETRON

As noted previously, palonosetron is the newest approved 5-HT₃ receptor antagonist. When compared to dolasetron and ondansetron in prospective clinical trials, a single prechemotherapy dose of palonosetron was more effective at decreasing delayed CINV.^{41,56} These trials have been criticized, however, as no corticosteroids were routinely utilized.

However, palonosetron was recently approved by the FDA for the prophylaxis of delayed nausea and vomiting associated with initial and repeated courses of moderately emetogenic chemotherapy.

NEUROKININ 1 ANTAGONISTS

In March 2003, the FDA approved aprepitant, a neurokinin 1 antagonist, for the prevention of acute and delayed nausea and vomiting associated with highly emetogenic chemotherapy. The implication of neurokinin, substance P, in the pathogenesis of acute and delayed CINV led to the development of aprepitant, a novel neurokinin 1 antagonist that demonstrated antiemetic activity in humans receiving chemotherapy. Early trials conducted in the late 1990s demonstrated the high clinical efficacy of neurokinin receptor blockage for the prophylaxis of acute and delayed emesis associated with highly emetogenic chemotherapy.^{57,58} Subsequently, Campos et al. demonstrated, in a multicenter, double-blind, parallel group trial, that once-daily oral administration of aprepitant was effective in reducing delayed nausea and vomiting after high-dose cisplatin⁴⁶; 351 patients receiving high-dose cisplatin chemotherapy were divided into four groups (I–IV). Group I received an oral placebo on day –1 (the evening before cisplatin), granisetron (10 µg/kg IV) prechemotherapy, and an oral placebo days 2 to 5 after cisplatin; group II received an oral placebo on day –1, granisetron (10 µg/kg) IV and aprepitant (400 mg po) prechemotherapy, and aprepitant (300 mg po qd) on days 2 to 5. Group III received aprepitant (400 mg po) on day –1, an intravenous placebo and aprepitant (400 mg po) prechemotherapy, and aprepitant (300 mg po qd) on days 2 to 5; and group IV received an oral placebo on day –1, an intravenous placebo and aprepitant (400 mg po) prechemotherapy, and aprepitant (300 mg po qd) on days 2 to 5. All groups received dexamethasone 20 mg po precisplatin. Results showed that, in the delayed-period groups I, II, III, and IV, 27%, 63%, 51%, and 57%, respectively, had no emesis and minimal nausea (*P* less than 0.01). The overall conclusion was that once-daily oral administration of aprepitant was effective in reducing delayed nausea and vomiting after high-dose cisplatin. This study also showed that the triple combination of a 5-HT₃ antagonist, aprepitant, and dexamethasone provided superior control of acute emesis.

Poli-Bigelli et al. reported remarkably similar results in a randomized, double-blind, placebo-controlled trial conducted in Latin America,⁴⁵ in which 523 patients receiving high-dose cisplatin were randomized to one of two regimens: standard therapy (ondansetron 32 mg IV, dexamethasone 20 mg po day 1 and 8 mg po bid days 2–4) or standard therapy plus aprepitant (125 mg po day 1, 80 mg po days 2–3). Complete protection from delayed CINV was achieved in 68% of the aprepitant group, compared to 47% with standard therapy (*P* less than 0.001). Similar results were seen with acute CINV, with 83% completely protected in the aprepitant group versus 68% with standard therapy (*P* less than 0.001). Although optimal dosage and schedule have yet to be determined, NK-1 antagonists, such as aprepitant, appear very promising for the prevention of acute and delayed CINV. Aprepitant is the only NK1 antagonist approved for treatment of CINV. However, other NK1 antagonists are being investigated: L-758,298, a prodrug of aprepitant, CP-122,721, and CJ-11,974 all appear promising in Phase I and Phase II trials.

Although aprepitant is being incorporated into clinical practice in some settings, the cost of hundreds of dollars for a single course has limited a more universal acceptance of this therapeutic addition. The eventual role for this therapy in antiemetic guidelines has yet to be determined.

Treatment of Anticipatory Nausea and Vomiting

Although acute and delayed nausea and vomiting are direct effects of the chemotherapy drugs used, anticipatory nausea/vomiting is not, making standard antiemetics ineffective. Given that a major risk factor for the development of anticipatory nausea/vomiting is poor control of nausea/emesis with prior treatments, prevention is the key. Appropriate antiemetic regimens used to decrease acute and delayed CINV should also decrease the risk of anticipatory nausea/vomiting with subsequent cycles.

ANXIOLYTICS

A double-blind, placebo-controlled study by RAZIVI et al. compared alprazolam versus placebo in 57 breast cancer patients.⁵⁹ Despite a much higher occurrence of anticipatory nausea/vomiting (18% versus 0%) in the placebo arm before the third treatment, this difference was not maintained with a subsequent treatment cycle. Thus, although anxiolytics may appear to help individual patients with anticipatory nausea/vomiting, its usefulness should be evaluated on a case-by-case basis.

Aside from prevention, behavioral therapies are the mainstay of treatment for anticipatory nausea/vomiting. Systemic desensitization has been shown to be very effective in managing this problem. This technique is covered in detail in a subsequent section titled Unconventional Therapies for Nausea and Vomiting.

Radiation-Associated Nausea and Vomiting

Incidence, Etiology, and Predictive Factors

Nausea and vomiting in patients receiving radiation therapy is, in general, less problematic than that associated with chemotherapy but also less predictable. As with CINV, the exact mechanism by which patients receiving radiation develop nausea or vomiting is unclear. It has been postulated to be a combination of direct mucosal injury and neurotransmitter release, specifically, serotonin.⁶⁰

Whether antiemetics should be given on a preventive basis at the initiation of radiation therapy, versus as needed if nausea or vomiting becomes a problem, depends on the emetogenic potential of the radiation therapy being given. The major determinants of the emetogenicity of radiation appear to be irradiation site, dose, dose rate, and field size. Of these, the site plays the largest role predicting for the onset, peak, and duration of nausea and/or vomiting. Total-body irradiation carries the highest risk, with 90% developing nausea and 80% vomiting within 40 to 90 minutes.⁶¹ Intermediate-risk sites include hemibody irradiation (40%–83%) and radiation therapy to the upper abdomen (50%). Abdomen-pelvis, mantle, craniospinal, and cranial radiation therapy appear to cause nausea and vomiting in 40% to 50% of recipients. Single-port irradiation of the extremities, cranium,

breast, head and neck, pelvis, and thorax carries the lowest risk of nausea and vomiting.^{4,11}

Relative to dose functions, radiation delivered as a single high dose has more emetogenic potential than do smaller, fractionated doses. Higher dose rates and larger field size also carry increased risk, as does chemotherapy given immediately before, or concurrent with, radiation.

Treatment of Radiation-Associated Nausea and Vomiting

As with CINV, antidopaminergic agents were the mainstay of treatment, before the advent of 5-HT₃ antagonists. The use of metoclopramide or chlorpromazine for radiation-induced nausea and/or vomiting (RINV) produced response rates of only 50%. Cannabinoid derivatives were also tried with similar results.⁶²

In 1990, Priestman et al. performed a prospective, double-blind, randomized trial comparing ondansetron to metoclopramide for the prevention of nausea and vomiting in patients receiving high-dose upper abdominal irradiation.⁶³ Complete control was achieved in 97% of patients receiving ondansetron (8 mg po tid) versus 47% with metoclopramide (10 mg po tid). Several studies have shown 5-HT₃ receptor antagonists (ondansetron, granisetron) to be superior to placebo for treating radiation-induced nausea/vomiting related to total-body irradiation or upper abdominal radiation.^{64,65} However, there have been few studies comparing different antiemetic regimens or the role of nausea/vomiting prophylaxis in patients receiving intermediate- or low-risk radiotherapy.⁶⁶ In 2000, the National Cancer Institute of Canada Clinical Trials Group, performed a Phase III study investigating the efficacy of dexamethasone for radiation-induced emesis (RIE).⁶⁷ In this study, 150 patients receiving radiotherapy to the upper abdomen were accrued and randomized to dexamethasone (2 mg po tid) versus placebo; 70% of patients in the dexamethasone arm had complete protection from radiation-induced vomiting versus 49% of those receiving placebo. Recently, Matsuoka et al. performed a small, prospective randomized study comparing granisetron plus dexamethasone versus granisetron alone in the prevention of vomiting caused by stem cell transplant conditioning regimens.⁶⁸ For patients receiving total-body irradiation on day 1 of conditioning, complete emetic control was achieved in all patients (100%) in the granisetron plus dexamethasone group, compared with 63% in the granisetron only group ($P = 0.02$).

Current guidelines suggest using serotonin receptor antagonists (ondansetron 8 mg po bid-tid or granisetron 2 mg po qd), with or without corticosteroids, for patients receiving total body irradiation. For those in the intermediate-risk category, dexamethasone, serotonin, or dopamine receptor antagonists are recommended before each fraction. For patients receiving radiation to low-risk areas, antiemetics are suggested for use on an as-needed basis only.^{7,8,11,40}

Nausea and Vomiting in Patients with Advanced Cancer: A Common Problem

Independent of cytotoxic therapy and radiation therapy, patients with advanced incurable cancer can have prominent problems with nausea and vomiting. An illustration of this

situation became apparent in a clinical trial that evaluated megestrol acetate versus a placebo for patients with cancer anorexia/cachexia.⁶⁹ In this clinical trial, patients were asked whether they perceived nausea or vomiting to be problems that they attributed to the study medication that they were receiving. In reply to this question, 38% of the placebo recipients blamed nausea on the placebo they were taking (while they were blinded as to what they were receiving). Additionally, 25% of the respondents blamed vomiting on the placebo they were receiving. Another group of investigators, also evaluating megestrol acetate versus placebo, noted a similarly high instance of nausea and vomiting in these patients.⁷⁰ This latter group of investigators asked the patients about nausea and vomiting before starting any study medication and then after they were receiving study medications. They noted a similar high incidence of nausea and vomiting in patients before and after they started taking placebos. The conclusions of these investigators were that nausea and vomiting were common clinical problems in patients independent of anti-cancer treatments. The effect of megestrol acetate on nausea and vomiting in these two trials is described in a subsequent paragraph.

Etiology

The etiology of nausea and vomiting in patients with advanced incurable cancer is multifactorial. One of the causes relates to gastrointestinal structural changes, including tumor impingement and bowel obstruction. In addition, multiple electrolyte abnormalities, brain metastases, and multiple medications (including narcotics) can be responsible for causing nausea and vomiting. It is possible also that the tumor itself releases yet undefined substances that lead to nausea and vomiting in these patients.

Treatment of Nausea and Vomiting Related to Advanced Cancer

Remarkably little has been done to evaluate potential treatments for nausea and vomiting, independent of chemotherapy- or radiation therapy-induced causes, in patients with advanced incurable cancer. Nonetheless, the most obvious thing to do is to try to treat the underlying cause of the nausea and vomiting. Unfortunately, oftentimes this is not very feasible. If underlying causes have been treated as effectively as possible (for example, treatment of brain metastases, hypercalcemia, and/or bowel obstruction), there are some dietary suggestions that can be provided, including the intake of frequent small feedings, as opposed to less frequent larger meals. In addition, it has been recommended to keep patients away from food odors, as these may induce nausea. These dietary recommendations, however, have not been properly studied, and any clinician can relate that they have limited efficacy overall.

Medications that have been commonly utilized to treat such nausea and vomiting in patients with advanced incurable cancer, include prochlorperazine and haloperidol. Theoretically, dexamethasone may also have a role in this situation. However, this has not been well studied, and the long-term use of this drug causes its own set of problems.

MEGESTROL ACETATE

One medication that is not well appreciated as being an antiemetic in this situation is megestrol acetate. In the two noted trials described previously,^{69,70} significantly reduced incidences of nausea and vomiting were seen with megestrol acetate compared to placebos. In one of these trials, the incidence of nausea was 38% in placebo-receiving patients versus 13% in those receiving megestrol acetate ($P = 0.001$).⁶⁹ Correspondingly, the incidence of vomiting was 25% in placebo-receiving patients versus 8% in those receiving megestrol acetate ($P = 0.009$). Similar numbers were observed in the other trial.⁷¹ Additionally, another trial also demonstrated that patients randomized to receive megestrol acetate had significantly less trouble with nausea and vomiting than did patients receiving a placebo.⁷² Thus, megestrol acetate is a reasonable recommendation for attempting to control nausea and vomiting in this situation. Although these three described trials examined doses of 800 to 1,600 mg/day provided as tablets, it appears reasonable to utilize liquid megestrol acetate doses of 160 to 400 mg/day. The liquid preparation is a more bioavailable preparation and is more economically priced.

SEROTONIN RECEPTOR ANTAGONISTS

Interestingly, there have not been good data to establish the pros and cons of using serotonin receptor antagonists for nausea and vomiting associated with advanced malignancies in this situation. Anecdotal reports have suggested that serotonin receptor antagonists may provide reduction or relief of nausea and vomiting, unrelated to chemotherapy or radiation therapy, in patients with advanced cancer.⁷³⁻⁷⁷ Anecdotal information also suggests that the use of serotonin receptor antagonists may provide benefit in treating chronic nausea and vomiting in patients without advanced cancer.⁷⁶⁻⁷⁸ Nonetheless, anecdotal reports can be fraught with error, and no placebo-controlled study has been successfully performed to assess the efficacy of serotonin receptor antagonists in patients with advanced cancer who have chronic nausea and vomiting unrelated to chemotherapy. This lack of success is not from lack of effort, as the North Central Cancer Treatment Group (NCCTG), for example, developed a placebo-controlled, double-blind trial to address this question, but it was closed for lack of patient accrual.

Factors speaking against the use of chronic 5-HT₃ receptor antagonists in patients with nausea and vomiting from advanced cancer are that these agents do not appear to work very well for delayed nausea and vomiting from chemotherapy, as opposed to their substantial benefit in ameliorating chemotherapy-induced acute nausea and vomiting. In addition, these medications are quite expensive and do have their own set of side effects (mostly headache and constipation), as discussed previously. If such medications are started, some patients will consider them to have some efficacy. However, in clinical practice it is very difficult to determine whether a medication, such as this, is having a placebo effect versus being an effective antidote.

METOCLOPRAMIDE

Pilot trials have suggested that prokinetic agents, such as metoclopramide might reduce chronic nausea in patients

with advanced cancer.^{71,79,80} In follow-up to this, one small double-blind crossover, placebo-controlled trial of metoclopramide was conducted for patients with chronic nausea and dyspepsia associated with advanced cancer.⁸¹ This trial entered 26 patients, 20 of whom were evaluable, to study a controlled-release dose of metoclopramide (40 mg bid). Patients were treated for 4 days with metoclopramide versus placebo and then crossed-over to the alternative regimen on the subsequent 4 days. This trial reported that the patients receiving metoclopramide had a very modest reduction in nausea (12 ± 10 on a 100-point visual analogue scale versus 17 ± 12 ; $P = 0.04$). However, no reduction in vomiting was seen, and there was no reduction in the use of rescue medications for nausea or vomiting. The small size of this clinical trial, the borderline statistical results regarding nausea, and the lack of any effect on vomiting, provide suggestive evidence that metoclopramide, in this dosage, might be helpful in patients with chronic cancer-associated nausea. Further work is necessary to better confirm or refute this contention.

OTHER AGENTS

There is no information available concerning the use of NK1 receptor antagonists in this situation. Last, there is some information to suggest that somatostatin analogue therapy may be of some value in patients with nausea and vomiting related to a small bowel obstruction that is not surgically approachable.⁸² However, better information regarding its use in this situation is needed.

Cost-Effective Management of Nausea and Vomiting

In the early 1990s, 5-HT₃ receptor antagonists were the highest ticket drug item in many oncology practices because they were relatively expensive medications that were used across a wide variety of chemotherapy agents. Chemotherapy drugs themselves were a bit less expensive at that time compared to the prices of some chemotherapy drugs used today.

In addition to being a high-cost item, there was tremendous variation in practice, regarding the use of antiemetics, within and between different oncology groups. The high cost of these drugs, and the variation in their use, led to the development of guidelines by some large group practices.⁹ Guidelines were subsequently developed by different associations, such as the American Society of Clinical Oncology (ASCO), American Society of Health-System Pharmacists (ASHP), and National Comprehensive Cancer Network (NCCN) (see Tables 83.5, 83.6, and 83.7).^{8,11,40} These guidelines provide an algorithm for the utilization of antiemetics based on the emetogenic potential of different chemotherapeutic agents and regimens. Ideally, such guidelines provide for the relatively automated use of the different antiemetic regimens for chemotherapy treatments of similar emetogenic potential. When developed, these guidelines need to be updated at regular intervals as new information, and new agents, become available.

Unconventional Therapies for Nausea and Vomiting

The use of unconventional therapies for the control of cancer-related symptoms has gained increased acceptance over the past several decades. Rather than remaining on the medical fringe, interventions, such as acupuncture, massage, and hypnosis, are making their way into mainstream health care. Increasing patient and physician interest in unconventional supportive treatments created the need for randomized studies investigating their merit. In 2001, Vickers and Cassileth published a review of unconventional therapies for cancer-related symptoms.⁸³ In this, they made the important distinction between “alternative medicine” and “complementary medicine.” The former was defined as “those commonly promoted for use instead of, rather than as an adjunct to, mainstream therapy,” whereas complementary therapies were those “used together with mainstream care for management of symptoms to improve quality of life.” The advantages of alternative therapies remain largely unproven and, therefore, are not discussed in this text. However, many complementary therapies have been investigated in well-designed clinical trials and are of proven benefit.

Hypnosis

Hypnosis has been an area of interest for decades. It has been used for smoking cessation, phobia management, and anxiety. Its utility in the treatment of nausea and vomiting in cancer patients has been well described, mainly in children and adolescents.⁸⁴ Redd et al. describe it as a self-control technique, in which patients learn to invoke a physiologic state incompatible with nausea and/or vomiting.⁸⁵ With this method an altered state of consciousness is induced, followed by total-body relaxation. In this relaxed state patients are asked to visualize events associated with nausea/vomiting. The goal is teaching patients to relax despite the presence of anxiety-provoking stimuli.

Systematic Desensitization

Systematic desensitization, a subcategory of hypnosis, appears to be particularly effective in the management of anticipatory nausea and vomiting.^{86,87} The mainstay of this intervention is construction of a hierarchy of events related to the known stimulus, that is, chemotherapy.⁸⁴ To conduct this therapy, patients describe triggers for anticipatory nausea/vomiting and rank them from strongest to weakest triggers. A relaxed state is then induced, after which the patients use guided imagery to imagine the nausea-inducing situations. They are asked to start at the bottom of the list, with the least threatening trigger, and remain relaxed while picturing the scene. As the intensity of the triggers increases, the patients concentrate on remaining relaxed. Systematic desensitization can be taught to patients in about 20 minutes. Properly trained nurses and oncologists can be as effective instructors, as are behavioral consultants.⁸⁴ The goal of systematic desensitization is to create a sense of relaxation using guided imagery that can be accessed when patients encounter the actual trigger.

ACUPUNCTURE

Acupuncture may be the most well-studied complementary therapy for cancer- or chemotherapy-related nausea and vomiting. In 1996, Vickers performed a systematic review of acupuncture for nausea and emesis related to chemotherapy, pregnancy, or anesthetics. In that review, 11 of 12 placebo-controlled, randomized, double-blind studies showed benefit with acupuncture.⁸⁸ More recently, Shen et al. showed, in a randomized controlled trial, significant benefit in the use of electroacupuncture for control of myeloablative chemotherapy-induced emesis.⁸⁹ In the review by Vickers and Cassileth, they cited 16 clinical trials investigating potential benefits of acupuncture as a complementary therapy for nausea and vomiting. Of these, 11 found “significant differences or trends in favor of acupuncture.”⁸³ Therefore, at institutions where this therapy is available, acupuncture is reasonable to try.

Conclusion

Despite our best efforts, nausea and vomiting in cancer patients continue to challenge us. Those receiving chemotherapy and radiation are most certainly affected, as are patients with advanced malignancies. We are able to control this problem, to some degree, with medications and other therapeutic interventions. However, we are far from solving it. As oncologists, one of our ever-present goals is to relieve our patients’ symptoms related to cancer and its treatment. As our ability to do this improves, so too, should the quality of our patients’ lives.

Nutritional Support for the Cancer Patient

Lawrence E. Harrison

Cancer cachexia is a complex syndrome clinically manifested by progressive involuntary weight loss and diminished food intake and characterized by a variety of biochemical alterations. Importantly, cancer cachexia has been associated with increased morbidity and mortality and decreased response to therapy. The impact of cancer cachexia on patient outcome and healthcare resources continues to be significant. It is therefore important to identify those cancer patients who are malnourished in an attempt to reverse or at least abate the progression of malnutrition. The goal of nutritional supplementation is to translate repletion into clinical benefit, thereby decreasing morbidity or mortality and increasing the response rate to treatment. The focus of this chapter is to review the etiology of cancer cachexia, summarize the biologic and clinical effects of nutrition, define specific indications for nutrition in the cancer patient population, and explore new therapies available to reverse cancer cachexia.

Prevalence and Clinical Implications of Malnutrition in the Cancer Patient

Cancer patients are at high risk for malnutrition, and cachexia is often a presenting manifestation of malignancy. As early as 1932, cancer cachexia was noted to be a common syndrome. In an autopsy series of 500 cancer patients, Warren reported that the immediate cause of death was inanition in 22%, and that as many as two-thirds of these cancer patients exhibited some degree of cachexia.¹ The predictive nature of outcome from wasting and malnutrition associated with malignancy has been well documented. In a large series, 3,047 patients that were enrolled in 12 Eastern Cooperative Oncology Group (ECOG) chemotherapy protocols for a variety of tumor types, were assessed for weight loss before initiation of chemotherapy. Survival was significantly shorter in patients who demonstrated weight loss compared with those who had not lost any weight before chemotherapy treatment.²

In addition to the presence of cancer, the type and stage of malignancy is an important determinant for weight loss. In the ECOG study, patients with breast cancer, acute non-lymphocytic leukemia, sarcomas, and favorable subtypes of non-Hodgkin's lymphoma, had the lowest frequency of weight loss (31%–40%), whereas those with colon cancer, prostate cancer, lung cancer, and unfavorable non-Hodgkin's lymphoma, presented with an intermediate frequency of weight loss (48%–61%). Patients with pancreatic and gastric

cancer had the highest frequency of weight loss (83%–87%), with about one-third having greater than 10% weight loss³ (Table 84.1). In a prospective study of 280 cancer patients, malnutrition was related mainly to the type and site of the tumor, with stomach and esophageal cancer patients demonstrating significant malnutrition as compared with other groups. As expected, malnutrition became more severe as the disease advanced.³ In an additional study of gastrointestinal cancer patients, almost one-half of the 365 patients were determined to be malnourished, and the incidence of malnutrition was related to site of disease. Stage also predicted weight loss, with more than 50% of stage III patients manifesting malnutrition.⁴

Assessment of Malnutrition

Malnutrition has been associated with increased morbidity and mortality, and therefore, assessment of treatment risk should include a nutritional evaluation. Clinical assessment is the simplest method of nutritional evaluation. The usefulness of a good history and physical examination in this regard cannot be overstated. Prior medical history provides clues to nutritional deficiencies. For example, previous gastrectomy may lead to dumping syndrome, diarrhea, or folate insufficiency, whereas ileal resection or chronic pancreatitis may be associated with steatorrhea and deficiencies in fat-soluble vitamins. A history of alcoholism is associated with protein-calorie malnutrition as well as deficits in niacin and zinc. A history of perioperative chemotherapy or radiation treatment may indicate a malnourished state. A careful review of systems should focus on recent weight loss, weakness, fatigue, and anorexia. Gastrointestinal symptoms, such as nausea, vomiting, abdominal pains, diarrhea, melena, and dysphagia, may also provide insight in determining the presence and magnitude of malnutrition.

The physical examination should include overall appearance, noting muscle and fat wasting. Although muscle wasting is commonly associated with protein-calorie malnutrition, most patients are not overtly emaciated, and evaluation of muscle atrophy may be more readily appreciated in the hypothenar muscles of the hand and the muscles of facial expression. Other indicators of malnutrition include loss of subcutaneous adipose tissue, peripheral edema, skin lesions, and loss of skin turgor.

Weight loss has been shown to be an important index of the presence, severity, and progression of malignancy. The

TABLE 84.1. Incidence of weight loss and effect on survival.

importance of weight loss was noted early in the classic study of Studley, who reported that patients who had lost more than 20% of their body weight before surgery for peptic ulcer disease had a higher operative mortality.⁵ Although body weight is the most commonly used anthropometric measurement, its interpretation as a sole indicator of malnutrition should be tempered. Weight is highly dependent on the hydration status of the patient and offers no information about the composition of the individual compartments of the body.

Laboratory measurements may provide additional insight for the diagnosis and extent of malnutrition. Albumin is the most commonly used laboratory parameter to evaluate malnutrition. Multiple studies associate increased morbidity and mortality in patients with decreased serum albumin levels.^{6,7} The use of albumin as a nutritional index is limited by the fact that (1) use of albumin levels as an indicator of visceral protein synthesis assumes steady-state synthetic rates, which is not the case during acute illness; (2) the long half-life makes it a poor marker to follow acute nutritional changes; (3) reduced serum levels are seen with multiple conditions besides malnutrition; and (4) serum levels are changed by altering hydration status and redistribution. Nevertheless, albumin levels remain the most frequently used index of visceral protein synthesis because this test is widely available and relatively inexpensive.

The diagnosis of malnutrition is based generally on subjective and objective measurements of nutritional status already described, including history of appetite, weight loss, changes in body weight, and serum albumin levels. Although these indicators are useful, alone they do not have significant predictive value for malnutrition and, more importantly, patient outcome with treatment. Based on the unsatisfactory performance of any single assessment value to determine outcome with malnutrition, attention has been turned to combinations of nutritional assessment values to improve the sensitivity and specificity. Various nutritional indices have been examined with the goal of identifying these malnour-

ished patients. Buzby et al. developed a linear predictive model that related nutritional status with risk of operative morbidity or mortality that was based on a variety of parameters from 161 patients undergoing elective general surgery procedures. Using multivariate analysis, the authors developed a weighted combination of four prognostic factors that predicted the risk of operative mortality and morbidity. The index, termed prognostic nutritional index (PNI), is defined as

$$\text{PNI}(\%) = 158 - 16.6 (\text{ALB}) - 0.78 (\text{TSF}) \\ - 0.20 (\text{TFN}) - 5.8 (\text{DH})$$

where ALB is serum albumin level (g/100mL), TSF is triceps skinfold (mm), TFN is serum transferrin level (mg/100mL), and DH is cutaneous delayed-type hypersensitivity reactivity to any three recall antigens graded as 0 (nonreactive), 1 (less than 5mm induration), or 2 (5mm or more induration). Patients determined to be high risk have a PNI of 50% or more, those of intermediate risk, 40% to 49%, and low-risk patients, less than 40%. In the subsequent validation of this model, 62% of the 100 patients undergoing similar procedures were determined to be intermediate- or high-risk patients and 89% of these ultimately developed complications. Of note, 27 of the 44 cancer patients (61%) studied were either intermediate or high risk.⁸ Subsequently, Buzby et al. also reported the nutritional risk index (NRI), which is derived from the serum albumin and the ratio of actual to usual weight:

$$\text{NRI} = 1.519 (\text{serum albumin, g/dL}) \\ + 41.7 (\text{present weight/usual weight})$$

where an NRI greater than 100 indicates that the patient is not malnourished, 97.5 to 100 means mild nutrition, 83.5 to 97.5 relates to moderate malnutrition, and less than 83.5 means severe malnutrition.⁹

Nutritional status is conventionally assessed by a means of a combination of anthropometric and laboratory measure-

ments. Clinically, these methods, such as skin-fold thickness, are time consuming and not readily available. To address this issue, the Subjective Global Assessment (SGA) was developed, which provided a clinical score based on a standardized questionnaire concerning food intake and complaints, such as weight change, gastrointestinal symptoms, edema, ascites, and performance status. Based on these data, patients are classified as well nourished (SGA-A) or mildly (SGA-B) or severely malnourished (SGA-C). Importantly, this tool does not use any anthropometric measurements or laboratory tests.¹⁰ SGA has been validated in surgical patients, and a modified form has been developed for use in cancer patients.^{11,12} In addition to the scores already described, a variety of other indices, including the Gassull classification, Mini Nutritional Assessment, and Instant Nutritional Assessment, have also been reported.¹³⁻¹⁵ Currently, there is no consensus on the best method for assessment of nutritional status. However, the use of clinical scores may assist in the detection of malnourished patients, and clinical scores are probably more accurate than any single nutritional parameter.

In summary, all cancer patients being evaluated for treatment should have evaluation of nutritional status. By whatever means, it is important to assess and identify all patients who are at risk for malnutrition. Although there is no single parameter that distinguishes the depleted patient, combinations of parameters, incorporating the previously mentioned techniques, are useful in defining this patient population.

Mechanisms of Cancer Cachexia

Host tissue depletion is dependent on the imbalance between nutrient intake and metabolic demands of the host and tumor. Although diminished food intake is one feature of cancer cachexia, nutrients must also transgress the gastrointestinal tract into the portal system and ultimately be utilized

systematically to maintain host body mass. Alterations in food intake, absorption, and nutrient utilization ultimately lead to cachexia (Figure 84.1).

Abnormalities in Host Metabolism

Although anorexia is a component of cancer cachexia, restoration of caloric intake does not reverse these alterations. The tumor-bearing state is often associated with abnormalities in energy, protein, carbohydrate, and fat metabolism, and therefore, additional factors must be involved. Although increased nutrient demand by the tumor mass has been suggested as a contributing mechanism, tumor substrate consumption is rarely significant enough to account solely for host weight loss and metabolic alterations (Table 84.2).

Alterations in Protein Metabolism

It has been hypothesized that tumors act as "nitrogen sinks," depleting the host of protein mass, resulting in characteristic alterations in protein metabolism. This tumor avidity for nitrogen accompanies cancer cachexia and involves alterations in whole-body, liver, and skeletal muscle protein metabolism. In general, although whole-body and hepatic protein synthesis is elevated, muscle protein synthesis is depressed. This pattern is unlike simple starvation, where liver and muscle protein synthetic rates are decreased. Tumors derive protein at the expense of the host, resulting in an increased whole-body protein turnover. With few exceptions, whole-body protein turnover, synthesis, and catabolism have been reported to be elevated in both weight-stable and weight-losing cancer patients. Jeevanandam and colleagues compared whole-body protein kinetics in malnourished cancer patients with malnourished patients with benign disease, and with starved normal controls. They found whole-

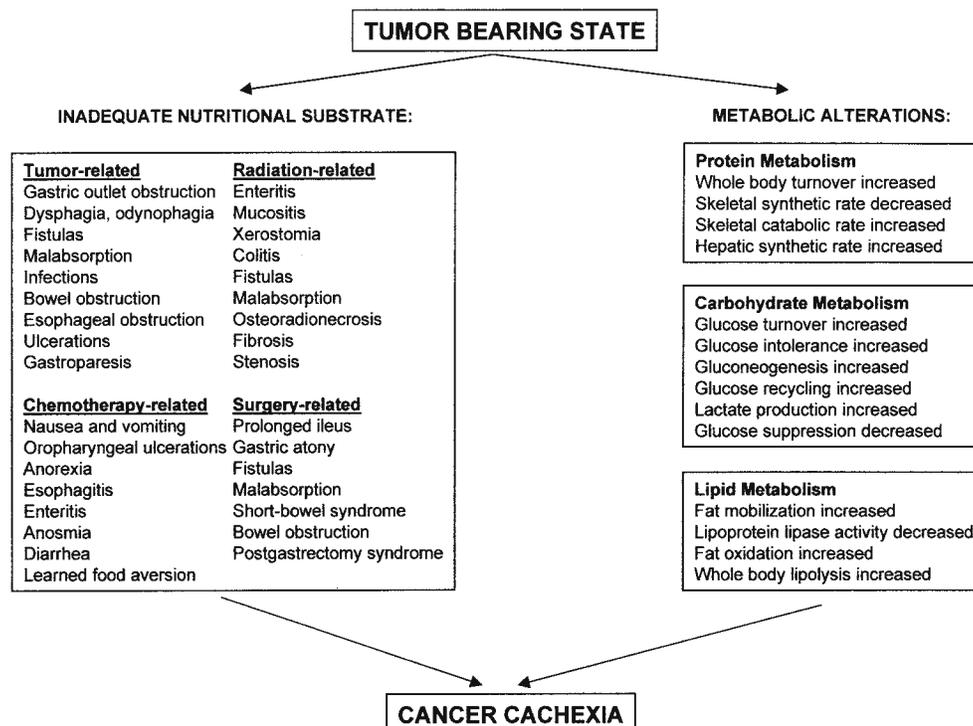

FIGURE 84.1. Inadequate nutritional substrate and metabolic alterations can lead to cachexia.

TABLE 84.2. Metabolic effects of malignancy.

Metabolic component	Parameter	Effect	Reference
Energy expenditure	Resting energy expenditure	±	66, 133–140
Protein metabolism	Whole-body turnover	↑	26, 141–144
	Skeletal synthetic rate	↓	145
	Skeletal catabolic rate	↑	145
	Hepatic synthetic rate	↑	16, 146–148
Carbohydrate metabolism	Glucose turnover	↑	149, 150
	Glucose intolerance	↑	151, 152
	Gluconeogenesis	↑	153
	Glucose recycling	↑	17, 154–157
	Lactate production	↑	21
	Glucose suppression	↓	22, 23, 24, 150
Lipid metabolism	Fat mobilization	↑	20, 158
	Lipoprotein lipase activity	↓	18, 152, 159
	Fat oxidation	↑	19, 140
	Whole-body lipolysis	↑	158

body protein turnover to be 32% and 35% higher in the cancer patients compared to those with benign disease and starvation, respectively. In addition, the rate of protein synthesis was 35% and 54% higher in the cancer group compared to those with benign disease and normal starved controls.¹⁶ Depression of muscle protein synthetic rates and overall muscle wasting is commonly seen in cancer patients. Comparing rectus abdominus muscle biopsied from a heterogeneous group of 43 cancer patients with 55 age- and sex-matched controls, Lundholm demonstrated a decreased rate of protein synthesis and increased rate of protein catabolism.¹⁷

Carbohydrate Metabolism

The literature is replete with evidence documenting alterations of carbohydrate metabolism in the cancer patient and is the basis for the ability of positron emission tomography (PET) scans to detect malignancy. The changes seen are similar to a type II diabetic state, but also share elements similar to the stress state. Specifically, these abnormalities include the following:

1. Increased hepatic glucose production^{18,19}
2. Decreased skeletal muscle glucose utilization²⁰
3. Increased tumor glucose utilization with increased lactate production²¹
4. Increased glucose recycling (Cori cycle)^{22–25}

Cancer patients, similar to diabetic patients, have a 25% to 40% increase in hepatic glucose production compared to normal controls. However, in contrast to diabetics, cancer patients continue to produce increased hepatic glucose in the face of starvation. The mechanism for this increased glucose production has been implicated as either upregulation of gluconeogenic enzyme activity or increased availability of gluconeogenic precursors, such as alanine, lactate, and glycerol.

The tumor-bearing state is also associated with reduced suppression of endogenous hepatic glucose production by adequate glucose availability. In normal volunteers, a glucose infusion completely suppresses endogenous glucose production. However, in patients with advanced gastrointestinal cancers, gluconeogenesis is suppressed only 70%. Patients with sarcoma and leukemia demonstrate approximately 30% suppression of hepatic glucose production. Most solid tumors produce large amounts of lactate, which is subsequently con-

verted to glucose in the liver through the Cori cycle. Gluconeogenesis from lactate is a very energy inefficient pathway, and this futile cycle may be responsible, in part, for the increased energy expenditure observed in cancer patients.

Lipid Metabolism

Although reduced food intake contributes to the depletion of host fat reserves, alterations in lipid metabolism resulting from tumor burden have also been implicated. Increased fat mobilization has been demonstrated in the cancer patient. The tumor-bearing state is associated with increased lipid mobilization, as well as decreased serum clearance. As a result, hyperlipidemia has been reported to be associated with some tumor types.²⁶ The hypertriglyceridemia associated with the tumor-bearing state is due, in part, to suppression of lipoprotein lipase (LPL).²⁷ LPL is synthesized by adipose and muscle parenchymal cells and is responsible for triglyceride clearance from plasma. In the uncomplicated starved state, LPL is decreased as a result of reduction in insulin levels. In cancer patients, a reduction of LPL activity is seen without a change in insulin levels. Vlassara et al. reported a 35% decreased lipoprotein lipase activity in a group of 28 cancer patients with weight loss while maintaining normal or elevated insulin levels. In addition, the degree of reduction correlated with weight loss.²⁸

Studies in human and animals models provide evidence for a lipid-mobilizing factor (LMF), which is elevated in the tumor-bearing state. An LMF was recently isolated from a cachexia-inducing tumor and from the urine of patients with advanced cancer.^{29,30} This factor acts directly on adipocytes to stimulate lipolysis in a cyclic adenosine monophosphate (AMP)-dependent manner by a mechanism similar to that of lipolytic hormones, and may account, in part, for the lipid metabolic abnormalities observed in cancer patients. Treatment of mice with LMF caused a decrease in body weight that consisted entirely of loss of carcass lipid without any change in food or water intake.³⁰ Another factor, leptin, is a hormone secreted by adipose tissue that appears to play an important role in triggering the adaptive response to weight loss. In addition, leptin acts as a negative feedback signal critical to the normal control of food intake and body weight. Leptin modifies the gene expression and synthetic pathway of both orexigenic (appetite-stimulating) and anorexigenic (appetite-suppressing) mole-

cules in the hypothalamus, thereby controlling adipocyte energy stores. Further studies are needed to elucidate the role of leptin in cancer cachexia.^{31,32}

Routes of Nutritional Support

Nutritional supplementation is an important aspect in the treatment of cancer. Although parenteral nutrition is indicated for patients with nonfunctioning gastrointestinal (GI) tracts, disadvantages of total parenteral nutrition (TPN) include the high cost of parenteral solutions, catheter maintenance, and increased need for absolute sterile technique. In addition, prolonged TPN administration leads to intestinal mucosal atrophy, enterocyte hypoplasia, and decreased intestinal enzyme activity.³³ These changes are associated with a break in the enterocyte barrier, allowing transgression of bacteria and endotoxin into the portal and lymph systems.³⁴ These observations led to the hypothesis that the intestinal tract is a source of sepsis in the critically ill patient, and there are data to support that TPN is associated with higher rates of infection in certain patient populations.^{35,36}

Therefore, enteral feeding, when possible, is the preferred route of nutrition. Enteral feeds, either by oral supplementation or tube feedings, are less costly, easier to maintain, and are more physiologic. Luminal nutrient in the small bowel maintains normal villous architecture and function. Enteral feeding also has been reported to decrease infectious complications and sepsis compared to TPN,³⁵ which is most likely the result of maintenance of the enterocyte barrier and splanchnic immune function. Studies have demonstrated that enteral nutrition is superior to TPN in maintaining the host immunologic function. Fong et al.³⁷ demonstrated that endotoxin administered to human volunteers maintained on either TPN or enteral nutrition, resulted in an exaggerated counterregulatory hormone response and hepatic and splanchnic production of TNF in the TPN group. In summary, enteral feeding is at least as efficient as, if not more efficient than, parenteral alimentation in terms of nutritional repletion. Feeding via the gut is cheaper, easier, and offers a method of maintaining intestinal enterocyte integrity. This advantage translates into a decreased incidence of bacterial translocation, affecting on sepsis in a patient population that is already at high risk for infectious complications.

Site-Specific Cancer Therapy and Nutrition

Malnourished cancer patients are at a higher risk for treatment morbidity and mortality compared to well-nourished patients. Although nutrition support has been shown to be important in sustaining patients with "benign" causes of malnutrition, it remains unclear whether feeding of patients with cancer will reduce the morbidity and mortality associated with therapy. A variety of studies have attempted to define the role of nutrition in the cancer patient (Table 84.3).

Head and Neck Cancer

Approximately 40% of patients with advanced head and neck cancers initially present with some form of protein depletion. Although malignancy itself contributes to their malnutrition, they often have an associated history of chronic alcohol

abuse, which places them at an even higher nutritional risk. To compound the problem, treatment of head and neck cancer significantly contributes to the severe malnutrition seen in these patients. Head and neck cancer patients are a high-risk group for malnutrition and are perfect candidates for enteral feeding because the majority of the gastrointestinal tract is not involved by tumor or affected by treatment. Therefore, these patients may be fed enterally, either by small-bore nasogastric tubes or percutaneously placed gastrostomies or jejunostomies. If anatomy does not allow entry into the gastrointestinal tract through an endoscopic route, surgical placement of a gastrostomy or jejunostomy tube is a viable option. Sako et al. prospectively randomized 69 patients with head and neck cancer to either preoperative TPN or enteral tube feeding. Nutritional support was given for 14 days. Nitrogen balance was improved in the TPN group, but they were unable to demonstrate any differences in terms of immune parameters, wound healing, complications, or survival.³⁸ In a report of nutritional supplementation in head and neck cancer patients, Daly et al. compared nasogastric tube feedings versus optimal oral nutrition during radiation therapy. Caloric intake was higher in the tube-fed group, with significant improvement in body weight and normalization of serum albumin at the completion of radiotherapy. However, there was no significant difference in survival between the two groups.³⁹

Esophageal Cancer

Malnutrition is a common finding in patients with esophageal cancer. The malnutrition associated with esophageal cancer is, in part, caused by mechanical obstruction and anorexia, but tumor-dependent metabolic alterations also contribute to the cachexia syndrome.⁴⁰ Therapy associated with esophageal cancer also contributes to worsening nutritional conditions. Radiation may induce esophagitis and subsequently, fibrosis and stricture. Chemotherapy induces nausea, vomiting, and anorexia, which further worsen the patient's nutritional status. Surgical treatments interfere with the normal anatomy and invariably result in decreased food intake. In addition, esophageal anastomotic leak, regurgitation, early satiety, decreased gastric emptying, and diarrhea are common complications and sequelae after surgery. A few studies have attempted to study the effects of nutrition in the esophageal cancer patient. Lim et al. treated a small group of esophageal cancer patients with preoperative gastric tube feeds and reported weight gain after approximately 1 week and a positive nitrogen balance after 5 days. After 4 weeks of nutrition, albumin levels increased 7.4%. However, the TPN group demonstrated a greater weight gain (although this study did not differentiate whether this reflected protein accrual or just water retention) and early positive nitrogen balance.⁴¹ In another study, Burt et al. randomized patients with localized squamous cell carcinoma of the esophagus to three nutritional regimens: oral feeding, jejunal feeding, or TPN. After 2 weeks of therapy, both jejunal feeding and TPN were efficacious in markedly suppressing gluconeogenesis while increasing glucose turnover, pool size, and clearance rate.²⁵ Haffejee studied 20 patients with esophageal carcinoma. Patients were evaluated for nutritional status, as well as immune status 1 week before and 3 weeks after enteral supplementation. After supplementation, the average weight gain was almost 4 kg,

TPN, total parenteral nutrition; BCAA, branched-chain amino acids.

^aRandomized control trial.

nitrogen balance became positive, and serum albumin and total iron-binding capacity were also improved. In addition, both cellular and humoral parameters were improved.⁴² Although the cited studies report improved biologic endpoints, they do not demonstrate improved survival or decreased morbidity associated with supplemental nutrition.⁴³

Pancreatic Cancer

Pancreatic cancer is associated with a high incidence of malnutrition and weight loss. Numerous etiologies are identified. Mechanical impingement of the tumor can result in gastric outlet obstruction with associated nausea and vomiting, and biliary obstruction can cause fat malabsorption and vitamin K deficiency. With these potential mechanical and endocrine problems, it is not surprising that patients with pancreatic cancer often have malnutrition. Unfortunately, there is no evidence to support perioperative nutritional support for patients with pancreatic cancer. Brennan et al. studied a homogeneous patient population undergoing a pancreatic resection, to test the hypothesis that TPN could reduce postoperative morbidity and decrease length of hospital stay in patients with pancreatic malignancy. Pancreatic resection was chosen based on the assumption that the operative pro-

cedure produces a significant catabolic insult with a definable morbidity and mortality that could be ameliorated by TPN. One hundred seventeen patients were randomized to either postoperative TPN ($n = 60$) or IV hydration ($n = 57$). The average preoperative weight loss in this cohort was 6%. Treatment in both groups continued until oral intake exceeded 1,000 kcal/day. Ten patients in the control arm required cross-over to TPN secondary to complications. The authors reported no significant differences in length of hospital stay (16 days for TPN versus 14 days for control), postoperative mortality (7% in TPN versus 2% in control), or overall survival (mean, 24 months). However, the incidence of intraabdominal abscess formation was significantly higher in the TPN group. A trend toward significance in the incidence of peritonitis and intestinal obstruction was also seen in the TPN group.⁴⁴ In summary, the data suggest that perioperative parenteral nutrition may be detrimental, and few data exist examining the efficacy of enteral nutrition in this setting.

Chemotherapy

Chemotherapeutic agents contribute to host malnutrition by a variety of mechanisms, including nausea and vomiting,

mucositis, gastrointestinal dysfunction, and learned food aversions. These effects may compound the already malnourished cancer patient, ultimately influencing the outcome after chemotherapy and leading to increased morbidity and mortality. In addition, increased toxicity from chemotherapy is associated with poor nutritional status of the patient.⁴⁵

Although the impact of malnutrition on survival in cancer patients is well documented, the ability of nutritional intervention to influence clinical outcome in patients undergoing chemotherapy is yet to be defined (Table 84.4). TPN was first suggested by Schwartz et al. to potentially decrease chemotherapy-related toxicity and improve host tolerance.⁴⁶ Early retrospective studies suggested that nutritional repletion might allow patients to undergo chemotherapy with improved results and less morbidity.⁴⁷⁻⁴⁹ These encouraging results prompted prospective, randomized nutrition trials in a variety of malignancies; however, these trials have not demonstrated improved tumor response or longer survival in patients receiving nutritional support.⁵⁰⁻⁵⁵ Summarized in a position paper by the American College of Physicians, a meta-analysis of 12 randomized TPN trials resulted in an odds ratio

for overall survival of 0.81. In other words, patients receiving TPN were only 81% as likely to survive as control patients. For short-term survival (3 months), the odds ratio fell to 0.74. In patients receiving TPN, tumor response rate was 68%. They recommended that "routine use of parenteral nutrition for patients undergoing chemotherapy should be strongly discouraged, and, in deciding to use such therapy in individual patients whose malnutrition is judged to be life threatening, physicians should take into account the possible exposure to increased risk."⁵⁶ Enteral nutrition studies have demonstrated improvement in biologic endpoints in patients undergoing chemotherapy but have not demonstrated any significant improvement in response or survival.

Nutritional support has been shown to affect positively clinical outcome in one particular cancer patient population undergoing chemotherapy. Bone marrow transplantation (BMT) requires intensive chemotherapy, resulting in severe adverse nutritional effects. At least 50% of BMT patients suffer enteritis severe enough to result in protein-losing enteropathy, as well as frequent bouts of mucositis and esophagitis. As a result, these patients seem to benefit from

nutritional support.^{57,58} In a prospective randomized trial, Szeluga et al. randomized 61 patients requiring BMT to either TPN or individualized enteral feed program. Although the enteral feeding program was less effective in maintaining body cell mass, there was no difference in rates of hematopoietic recovery, length of hospital stay, or overall survival between the two groups.⁵⁸ In another randomized, prospective trial, 137 patients were randomized to receive either TPN 1 week before BM transplantation or standard hydration. TPN was continued for 4 weeks after BMT. Overall survival, disease-free survival, and time to relapse were significantly improved in those patients receiving TPN. Average protein and calorie intake was also increased in the TPN group. No differences in engraftment, duration of hospitalization, bacteremia, or graft-versus-host disease were noted. Importantly, 40 of 66 control patients were crossed over to TPN when nutritional depletion was documented, and these patients were still analyzed with the control group.⁵⁹

Nutritional support has not been shown to improve accrual of lean body mass, improve nutritional parameters, or ameliorate chemotherapy-related gastrointestinal and hematologic toxicity. Importantly, randomized trials have not demonstrated an improvement in response rate or overall survival in patients receiving nutritional support during courses of chemotherapy, with the exception of patients undergoing BMT. Based on these data, there is relatively little indication that enteral feedings or TPN have any role as an adjunct for chemotherapy.

Radiation Therapy

In addition to chemotherapy, radiation therapy contributes to the cancer patient's malnourished state. The severity and incidence of malnutrition and weight loss are determined by

the body region undergoing radiation and by dose, duration, and volume of therapy. Retrospective studies have supported the use of nutrition supplementation in patients undergoing radiation, claiming to improve the nutritional state, as well as offering a protective effect against acute and chronic radiation changes. However, there are no randomized prospective studies demonstrating improvement in local control or survival with nutritional support.

There is experimental evidence to support enteral nutrition as a form of prophylaxis against radiation injury.⁶⁰ Bounous reported that elemental nutrition works by suppressing pancreatic and biliary secretions. In addition, he states that it prevents alterations in microvilli, reduction in the enterocyte glycocalyx, and suppression of brush border enzymes.⁶¹ Some of these findings have been reproduced in human trials. McArdle et al. fed 20 patients 3 days before and 4 days during radiotherapy for bladder cancer. All patients underwent cystectomy and ileal conduit. Tube feedings were restarted on the first postoperative day. These patients were compared with treatment-, age-, sex-, and grade-matched historical controls. The authors concluded that the control group had increased amounts of diarrhea, nausea, and vomiting in both the pre- and postoperative period, and that the time for the return of gastrointestinal function was decreased. In addition, histologic examination of biopsy specimens of the terminal ileum in 3 patients who were not fed the elemental diet, demonstrated moderate to severe radiation damage compared to those receiving enteral feedings, who demonstrated normal morphologic findings.⁶²

In summary, there is good evidence that nutrition positively affects the cancer patient in terms of metabolic parameters.^{63,64} However, at the present time, there is a paucity of data demonstrating a positive clinical impact (Tables 84.3, 84.4, 84.5). Reasons for this are many. Most importantly,

studies demonstrating improvement in survival and morbidity require a large number of patients with significant follow-up time. Unfortunately, there are few studies large enough and with homogeneous populations and sufficient follow-up time to definitively state conclusions about nutrition and its impact on overall survival. Although promising, large prospective, randomized studies are still required before nutrition is instituted globally in cancer patients in an attempt to improve outcome and overall survival.

Pharmacologic Support

Enteral or parenteral nutritional supplementation is one approach to overcome nutritional impairment, but “force feeding” alone cannot always reverse the effects of cancer cachexia. It is possible that the failure of conventional nutritional interventions to improve clinical outcome in cancer patients may be because standard formulations do not affect or reverse the abnormalities of intermediate metabolism seen in cancer cachexia. Therefore, there has been an interest in developing certain pharmacologic agents to improve weight gain and nutritional status in cancer patients by addressing these issues (Figure 84.2; Table 84.6).

Promotility Agents

Patients with advanced cancers experience early satiety based, in part, on delayed upper gastrointestinal motility. In addition, factors, such as postoperative ileus and opiate-associated dysmotility, contribute to delayed emptying.⁶⁵ The cancer-associated dyspepsia syndrome, including nausea, vomiting, loss of appetite, and bloating, is related to auto-

nomic dysfunction. Metoclopramide is a benzamide derivative with marked dopamine receptor antagonism and weak antagonism of the 5-hydroxytryptamine-3 receptor. It has direct effects on gastrointestinal motility, as well as having an antiemetic effect. Metoclopramide has been shown to relieve anorexia and early satiety in small trials.^{66,67} A controlled release form of metoclopramide studied in a cancer patient population, showed the drug to be moderately effective, with improvement in nausea.^{68,69} Although it has been shown to improve gastric emptying and provide symptomatic improvement, demonstration of an effect on clinical nutritional endpoints is necessary before metoclopramide is used in routine clinical practice. Erythromycin and other macrolide antibiotics have also been studied as anticachectic agents.⁷⁰ In addition to their promotility effects, macrolides also possess antiinflammatory properties. In a small trial, 33 patients with unresectable primary non-small cell lung cancer were treated with clarithromycin for 3 months. As compared to a similar cohort of patients not receiving clarithromycin, patients receiving the macrolide demonstrated reduced serum interleukin (IL)-6 levels, which correlated with improved weight gain.⁷¹

Orexigenic Agents

Orexigenic agents are drugs that stimulate appetite. The most studied orexigenic agent is megestrol acetate. Megestrol acetate (Megace), a synthetic progestational agent, has been used for hormonal management of breast cancer. Studies with megestrol acetate noted that the drug produced weight gain, increased appetite, and promoted a sense of well-being, unrelated to its antitumor effect.⁷² In a randomized, double-blinded study, 133 cancer patients with anorexia and weight

RCT, randomized control trial; NSCLC, non-small cell lung cancer; BCAA, branched-chain amino acids; GH, growth hormone.

loss were treated with megestrol acetate (800mg/day) or placebo. Megestrol acetate resulted in a significantly improved appetite and food intake, while leading to less nausea and vomiting. Although overall weight gain was no different, weight gain greater than 10% was reported in more patients taking megestrol acetate (16%) compared to placebo (2%). The only side effect noted was mild edema.⁷³ In a mul-

tiinstitutional, placebo-controlled trial, megestrol acetate was also found to improve weight gain and appetite.⁷⁴ The primary concern with megestrol acetate has been that weight gain results from the deposition of fat and not lean body mass.⁷⁵ Related to megestrol acetate, medroxyprogesterone acetate (MPA) is a synthetic progesterone derivative that has also been studied as an appetite stimulant, as well as a mod-

ulator of cytokine release.⁷⁶ In a randomized, prospective trial, Simons et al. report that MPA stimulated food intake and reversed fat loss in 54 nonhormone-sensitive cancers.⁷⁷

Another orexigenic agent considered for use in cancer patients is dronabinol (marinol), which is the major active ingredient of marijuana (tetrahydrocannabinol). It is currently approved as a treatment of refractory nausea and vomiting. It has also been noted to be an appetite stimulant. In a small study, patients with advanced cancers were treated with dronabinol and, although there was improvement in appetite, weight loss continued unabated.⁷⁸ In a similar study, dronabinol improved both appetite and reduced the rate of weight loss.⁷⁹ Dronabinol has recently been compared to megestrol acetate in a prospective study of 469 patients with advanced cancer. Patients were randomized to megestrol acetate, dronabinol, or a combination of both agents. Although 75% of patients taking megestrol acetate reported an improved appetite, only 49% of the patients receiving dronabinol had significant improvements. The combination therapy did not confer any additional benefit over megestrol acetate alone.⁸⁰ Further prospective trials are needed to ascertain the utility of this agent in clinical practice.

Cyproheptadine is an antiserotonin agent with known appetite stimulatory effects. In a randomized, double-blinded, placebo-controlled study, 295 patients with advanced malignancy were treated with cyproheptadine or placebo. Patients receiving the active drug demonstrated a slight improvement in appetite.⁸¹ However, no increase in weight gain was noted. Other antiseritonic agents have also been studied. Ondansetron and granisetron are newer 5-HT₃ receptor antagonists and powerful antiemetics. In a study of 20 metastatic cancer patients, ondansetron improved the ability of patients to enjoy eating, but this effect did not translate into weight gain or improvement of other biochemical parameters of cachexia.⁸² Future trials with antiseritonic agents are needed to define their role in the treatment of cancer cachexia.

ANABOLIC AGENTS

Anabolic agents have the potential to improve body composition by maintaining or enhancing lean body mass. This class of agents includes growth hormone (GH), insulin, steroids, and amino acids.

Corticosteroids have been used in the palliative setting for cancer patients because they have been shown to possess a significant anti-nausea effect and to improve appetite and pain control. In a double-blinded cross-over study comparing placebo to prednisolone in more than 300 cancer patients with advanced disease, 80% of the patients experienced improved appetite and a sense of well-being, compared with 50% on placebo. However, no increase in caloric intake or body weight resulted.⁸³ In a randomized, double-blinded placebo-controlled study, dexamethasone was studied in preterminal gastrointestinal cancer patients and found to improve appetite, but it had no effect on weight gain.⁸⁴ Advanced cancer patients randomized to megestrol acetate, fluoxymesterone, and dexamethasone, demonstrated equal weight gain and appetite enhancement in the megestrol acetate and dexamethasone groups, but toxicity of dexamethasone was somewhat greater.⁸⁵ Although the short-term toxicity of steroids is well tolerated, chronic use of steroids

would be necessary to achieve clinical improvement. The long-term side effects and morbidity associated with steroid use outweigh its potential benefit.

Insulin has been extensively investigated as an anabolic agent in cachectic animal models, demonstrating decreased weight loss, preservation of normal host composition, and improved survival after tumor resection. When administered to rats, insulin increased host weight and muscle weight compared to controls. The mechanism of the effects of insulin in these studies included improved food intake, but insulin may also be involved in overcoming tumor-induced metabolic defects, which promote protein catabolism.^{86,87} Although both animal and human data have demonstrated that insulin can improve protein and carbohydrate metabolism in the tumor-bearing state, and despite that it is an inexpensive, readily available agent, the clinical correlates have never been demonstrated.

Growth hormone (GH) has been shown to attenuate both the loss of body protein and body cell mass when administered to noncancer, catabolic patients. However, there is a paucity of studies using GH in the cancer population. The relatively few studies using GH as a nutritional adjunct in cancer patients may be because many investigators are reticent to administer GH to cancer patients, because of the potential for stimulating tumor growth. There are limited data to suggest that GH and/or its mediator, insulin-like growth factor (IGF)-I, may support tumor growth, and it is possible that the potentially salutary effects of GH may be offset by a tumor-promoting effect.⁸⁸ Concerns regarding potential stimulation of tumor growth by GH have not been substantiated. Numerous *in vivo* animal studies provide no evidence to suggest that studies of GH in the cancer patient should not be performed.^{89,90}

In a prospective, randomized trial, Berman et al. treated cancer patients following surgical resection of upper gastrointestinal malignancies with GH (0.1 mg/kg) daily for 4 postoperative days in conjunction with standard TPN ($n = 10$). Patients receiving standard TPN served as a control ($n = 10$). Patients underwent a whole-body and skeletal muscle protein kinetic study. Patients receiving GH demonstrated improved whole-body protein net balance. While the patients receiving only TPN demonstrated a decrease in serum IGF-1 levels postoperatively, GH was able to normalize IGF-1 levels back to preoperative levels.⁹¹

Growth hormone has been shown to improve protein metabolism, wound healing, and immunologic status in the surgical patient.⁹² Although expensive and inconvenient to administer, GH still has potential to improve the clinical response in malnourished cancer patients. Further studies are needed to define the role of GH in the nutritional supplementation of cancer patients.

Branched-chain amino acids (BCAA) have been proposed as modulators of protein metabolism. Infusion of BCAA has been shown to reduce protein catabolism in healthy as well as cancer-bearing animals and humans.^{93,94} Tayek et al. studied 10 malnourished cancer patients using a cross-over design, providing conventional TPN and BCAA-enriched TPN (50% of amino acids as BCAA) for 2 to 5 days. The authors reported an increase in whole-body protein synthesis, with no difference in protein breakdown, in patients receiving the BCAA-enriched TPN.⁹⁵ This beneficial effect on protein metabolism has been confirmed in a subsequent

study.⁹⁶ Although these clinical trials have reported improvements in protein kinetics, studies addressing clinical outcome are required before BCAA-enriched TPN should be routinely administered to cancer patients.

Other amino acids have been studied as supplements. Glutamine is a nonessential amino acid that is often depleted in cancer patients. The mechanism of this depletion is unknown, but likely is caused by alterations in host protein metabolism, avidity of tumors for host glutamine, and the catabolic effects of cancer therapy.⁹⁷ The glutamine-depleted state may have a negative impact on the patient's clinical course.⁹⁸ In a double-blinded, prospective trial, Ziegler et al. randomized 45 patients undergoing BMT for hematologic malignancies to either conventional TPN or isonitrogenous, isocaloric TPN supplemented with glutamine. Patients were treated for 4 weeks posttransplantation. Those patients who had received the glutamine-enriched TPN had an improved nitrogen balance, significantly fewer infectious complications, and shortened length of hospitalization.⁹⁹

There is an extensive literature suggesting low circulating levels of serum testosterone in patients with malignancy.^{100,101} Most data related to testosterone replacement are derived from human immunodeficiency virus (HIV) studies. Oxandrolone is a testosterone derivative approved by the U.S. Food and Drug Administration for weight gain in chronic wasting diseases. Oxandrolone increases lean body mass, strength, weight gain, and perhaps quality of life in men with acquired immunodeficiency syndrome (AIDS)-related cachexia,^{102,103} and ongoing studies are evaluating the use of oxandrolone in the cancer cachexia population.

Anticatabolic Agents

Pentoxifylline is a methylxanthine derivative that is approved for intermittent claudication. Based on the observation that pentoxifylline blocks tumor necrosis factor- α (TNF- α), which is believed to be a mediator of cancer cachexia, a randomized, double-blinded, placebo-controlled study was performed to evaluate its use in treating cancer cachexia. Seventy patients with documented cancer cachexia were randomized to pentoxifylline or placebo. Although well tolerated, pentoxifylline failed to improve the appetites of study patients.¹⁰⁴ Hydrazine sulfate inhibits the enzyme PEP-CK, and interferes with gluconeogenesis, and has been reported to normalize the carbohydrate metabolism of cancer patients with cachexia.¹⁰⁵ Although some have claimed it improves appetite and has antitumor effects,¹⁰⁶ multiple clinical studies have not shown any benefit from the drug.¹⁰⁷⁻¹⁰⁹

The polyunsaturated fatty acids, such as eicosapentanoic acid (EPA), have been shown to inhibit lipolysis and muscle degradation in cancer cachexia animal models. In a study of patients with unresectable pancreatic cancer, dietary fish oil supplements, including EPA, were administered. After 3 months, patients showed decreased fatigue, a median weight gain of 0.3 kg/month, and stabilization of resting energy expenditure.^{110,111} The effects of EPA on inflammatory cytokines, prostaglandin E₂, and the proteolytic cachectic factor may explain, at least in part, the reversal of weight loss reported in cachectic pancreatic cancer patients and tumor-bearing mice supplemented with fish oil.¹⁰⁰ In another study by Gogos and colleagues, 60 patients with advanced solid

tumors were randomized to supplemental omega-3 polyunsaturated fatty acids or placebo. Patients receiving the fish oil supplementation demonstrated an improved immune response, as well as a longer mean survival.¹¹² These findings suggest a potential role of EPA as a useful supplement to treat or prevent cancer cachexia.

Forty years since its worldwide withdrawal for its teratogenic effects, thalidomide is currently undergoing a remarkable renaissance as a powerful immunomodulatory agent. Over the past decade, it has been found to be active in a wide variety of inflammatory and malignant disorders. One of the effects of thalidomide is its ability to inhibit TNF- α , and it has recently been studied as a drug to treat HIV-associated wasting and cancer cachexia.^{113,114} Khan and colleagues reported on 10 patients with nonobstructing and inoperable esophageal cancer who were established on an isocaloric diet for 2 weeks, followed by 2 weeks on thalidomide, 200 mg daily. Thalidomide treatment appeared to reverse the loss of weight and lean body mass over the 2-week trial period, with a mean gain in lean body mass of 1.75 kg.¹¹⁵ Thalidomide is very well tolerated, and further randomized clinical trials are warranted. Melatonin is the main hormone released from the pineal gland and has been shown to have antitumor and anticachectic effects.¹¹⁶ One potential mechanism is through melatonin's ability to decrease circulating levels of TNF in patients with advanced cancers.¹¹⁷ In a large trial, Lissoni et al. studied 1,440 patients with untreatable advanced solid tumor who received supportive care alone versus supportive care with melatonin. They demonstrated that melatonin decreased the frequency of cachexia in those patients taking supplemental melatonin.¹¹⁶ In a randomized trial of 100 patients with non-small cell lung cancer undergoing chemotherapy, patients receiving concomitant melatonin demonstrated a higher tumor response and survival.¹¹⁸ These trials provide early evidence to support further trials evaluating melatonin in the supportive care of patients with cancer-related malnutrition.

Despite being an attractive concept, there is no universally accepted "cocktail" of nutritional supplementation, coupled with pharmacologic support, that improves the nutritional status of patients with cancer cachexia. Further work with these and newer agents is needed before the standard of care changes.

Nutritional Support and Tumor Stimulation

Nutritional status plays an important role in the complex relationship between tumor and host, and nutritional repletion in cancer patients elicits a potential concern of stimulation of tumor growth. Tumors may preferentially extract exogenous nutrients at the expense of the host, resulting in accelerated tumor growth. Numerous laboratory and clinical studies have addressed the effect of nutritional supplementation on tumor development, tumor growth, and metastasis. Animal studies have shown that both intravenous and oral nutritional repletion of malnourished tumor-bearing animals restores host body weight, immunocompetence, and serum protein to normal, but tumor growth has also been shown to be concomitantly stimulated.¹¹⁹⁻¹²¹ Few human trials address the effects of nutritional repletion on tumor growth. In a study of head and neck cancer patients with a weight loss

greater than 10%, Baron et al. reported that tumors aspirated before and after 3 to 17 days of TPN, demonstrated an increase in hyperdiploid cells after TPN, by flow cytometry. In contrast, there was no difference in cell-cycle kinetics in adjacent normal mucosa.¹²² Frank et al. also studied head and neck cancer patients before and after 7 days of TPN and reported similar results. They observed an increase in incorporation of bromodeoxyuridine into the tumor cells after completion of TPN.¹²³ Tumor protein kinetics has been studied in patients undergoing nutritional support. In a prospective randomized study of gastrointestinal malignancies, Mullen et al. reported on 25 patients randomized to either oral diet or TPN for 7 to 10 days before operation. On the day of surgery, patients were infused with ¹⁵N-glycine, and tumor biopsies were analyzed for protein fractional synthetic rate. No differences in protein fractional synthetic rates were observed between patients receiving TPN (14.2%/day) versus oral diet (15.1%/day). In addition, the rate of protein synthesis was independent of the extent of disease and was related to the rate of protein synthesis of the adjacent normal tissue.¹²⁴

Overall, most animal studies support the findings that tumor growth is stimulated with nutritional repletion. Definitive conclusions from these animal models, however, are limited by the fact that they use rapidly growing, nonmetastasizing transplantable tumors with tumor burdens reaching nonphysiologic proportions. Therefore, the effects of nutritional repletion on host and neoplastic tissues observed in animal models may be different in humans. There is no objective evidence that nutritional support in humans actually stimulates tumor growth and, utilizing clinical endpoints, there is no evidence that nutritional support increases tumor growth or promotes metastatic potential. Therefore, the selective use of nutritional support in the cancer patient population, where indicated for nutritional repletion, should not be discouraged based on this theoretical concern.

Ethics

There is little debate about providing nutritional support for a reversible acute illness. However, the controversy exists in initiating and sustaining nutritional support for patients with incurable or end-stage cancer with little prospect of reversing the underlying disease and regaining nutritional independence. Patients with cancer may fall anywhere within this spectrum, and careful consideration of patient, family, and physician expectations should be included in the decision-making process.

Through the ages, the act of giving food and drink has been symbolic of caring and compassion. Supplemental nutrition is believed by some to be a logical continuation of this basic tenet, while others feel that "forced feeding" is an invasive medical intervention, requiring definitive indications and consent. The debate has yet to be resolved, and each case needs to be evaluated by its own merits and circumstances. Although nutritional support is considered ethically similar to any other life-sustaining treatment, such as ventilator support, dialysis, and antibiotics, physicians are not obligated to offer nutritional support and hydration unless potential benefit is anticipated. In terms of legal considerations, almost every court has ruled in favor that nutritional support is a medical intervention that can be refused by either a compe-

tent patient or a surrogate (when there is clear and convincing evidence that the patient would want therapy withdrawn). Excellent reviews and essays on the legal precedent are available.¹²⁵⁻¹²⁷

In addition to a life-prolonging intervention, there is also debate regarding the palliative effects of nutritional support in the terminal cancer patient. The placement of a gastrostomy tube can provide suitable nutrition and hydration and may also be useful for palliative decompression of the gastrointestinal tract.¹²⁸ Bozzetti et al. report that home TPN in severely malnourished, almost aphagic terminal cancer patients improved their quality of life, especially in patients surviving more than 3 months.¹²⁹ Home TPN or enteral nutrition also may be useful interventions to facilitate hospital discharge so that, if so desired, patients can die at home rather than in the hospital. On the other hand, the salutary aspects of palliative nutritional support must be tempered.¹³⁰ While it is difficult to "watch some one starve to death," investigators have shown that contrary to popular belief, patients with terminal illness can be made quite comfortable despite very limited food and fluid intake.¹³¹ Importantly, the use of nutritional support should not provide unrealistic hope and prevent the involvement of hospice services.

Overall, several principles can be used to direct the decision process, which are based on active patient, family, and physician participation¹³²:

1. A patient's expressed wishes, either in the present or through a prior directive, should be the primary guiding force when nutritional support is a medical option.
2. Although nutrition may prevent dehydration and malnutrition, there are no data supporting its efficacy in providing comfort by alleviating the subjective conditions of thirst or hunger.
3. The decision to use nutritional support must be made by assessing the benefits and burdens for each individual case.
4. A therapeutic trial of nutritional support should be discontinued when the burdens clearly outweigh the benefits.
5. The patient should be the final arbiter in assessing benefits and burdens.

In summary, a thoughtful approach is necessary in the initiation and continuation of nutritional support in the cancer patient. Potential benefits must be weighed against burdens, and realistic goals must be evaluated. Although the patient is the final arbiter, the family and physician must participate and communicate in the decision-making process.

Paraneoplastic Syndromes

Shirish M. Gadgeel and Antoinette J. Wozniak

Malignancies most often produce symptoms by local tumor growth and invasion, or by metastatic spread. However, there are remote effects of the primary cancer termed paraneoplastic that can result in significant symptomatology and organ dysfunction.¹ It is postulated that these syndromes result from the production of substances, such as hormones or their precursors, steroid metabolites, enzymes, and various cytokines.² Neurologic syndromes associated with neoplasms may be the result of antibody production related to immunoaccessible antigens produced by the neoplasm.

In general, it is common for malignancies to produce these substances, but it is less common that actual clinically relevant paraneoplastic syndromes develop. About 7% to 10% of cancer patients present with a paraneoplastic syndrome as the first manifestation of disease.³ If one considers some of the more common problems associated with malignancy, such as anemia, anorexia, and fever as paraneoplastic, a significant number of patients are affected by these syndromes. This chapter discusses some of the more common paraneoplastic syndromes associated with malignancies.

Endocrinologic Syndromes

The manifestations of the endocrinologic paraneoplastic syndromes are associated with the production of hormones or hormone-like substances. Table 85.1 lists the syndromes that have been reported and some of the malignancies with which they are associated.⁴⁻⁶

Hypercalcemia

Hypercalcemia is a fairly common metabolic problem that can occur in the presence of osseous metastases or as a result of a paraneoplastic process. A number of different cancers, including breast, lung, head and neck, kidney, and hematologic malignancies can cause hypercalcemia.⁷ Associated humoral and cytokine etiologic factors include parathyroid hormone-related protein (PTH-RP), transforming growth factor- α , interleukin 1, tumor necrosis factor, prostaglandins, and lymphotoxin.⁸ The clinician should be aware that benign conditions, such as hyperparathyroidism can coexist with malignancy and be the source of the hypercalcemia. The interaction of PTH, calcitonin, and 1,25-dihydroxyvitamin D in the bone, kidney, and gastrointestinal tract physiologically

controls body calcium. Intact PTH is generally normal or suppressed in malignancy-related hypercalcemia, indicating that there are other causative factors. PTH-RP is a small peptide homologous with the amino-terminus of PTH, which is also the portion that binds to the PTH receptor.⁹ PTH-RP can stimulate bone resorption and renal phosphate wasting resulting in hypercalcemia and hypophosphatemia. PTH-RP production is often found in squamous cell carcinomas and other solid tumors. Hematologic malignancies may cause hypercalcemia by production of several cytokines, including osteoclast-activating factor (OAF), lymphotoxin, and tumor necrosis factor (TNF).¹⁰ Lymphomas can produce 1,25-dihydroxycholecalciferol, promoting gastrointestinal (GI) absorption of calcium, resulting in suppressed PTH, normal to increased phosphorus, and hypercalcemia.⁶

Hypercalcemia is a significant source of morbidity and mortality in the cancer patient. Early manifestations can include anorexia, fatigue, lethargy, nausea, constipation, pruritis, polydipsia, and polyuria. These symptoms may not always be recognized because of attribution to the existing malignancy, other comorbid conditions, and treatment toxicities. If left untreated, symptoms can progress, resulting in severe dehydration, renal insufficiency, constipation, ileus, confusion, obtundation, seizures, and coma.

Patients who have a serum calcium level greater than 13 mg/dL usually exhibit symptoms. The degree of symptomatology is variable depending on the level of serum calcium, the rapidity with which the level was achieved, and the patient's overall health (i.e., performance status, age, preexisting organ dysfunction). The initial goal of treatment is restoration of intravascular volume and promotion of calcuresis, which can be accomplished with normal saline hydration (100–400 mL/h). Slower hydration may be more appropriate in patients with cardiovascular or renal impairment. Diuretics, such as furosemide, should be used judiciously to balance fluid intake and output. Dialysis may be necessary in cases of renal failure.

The bisphosphonates are the most common pharmaceutical agents used to treat hypercalcemia. These agents are analogues of pyrophosphate and inhibit osteoclast activity by binding to hydroxyapatite. Pamidronate and the newer generation, zoledronic acid, are the bisphosphonates used in the treatment of hypercalcemia. In randomized trials, zoledronic acid (4 and 8 mg) proved to be superior to pamidronate (90 mg), by yielding a more rapid and sustained decrease in serum calcium.¹¹ The current recommended dose of zoledronic acid is 4 mg intravenously over 15 minutes. The bisphosphonates

TABLE 85.1. Endocrinologic paraneoplastic syndromes.

<i>Syndrome</i>	<i>Etiologic factors</i>	<i>Common associated tumors</i>	<i>Biochemical presentation</i>	<i>Clinical presentation</i>
Hypercalcemia	PTH-RP; lymphotoxin; TGF; IL-1; TNF; PGE; OAF; IL-6; 1,25-OHD	Squamous cell carcinomas, lung, breast, kidney, ovary, myeloma, lymphoma, and others	↑ Serum calcium, variable serum phosphate, calcuria	Fatigue, anorexia, constipation, dehydration, neurologic symptoms, cardiac arrhythmias
Ectopic ACTH	ACTH production via POMC or CRH	SCLC, carcinoid, medullary thyroid, thymus, islet cell, pheochromocytoma, ganglioneuroma, and others	↑ ACTH Hypokalemia Metabolic alkalosis Hyperglycemia	Cushing's syndrome
SIADH	ADH (vasopression)	Lung (especially SCLC), head and neck, brain, GI, prostate, breast, sarcoma, carcinoid, hematologic	Hyponatremia, serum hyposmolality, inappropriately high urine osmolality and urine sodium	Anorexia, headache, lethargy, mental status changes, seizure, coma
Gonadotropin Production	HCG	Germ cell tumors, lung, GI, melanoma, kidney, breast, islet of pancreas	↑ β-HCG	Gynecomastia (adult males), precocious puberty (young females), hyperthyroidism
Hypoglycemia	(1) Insulin (2) Insulin-like substance	(1) Insulinoma, islet (2) Sarcoma mesothelioma hepatoma, GI, adrenal, hematologic	↓ Fasting glucose	Symptoms of hypoglycemia
Hypocalcemia	Calcitonin	Medullary thyroid	Hypocalcemia	Rare clinical symptoms
Prolactin Production	Prolactin	Kidney, lung, breast, cervix, colorectal, others	↑ Prolactin	Asymptomatic loss of libido, galactorrhea
Osteomalacia	Inhibition 1,25-OHD, phosphaturic substance	Mesenchymal tumors, lung, prostate	Hypophosphatemia, phosphaturia, ↓ 1,25-OHD, glycosuria	Myopathy, bone pain

See text for explanation of abbreviations.

Source: Data from references 4, 5, 6.

should be administered with caution in patients with renal insufficiency.

Gallium nitrate is another agent that can inhibit bone resorption via inhibition of osteoclast activity. It is administered at a dose of 100 to 200 mg/m²/day by continuous infusion for up to 5 days. Gallium nitrate was proven to be superior to pamidronate in a randomized clinical trial,¹² but it has not been compared to zoledronic acid. As with the bisphosphonates, there is potential for nephrotoxicity. Calcitonin has a rapid onset of action and can be used in critically ill patients with renal insufficiency. The main disadvantage to this agent is that its hypocalcemic effect diminishes and it is rarely effective long term. Plicamycin (mithramycin) is an antineoplastic agent, toxic to osteoclasts, that was used in the prebisphosphonate era. Because of its toxic side effects and the availability of other agents, it is no longer commercially available. Corticosteroids can inhibit calcium resorption and are frequently used in hypercalcemia related to hematologic malignancies, where they are part of the systemic therapy.

The pharmaceutical agents used to treat hypercalcemia are a temporary "fix" for the situation, and ultimately, successful treatment of the malignancy controls hypercalcemia. This aim may not be achievable in patients who have disease that is refractory to treatment, and eventually, inability to treat the malignancy will result in death.

Ectopic ACTH Production

The precursor of adrenocorticotropic hormone (ACTH), pro-opiomelanocortin (POMC), is made by normal tissue but

malignancies can produce this same precursor in much larger quantities. Some neoplasms are capable of converting POMC to biologically active ACTH, resulting in ectopic ACTH syndrome.⁶ Excessive ACTH can also occur via tumor production of corticotropin-releasing hormone (CRH).¹³ Small cell carcinoma of the lung (SCLC) is the most common tumor associated with ectopic ACTH production, although most patients do not develop clinically apparent Cushing's syndrome. A number of other malignancies that are also capable of producing ACTH are listed in Table 85.1.

The clinical syndrome is characterized by features associated with Cushing's disease, including centripetal obesity, hypertension, easy bruisability, muscle weakness, hyperpigmentation, glucose intolerance, and metabolic alkalosis. In patients with a rapidly growing tumor such as SCLC, the metabolic abnormalities, muscle wasting, and hypertension predominate. When overproduction of ACTH is clinically suspected it is important to distinguish between pituitary or adrenal disorders or ectopic ACTH production. An elevated ACTH plasma level often rules out primary adrenal disease as a causative factor. The high-dose dexamethasone suppression test generally suppresses cortisol production in pituitary-related Cushing's disease but not in ectopic ACTH related to tumors. Unfortunately, there are false positives and false negatives associated with the testing. The metyrapone suppression and CRH stimulation tests add to the accuracy of the dexamethasone suppression test.^{14,15} Other techniques, such as petrosal venous sinus sampling, continuous dexamethasone suppression, and serum chromogranin have been used with some success, but the results have not been verified.⁵

In patients who have early-stage tumors, with the exception of SCLC, surgery with removal of the primary tumor is the treatment of choice. In one series, 75% of patients with ACTH production and localized primary tumors were cured of their Cushing's syndrome with surgery.¹⁶ In patients who have disease that is not surgically resectable, symptoms can be palliated by bilateral adrenalectomy or medical therapy. Medical intervention can include cytotoxic chemotherapy with or without other medications, such as aminoglutethimide, metyrapone, mitotane, or ketoconazole, all of which suppress cortisol production. Ketoconazole (400 to 1,200mg/day), because of its effectiveness and favorable toxicity profile, is probably the medical treatment of choice.¹⁷ Treatment of SCLC involves cytotoxic chemotherapy. Treatment outcomes with SCLC patients who have ectopic ACTH secretion appear to be inferior, possibly secondary to increased complications (i.e., infection) related to high levels of corticosteroid.¹⁸

Syndrome of Inappropriate Antidiuretic Hormone

The syndrome of inappropriate antidiuretic hormone (SIADH) is caused by excessive release of vasopressin or ADH, which binds to receptors in the renal collecting ducts and the ascending loop of Henle, resulting in increased water reabsorption and increased sodium excretion via decreased proximal reabsorption. SCLC is the most common malignancy associated with SIADH. Most small cell cancers demonstrate positive staining for vasopressin, but only 15% or less actually have the clinical syndrome.¹⁹ Other malignancies that can have excessive ADH secretion are mentioned in Table 85.1. There are a number of nonmalignant conditions associated with SIADH, including intracranial processes (i.e., cerebral vascular accident, trauma, infection), pulmonary disease, and drug treatment (i.e., narcotics, chlorpropamide, chlorfibrate, carbamazepines, vincas, cisplatin, cyclophosphamide).²⁰ When evaluating patients for hyponatremia, other causes in addition to SIADH should be considered, such as congestive heart failure, renal and liver disease, hypothyroidism, and adrenal insufficiency.

The hallmark features of SIADH include hyponatremia, euvolemia, low serum osmolality, inappropriately elevated urine osmolality and sodium, and normal renal, adrenal, and thyroid function. Most patients are asymptomatic or complain of weakness, lethargy, anorexia, and headache. As the serum sodium level drops, patients may develop mental status changes, seizures, focal neurologic signs, and coma. Mild hyponatremia can be managed with fluid restriction, whereas patients with severe symptoms may require treatment with 3% hypertonic saline; this requires careful monitoring, usually in an intensive care unit. The correction rate should be no more than 1mEq/L/h to avoid the potential complication of central pontine demyelination.²¹ Demeclocycline (600mg/day), which can inhibit the action of vasopressin, may also be used.²² Patients with SCLC are treated with cytotoxic chemotherapy. The presence of SIADH does not necessarily portend a poor prognosis.²³ Redevelopment of low sodium after treatment completion may herald disease recurrence.

Gonadotropins

The gonadotropins include follicle-stimulating hormone (FSH), luteinizing hormone (LH), and human chorionic gonadotropin (HCG).²⁴ They have a common subunit and a hormone specific β -subunit that determines biologic specificity. HCG production is found in a number of malignancies (see Table 85.1), and the β -subunit of HCG is measured in the serum. The most common clinical presentation in adults is unexplained gynecomastia, usually as a result of a germ cell tumor or lung cancer. In young women, precocious puberty can develop from ovarian stimulation. When β -HCG is present at high levels, hyperthyroidism can result from stimulation of thyroid-stimulating hormone.

Hypoglycemia

Hypoglycemia is an uncommon paraneoplastic syndrome most often associated with sarcomas and mesothelioma. Other tumors that reportedly can cause hypoglycemia are listed in Table 85.1. A number of etiologies have been proposed, but the suspected cause is the tumor secretion of a nonsuppressible insulin-like substance.²⁵ Insulin itself can be produced by insulinomas and islet cell malignancies. Fasting hypoglycemia is the most common clinical presentation. Patients are treated by surgical resection of the tumor or anti-neoplastic therapy. When this is not possible, symptoms of hypoglycemia can be palliated by frequent meals and the use of various agents, including glucagon, corticosteroids, diazoxide (inhibits insulin secretion), and growth hormone.

Other Endocrine Paraneoplastic Syndromes

Calcitonin is secreted by the cells of the thyroid and can be produced by medullary thyroid carcinoma and a number of other tumors. Clinically apparent hypocalcemia is rare. Acromegaly has been attributed to the secretion of a growth hormone-releasing factor.²⁶ Elevated prolactin levels have been reported in a variety of tumors. Clinical symptoms are uncommon, but galactorrhea has been reported.²⁷ Tumor-induced osteomalacia is a syndrome characterized by severe hypophosphatemia, phosphaturia, glycosuria, bone pain, myopathy, and inadequate bone mineralization.²⁸ It is thought to be caused by inhibition of the conversion of 1,25-hydroxyvitamin D and phosphaturic substance.⁵ It is most commonly seen in benign mesenchymal tumors and has rarely been reported in other malignancies (see Table 85.1).

Paraneoplastic Syndromes of the Nervous System

Paraneoplastic syndromes can affect any part of the nervous system (Table 85.2). The frequency of clearly defined symptomatic neurologic paraneoplastic syndromes is less than 1% of cancer patients.²⁹ However, the frequency is underestimated because in many patients the neurologic disorder may precede the diagnosis of the underlying cancer. Interestingly, clinical and electrophysiologic studies in cancer patients often disclose neuromuscular dysfunction in otherwise asymptomatic patients. In some, the signs and symptoms of

TABLE 85.2. Neurologic paraneoplastic syndromes.

<i>Antibody</i>	<i>Targeted neuron</i>	<i>Paraneoplastic syndrome</i>	<i>Tumors</i>
Anti-Hu (ANNA-1)	All neurons	Encephalomyelitis, sensory neuronopathy, cerebellar degeneration	Small cell, neuroblastoma, prostate cancer, sarcoma
Anti-Yo (PCA-1)	Purkinje cell	Cerebellar degeneration	Small cell, breast, ovarian
Anti-Ri (ANNA-2)	Central nervous system neurons	Opsoclonus-myoclonus, cerebellar degeneration	Small cell, breast, ovarian, bladder
Anti-Tr	Purkinje cell	Cerebellar degeneration	Hodgkin's and non-Hodgkin's Lymphoma
Anti-CAR	Photoreceptors	Cancer-associated retinopathy	Small cell, Melanoma
Anti-VGCC	Presynaptic neuromuscular junction	Lambert–Eaton myasthenic syndrome	Small cell, Hodgkins Lymphoma
Anti-Ta	Neurons (nucleus)	Limbic encephalitis	Testis
Anti-MAG	Peripheral nerve	Peripheral neuropathy	Waldenstrom's macroglobulinemia
Antiamphiphysin	Presynaptic nerve terminals, central nervous system neurons	Encephalomyelitis, stiff-man syndrome	Breast cancer, small cell
Anti-AchR	Postsynaptic neuromuscular junction	Myasthenia gravis	Thymoma

Ach, acetylcholine; CAR, cancer-associated retinopathy; MAG, myelin-associated glycoprotein; VGCC, voltage gated calcium channel.

the neurologic disorder appear months or even a few years before the underlying tumor is diagnosed. The probability that a neurologic syndrome is associated with a tumor varies with the specific type of paraneoplastic syndrome.

Pathogenesis

There is increasing evidence that most if not all the paraneoplastic neurologic disorders are immune mediated. The pathogenic mechanism involves the ectopic expression by the tumor of an antigen that is normally expressed in the nervous system. The immune system, for reasons that are not entirely clear, recognizes these antigens as foreign and mounts an immune response, in the form of antibodies and/or cytotoxic T cells. These antibodies and T cells then attack the neural tissues that express the antigens shared with the tumor.

The relative role of humorally mediated immunity and cellular immunity in paraneoplastic neurologic disorders is unresolved. In disorders, such as Lambert–Eaton syndrome, myasthenia gravis, opsoclonus-myoclonus, and cerebellar degeneration surface receptors serve as target antigens and antibodies appear to have a dominant role. The actual role of the antibodies is unproven. There have been several attempts to reproduce these paraneoplastic neurologic syndromes by passive transfer of antibodies, such as anti-Hu and anti-Yo, and by immunization of animals with recombinant antigens.^{30,31} These experiments did not result in neurologic dysfunction. However, most patients with antibody-associated paraneoplastic syndromes of the central nervous system have continuous intrathecal synthesis of antibodies.

Many studies have also documented the role of cellular immunity in neurologic paraneoplastic disorders. Tumors of patients with neurologic disorders have an intense inflammatory infiltrate that have been recently shown to contain CD4 and CD8 lymphocytes.^{32,33} Receptor studies of T cells in these infiltrates show that they are specifically targeted to the neuronal antigens. Activated T cells have been found in the peripheral blood of patients with acute paraneoplastic cerebellar degeneration that react to cells with the Yo (cdr2)

antigen. In many cases, the antibodies and T cells are directed against the same neuronal antigen, suggesting that the neurologic paraneoplastic disorders may result from the combined effect of the two arms of the immune system.

The presence of antibodies in the serum or particularly in the cerebrospinal fluid (CSF), may aid in the diagnosis of paraneoplastic neurologic disorders.³⁴ This fact may focus attention on certain neoplasms, and it is important to consider that these antibodies may be present in the serum of patients without paraneoplastic syndromes.

The clinical spectrum of paraneoplastic syndromes is varied. Many patients present with rapid development and progression of symptoms. Therefore, by the time a diagnosis is made, many patients may have irreversible pathologic changes. This may be the reason that patients with disorders involving the peripheral nerves or neuromuscular junction may respond to therapy, whereas disorders with neuronal damage may be permanent.

Paraneoplastic Encephalomyelitis

Paraneoplastic encephalomyelitis is characterized by multifocal involvement of the nervous system with signs of inflammation demonstrated by radiologic studies, such as magnetic resonance imaging (MRI), CSF examination, or biopsy. The manifestations of this disorder are varied. Some patients present with focal encephalitis involving the limbic system or brainstem. However, when these cases have been analyzed there is pathologic evidence of multifocal involvement.^{35,36} Paraneoplastic encephalomyelitis is most often associated with small cell lung cancer. Young patients with symptoms of limbic and/or brainstem dysfunction may have associated germ cell tumors. They often have Ma antibodies in the peripheral blood.

Encephalomyelitis responds poorly to therapy. Stabilization of the symptoms could be expected if the tumor responds well to anticancer treatment. Limbic encephalitis is an exception because it may improve with therapy.³⁵ The role of immunosuppressive therapy, such as plasma ex-

change, cyclophosphamide, and steroids in the treatment of encephalomyelitis is questionable.³⁷ Patients with encephalomyelitis could die of the consequences of the paraneoplastic disorder. Factors that are likely to increase the possibility of death are older age, multiple sites of involvement, and impaired performance status.

Cerebellar Degeneration

Paraneoplastic cerebellar degeneration is the most common paraneoplastic disorder affecting the central nervous system. A variety of tumors, especially SCLC, breast cancer, and ovarian cancer, are the most frequent sources. Paraneoplastic antibodies are associated with this disorder.³⁸ The predominant pathologic feature is the loss of Purkinje cells, with a variable involvement of the other neurons. Clinical presentation of this disorder is characterized by symmetric cerebellar ataxia but patients may also have dysarthria, dysphagia, and diplopia. The onset of symptoms is usually sudden, and progression occurs over weeks to months. Patients with paraneoplastic antibodies progress much more rapidly.³⁹ Radiologic studies in the early stages of the disease are generally unremarkable. Cerebellar atrophy may be observed on MRI and computed tomography (CT) scans in patients who have had the disease for a long period. CSF studies may show evidence of pleocytosis and, in seropositive cases, higher titers of antibodies than appear in serum. The best therapeutic approach to this disorder is prompt treatment of the tumor. Unfortunately, most patients do not respond to antitumor therapy or to immunosuppression.

Opsoclonus-Myoclonus

Opsoclonus consists of involuntary conjugate saccadic eye movements. The paraneoplastic syndrome is often associated with focal myoclonic movements and ataxia. The syndrome is more common among children than adults. In children, almost 50% who present with opsoclonus have an underlying neuroblastoma.^{40,41} Opsoclonus can also occur following a viral infection. Paraneoplastic opsoclonus responds to treatment of the tumor and steroids; however, the majority of the patients have residual neurologic deficits including behavioral abnormalities. In adults, only 20% of the opsoclonus cases are associated with tumors. The most common tumor type is lung cancer.⁴² Prompt therapy of the tumor results in a better prognosis, but most adult patients have persistent deficits. Some patients may respond to the use of steroids.

Limbic Encephalitis

Limbic encephalitis is a rare paraneoplastic disorder characterized by personality changes, short-term memory loss, and, occasionally, seizures and hallucinations. Pathologic changes predominantly involve the amygdala, hippocampus, and insular cortex. The syndrome can occur with testicular cancers, small cell lung cancer, and other tumors. In testicular cancer, it is associated with antibodies to Ma1 and Ma2 proteins, which are neuronal proteins with unknown func-

tion. Patients with seropositive disease may have good responses to antitumor therapy and immunosuppression.⁴³

Sensory and Motor Neuronopathies

Paraneoplastic sensory neuronopathy is characterized by progressive sensory loss in limbs, trunk, and face. The sensory loss progresses over weeks and then stabilizes after several months. The vibration and joint position sensations may be more affected than nociceptive sensation. The sensory loss can affect the patient's ability to ambulate. The associated tumor is usually small cell lung cancer and these patients often harbor anti-Hu antibodies.⁴⁴ Pathologic findings consist of neuronal loss in the dorsal root ganglia. Response to therapy is limited, and patients often remain disabled.

Motor neuronopathy is associated primarily with lymphomas.⁴⁵ Pathologic findings consist of neuronal degeneration in the anterior horn with demyelination of the anterior nerve roots. Patients have a progressive motor weakness, primarily in the lower extremities. In contrast to other paraneoplastic disorders, patients may develop this syndrome after the diagnosis of the underlying neoplasm.

Sensorimotor Neuropathy

Differentiating the various causes of neuropathies in cancer patients could be challenging. Peripheral neuropathy can occur in cancer patients from a variety of sources, including cytotoxic therapy and metabolic and nutritional etiologies. A paraneoplastic chronic sensorimotor neuropathy has been described with lung cancer.⁴⁶ Patients usually have mild symptoms in a typical glove-and-stocking distribution.

In patients with osteosclerotic myeloma, a group of symptoms referred to as POEMS may develop. POEMS consists of neuropathy, organomegaly, endocrine dysfunctions, and skin changes. The pathologic basis of this syndrome is unclear. Symptoms including neuropathy may respond to myeloma therapy.

Stiff-Man Syndrome

This syndrome is characterized by chronic muscle rigidity with superimposed muscle spasms. It results from autoimmunity affecting synaptic antigens, and the majority of patients with this disorder do not have an underlying tumor. Paraneoplastic stiff-man syndrome is associated with antibodies to amphiphysin, a protein expressed at high levels in the brain and skeletal muscle.⁴⁷ The tumor type most commonly associated with the paraneoplastic stiff-man syndrome is breast cancer. Treatment of the tumor and steroids may improve the symptoms.^{47,48}

Myopathies

Various myopathic syndromes may have a paraneoplastic origin. However, in most patients with these syndromes there is no underlying tumor. Lambert-Eaton syndrome (LES) could be nonparaneoplastic in 50% of the cases.⁴⁹ It results from an antibody directed against the voltage-dependent calcium channels in the presynaptic nerve terminal.⁵⁰ These antibod-

ies block calcium entry into the channels, resulting in reduced acetylcholine release and thus, reduced muscle activity. The tumor type most commonly associated is small cell lung cancer, although other malignancies, such as lymphoma have been reported with this syndrome. The clinical features are characterized by muscle weakness, particularly in the proximal muscles with easy fatigability. This syndrome does respond to immunosuppressive therapy, plasmapheresis, and intravenous immunoglobulin (IVIG). Treatment of the underlying tumor is most important.

Myasthenia gravis is a myopathy characterized by increasing muscle weakness with repeated use of the muscles. The most commonly involved muscles are the bulbar muscles, muscles of the face and neck, and the distal muscles of the extremities. In 90% of the patients with myasthenia gravis, there is no underlying tumor. The most common tumor type associated with paraneoplastic myasthenia is thymoma.

Dermatomyositis and polymyositis are inflammatory myopathies with features of pain, muscle tenderness, and symmetric proximal muscle weakness. The rash in dermatomyositis is on the face, elbows, and knees. The disorders are paraneoplastic in only about 10% of the cases.⁵¹ The probability that an underlying cancer is present is higher in older individuals. The most common associated tumor types are lung and breast cancer. These myopathies may respond to steroids.

Cutaneous Paraneoplastic Disorders

Similar to other paraneoplastic disorders, cutaneous syndromes may precede, occur concurrently, or follow the diagnosis of cancer (Table 85.3). In 1976, Curth set out criteria regarding paraneoplastic dermatoses: (1) both start at approximately the same time; (2) both follow a parallel course; (3) a specific tumor is associated with a specific skin manifestation; (5) the dermatoses are not common in the general population; and a high percentage of association is observed between the cancer and the dermatoses.⁵²

Acanthosis Nigrans

Acanthosis nigrans is characterized by velvety hyperpigmentation and papillomatosis of the skin folds. The neck, axillae, antecubital, popliteal, and anogenital region are the areas commonly affected. Acanthosis nigrans may be idiopathic or could be associated with endocrine disorders, such as diabetes, obesity, and polycystic ovary syndrome. Paraneoplastic acanthosis nigrans is most commonly linked with abdominal adenocarcinomas, such as gastric cancer.⁵³ It has also been observed with other adenocarcinomas, such as lung, breast, ovarian, and endometrial as well as lymphomas. The malignant form of acanthosis nigrans progresses rapidly and diffusely. In one series, it preceded the diagnosis of the associated cancer in 69% of the cases.⁵³ The condition may improve with the therapy of the underlying tumor.

Tripe palms are hyperkeratotic palms with exaggerated ridges and a velvety texture. They commonly occur with acanthosis nigrans. Tripe palms are associated with malignancy in almost 90% of the cases.^{53,54} Lung cancer and gastric cancer are the most common malignancies.

Ichthyosis

Ichthyosis is characterized by dry skin with rhomboidal scales having free edges. There are two forms of ichthyosis, congenital and acquired. Acquired ichthyosis is associated with many disorders, such as cancer, acquired immunodeficiency syndrome (AIDS), sarcoidosis, and leprosy and can be drug induced. The most common malignancy is non-Hodgkin's lymphoma but the syndrome has been seen in breast cancer, lung cancer, leiomyosarcomas, and Kaposi's sarcoma (with or without AIDS).⁵⁵ In cancer-related ichthyosis, the areas most commonly affected are extensor surfaces of extremities, with relative sparing of the flexor surfaces and palms and soles. The condition in most patients follows the diagnosis of the cancer and usually is observed in the late stages of the disease.⁵⁶ Treatment is

TABLE 85.3. Cutaneous paraneoplastic syndromes.

Cutaneous syndrome	Features	Tumors
Acanthosis nigrans	Velvety pigmentation and papillomatosis in the neck, axilla, flexor areas, and anogenital area	Adenocarcinomas, mainly gastric, but also seen with lung, ovarian
Ichthyosis	Dry skin with rhomboidal scales having free edges; extensor surfaces of extremities	Non-Hodgkin's lymphoma, lung cancer, breast cancer
Bazex's syndrome	Dry and scaly skin plaques on the acral surfaces of ears, nose, hands, and feet	Squamous cell carcinomas of the aerodigestive tract
Sign of Leser-Trelat	Seborrheic keratoses on the trunk with pruritus	Gastric, colon, breast, lung adenocarcinomas
Paraneoplastic pemphigus	Bullous lesions that may erode, present over the trunk and the extremities; internal organ involvement may also occur	Lymphomas, Waldenstrom's macroglobulinemia
Erythroderma	Exfoliative dermatitis with erythema and scaling of the skin	Leukemias and lymphomas
Necrotizing migratory erythema	Erythematous macules and papules, which may erode, in the inguinal area, thighs, buttocks, perineum, and central face	Glucagonomas
Erythema gyratum repens	Migrating concentric rings of erythema with trailing scale on the trunk and extremities	Lung cancer
Paget's disease	Erythematous keratotic patches at the affected sites, which include breast, vulva, perianal area, male genitalia	Breast, prostate, bladder, vaginal, endometrial, rectal
Sweet's syndrome	Erythematous plaques on the face, neck, and extremities	Acute myeloid leukemia

primarily directed at the underlying cancer. Application of lubricating agents and keratolytic agents, such as 2% salicylic acid may help reduce the symptoms of dry skin and pruritus. Use of antihistamines and nonsteroidal antiinflammatory drugs (NSAIDs) to treat pruritus may also be helpful.

Bazex's Syndrome

Bazex's syndrome, also known as acrokeratosis paraneoplastica, is characterized by dry, scaly skin plaques on the acral surfaces of the ears, nose, hands, and feet. These lesions may exhibit a violaceous erythema. Nail changes, including ridging, discoloration, thickening, and paronychia, may also occur. The syndrome is almost always associated with squamous cell carcinoma of the aerodigestive tract.⁵⁷ Males are affected much more frequently than females.

The pathogenic mechanism of the disorder is unknown but is postulated to be a result of cross-reactivity between tumor antigens and epidermal or basement membrane antigens. Tumor secretion of growth factors, such as transforming growth factor or insulin-like growth factor may contribute to the development of the syndrome.⁵⁸ The syndrome may precede, occur with, or follow the diagnosis of the cancer. In patients with Bazex's syndrome without a known malignancy, a search for an underlying tumor should be done. The condition generally tends to improve with effective tumor therapy, although the nail changes may persist. Good skin care and antibiotic therapy in the event of a secondary infection are crucial.

Sign of Leser-Trelat

Sign of Leser-Trelat is the sudden appearance of seborrheic keratoses. The keratoses often erupt on the trunk and can be pruritic. The significance of this condition is thought to be controversial but its presence is generally considered to require a cancer workup. This sign is most often found in patients with adenocarcinoma of the stomach and colon but has been reported in other tumors, such as breast, lung, and ovary.^{59,60}

Paraneoplastic Pemphigus

In this disorder, there are bullous lesions that may erode and which are present on the skin over the trunk and the extremities. Internal organ involvement may also occur, and respiratory failure causes death in some patients with this disorder. The tumors with which this paraneoplastic syndrome is associated are lymphomas, Waldenstrom's macroglobulinemia, and spindle cell tumors.⁶¹ The course of the disease is independent of the underlying tumor. Corticosteroids, cyclosporine, and mycophenolate mofetil have been recommended as therapy.^{61,62}

Erythroderma

Erythroderma is an exfoliative dermatitis characterized by erythema and scaling of the skin. It usually starts as scattered erythematous pruritic patches that become generalized. Inflammatory lymphadenopathy may be present in association with the erythema.⁶³ Leukemias and lymphomas are

most commonly associated with this disorder.^{63,64} Solid tumors that have been implicated include liver, lung, and colon.

Necrotizing Migratory Erythema

Necrotizing migratory erythema is the skin manifestation of glucagonomas.⁶⁵ Patients develop a dermatitis characterized by erythematous macules and papules in the inguinal area, thighs, buttocks, perineum, and central face. These lesions may progress to erosions secondary to epidermal necrosis. Opportunistic infections including *Candida* may occur. The skin disease has a waxing and a waning course. It tends to occur late in the course of the tumor although it could occur before the diagnosis. The pathogenesis of the skin condition is believed to be from the catabolism induced by glucagons.⁶⁶ Treatment for the condition is usually surgical resection of the glucagonoma. Somatostatin or chemotherapy may be used in an attempt to reduce glucagon secretion if surgery is not feasible. The catabolic state induced by glucagon hypersecretion may result in amino acid deficiencies. Therefore, it has been suggested that an amino acid infusion may correct the underlying catabolic state and help the cutaneous condition.

Erythema Gydatum Repens

Erythema gydatum repens consists of migrating concentric rings of erythema with trailing scale on the trunk and extremities.⁶ It is often pruritic by nature. The most common underlying malignancy is lung cancer, although other tumors, such as breast, cervix, and stomach cancers have been reported with this skin condition.^{67,68} Treatment involves management of the underlying tumor and antipruritic measures.

Paget's Disease

Paget's disease may be mammary or extramammary and consists of erythematous keratotic patches at the affected site.⁶⁹ Histologic examination of the skin reveals large round cells with clear cytoplasm in the epidermis of the skin and often in the cutaneous appendages. Mammary Paget's disease is associated with breast cancer and involves the areola and the nipple. The presenting symptom may vary from a "pimple" to scaling with rash and erosion. Crusting and weeping exudates may occur. Extramammary Paget's disease occurs in the vulva, the genitals in men, and perianal area in both sexes. It is associated with tumor in 50% of the cases.⁵⁵ Most of the cancers arise from a site close to the Paget's disease. The most common tumor types are rectal, prostate, bladder, vaginal, and endometrial. Surgical resection of the underlying malignancy is the treatment of choice.

Sweet's Syndrome

Sweet first reported this syndrome in 1964⁷⁰; it consists of erythematous plaques on the face, neck and extremities resulting from dermal infiltration of neutrophils. The skin changes occur with fever and neutrophilia. This syndrome may be associated with an underlying malignancy, particularly acute myeloid leukemia (AML).⁷¹ AML patients may develop leukemia cutis, which is characterized by infiltration of the

skin with leukemic blasts; however, in Sweet's syndrome there is only infiltration with mature neutrophils. This syndrome may be associated with other hematologic malignancies as well as solid tumors.⁵² Treatment with steroids usually resolves the symptoms promptly.

Paraneoplastic Rheumatic Disorders

Rheumatic disorders may occur in cancer patients either as direct invasion by the tumor or as a paraneoplastic phenomenon. Antineoplastic drugs may also induce rheumatic disorders. Patients with certain rheumatic disorders, such as rheumatoid arthritis and Sjogren's syndrome may have a higher risk of developing cancer.^{72,73}

Polyarthrititis Syndrome (Including Hypertrophic Osteoarthropathy)

Cancer-associated polyarthrititis is generally seronegative, asymmetric, and can occur suddenly. Polyarthrititis has been associated with solid tumors, such as lung, breast, ovarian, and pancreatic tumors, and lymphoma and leukemias.^{74,75} In leukemias and, rarely, in lymphomas patients may have infiltration of the joint with malignant cells.

Hypertrophic osteoarthropathy (HOA) is the best known cancer-associated arthropathy. Patients are required to have both clubbing and periostitis to make the diagnosis. Clubbing results from paronychia soft tissue expansion, which in turn results from an increase in vascular and connective tissues in the nail bed. Periostitis develops from periosteal proliferation in the long bones, particularly the tibia and femurs. Patients may present with only certain components of the syndrome, such as clubbing.

HOA may be primary or secondary. Secondary HOA is seen in pulmonary, cardiac, intestinal, and hepatic disorders. The common link among disorders associated with HOA appears to be right to left shunting either in the heart or in the lung parenchyma, which permits megakaryocytes to access the peripheral circulation instead of being fragmented in the pulmonary circulation. These megakaryocytes in the distal digital circulation possibly release platelet-derived growth factor, which induces the changes observed with clubbing.^{76,77} It is unclear if the same mechanism explains the periostitis. The tumors most commonly associated with HOA are pulmonary or mediastinal tumors, such as lung and esophageal cancers and thymoma. The symptoms with HOA may cause significant morbidity. Treatment is primarily focused toward the underlying cancer. NSAIDs may relieve the pain associated with HOA.⁷⁸

Several studies have shown that patients with rheumatoid arthritis (RA) have higher rates of cancer than the general population. Lymphomas and myeloma are most commonly associated with RA.⁷⁹ The increased observed rate may be related to the use of immunosuppressive therapy.

Nonarticular Syndromes

Cancer patients may develop various inflammatory muscle conditions or vasculitis. Dermatomyositis, the most common paraneoplastic muscular syndrome, was discussed earlier. Other myositis syndromes observed in cancer patients

include body myositis and paraneoplastic necrotizing myopathy.^{80,81}

Patients with hematologic malignancies, such as myelodysplasia, lymphoma, or leukemia and sometimes patients with solid tumors may develop vasculitis. Patients can present with lupus-like symptoms including arthralgias/arthritis, neuropathy, and skin rashes. Cancer patients may also have Raynaud's phenomenon, which may be associated with the presence of cryoglobulins, and improves with cancer treatment.

Paraneoplastic Renal Syndromes

Renal complications of cancer can develop through many mechanisms, including tumor infiltration (leukemias, lymphomas), treatment-related complications, tumor lysis, and fluid and electrolyte disturbances. Paraneoplastic renal syndromes consist primarily of glomerular disorders resulting in renal dysfunction and/or nephrotic syndrome. Membranous nephropathy is the most common form of paraneoplastic glomerular disease.⁸² Patients present with proteinuria in the nephrotic range, hypertension, and microscopic hematuria. Immune complexes appear to play a role in the pathogenesis of this nephropathy.⁸³ Tumors commonly associated with membranous nephropathy are lung, ovarian, and gastric cancers.

Other glomerular diseases include membranoproliferative glomerulonephritis associated with chronic lymphocytic leukemia (CLL), hairy cell leukemia, and lymphomas; an IgA nephropathy with pancreatic and lung cancers; minimal change disease in Hodgkin's lymphoma; and focal and segmental glomerulosclerosis with CLL, T-cell lymphomas, and AML. Patients may also develop hemolytic uremic syndrome with prostate, gastric, and pancreatic cancers. Renal vasculitis with cryoglobulinemia can be seen in patients with hepatomas associated with hepatitis C.⁸⁴

Hematologic and Vascular Syndromes

Erythrocyte Disorders

A number of hematologic abnormalities and vascular complications have been associated with malignancies (Table 85.4), and are presumed to be paraneoplastic in nature. One of the most common problems is anemia. Cancer-related anemia can be multifactorial, resulting from nutritional deficiency, bone marrow involvement by tumor, bleeding, treatment-related marrow depression, and coexisting comorbid conditions. Anemia with no other apparent cause can be termed neoplastic. The anemia is characterized by normochromic or slightly hypochromic red blood cells. Ferritin levels and iron stores are normal to increased, and both reticulocytes and erythropoietin levels are inappropriately low. Normal bone marrow morphology is usually present. A number of cytokines (tumor necrosis factor, interleukin 1, transforming growth factor- β) are thought to blunt erythropoietin response.⁸⁵ There are other rarer causes of anemia. Autoimmune hemolytic anemias are usually associated with chronic lymphocytic leukemia and lymphomas and rarely with solid tumors.^{86,87} Both warm and cold antibodies can be

TABLE 85.4. Hematologic paraneoplastic syndromes.

Erythrocyte disorders
Anemia
Autoimmune hemolytic anemia
Microangiopathic hemolytic anemia
Erythrocytosis

Platelet function disorders
Coagulation and vascular disorders
Thrombophlebitis/Trousseau's syndrome
Disseminated intravascular coagulation
Amyloidosis
Acquired von Willebrand's disease
Nonbacterial thrombotic endocarditis

present. They may arise secondary to immunoregulatory problems rather than production of an abnormal substance by the tumor.⁸⁶ Steroids often control hemolysis but are less effective when carcinomas are involved. Even less common is microangiopathic hemolytic anemia, which can occur with mucinous adenocarcinomas.⁸⁸ Pure red cell aplasia is rare and has been associated with thymoma and hematologic malignancies.^{89,90}

Erythrocytosis can be caused by overproduction of erythropoietin and is most commonly associated with renal cell carcinoma. A number of other tumors, such as hepatomas and hemangioblastomas have also been reported to cause erythrocytosis.⁸⁶ This condition is controlled by management of the primary neoplasm, but phlebotomy may also be necessary.

Leukocytosis/Leukopenia

Leukocytosis has been associated with malignancies. At times the leukocyte count can be fairly high, and myeloproliferative disorders and infection should be part of the differential diagnoses. Leukocytosis has been linked to cytokines, such as interleukin 1 and granulocyte-stimulating factor.⁹¹ Leukopenia has rarely been reported as a paraneoplastic syndrome. Monocytosis and/or eosinophilia are more commonly seen with a number of malignancies.

Thrombocytosis/Thrombocytopenia

Thrombocytosis, excluding other etiologies, such as iron deficiency anemia and inflammatory disorders, is a common occurrence in a number of malignancies. It may be related to prevalence of cytokine growth factors, such as thrombopoietin and interleukin^{92,93} and it may have a role in the hypercoagulable state associated with malignancies. Thrombocytopenia usually occurs with nonparaneoplastic causes, such as the effects of treatment, drug-induced thrombocytopenia, and marrow involvement by tumor. Idiopathic thrombocytopenic purpura has been found in hematologic malignancies but rarely in solid tumors.

Coagulation/Vascular Disorders

Thrombophlebitis is commonly associated with malignancies. It can be migratory in nature (Trousseau's syndrome) and can present at unusual sites. It is most often seen in pancreatic cancer and other GI malignancies, as well as other adenocarcinomas, including lung, breast, ovarian, and prostate cancers.⁹⁴ The etiology of the hypercoagulable state in malignancy is quite complex. Contributing factors can include release of procoagulant materials, such as a sialic acid from mucin, release of cytokines with procoagulant activity, platelet hyperactivity, and the release of tissue factors via abnormal tumor vasculature.⁹⁵ Unless the underlying malignancy is controlled, treatment can be difficult in that heparin and particularly, warfarin resistance is often encountered.

Disseminated intravascular coagulation (DIC) with consumption of platelet and clotting factors resulting in hemorrhage and/or thrombosis is associated with malignancy. Overt DIC is uncommon and is most often seen in association with acute promyelocytic leukemia.⁹⁶ A lower grade of DIC can be found in a number of solid tumors, particularly adenocarcinomas. Therapy involves treatment of the underlying malignancy as well as other interventions, such as heparin, platelets, and cryoprecipitate, depending on the situation. Other bleeding disorders that have been reported, include hemostatic disruptions related to the paraproteins in plasma cell dyscrasias and acquired von Willebrand's disease in association with hematologic malignancies. Nonbacterial thrombotic endocarditis presents with sterile verrucous fibrin platelet lesions in the left-sided heart valve. Emboli to the brain and other organs can occur, and hemorrhage may also be seen at a number of sites. Adenocarcinoma of the lung is the most common etiology but other malignancies have also been implicated.⁹⁷ Anticoagulation is not beneficial in this disorder.

Other Paraneoplastic Syndromes

Fever can be seen in cancer patients as a paraneoplastic process. Before this diagnosis is considered, other etiologies, particularly infections, need to be ruled out. Renal carcinoma is the most common cancer associated with fever.⁹⁸ Fever can also occur in a number of hematologic malignancies, particularly Hodgkin's and non-Hodgkin's lymphoma, and is indicative of a worse prognostic category.

A number of other malignancies have also been reported to produce fever.⁹⁹ Pyrogenic cytokines produced by the tumor cells or induced via white blood cells are thought to be the source of "tumor fever." Some of these cytokines include interleukin 1, tumor necrosis factor, interleukin 6, and the interferons.⁹⁹ The production of the pyrogen cytokines can result in an acute response by the host. The pyrogen cytokines induce prostaglandin 2 (PGE₂) synthesis as an important part of fever production, which is likely the reason nonsteroidal antiinflammatory drugs (NSAIDs) have been effective at managing fever. It has been suggested that the NSAID naproxen can be used to distinguish fever related to tumor versus that of an infectious nature.¹⁰⁰ One randomized trial found three different NSAIDs to be equally effective.

tive.¹⁰¹ Corticosteroids are also useful antipyretics. Similar to the NSAIDs, they reduce prostaglandin synthesis and can block the transcription of the mRNA for the pyrogenic cytokines.⁹⁹

Cancer cachexia is one of the most frequent and difficult to manage problems encountered in the cancer patient. The cancer cachexia syndrome is characterized by anorexia, weight loss, and weakness resulting in impaired immune status, tissue wasting, and a decline in performance status.¹⁰² The most obvious clinical manifestation is weight loss. A study from the Eastern Cooperative Oncology Group showed that weight loss was associated with a significantly shorter survival and was dependent on the tumor type.¹⁰³ Anorexia resulting in decreased caloric intake is the main symptom contributing to the weight loss. Patients develop altered taste sensation and food aversions, particularly for protein-rich foods.¹⁰⁴ The anorexia and weight loss can be potentiated by location of the tumor (i.e., involvement of the GI tract, obstruction), pain, effects of cancer treatment, and psychologic factors.

The etiology of cancer cachexia is not totally understood but is believed to be multifactorial. There are a number of metabolic abnormalities that are characteristic of the cancer patient. Glucose metabolism is abnormal. There is increased hepatic production of glucose, increased use of glucose by the tumor, and the development of insulin resistance. There are also problems with protein, amino acid, and lipid metabolism, all favoring the nutritional needs of the tumor over the host.¹⁰² A number of cytokines, tumor factors, and hormones have been implicated in cancer cachexia, including tumor necrosis factors, interleukins, proteoglycan, insulin, corticotropin, epinephrine, human growth factor, and insulin-like growth factor.^{105,106} The management of cancer cachexia is particularly challenging. Despite the fact that malnutrition is evident, a number of trials failed to show any significant clinical benefit for nutritional support. In a review of more than 70 prospective randomized controlled trials that evaluated the clinical efficacy of parenteral and enteral nutrition in cancer patients, the data fail to show a therapeutic effect.¹⁰⁷ Parenteral and enteral nutritional support should still be considered in patients who have complications from therapy (e.g., esophagitis) or in those who cannot maintain adequate nutrition secondary to tumor obstruction. A number of pharmacologic agents have been evaluated in the treatment of cancer cachexia. The most commonly utilized drug is megestrol acetate (MA). In a trial by Loprinzi et al., a positive dose-response effect on appetite resulted with increasing doses of MA (no benefit beyond 800mg/day) and a trend toward nonfluid weight gain was apparent.¹⁰⁸ Steroids are frequently used but they generally do not have any prolonged benefit. Some of the other agents that have been evaluated include cannabimol derivatives, hydrazine sulfate, metaclopramide, cyproheptadine, melatonin, and pentoxifyllene. The studies utilizing those drugs either have been too small or did not show significant clinical benefit. Eicosapentaenoic acid (EPA), an omega-3 fatty acid, appeared to have promising results in early trials. Unfortunately, in a recent randomized study, EPA supplement, either alone or in combination with MA, did not improve weight or appetite better than MA alone.¹⁰⁹ Clearly, a better understanding of the etiology of cancer anorexia/cachexia and improved cancer treatment is needed before advances can be made.

Malignant Effusions

Shamus R. Carr and Joseph S. Friedberg

Epidemiology

Malignant pleural effusions are a common clinical problem. The estimated annual incidence of malignant pleural effusions in the United States is greater than 150,000 cases per year, with lung cancer accounting for nearly half.¹⁻³ Breast cancer, lymphoma, and ovarian cancer round out the top four leading causes of malignant pleural effusions.⁴⁻⁷

Anatomy and Physiology

The pleura has a dual innervation and blood supply. The visceral pleura lacks somatic innervation, whereas the parietal pleura has extensive somatic innervation, in addition to sympathetic and parasympathetic fibers. Although the visceral pleura is insensate, irritation of the parietal pleura can elicit pain, or "pleurisy."⁸ The visceral pleura receives arterial blood from both bronchial and pulmonary arteries, whereas the parietal pleura receives it from systemic arteries.⁹

Significant differences also exist between the lymphatic drainage routes of the visceral and parietal pleurae. Lymph from the visceral pleura drains into the pulmonary lymphatic network and is directed toward the pulmonary hilum. Depending upon the region of the parietal pleura, lymph from the parietal pleura drains into the corresponding internal thoracic, mediastinal, tracheobronchial, axillary, intercostal, or phrenic lymph nodes. Drainage into transverse cervical, celiac, or retrosternal lymph nodes also may occur. The visceral pleura has the majority of its lymphatic drainage concentrated in the lower lobes and is relatively sparse in the upper lobes; this is thought to be compensation for the greater connective tissue separation and higher venous pressure in the lower lobes compared to the upper lobes.¹⁰

The pleura is also important for maintaining local fluid homeostasis. The exact mechanisms of pleural fluid production and absorption are complex and not fully understood.^{11,12} Pleural fluid originates from parietal pleura capillaries and is produced at a rate of 0.01 mL/kg/h under normal conditions¹³ and is in equilibrium with reabsorption. The potential reabsorptive capabilities of normal pleura may be well in excess of 0.20 to 0.40 mL/kg/h, making it possible to process more than 700 mL fluid per day.^{14,15}

Pleural effusions accumulate when the balance between fluid formation and uptake favors the former. Causes of increased production of pleural fluid include increased hydrostatic or decreased oncotic pressures within the interstitial

microvasculature, loss of pulmonary volume, inflammation, increase in microvascular permeability, pleural involvement with metastatic malignancies, and either direct or indirect transfer of peritoneal fluid to the pleural cavity.^{15,16} In addition, obstruction of the thoracic duct or direct pleural invasion may result in fluid accumulation and are considered mechanisms leading to the formation of malignant pleural effusions.^{6,7}

Clinical Evaluation and Diagnostic Considerations

Patients with malignant pleural effusions are frequently symptomatic, but up to 25% of patients may be asymptomatic with effusions noted incidentally on a chest radiograph.^{6,17} Patients with pleural effusions may complain of cough, shortness of breath, dyspnea on exertion, or chest pain. Dyspnea may be caused by diminished chest wall compliance, decreased lung volumes, diaphragmatic depression, and/or contralateral mediastinal shift.¹⁸ Pleuritic chest pain may indicate involvement of the parietal pleura or direct chest wall involvement by underlying malignancy.⁸ As many as a third of patients with malignant pleural effusions present with weight loss and cachexia and appear debilitated by chronic illness.¹⁹ The presence of a malignant pleural effusion usually indicates advanced disease that is incurable with surgery alone.

Physical examination of patients with pleural effusions may reveal diminished breath sounds, pleural rub, dullness on percussion, reduced tactile fremitus, or decreased diaphragmatic excursion. Shift of the trachea or heart sounds to the contralateral side may be present with large effusions.

A chest radiograph is an excellent first test for a patient with a suspected pleural effusion. It can establish the diagnosis of pleural effusion, its size, if there is tracheal or mediastinal shift, and, with a lateral decubitus film, if it is free flowing. Blunting of the costophrenic angle is suggestive of a small pleural effusion and can be present with as little as 200 mL free fluid.²⁰ Complete opacification of the hemithorax may be present with massive effusions. Large pleural effusions are frequently associated with some contralateral mediastinal shift. When mediastinal shift is absent, it may be due to several reasons: volume loss of the ipsilateral lung secondary to bronchial occlusion or fixation of the mediastinal structures by pleural carcinomatosis/mesothelioma or malignant lymph nodes.¹⁹

Currently, the most useful radiographic study is a chest computed tomography (CT) scan. CT scans help establish the presence of a loculated pleural effusion, allow for evaluation of the pulmonary parenchyma if there is not complete lung compression, and distinguish pleural thickening from effusion. It also provides an excellent way to evaluate the mediastinum for the presence of masses or lymphadenopathy and permits detection of pleural-based nodules.²¹ The role of magnetic resonance imaging (MRI) in the evaluation of pleural effusions is limited, but it may be beneficial in better characterizing possible tumor involvement of the chest wall or diaphragm.²² Positron emission tomography (PET scan) with ¹⁸F-fluorodeoxyglucose provides less anatomic information but has the potential advantage of providing diagnostic information about the effusion. In one study of 35 patients with biopsy-proven lung cancer, PET scans had a sensitivity and specificity of 88.8% and 94.1%, respectively, in distinguishing between benign and malignant pleural effusions.²³ It is our feeling that this information may prove useful, but the true value of a PET scan in this setting would be to provide additional information about disease elsewhere, not to give a diagnosis of malignancy. In addition, treatment of a malignant effusion will depend on the type of cancer, and this cannot be determined with a PET scan.

Once a pleural effusion is documented, diagnostic or therapeutic thoracentesis should be performed to establish the nature of the effusion. Effusions are classified as either exudative or transudative based on established criteria:²⁴

1. Ratio of pleural fluid protein to serum protein concentration is greater than 0.5
2. Ratio of pleural fluid lactate dehydrogenase (LDH) to its serum concentration is greater than 0.6
3. LDH concentration in pleural effusion is greater than two-thirds of the upper normal value for the serum LDH

The overall accuracy of these criteria is 93% to 95%.^{25,26} Patients with congestive heart failure treated with diuretics, may benefit from pleural fluid cholesterol measurements because the accuracy of Light's criteria is decreased in this setting and transudates can be mistakenly classified as exudates. A pleural cholesterol level greater than 60mg/dL is indicative of an exudate and seems to be independent of the serum level.²⁷ In addition, the appearance of the fluid, its consistency and color, should be noted. Sanguinous effusions are commonly malignant. Measurements of pleural pH, glucose level, and differential cell count are routinely performed as well. In the absence of esophageal rupture, elevation of amylase and its salivary isotype is associated with lung cancer.²⁸ A prospective study of 841 patients with pleural effusions evaluated the cause and relative frequency of amylase-rich pleural effusions. High amylase levels were associated with three times the likelihood of finding tumor cells, most frequently, with adenocarcinomas of lung origin.²⁹

Pleural effusions are malignant when cancer cells are found on cytologic examination.³⁰ Malignant pleural effusions may be serous, serosanguineous, or bloody, and usually are exudative in nature,¹⁹ but about 5% to 10% of malignant pleural effusions are transudative. This finding is most commonly seen in patients with underlying conditions that may cause transudative effusions, such as renal failure, congestive heart failure, or early stages of lymphatic or bronchial obstruction.³¹

In addition to classifying pleural effusions as transudative or exudative, specific immunohistochemical tests and tumor markers have been evaluated to aid in the diagnosis of malignant pleural effusions. Immunohistochemical markers, such as anti-CEA, anti-B72.3, and anti-Leu M1, tend to be positive with metastatic adenocarcinoma and negative with either reactive or malignant mesothelial cells. More than 95% of adenocarcinomas are positive for at least two of the three listed antigens.³² Tumor markers, such as alpha fetoprotein (AFP), CA 19-9, CA 15-3, CYFRA 21-1, and CA 125 have been evaluated, but none has proven reliable to establish the diagnosis of malignant pleural effusion.^{33,34}

Cytology establishes the diagnosis of a malignancy in approximately half the patients during first cytologic examination.³⁵ The yield is increased to 65% to 70% with two subsequent thoracenteses, if examined by an experienced cytopathologist³⁵⁻³⁸; this results in a positive diagnosis in 80% of patients.³⁹ The type of primary malignancy affects the diagnostic yield of cytology. The diagnosis of adenocarcinomas can be established in nearly all patients, whereas patients with pleural effusions secondary to Hodgkin's disease, have a positive cytologic exam in less than 25% of cases.^{15,40-43}

Blind percutaneous pleural biopsy is another method to ascertain the diagnosis of pleural malignancy. It carries an 8% risk of pneumothorax, and adds little to the workup of the patient with suspected malignancy, because fluid cytology is much more sensitive in establishing the diagnosis of malignant pleural effusion. In a series of 118 patients with pleural effusions and negative cytology, closed pleural biopsy established the diagnosis of malignant pleural effusion in only 17% of cases.³⁵ The low diagnostic yield of closed pleural biopsy in patients with malignant pleural effusions can be explained by the fact that costal pleura is not involved by cancer in about 50% of patients, as initial metastatic disease most commonly occurs on the visceral, mediastinal, and diaphragmatic pleurae.⁴⁴

Video-assisted thoracic surgery (VATS) can be used to investigate the nature of pleural effusions. In a study of 620 patients where VATS was utilized to diagnose the underlying cause of effusion, only 8% percent remained without a diagnosis after the procedure.⁴⁵ The advantages of VATS include visually directed and selective biopsies of parietal, mediastinal, and visceral pleura, direct visualization and examination of the entire hemithorax, and simultaneous lung or lymph node biopsy if required. The procedure is well tolerated with less than 1% mortality.^{46,47} In addition, VATS provides the ability to divide adhesions and perform pleurodesis at the time of the operation with excellent results.⁴⁷ Thoracotomy for diagnostic purposes is almost never indicated, because less invasive methods can provide diagnosis in up to 97% of cases.⁴⁸⁻⁵⁰

Management

Once the diagnosis of malignant pleural effusion is established, palliative therapy is usually indicated because life expectancy in these patients is typically limited to a few months.^{15,19} Treatment should be directed toward symptomatic relief of dyspnea, control of the effusion, prevention of its recurrence, improvement of performance status, reducing duration and the number of hospitalizations, and patient and

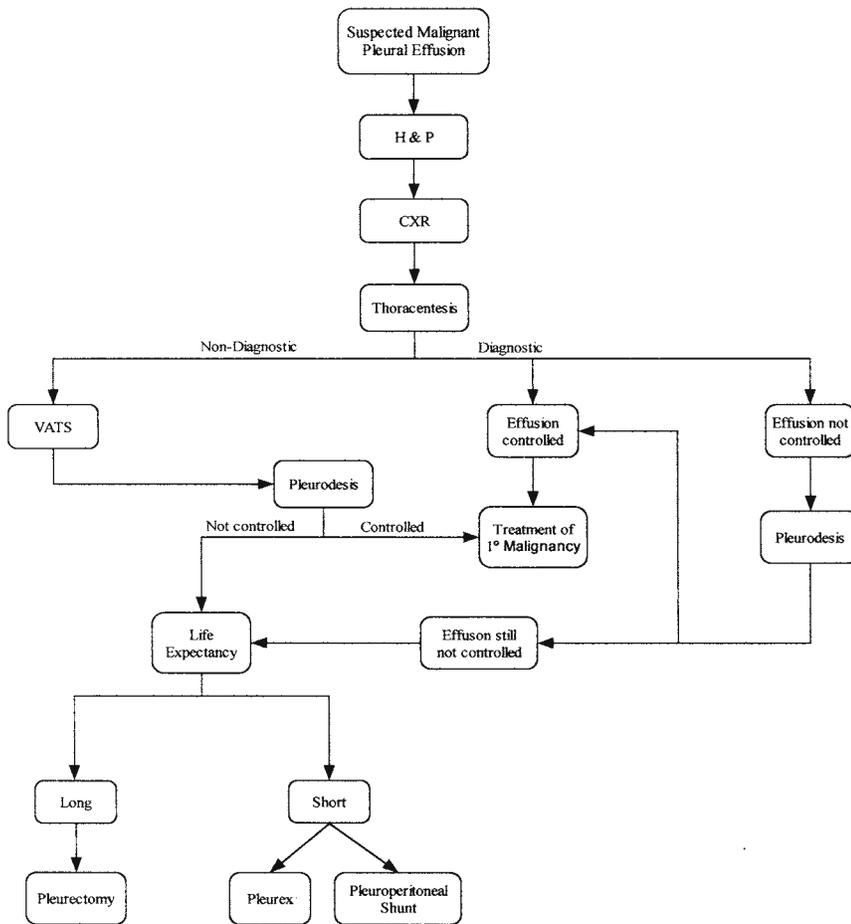

FIGURE 86.1. Algorithm for treatment options for pleural effusion.

family support (Figure 86.1). Prolonged survival has been documented in a few studies, if control of the primary tumor can be achieved.⁵¹ Several options are available to achieve these goals and are summarized in Table 86.1. There is rarely a role

for aggressive surgery in these patients outside a protocol setting.

Therapeutic thoracentesis is the first step in the management of patients with symptomatic malignant pleural effu-

TABLE 86.1. Options to prolonged survival if the primary tumor can be controlled.

	<i>Advantages</i>	<i>Disadvantages</i>
Thoracentesis	Rapid relief of symptoms, if lung is not trapped Potentially diagnostic Outpatient procedure	High recurrence rate Formation of loculations with repeat procedures
Pleurodesis	60%–93% success rate, based on sclerosant Can be done immediately after drainage, if lung reexpands	Morbidities based on sclerosants (see Table 86.2)
Pleurex catheter	Can be placed as outpatient Can be used with trapped lung Greater than 90% efficacy Up to 46% have spontaneous pleurodesis	10% need to be replaced for either infection or occlusion Risk of nutritional depletion
Pleuroperitoneal shunt	Relatively easy to use Can be used with trapped lung	Up to 15% rate of occlusion or infection Risk of nutritional depletion Pumping transfers only 2 mL fluid per pump; therefore, it is time consuming
VATS with pleurodesis	Directed biopsies provide the highest yield for diagnosis; 93% success rate when combined with pleurodesis	General anesthesia
Pleurectomy	Successful when effusion is refractory to other measures, if lung will reexpand	Painful High morbidity and mortality Very limited indications

VATS, video-assisted thoracic surgery.

sions and can be easily accomplished with a standard central venous line catheter, a commercially available thoracentesis kit, or image-guided drainage. The goal is to determine if drainage of the fluid will improve the patient's breathing. Drainage alone is very unlikely to prevent the recurrence of the effusion.^{41,52} Those who demonstrate symptomatic improvement and have reexpansion of the lung should be considered for pleurodesis. For this to be successful, obliteration of the pleural space, creating symphysis between the parietal and visceral pleura, is paramount to prevent the recurrence of the effusion. Although many clinicians believe there must be only minimal drainage to achieve pleurodesis, a randomized trial evaluating the volume of chest tube drainage before pleurodesis, demonstrated that, regardless of the amount of chest tube output, pleurodesis was successful 80% of the time.⁵³ This approach allows for earlier ambulation, shorter hospitalization, and better cost containment. Pleurodesis is appropriate for all patients with malignant pleural effusions who respond to thoracentesis except, perhaps, those with a life expectancy of less than 1 month.

Since the 1930s, more than 30 sclerosing agents have been evaluated and proved either ineffective, toxic, expensive, or inconvenient and, therefore, are no longer used.⁵⁴⁻⁵⁶ In 1972, tetracycline was introduced and remained the agent of choice until 1993, when it became unavailable in the United States.⁵⁷ Currently, sterile talc, bleomycin, and doxycycline are approved by the U.S. Food and Drug Administration for pleurodesis and are the most commonly used pleurodesing agents in the United States (Table 86.2).⁵⁸ There is an ongoing debate about which of these sclerosing agents provides the highest success rate. Multiple studies have shown talc to be effective in up to 93% of the cases, whereas bleomycin has a reported response rate between 60% and 80%. Doxycycline has a similar efficacy when compared to bleomycin.⁵⁹⁻⁶¹

When undergoing pleurodesis, it was previously assumed that patients should remain in bed and be frequently turned from side to side to provide equal dispersion of the sclerosing agent within the pleural space. A randomized trial using radiolabeled talc examined its dispersion and the success rate of pleurodesis in patients who were subjected to a standard turning protocol and those who were not. There was no difference in talc dispersion, and the success rate of pleurodesis for both groups was 85% at 1 month.⁶² These data echo animal studies that showed no evidence of improved distribution of pleural injectant with rotation.⁶³ Based on these studies, it is not recommended that patients be restricted to bed or posturally rotated after pleurodesis. Elimination of these protocols has increased patient comfort and decreased time consumed by medical personnel in turning patients.⁶⁴

Fever and chest pain are the most common side effects of pleurodesis.⁶⁰ In addition, talc and bleomycin have been reported to cause acute pneumonitis and acute respiratory distress syndrome.⁶⁵⁻⁶⁸ A major disadvantage of bleomycin is its cost. Bleomycin costs nearly \$1,200 per 60 unit dose, whereas the cost of 500 mg doxycycline is about \$75 and that of 4 g talc is less than \$5.

Another modality that can be used in the treatment of malignant pleural effusions, with or without pleurodesis, is pleurectomy. Pleurectomy involves removal of the parietal pleura and, if required, decortication of the lung. With pleurectomy, it is possible to control pleural effusions in more than 90% of cases, but with a documented morbidity of 23%, and a mortality of 10%,^{20,52,69} there are very limited indications. It has been reported that pleurectomy should be considered in a patient who is undergoing a surgical intervention for undiagnosed pleural effusion and malignant disease is found, or when chemical or mechanical pleurodesis is likely to fail, as in patients with persistent or recurrent pleural effusions and patients with trapped lung.²⁰ Some authors have stated that pleurectomy should not be undertaken in patients with a poor performance status or an expected survival of less than 6 months.⁵⁸ It is our preference that pleurectomy should be employed extremely selectively, either as part of a protocol or in unusual cases where the pleural malignancy has demonstrated a very indolent course but is causing symptoms refractory to other palliative measures.

In some institutions, VATS has become the procedure of choice in the management of patients with malignant pleural effusion, with a reported mortality of less than 1%.^{47,70,71} VATS allows for complete evacuation of the pleural fluid, precise biopsies, division of adhesions, implantation of indwelling catheters, mechanical or talc pleurodesis, and parietal pleurectomy. When VATS is combined with a maneuver to obliterate the pleural space, success rates as high as 93% have been reported.^{71,72}

An alternative to pleurodesis or pleurectomy is intermittent drainage. In the past, selected patients with malignant pleural effusions were managed by repeated therapeutic thoracentesis for symptomatic relief. The disadvantages of this method include rapid reaccumulation of the pleural effusion, development of intrapleural adhesions, resulting in a trapped lung, risk of infection, and the need for repeating the procedure, sometimes as often as weekly.⁴¹ Analysis of the fluid removed with serial thoracenteses has shown biochemical and cytologic evidence of an increased pleural inflammatory response and could explain the phenomenon of spontaneous pleurodesis and ultimate resolution of the effusion in a small percentage of patients.⁷³

TABLE 86.2. Sclerosants.

	<i>Talc</i>	<i>Doxycycline</i>	<i>Bleomycin</i>
Success rate ⁶⁰	93%	60%–80%	50%–60%
Cost	Less than \$5 for 4 g	\$75 for 500 mg	\$1,200 for 60 units
Pain ⁸³⁻⁸⁶	Painful (10%–30%)	Probably most painful (40%–80%)	Least painful (5%–20%)
Fever ⁸⁴⁻⁹⁰	35%	20%–30%	5%–20%
Morbidities ⁹¹	Empyema, pulmonary edema: less than 5%	None reported in literature	None reported in literature
Mortalities ^{92,93}	ARDS 1.2%	None reported in literature	Three cases of diffuse alveolar injury

ARDS, acute respiratory distress syndrome.

TABLE 86.3. Phase III randomized trials for treatment of malignant pleural effusion.

Author	Agents	No. of patients	Result
Bayly ⁹⁴	TCN vs. quinacrine	20	Equivalence
Fentiman ⁹⁵	Nitrogen mustard vs. talc	46	Talc better
Leahy ⁹⁶	CP vs. TCN	32	Equivalence
Fentiman ⁹⁷	TCN vs. talc	41	Talc better
Kessinger ⁸⁶	Bleo vs. TCN	34	Equivalence
Hamed ⁹⁸	Bleo vs. talc	29	Talc
Masuno ⁹⁹	Doxorubicin vs. doxorubicin and LC 9018	95	Doxorubicin and LC9018 better
Ruckdeschel ¹⁰⁰	Bleo vs. TCN	85	Bleo better
Hartman ⁵⁹	Bleo vs. TCN vs. talc	99	Talc better than Bleo better than TCN
Loutsidis ¹⁰¹	Talc vs. metchlorothamine	40	Talc
Yim ¹⁰²	VATS talc vs. talc slurry	57	Equivalence
Emad ¹⁰³	Talc vs. Bleo vs. talc and Bleo	60	Talc and Bleo best
Zimmer ¹⁰⁴	Talc slurry vs. Bleo	29	Equivalence
Martinez-Moragon ¹⁰⁵	TCN vs. Bleo	62	Equivalence
Patz ¹⁰⁶	Bleo vs. doxycycline	106	Equivalence
Putnam ⁷⁹	Pleurex vs. doxycycline	144	Equivalence
Diacon ⁸⁹	VATS talc vs. Bleo	36	VATS talc better
Sartori ¹⁰⁷	Bleo vs. interferon	160	Bleo better

Bleo, bleomycin.

The pleuroperitoneal shunt was introduced in 1982 for the management of pleural effusions.⁷⁴ Several series have shown that effective palliation can be achieved in up to 90% of cases.^{70,75-77} It is used for patients who have failed pleurodesis or systemic chemotherapy, are not surgical candidates, or have trapped lung. The major disadvantage of the pleuroperitoneal shunt is the length of time required to drain the pleural space. The volume of pumping chamber is only 1.5 to 2 mL, which translates into the necessity for frequent and protracted pumping sessions, a major inconvenience for patients. Infection and shunt occlusion are the most common complications, occurring in up to 15% of cases.⁷⁸

Recently, the Pleurex catheter (Denver Biomedical, Golden, CO, USA) was added to the armamentarium for the treatment of symptomatic, recurrent malignant pleural effusions. The catheter is placed into the pleural cavity under either local or general anesthesia, and allows for rapid drainage of pleural fluid by connecting the catheter to a drainage bottle or system as often as necessary to relieve symptoms. Additionally, spontaneous pleurodesis occurs in up to 46% of patients within 1 month of insertion of the catheter.⁷⁹ Compared to the pleuroperitoneal shunt, it is possible to drain the effusion quickly, manual pumping is not required, the catheters are well tolerated by the patients, and they are easy to manage by caregivers in outpatient settings. In prospective randomized multiinstitutional trials, the Pleurx catheters have been proved to be safe, practical, and cost-effective.^{80,81}

Table 86.3 shows the randomized trials for the management of malignant pleural effusion since 1983. One is struck by the small number of patients in the trials, leading to potentially misleading conclusions based on inadequate power. Nevertheless, it is generally agreed that talc is as good if not better than most agents and has the best cost profile. There does not seem to be an advantage to performing talc poudrage

as a VATS procedure. The Pleurex catheter, as already described, however, is becoming increasingly popular for these individuals because of its equivalent performance of effusion management, as well as the minimal toxicity profile and the ability to perform the procedure as an outpatient. There has been some concern in isolated centers about infectious complications with the catheter. Whether a randomized trial of the Pleurex catheter versus talc slurry will be performed is under discussion at a number of institutions.

Summary

Malignant pleural effusions remain a significant cause of morbidity for patients with cancers metastatic to the pleura or primary pleural malignancies. Once the diagnosis of malignant effusion is ascertained, a therapeutic thoracentesis should be performed to provide relief if the patient is symptomatic. If dyspnea resolves, chemical pleurodesis should be considered for permanent control of symptoms. Several methods of pleurodesis are available, and careful patient selection is a prerequisite for successful management. For an effusion that has defied diagnosis, or even as a primary diagnostic procedure, VATS should be considered. This operation can usually be performed through a single "chest tube" incision and can allow unification of the pleural space, complete drainage of the effusion, a diagnostic biopsy, instillation of talc, and accurate chest tube placement. Pleurectomy and/or decortication have a very limited role and should generally be considered in the setting of a protocol. External or internal drainage of effusions are other options, generally considered for patients who have failed pleurodesis. Future investigative efforts should be directed toward improved diagnosis, evaluation of novel immunomodulation methods, gene therapy, and clarification of current management protocols.⁸²

Evidence-Based Use of Hematopoietic Growth Factors for Optimal Supportive Care of Patients with Cancer

George D. Demetri

Hematopoiesis, the production and maintenance of blood elements, is critical to life. Many of the complications of cancer and anticancer therapies can be clinically damaging to patients as a result of adverse effects on normal hematopoietic mechanisms. Since the early 1990s, it has been possible for physicians to intervene with genetically engineered biotherapies, such as hematopoietic growth factors to mitigate the hematopoietic dysfunction of cancer patients.¹⁻⁴ In this chapter, the evidence is examined upon which physicians and other caregivers may base rational clinical decision making to provide patients with optimal supportive care to improve the hematopoietic problems associated with cancer.

Mechanisms and Differential Diagnosis of Cancer-Associated Hematopoietic Dysfunction

Cancer and its treatment may alter normal blood cell production, either by direct effects on hematopoietic stem and progenitor cells or by indirect mechanisms, such as inadequate nutritional status. The physical interactions in the marrow microenvironment among hematopoietic cells, microvascular endothelial cells, and connective tissue stromal cells, can be disrupted by hematologic cancers or metastatic solid tumor cells, leading to abnormal function. The anemia of cancer is a remarkably common feature of many diseases, likely representing a form of the complex syndrome known as the anemia of chronic disease. One of the most common causes of hematopoietic dysfunction in patients with cancer is iatrogenic, as a side effect of the cytotoxic therapies commonly used to treat many malignancies. Many variables can determine the hematopoietic impact of anticancer therapy, such as (i) the cytotoxic insult itself (e.g., chemotherapies with various mechanisms or radiation therapy), (ii) the doses and duration of therapy administered,

and (iii) host factors reflecting variables, such as nutritional adequacy and marrow functional reserve.

An understanding of the normal physiologic function of the hematopoietic elements can help explain the negative impact of cytotoxic therapies and can also allow physicians to predict how hematopoietic cytokines can mitigate the damage from such factors. Bone marrow “stem cells” generally exist in a relatively inactive, nonproliferative state. Selective expansion of a few clones of stem cells leads to a sizeable marrow-based compartment of proliferating cells at various stages of differentiation. This proliferative compartment of progenitor cells can supply the mature elements of the peripheral blood for up to 8 to 10 days after a cytotoxic insult; this can explain the delayed nadirs seen with most cytotoxic chemotherapy treatments, with repopulation of the cycling progenitor cell compartment ultimately leading to full recovery of normal blood cell levels.

The timing of hematopoietic dysfunction may vary depending on the mechanism of action of the chemotherapy, because cell-cycle-active agents affect the proliferating progenitor pool, whereas “stem cell poisons” (G_0 active agents, such as BCNU and busulfan) typically cause a much more delayed nadir and recovery (e.g., occurring 4 to 6 weeks after drug administration). The adverse impact of radiation on hematopoiesis will also vary based on the amount of radiation (dose and size of the irradiated field) as well as the duration of exposure.

It is essential to keep in mind the numerous derangements in normal physiology that may occur in the setting of cancer and/or cytotoxic treatment and which may contribute to pancytopenia. These factors may include deficiencies or lack or bioavailability of nutritional factors, such as folate, iron, or other vitamins. There may be abnormal regulatory mechanisms in hematopoiesis, such as cell-mediated suppression of hematopoiesis in aplastic anemia,⁵ the blunted response to erythropoietin with anemia in cancer patients,⁶ or the stimulation of thrombopoiesis associated with iron

deficiency anemia. Marrow fibrosis and stromal damage can occur either as part of a disease process or as a reaction to therapy, thereby compromising bone marrow reserve and function. Immunologically mediated destruction of cells, as well as other factors, such as splenomegaly, can result in clinically significant cytopenias. Most importantly, occult bleeding must always be considered in the differential diagnosis of persistent anemia and refractory thrombocytopenia. These clinical examples emphasize the importance of assessing cancer patients carefully for reversible medical etiologies of their hematologic complications before attributing these effects to the underlying neoplasms as a diagnosis of exclusion.

Hematopoietic Dysfunction by Cell Lineage

Leukopenias and the Risk of Fatal Infections or Other Adverse Outcomes

Cancer and the nonspecific cytotoxic approaches to treating cancers commonly result in abnormally low levels of white blood cells, leaving the patient vulnerable to an increased risk of infection. The immunocompromised status of leukopenic cancer patients has been recognized since the mid-1960s, when Hersh et al.⁷ and Bodey et al.⁸ reported that leukemia patients treated at the National Cancer Institute, had a significant risk of fatal infections, especially marked with lower levels of circulating leukocytes. Both the severity and duration of leukopenia were noted to be key variables which defined the risk of these immunocompromised cancer patients for fatal outcomes from the infections. This work has served as the basis for the subsequent evolution of clinical management of leukopenic cancer patients.

Patients with leukemias generally have more severe leukopenia that extends for a longer period of time than patients with common solid tumors, such as cancers of the prostate, gastrointestinal tract, breast, or lung. Nonetheless, the relationship between leukopenia and risk of fatal outcome has been assumed to be essentially the same in patients with leukemias, as well as those with solid tumors despite the shorter duration of risk in the latter group. This raises the issue of whether all cancer patients really are equally at risk for adverse outcomes from leukopenia. Clinical predictive models have been developed and tested by investigators, such as Talcott et al.⁹ and Klastersky et al.,¹⁰ in an effort to identify key clinical criteria that would reliably predict subsequent outcomes at the time a patient presents with fever and neutropenia, but these models have not been widely applied in practice. Cancer patients differ broadly, from young, otherwise healthy individuals with sarcomas and germ cell tumors, to frail elderly patients with multiple coexisting medical problems and multiorgan dysfunction. These individual patient-specific differences can also change the risks of leukopenia markedly. The risk of even a single patient having an adverse or fatal outcome from a potentially treatable infectious event has led to a widespread conservatism in this field, with conventional supportive care generally based on the administration of empiric broad-spectrum antibiotics, often with hospitalization. Research in this field has also been challenging because large numbers of very heterogeneous patients are required to assess rare events: the incidence of

fatal complications of leukopenia has, thankfully, been very low in most clinical trials over the past two decades. Reducing iatrogenic morbidity, such as hospitalization and potential toxicities of nephrotoxic antibiotics, is a reasonable goal to justify the use of hematopoietic growth factors; the costs of inpatient hospitalizations and other expensive interventions also may be sufficiently high to serve as an alternative rationale to change practice.

Leukopenia may also affect clinical outcomes for cancer patients in other indirect ways. The safe administration of cytotoxic chemotherapy is dependent upon a functional immune system, most often measured by the level of circulating neutrophils. In the setting of severe neutropenia, chemotherapy administration may be delayed or reduced to subtherapeutic doses. The impact of inadequate chemotherapy dosing may be particularly acute with malignancies in which chemotherapy is highly effective, such as patients with lymphomas¹¹ or even in the adjuvant therapy of breast cancer.¹² The importance of chemotherapy dose and schedule remains an area of active clinical investigation for many malignancies, and the availability of hematopoietic growth factor support has allowed many clinical trials to answer novel questions about dose and schedule of myelotoxic therapies.

Applications of Hematopoietic Growth Factors to Neutropenia

Table 87.1 lists the bioengineered human hematopoietic growth factors that are currently approved by the U.S. Food and Drug Administration (FDA) for clinical use. These agents have been widely adopted as a standard of practice in many clinical settings. However, the substantial costs of these agents as supportive care for patients receiving myelosuppressive chemotherapy makes it imperative to understand the benefits and limitations of the evidence, as well as to identify the optimal settings in which their use can make a significant difference in patient outcomes.

A more detailed review of recommendations for the use of the hematopoietic growth factors that act to mitigate leukopenia has been prepared by a clinical practice guidelines subcommittee of the American Society of Clinical Oncology (ASCO). These guidelines for the use of "colony-stimulating factors (CSFs)" were initially developed in 1994 and have subsequently been updated biennially.¹³⁻¹⁶ The ASCO guidelines were developed to encourage best practice, specifically, to encourage evidence-based use of CSFs in situations where efficacy was well documented, and also to discourage inappropriate use when no meaningful improvements in clinical outcomes were expected. These clinical practice guidelines have been published¹³⁻¹⁶ and can be accessed easily at the official Web site of ASCO (www.asco.org).

The first hematopoietic growth factors with the ability to increase the levels of circulating neutrophils to be tested in the clinic were granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). These agents proved remarkably effective in increasing the circulating levels of leukocytes, particularly neutrophils,^{1-4,17-20} even in the earliest stages of clinical testing. Administration of pharmacologic doses of these recombinant molecules was well tolerated overall: dose-limiting toxicities at very high doses of GM-CSF were identified as

TABLE 87.1. Hematopoietic growth factors commercially available for oncology indications in the United States.

Growth factor	Generic name	Trade name	Distributor(s)/ manufacturer(s)	Indication(s)
G-CSF	Filgrastim	Neupogen	Amgen	Cancer patients receiving myelosuppressive chemotherapy Patients with nonmyeloid malignancy following progenitor/stem cell transplantation For mobilization of PBPCs Patients with severe cyclic/chronic neutropenia Following induction chemotherapy in AML
Pegylated G-CSF	Pegfilgrastim	Neulasta	Amgen	Cancer patients receiving myelosuppressive chemotherapy
GM-CSFs	Argramostim	Leukine	Berlex	Following autologous or allogeneic progenitor/stem cell transplantation engraftment delay or failure following autologous progenitor/stem cell transplantation Following induction chemotherapy in older patients with AML Allogeneic stem cell transplantation For mobilization of PBPCs
EPO	Epoetin alfa	Procrit	Ortho Biotech	Anemia in patients with nonmyeloid malignancies receiving chemotherapy
NESP	Darbepoietin alfa	Aranesp	Amgen	Anemia in patients with nonmyeloid malignancies receiving chemotherapy
IL-11	Oprelvekin	Neumega	Wyeth	Mitigation of thrombocytopenia following myelosuppressive chemotherapy in patients with nonmyeloid malignancy who are at high risk of severe thrombocytopenia

AML, acute myelogenous leukemia; G-CSF, granulocyte colony-stimulating factor; EPO, erythropoietin; PBPC, peripheral blood progenitor cell.

pleuropericarditis, capillary leak, and venous thromboses, whereas clinical activity was clearly documented at doses far below the high doses associated with these adverse effects.²¹ Interestingly, no true dose-limiting toxicities have ever been described for G-CSF, even at massive doses (e.g., greater than 100 µg/kg/day) higher than one would ever use in the clinic.^{18,22,23}

G-CSF was first approved by the FDA in 1991, which gave it a very broad indication for commercial distribution and clinical application: reducing the incidence of febrile neutropenia in cancer patients with nonmyeloid malignancies receiving any sort of myelosuppressive chemotherapy. GM-CSF received a more narrow FDA approval in 1991, which limited the initial therapeutic indication to accelerating the hematopoietic recover, of patients with nonmyeloid malignancies undergoing autologous bone marrow transplantation (BMT). However, since the initial FDA approval, the clinical indications for GM-CSF have been expanded to include other indications, such as accelerating the recovery from myelosuppression in patients with leukemia who are undergoing induction chemotherapy, as well as indications in other transplantation-related settings.

A new formulation of G-CSF has been developed to modify the pharmacology of the recombinant protein. Pegylated G-CSF (pegfilgrastim) has a longer circulating half-life due to the pegylation of the protein backbone of the molecule, allowing a single injection per chemotherapy cycle to suffice, rather than the multiple daily injections required of unmodified G-CSF or GM-CSF. The convenience of this agent has driven its rapid acceptance by physicians and patients, and the safety and efficacy profile appears to justify the utility of this agent as equally effective as multiple daily doses of G-CSF. However, because a single dose of pegfilgrastim is the pharmacodynamic equivalent of G-CSF given in multiple doses, there may still be clinical indications for G-CSF, such as in the support of less intensive or more frequent chemotherapy where more flexibility of hematopoietic

support would be desired. The decision about whether to use filgrastim or pegfilgrastim is a complex one that must therefore, take into account the expected number of days for which hematopoietic support would be needed. In general, if approximately 7 or more days of filgrastim would be required, pegfilgrastim would be a reasonable agent to use for patient convenience. However, if frequent dosing or complex dosing schedules are required, filgrastim may offer the needed flexibility to avoid the concurrent administration of cell-cycle-active cytotoxics with CSF dosing. Concurrent dosing of CSF with chemotherapy may result in excessively severe myelosuppression, as the hematopoietic progenitors are shifted into proliferation at the same time that high levels of cytotoxic drug circulate in the patient.

Defining the Indication for Neutrophil-Stimulating Hematopoietic Growth Factors

Clinicians may be faced with several situations in which hematopoietic stimulation of neutrophil production might be advantageous for the patient. Broadly defined, the two major settings can be classified as either *prophylactic use* or *therapeutic use*. Prophylactic use of hematopoietic growth factors is defined as the use of an agent to prevent or minimize neutropenia that could be therapeutically detrimental (e.g., to prevent fever with neutropenia or other infections, or to allow continued dosing of chemotherapy on a specific dosing schedule). Prophylaxis is further subcategorized into *primary* or *secondary* prophylaxis. Primary prophylaxis is the setting in which patients who have never previously suffered any infectious episode (i.e., no prior fever or infectious episode during neutropenia) receive hematopoietic growth factor dosing in an effort to prevent any future occurrence. Secondary prophylaxis is defined as administering hematopoietic growth factor to a patient who previously experienced some infectious complication (e.g., prior episode of fever with

neutropenia), with the goal of preventing recurrent episodes of any infectious complication. The therapeutic use of hematopoietic growth factors may be defined as the administration of these agents to a patient once an infection or infectious complication is actively in progress, especially in the absence of prior prophylactic use of the agent (e.g., attempting to minimize the duration of ongoing fever with neutropenia).

Evidence Supporting the Use of Hematopoietic Growth Factors as Primary Prophylaxis

Extensive data from well-designed prospective randomized studies^{24,25} support the use of hematopoietic growth factors to minimize the risks of aggressively dosed cytotoxic chemotherapy to patients with cancer. Both the incidence and the duration of myelotoxicity have consistently been documented to be improved with the support of CSFs. A meta-analysis of eight randomized controlled trials that tested primary prophylaxis with CSFs in a range of malignancies treated with aggressively dosed chemotherapy regimens, supported the finding that primary prophylaxis could be quite effective at minimizing toxicities, with a reduction in the risk of fever with neutropenia [odds ratio (OR) = 0.38], fewer documented infections (OR = 0.51), and less infection-related mortality (OR = 0.60).²⁶ Similar benefits have been noted with a single injection of the longer-acting pegylated form of G-CSF as with multiple daily injections of G-CSF.^{27,28}

The costs of CSF support have driven much debate about the appropriate utilization of these agents. Previous editions of the ASCO CSF Practice Guidelines have emphasized that the expected incidence of fever with neutropenia or other expected complications would have to be 40% or more to justify the costs of CSF administration as primary prophylaxis. However, more recent data have noted that CSF support can be effective also in decreasing the incidence of infectious complications of chemotherapy, such as fever with neutropenia, in clinical settings where the expected risk is approximately 20%.²⁹ Despite the fact that the expected cost of CSF support is in the range of US \$2,800 per cycle, there are economic analyses that suggest that primary prophylaxis can be economically justified and favorable (given the alternative costs of inpatient hospitalization and management of infectious morbidity) for patients in whom the expected risk of fever with neutropenia exceeds 20% per cycle.^{30,31} It is noteworthy that, for many chemotherapy regimens in standard practice, the incidence of fever with neutropenia or other infectious complications, remains less than 10%. Therefore, for most chemotherapy regimens, the use of CSF support as primary prophylaxis is generally neither required nor suggested by the ASCO Guidelines. However, it is also important to note that there may, nonetheless, be advantages to the use of primary CSF prophylaxis in certain special populations, including the frail elderly with multiple comorbid diseases, patients with past history of serious infection, patients with bulky or very symptomatic disease with poor performance status or organ dysfunction, and others. Medical judgment should always be used in assessing the relative risks of chemotherapy in any given patient.

Although other clinical strategies also may be used in place of CSF support as primary prophylaxis, none are par-

ticularly relevant for broad use. Chemotherapy dose reduction is probably the most widely used technique to minimize chemotherapy toxicity in the first cycle of administration, but this could conceivably compromise therapeutic outcomes. The use of prophylactic oral antibiotics has been tested with varying success, but this strategy induces other toxicities [including gastrointestinal (GI) toxicities and rash from the antibiotics] and may facilitate the development of antibiotic-resistant organisms. Based on these concerns, the Infectious Disease Society of America has recommended against the routine use of antibiotics such as fluoroquinolones as prophylaxis of chemotherapy-associated infections.³²

The initial registration trial for GM-CSF used that agent to accelerate hematopoietic recovery from high-dose chemoradiotherapy with autologous bone marrow transplantation. To date, this agent has not been formally approved by the FDA for use in the broader context of chemotherapy-induced myelosuppression outside of transplantation or aggressive chemotherapy for acute leukemias.

Special Cases of "Prophylaxis"

Use of CSF Support to Deliver High-Dose or More Frequent ("Dose Dense") Chemotherapy

Traditional schedules of administration for many cytotoxic chemotherapy agents were generally developed in the era before the availability of CSF support. The "cycling" of chemotherapy was designed to induce damage to tumor (along with the hematopoietic and mucosal pools of stem and progenitor cells) with subsequent recovery of normal hematopoietic and mucosal elements, but with less recovery of malignant cells. Although preclinical models have demonstrated a steep dose-response relationship for many chemotherapy agents, these findings have generally failed to translate into meaningful clinical benefits for most common solid tumors. In the adjuvant systemic therapy of breast cancer, for example, improvements can be demonstrated for delivering standard versus substandard doses, although higher delivered doses requiring CSF support do not appear to result in major additional benefits.^{33,34} In a large number of clinical trials for solid tumors, administration of higher doses of chemotherapy with CSF support has failed to result in major improvements in clinical outcomes, although toxicities and costs have increased along with the doses. However, modest increases in "dose density" (defined as increasing drug delivery per unit time) have been more tolerable and may be associated with improved outcomes in some studies.¹² A judicious recommendation would be to consider as investigational the use of CSF support to increase chemotherapy doses above "conventional levels" unless well-designed prospective trials have confirmed the benefits in meaningful clinical outcomes of this approach.

Use of CSF Support for Patients Undergoing High-Dose Chemotherapy or Chemoradiotherapy with Stem Cell Transplantation

CSF support is critical to enable the modern approach to hematopoietic cell transplantation, both autologous trans-

plantation of peripheral blood progenitor cells as well as conventional allogeneic marrow transplantation. The use of CSFs in the autologous setting is at least twofold: first, to mobilize the circulation of high numbers of hematopoietic stem and progenitor cells into the bloodstream where they can be collected for subsequent transplantation use, and second, to stimulate the hematopoietic functions (proliferation and differentiation) of the transplanted stem and progenitor cells. The use of a CSF (either G-CSF or GM-CSF) in the setting of hematopoietic stem cell transplantation is generally considered a standard of care for these procedures associated with prolonged myelosuppression.¹³⁻¹⁶

Use of CSF Support for Patients with Acute Leukemia Undergoing Aggressive Induction Chemotherapy

Several studies worldwide have evaluated the use of CSF support to mitigate the enormous and expected myelotoxicity of induction chemotherapy for acute leukemias [both acute lymphocytic leukemia (ALL) and acute myeloid leukemia (AML)]. The results of these studies have shown that there is no major impact on the CSF support with regard to the malignant leukemic clones: no major impact to improve or reduce the incidence or duration of remissions has been observed. This finding is in many ways reassuring: there is no apparent antiapoptotic effect on the leukemic clones that might lead to an adverse impact on survival in these clinical trials. In fact, although there is no overall impact on survival, there does appear to be some modest ability of CSF support to decrease the lengthy inpatient hospitalizations that characterize the induction therapy for acute leukemias. These benefits might be justifiable purely on the basis of cost-saving, and certainly on the basis of allowing these patients more time out of hospital, with expected improvements in their function and quality of life,³⁵ as would be particularly true for elderly patients or those with poor performance status. Again, patient-specific variables are best applied to this important therapeutic decision.

In the setting of pediatric leukemias, especially ALL, extreme caution is warranted in the use of CSF as supportive care because this is a situation in which high levels of cure are expected. Although CSF support can improve certain acute toxicities, such as duration of neutropenia and hospitalization,³⁶ there may also be a higher risk of subsequent secondary myeloid leukemias or myelodysplastic marrow failures.³⁷ Based on this potential risk, the routine use of CSF support for pediatric patients with ALL treated with curative intent, generally has not been recommended.

Evidence Supporting the Use of Hematopoietic Growth Factors as Secondary Prophylaxis

Once a patient experiences an infectious complication of chemotherapy, such as fever with neutropenia, that patient is at increased risk of subsequent recurrences of infectious episodes. Hematopoietic growth factor support may decrease the risk of subsequent infectious complications if given prophylactically after chemotherapy ("secondary prophylaxis"). Analyses of the placebo-controlled trials of G-CSF support for patients receiving chemotherapy provided data that sec-

ondary prophylaxis can effectively decrease the risk of subsequent myelotoxicity from chemotherapy.^{24,26,29} An alternative approach, of course, might be to reduce the doses of chemotherapy administered, and no trial to date has proven that the "full dose, on time" strategy (with CSF support) leads to significant improvements in meaningful patient outcomes, such as overall survival, progression-free survival, or improved patient-reported quality of life. However, these hypotheses have not been fully tested in appropriately powered trials, and there may be some effect of dose and schedule on survival outcomes, especially for patients with very chemosensitive diseases, such as lymphomas or adjuvant breast cancer in which curative intent is being pursued.^{11,33} Therefore, medical judgment and specific clinical details are critical to guide practice regarding the choice between dose reduction, CSF support, or possibly both in highly compromised patients treated for palliation.

Evidence Supporting the Therapeutic Use of Hematopoietic Growth Factors

Although the foregoing studies evaluated the prophylactic use of CSF support, another logical option might be to treat only that subset of patients who suffer an active infectious episode once it has already occurred (so-called therapeutic intent). Multiple studies have been performed in this setting. Overall, the data suggest that, although there may be limited clinical benefit to this approach in certain patient subsets, the total benefit appeared to be less than if the CSF support were to have been used as prophylaxis.³⁸ Several reviews have summarized the results of many trials testing whether therapeutic application of CSF support during a period of fever with neutropenia would result in improved clinical outcomes.^{39,40} Although some marginal decrease in the duration of hospitalization was occasionally reported, overall there have not been major differences in the outcomes of patients who did or did not receive CSF support during hospitalizations for fever with neutropenia. It is again important to note that selected subsets of very high risk patients may nonetheless obtain benefit from the judicious use of CSF given with therapeutic intent in addition to standard antibiotics and supportive care. Predictive features of patients at very high risk for adverse outcomes during an episode of fever with neutropenia include such variables as the severity of neutropenia (e.g., fewer than 1,000 neutrophils/mL), the expected duration of neutropenia (with more than 7 days being an adverse prognostic indicator), poor performance status with sepsis features, and multiorgan dysfunction.^{9,10} Physicians must take all this into account when deciding whether therapeutic use of CSF support is indicated for any given patient presenting with an infectious complication of chemotherapy.

One area in which there is definitive evidence against the use of CSF support is in the setting of asymptomatic neutropenia without fever. In this setting, a randomized prospective clinical trial has definitively shown that there is no impact on clinical outcomes from the administration of CSF support to improve neutrophil levels in the absence of clinical problems.⁴¹ There is no reason to give CSF support to patients simply because of asymptomatic low neutrophil counts.

Special Cases of “Therapeutic Intent”: Use of CSF Support for Patients with Myelodysplastic Syndromes or Congenital Neutropenias

In patients with myelodysplastic syndromes (MDS) and other rare congenital neutropenias (such as cyclic neutropenias), marrow failure can lead to chronic or intermittent neutropenia, with occasional clinical problems of recurrent or severe infections. In these situations, intermittent dosing of CSF support may help alleviate the problems. In the case of cyclic neutropenia, intermittent dosing with G-CSF can effectively eliminate clinical problems with this disease.⁴² For other forms of MDS, intermittent dosing with CSF support may be appropriate, with the caveat that there are still no definitive data about whether CSF stimulation might accelerate further malignant transformation of the abnormal clones in MDS and lead to more rapid onset of secondary leukemias.

Dosing of Myeloid CSFs

The conventional dosing of G-CSF (filgrastim) is on a flat daily dose scale (5 µg/kg/day), administered subcutaneously, beginning approximately 24 hours after the last dose of chemotherapy and continuing until hematologic recovery (generally defined as a peripheral neutrophil count of 2,000–3,000 cells/µL). Dosing for pegfilgrastim is also on a flat basis, given as a single dose of 6 mg subcutaneously, approximately 24 hours after the last dose of chemotherapy. Dosing of GM-CSF (sargramostim) is recommended to be based on patient size, given as 250 µg/m²/day, subcutaneously, approximately 24 hours after the last dose of chemotherapy. Higher doses of G-CSF (10 µg/kg/day) are used generally for mobilization of peripheral blood progenitor/stem cells in patients preparing for transplant procedures.

Toxicities of Myeloid Hematopoietic Growth Factors

All genetically engineered versions of myeloid CSFs (G-CSF, pegylated G-CSF, and GM-CSF) have been remarkably well-tolerated agents overall, based on extensive clinical experience with these agents over the past 15 years. Nonetheless, as for any drug, certain side effects have been noted occasionally.

Bone Pain

The most common side effect observed with the use of G-CSF is mild to moderate bone pain, which typically occurs in the marrow-containing bones (such as the lower back, pelvis, or sternum) in about one-third of treated patients. Bone pain is usually noted at the initiation of G-CSF therapy or at the early phases of neutrophil recovery. Rarely, the pain can be severe and may even require analgesics for control. The pegylated version of G-CSF (pegfilgrastim) appears to have somewhat less prominent bone pain associated with its use. Bone pain has also been reported with GM-CSF, although it seems less pronounced with that agent.

Laboratory Abnormalities

Laboratory abnormalities observed with the rise in white blood cell (WBC) count that occurs during CSF administration, include elevations in serum lactate dehydrogenase (LDH), uric acid, and alkaline phosphatase levels (from leukocyte alkaline phosphatase sources).

Uncommon Side Effects

Uncommon side effects associated with the use of G-CSF include stimulation of preexisting psoriasis, Sweet’s syndrome (neutrophilic dermatitis), and cutaneous vasculitis. Chronic administration of G-CSF to patients with congenital or idiopathic neutropenia has been associated with splenomegaly, which could be dangerous in the case of traumatic rupture. Less frequently observed side effects associated with the use of GM-CSF, include diarrhea, anorexia, facial flushing, dyspnea, and edema. Other side effects that have been reported with the older *Escherichia coli*-derived version of GM-CSF, such as the first-dose phenomenon (hypoxemia within minutes of taking the first dose, resulting from leukostasis within pulmonary capillaries) and capillary leak syndrome, but these rarely have been observed with the currently available yeast-derived version of GM-CSF (sargramostim). Constitutional side effects, such as fevers, myalgias, headaches, and chills were reported in some of the earliest trials of GM-CSF, although these appear to be related to higher doses of GM-CSF.

In summary, the extensive clinical research in the development and application of CSFs to clinical oncology have led to many lines of high-quality evidence upon which to base practice.

Although survival outcomes are relatively easy to quantify, another dimension of improving clinical outcomes is the potential to increase the quality of life for patients undergoing myelosuppressive therapy. CSF support of myelosuppressive regimens may allow patients to tolerate these treatments with quantifiable improvements in their quality of life. To date, however, this has not been studied prospectively in a rigorous manner. Although costly in absolute terms, judicious use of CSF support has proven to add value and to be cost-effective (and even cost-saving) for certain clinically important outcomes.⁴³ Exhaustive analyses of evidence supporting the appropriate clinical utilization of hematopoietic growth factors for cancer patients have been developed and disseminated by the American Society of Clinical Oncology.^{13–16} These evidence-based clinical practice guidelines should be used as a practical reference as they are reviewed and updated on a regular basis.

Anemia in Patients with Cancer: Approach to the Problem and Practical Management with Hematopoietic Growth Factors

Anemia in patients with cancer is exceedingly common, ranges from mild to severe, and often is caused by multifactorial etiologies.⁴⁴ Both the incidence and severity of anemia in patients with cancer increase as the stage of the disease progresses. Cancer-associated anemia may be designated as an “anemia of chronic disease” only with a normal cellular

pattern in the marrow, low to normal serum iron and iron-binding capacity is demonstrated, the iron content of the marrow is normal or increased, and the serum ferritin is elevated.⁴⁵ Other causes of anemia, such as active hemolysis, occult bleeding, nutritional deficiencies, or marrow replacement by tumor, must be considered also in the diagnostic evaluation of anemia in cancer patients.

Serum erythropoietin (EPO) levels have been noted to be inappropriately low for a given level of anemia in patients with cancer compared to anemic patients without cancer.⁶ The expected increases in serum EPO levels can be further blunted by the administration of chemotherapy regimens with or without nephrotoxic agents, such as cisplatin.

Because the endogenous EPO response to anemia is inadequate in patients with cancer,^{44,46} treatment of the anemia of cancer with pharmacologic dosing of recombinant versions of human EPO represents a highly targeted and rational therapeutic approach. The logic is related to the "replacement therapies" that are often used in endocrine deficiency syndromes: in the case of erythropoiesis in cancer patients, the "inadequate hormone" is EPO itself, which can be replaced pharmacologically by provision of recombinant versions of this molecule. This hypothesis has been tested extensively in prospective, randomized, placebo-controlled trials, and the beneficial effects of supplemental EPO dosing are consistent and reliably documented, as discussed next. The ability of EPO to stimulate erythropoiesis in cancer patients and improve clinical outcomes, such as decrease, transfusion requirements, led the FDA to approve this agent in the early 1990s for the supportive care of anemic cancer patients with nonmyeloid malignancies receiving concurrent chemotherapy.

Prospective, randomized, placebo-controlled studies have been performed in heterogeneous populations of anemic cancer patients, either untreated with cytotoxic therapy or undergoing treatment with a wide variety of cytotoxic regimens. These trials generally have shown that EPO dosing induces a gradual increase in hemoglobin levels (occurring after approximately 3 to 4 weeks of EPO supplementation) in patients receiving pharmacologic dosing with EPO.⁴⁴

These initial findings have been confirmed and expanded in large community-based practice studies in approximately 7,000 cancer patients.^{44,47-49} In these large trials, one major goal was to quantify the patient-assessed quality of life using indicator scales measuring such dimensions as energy level, activity level, and overall sense of well-being. These studies confirmed preliminary findings from the initial placebo-controlled studies and showed that patients who respond to EPO dosing with an increase in hemoglobin levels, report clinically meaningful benefits in their quality of life parameters.⁴⁷⁻⁴⁹ Newer molecules based on the native molecular structure of human EPO, such as darbepoetin, have also been developed and tested. Darbepoetin was genetically engineered to increase the number of glycosylation sites exhibited by normal human EPO, and these extra carbohydrate residues increase the circulating half-life of darbepoetin by approximately threefold over the previous recombinant versions of human erythropoietin (either epoetin-alpha or epoetin-beta). In placebo-controlled studies, darbepoetin has also proven to have beneficial effects in stimulating erythropoiesis similar to the effects of EPO.⁵⁰⁻⁵²

The clinical value of treating cancer patients with EPO is based on the sustained clinical benefits that have now been

demonstrated in thousands of cancer patients receiving this supportive care. The costs of alternative strategies, such as transfusional support, as well as the opportunity costs of ignoring symptomatic yet mild anemias, allow the judicious use of EPO or darbepoetin to be cost-effective if appropriate metrics of value and utility are used to judge the benefits. Nonetheless, given the relatively high cost of optimal use of EPO or other recombinant versions of this agent, careful clinical assessments and data-based decision making on behalf of the prescribing physician is still warranted.⁵³ It is especially important to note the clinical situations in which EPO does not have the desired benefits for a patient, so that other elements in the differential diagnosis of persistent anemia can be evaluated and, if possible, resolved. Adequate iron levels, for example, are absolutely necessary for patients to achieve the full benefits of EPO supplementation. The optimal way to supplement iron, or even to measure functional iron reserves in cancer patients, remains controversial.

Besides patients with cancer, other forms of hematologic dysfunction also commonly exhibit anemia, either as the sole clinical manifestation or as part of a multilineage marrow failure state. Patients with myelodysplastic syndromes (MDS) are most often anemic and frequently have elevated levels of endogenous EPO. Several small pilot trials have attempted to stimulate more effective erythropoiesis in MDS patients by pharmacologic dosing of EPO.⁴⁵⁻⁵⁷ These clinical trials have consistently demonstrated clinical benefits with EPO supplementation in approximately 25% of patients with MDS. Although the prognostic factors that might predict a response to EPO supplementation remain poorly understood, most trials suggest that patients with exceedingly high endogenous EPO levels (generally defined as greater than 50 to 100 U/mm³ blood) have a very low probability of responding to EPO. EPO may also synergize with G-CSF supplementation in MDS patients, and attempts have been made to define the predictive factors for benefit.⁵⁷

For MDS patients who suffer from anemia and transfusion dependency, yet who exhibit relatively low, normal, or only slightly elevated levels of endogenous EPO, a trial of pharmacologic dosing with EPO is a very reasonable therapeutic strategy.

Dosing Considerations with EPO

The conventional dose and schedule with EPO was 150 units/kg given subcutaneously three times each week. However, EPO has also been approved by the FDA to be given as once-weekly subcutaneous injection of 40,000 units as a flat dose. Darbepoetin is recommended by the FDA in the package label to be given at the dose of 2.25 µg/kg administered subcutaneously on a once-weekly basis. However, less frequent administration has also been tested, and a flat dose of 200 µg every other week given subcutaneously is being widely promulgated for darbepoetin.

Safety Concerns in the Use of Erythropoietic Growth Factors in Cancer Patients

Certain safety considerations have arisen in recent years in specific clinical areas, particularly around the investigational use of EPO in settings, such as combined chemoradiotherapy.

First, a small number of patients in France treated with a recombinant version of EPO that is not commercially available in the United States, developed pure red cell aplasia,⁵⁸ which appeared to be caused by the presence of neutralizing antierythropoietin antibodies that arose during the EPO therapy.

This toxicity has not been reported with either epoietin-alpha or darbepoietin-alpha, the two EPO-related products that are available in the United States. It remains unclear what stimulated the low but real incidence of pure red cell aplasia in the European patients, but it was likely an issue of drug formulation that was unique to the European marketplace.

A more general concern was raised from other clinical trials that were testing EPO with the goal of achieving higher-than-standard levels of hemoglobin in cancer patients. The rationale for these studies was that higher levels of hemoglobin might improve the therapeutic effects of chemotherapy and/or radiotherapy by increasing oxygen delivery to tumor sites. Paradoxically, however, in a heterogeneous population of head and neck cancer patients, statistically worse survival was noted in the patients who achieved the higher hemoglobin levels with EPO supplementation.⁵⁹ Although the reasons for these observations remain obscure, it is possible that there may be potentially negative impact from the overly aggressive increases in hemoglobin levels targeted in this trial. It is likely that such excessively high hemoglobin levels might facilitate thrombotic and/or other vascular complications, especially because cancer patients have an excess incidence of clot formation and thrombovascular adverse events even in the absence of EPO. A public advisory board was held with the FDA based on these concerns, but the decision of the advisory board was that EPO and EPO-related molecules are safe when used as directed in the commercially approved labeling. Other clinical variables, such as the use of EPO with combination chemoradiotherapy, or the use of overly high hemoglobin target levels, may decrease the favorable safety profile of EPO, and therefore, these should be used only in well-defined and strictly monitored clinical trials.

Overall, EPO has been proven to have a very favorable safety profile when used in thousands of cancer patients worldwide. The appropriate utilization of agents to stimulate erythropoiesis has demonstrable and quantifiable clinical benefits for cancer patients in many settings.

Thrombocytopenia in Cancer Patients

Thrombocytopenia in cancer patients is usually attributable to iatrogenic issues, such as cytotoxic chemotherapy and radiation therapy, although impaired marrow reserve or marrow replacement by tumor can also lead to clinically relevant thrombocytopenia. Platelet function can be abnormal in cancer patients, even if normal numbers of platelets are observed. Bleeding and/or clotting complications are observed at an excess rate in cancer patients, most likely because of an underlying activation of inflammatory pathways and perhaps the release of tissue factors from proliferating tumor cells.

Data from 1960s trials in leukemia patients at the National Cancer Institute, demonstrated the quantitative relationship between platelet count and hemorrhage.^{60,61} These early studies proved that low circulating platelet counts increase the risk of potentially fatal bleeding complications.

Thrombocytopenia can also indirectly affect the outcomes of cancer patients by causing dose delays or dose reductions of planned cytotoxic drug regimens. Additionally, for patients receiving very aggressive chemotherapy, and certainly in the setting of induction therapy for leukemia or stem cell transplantation, thrombocytopenia can present major clinical challenges.

Hematopoietic Growth Factors to Stimulate Platelet Production in Cancer Patients: Challenges in Developing Clinically Useful Thrombopoietic Agents

The only thrombopoietic agent approved by the FDA to date is recombinant human interleukin 11 (IL-11) (Oprevelkin). Oprevelkin is a relatively nonspecific and pleiotropic cytokine that demonstrates some thrombopoietic activity.

IL-11 was approved by the FDA to prevent severe thrombocytopenia and to reduce the need for platelet transfusions following myelosuppressive chemotherapy in patients with nonmyeloid malignancies. This approval was based on the results of a randomized clinical trial of IL-11 in cancer patients who required at least one platelet transfusion after a prior chemotherapy cycle. In this trial, the use of IL-11 as secondary prophylaxis, reduced the need for platelet transfusions in a subsequent cycle of chemotherapy.⁶²

It is critical to recognize that severe thrombocytopenia requiring platelet transfusions is a relatively uncommon problem with administration of standard-dose chemotherapy. Nonetheless, thrombocytopenia can represent an increasingly severe problem over time, with cumulative damage to marrow cells developing with time.

Adverse Reactions

Patients treated with IL-11 commonly experience at least mild to moderate fluid retention, as manifested by peripheral edema and/or dyspnea. In some patients, preexisting pleural effusions have increased during IL-11 administration. Therefore, patients with a history of pleural or pericardial effusions or ascites, should be carefully monitored during IL-11 therapy. In addition, fluids and electrolytes should be monitored very carefully in any patients requiring diuretic therapy. Particular caution should be taken with the use of IL-11 in patients with a history of cardiac arrhythmias because palpitations, tachycardia, and atrial arrhythmias (atrial fibrillation or flutter) have been reported in association with this agent.

Future Directions for Stimulation of Thrombopoiesis

Improving the therapeutic index for thrombopoietic growth factors has proven difficult. Many of the adverse effects of IL-11 likely relate to the fact that this is an inflammatory cytokine, to some degree. Other more selective agents have been tested but have encountered problems. In particular, recombinant human thrombopoietin (TPO) has been tested extensively, with some early promising results.⁶³ However, the recombinant version also induced cross-reacting autoantibodies against native thrombopoietin in certain clinical trial subjects, and this safety concern led to discontinuation

of the development plans for this agent.⁶⁴ Newer agonists of the TPO receptor are in clinical development, and it is hoped that these might offer some improved activity for this hematopoietic lineage in the future.

Summary

The translation of basic scientific research into effective therapeutics has been a hallmark of the field of hematopoietic growth factors. Basic scientific inquiry has given us the knowledge and the recombinant proteins to manipulate human hematopoiesis for therapeutic use. The use of hematopoietic growth factors, coupled with an improved understanding of stem cell physiology and the signaling pathways that govern proliferation, differentiation, and apoptosis in hematopoietic cells, has already resulted in improved outcomes for patients, and new insights into basic mechanisms of physiology. Careful review of the data in this field will allow physicians to prescribe hematopoietic growth factors in a responsible, judicious manner to improve patient outcomes while being sensitive to economic values and costs of these agents.

Management of the Bone Marrow Transplant Patient

Daniel J. Weisdorf and Marcie Tomblyn

Progressive experience and success in application of blood and marrow transplantation has heightened attention to clinical management of the complications and long-term outcomes of such procedures. More than 20,000 patients yearly undergo transplant therapy and more than 25,000 patients survive beyond 5 years after transplantation. The recognition, prophylaxis, management, and screening for early complications and for late effects following successful transplant have developed by extrapolation of procedures for intensive therapy of hematologic malignancy (e.g., acute leukemia) and by recognition of specific toxicities, immunodeficiencies and problems encountered uniquely by the transplant recipient.¹ Similar to other hematology/oncology procedures, most management strategies are supported principally by empirically derived and some experience-supported evidence. Overall, less than one-quarter of transplant decision making is supported by Level 1 evidence.² We review the approach to transplant complications through the phases of therapy emphasizing the available evidence, the frequently held consensus opinions, and areas for future study.

Early Posttransplant Toxicities

Pretransplant chemotherapy and radiation are used for their immunosuppressive and antineoplastic impact but can be toxic to host tissues and organs, substantially augmenting peritransplant morbidity.³ Direct conditioning-associated toxicity may include oral mucositis,⁴ interstitial pneumonitis,⁵ hepatic veno-occlusive disease,⁶ gastrointestinal toxicity with nausea, vomiting, or diarrhea,⁷ desquamative dermatitis,⁸ and hemorrhagic cystitis.⁹ Much more infrequently, myocardial injury¹⁰ or central nervous system toxic encephalopathy¹¹ may occur. These toxicities may each mimic or be complicated by local or regional infection and can be compounded by delayed neutrophil recovery, poor tissue healing, and secondary infection.¹²

Delayed Engraftment/Graft Failure

Slow or incomplete hematopoietic recovery after transplantation yields ongoing neutropenia, transfusion dependence for platelets and red cells, and slow recovery from the initial toxicity of transplantation.¹³ Poor graft function can prolong and

exacerbate the risks of infection and directly increase peritransplant mortality. Criteria for a satisfactory autologous graft have been described in numerous, prospective single-arm studies (Level 2 evidence).^{14,15} Only a few comparative trials have addressed graft source or supportive techniques to improve the speed and completeness of autologous reconstitution.¹⁶⁻¹⁹

A suitable autograft should include at least 1×10^8 marrow aspirated mononuclear cells/kg. Since the late 1980s, blood-derived stem cell and progenitor cells have been collected by apheresis. Only a few formal comparisons of blood versus marrow autografts have been performed.^{17,19} Autologous marrow harvest was, for the most part, abandoned in the early 1990s.

Although direct quantitation of the hematopoietic stem cell content of autografts is still clinically unavailable, the surrogate measure of CD34+ cells/kg is used to judge the adequacy of an apheresis-collected progenitor population. A minimum of 2×10^6 CD34+ cells/kg is accepted as a suitable autologous graft likely to yield prompt neutrophil, platelet, and red cell recovery.¹⁵ Distribution of the cell infusion over several days²⁰ has been prospectively tested with no benefit. Similarly, formally testing delay in administration of granulocyte colony-stimulating factor (G-CSF) postgraft infusion to day 5,²¹ or use of higher daily doses of G-CSF,²² did not change the timing of multilineage recovery. No consensus about the dose or timing of G-CSF administration posttransplant has been well documented. Level 3 evidence from numerous retrospectively reported series,^{15,23,24} suggests that G-CSF may be unneeded if an autograft contains 5×10^6 CD34+ cells/kg, but still may have some supportive benefit if daily G-CSF (5–10 µg/kg/day) is administered for grafts containing 2 to 5×10^6 CD34+/kg. Growth factor-stimulated bone marrow-harvested autografts have been studied,^{18,25,26} but have not been pursued, largely because of suggested, although undocumented, concerns about tumor contamination in a marrow harvest or hypocellularity and difficult collections in heavily treated patients.

Engraftment After Allogeneic Transplantation

Allogeneic transplantation poses additional barriers to successful lymphohematopoietic reconstitution beyond the progenitor content of the infused graft. Supporting lymphoid and

stromal elements may be essential as well as immunosuppression sufficient to overcome histocompatibility barriers for a successful allograft. The intensity of immunosuppression, degree of histocompatibility between donor and host, and perhaps other poorly studied factors, such as NK-mediated rejection modulated by killer immunoglobulin receptor (KIR) alloreactivity or marrow stromal damage, may further limit the speed or completeness of alloengraftment. Extensive retrospective analysis suggests that alternative donor transplants (closely matched unrelated donor, URD) have limited graft failure risks (less than 5%),²⁷ although haploidentical-related transplants yield more frequent graft failure, which might be overcome by variant conditioning, megadose progenitor grafts, or favorable NK-mediated alloreactivity.^{28,29} No prospective data comparing strategies to limit risks of graft failure after allotransplant are available, although extensive single-arm and retrospective reports support these conclusions.

Peripheral Blood Versus Bone Marrow Allografts

After widespread adoption of peripheral blood stem cells (PBSC) for autologous transplants, G-CSF-mobilized allografts became extensively studied. Numerous prospective randomized trials comparing blood to marrow sibling donor allografts have been reported (Table 88.1). Although neutrophil recovery is generally quicker using PBSC, acute and, more often, chronic graft-versus-host disease (GVHD) occur more frequently after peripheral blood (PB) allografts.^{30,31} Few data support any long-term survival advantage for the use of G-CSF-mobilized PBSC for sibling donor transplantation. Nonetheless, early improvements in morbidity and mortality, reported in some series, accelerated worldwide adoption of G-CSF-mobilized PBSC for nearly all sibling donor transplants, at least in adults. Prospective studies are under way addressing these techniques in URD transplantation.

TABLE 88.1. Peripheral blood versus bone marrow allografts.

Trial	Reference	Year	N	Randomized	GVHD	DFS/survival	Conclusions

G-PB, granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood; BM, bone marrow; DFS, disease-free survival; OS, overall survival; PMN, polymorphonuclear neutrophil leukocytes; AL, acute leukemia; CML, chronic myelogenous leukemia; aGVHD, acute graft-versus-host disease; cGVHD, chronic GVHD; NS, not significant.

Children may suffer excessive GVHD after PB-derived allografting.³²

A newer approach, G-CSF-mobilized bone marrow harvest compared to G-CSF-mobilized PBSC apheresis, has been reported in a limited series³³ with equivalent survival, equally speedy engraftment, and more-frequent GVHD in PBSC recipients (see Table 88.1). Ji et al.³⁴ compared G-CSF-mobilized bone marrow to unprimed bone marrow harvest for sibling transplantation for chronic myelogenous leukemia (CML). The mobilized grafts had three-fold-higher CD34 content and lower CD4:CD8 ratios. Use of the cytokine-mobilized harvests led to significantly accelerated neutrophil (15 versus 20 days) and platelet (17 versus 24 days) recovery, and significantly less acute (6% versus 27%) and chronic (24% versus 33%) GVHD, although with similar relapse risks and similar survival. Additional experience from these small preliminary reports and others, suggests that G-CSF-mobilized bone marrow may add modestly to donor morbidity but yield possibly promising outcomes for the recipient.

G-CSF administration after allotransplantation is widely used but is not well supported by prospective study. Lee et al.³⁵ prospectively tested delayed administration of G-CSF post-PBSC allograft and observed equivalent neutrophil and platelet engraftment, although suggestively poorer survival in those receiving G-CSF starting day 0, but no other reports corroborate this negative effect. A single report³⁶ evaluated G-CSF initiated at either day 0, 5, or 10 after URD transplantation, and showed no differences in hematologic recovery, fever, use of antibiotics, relapse, or survival, although costs were reduced using later-onset G-CSF.

Overall, G-CSF-mobilized PBSC allografts result in prompt hematopoietic recovery and, if more than 5×10^6 CD34+ cells/kg are infused, posttransplant G-CSF may be unneeded. Uncertain risks of acute, and particularly, long-term development of chronic GVHD suggest that continuing follow-up of previous randomized trials and the prospective randomized trial currently under way in URD transplantation, will be necessary to conclude the equivalence or superiority of one graft source or another. Partial matched related donor transplants (haploidentical or better) are usually performed with PBSC, although no formal comparisons are available.

Umbilical Cord Blood Allografts

Unrelated donor umbilical cord blood (UCB) is increasingly frequently used to support allotransplanted patients without available HLA-compatible sibling or volunteer unrelated donors (URD).³⁷⁻³⁹ Used primarily for smaller or pediatric patients, increasing experience in adults shows promise, although delayed recovery or graft failure is frequent.⁴⁰ Infusion of two closely matched grafts may promote engraftment in adults.⁴¹ Only retrospective data are available, which suggest that both higher cell dose (more than $2-3 \times 10^7$ nucleated cells/kg) and progenitor content (more than $2-3 \times 10^5$ CD34+ cells/kg) are dominant predictors of satisfactory donor-derived neutrophil engraftment after UCB transplantation.^{37,39} Some retrospective data reported from Minnesota⁴² and France,⁴³ suggest that closely HLA-matched UCB donors yield more effective engraftment and survival, although only low-resolution HLA typing and matching have been studied. The impact of HLA-C or other locus matching has not been

analyzed or reported in depth. Developing experience, although limited, offers no strong evidence except to confirm that high cell dose and close HLA matching (four to five matched loci of six HLA-A, -B, -DRB1) is preferred, to expect prompt hematopoietic recovery after UCB transplantation.

Added host factors (myelofibrosis or splenomegaly) can augment risks of graft failure. Graft manipulation (T-lymphocyte depletion) may deplete stem cells or deplete essential, although uncertain, donor cellular elements necessary for satisfactory immunosuppression of the recipient and prevention of active graft allojection. Treatment of graft failure most often involves administration of G-CSF or granulocyte macrophage colony-stimulating factor (GM-CSF) in different doses or dose schedules. Randomized trials of growth factors given for delayed engraftment¹³ demonstrated acceleration of leukocyte, but not platelet, reconstitution. Limited testing of thrombopoietin or erythropoietin has been inconclusive in supporting their value. Additional stem cell infusions can be effective if graft failure develops.⁴⁴ Intensified immunosuppression, most often high-dose corticosteroids or antithymocyte globulin (ATG), has been used to prepare recipients for second allograft infusions. When the original donor (sibling or URD) is unavailable, such as with UCB, alternative donor sources (other UCB, volunteer URD, or partial matched related donors) have been tried, although only anecdotal and retrospective experience is available for review.

Oropharyngeal Mucositis

Direct toxicity to the oropharyngeal epithelium follows chemoradiotherapy conditioning and may be complicated by localized minimally invasive infection (viral, yeast, or bacterial), GVHD prophylaxis agents (e.g., methotrexate), or by GVHD.⁴ Prolonged neutropenia compounds the risk of local infections and delays oral healing. Painful swallowing, eating, talking, or airway compromise can follow severe oral mucositis, and its severity can directly augment risks of fever, systemic infection, requirement for parenteral nutrition or narcotics, prolonged hospitalization, peritransplant mortality, and increased costs of care.^{45,46}

The intensity of conditioning and use of methotrexate directly promotes greater epithelial trauma, apoptosis, and mucosal ulceration, yielding more frequent and more severe oropharyngeal mucositis. High-dose total-body irradiation (TBI) and etoposide are particularly mucosal toxic, but melphalan, especially if combined with TBI, yields severe mucositis as well. Management using local rinse debridement, topical anesthetics, and coating agents (magic mouthwash containing diphenhydramine), antacid solutions, or ice chips are largely supportive, and little formal study has documented their value. Formal prospective, and usually blinded, trials of antimicrobials (chlorhexidine, isoganan, calcium phosphate) have been undertaken with inconclusive results.^{4,47,48} Systemic cytokines have accelerated neutrophil recovery and concomitantly limited the duration of mucositis. Interleukin (IL)-11 worsened systemic toxicity and had no benefit.⁴⁹ Keratinocyte growth factor (KGF, palifermin) has significantly shortened the severity, duration, accompanying pain, and peritransplant morbidities of mucositis after intensively conditioning autografts.^{50,51} Similarly, amifostine has reduced the direct mucosal cytotoxicity of high-dose alkyla-

tors and has been used to facilitate intensive, augmented chemotherapy conditioning regimens.⁵² Only KGF and amifostine are of demonstrable benefit, but these have not been studied in widespread fashion nor yet been adopted for general use.

Hepatic Veno-Occlusive Disease

Jaundice, hepatomegaly, and fluid retention, resulting from stenosis or obliteration of terminal hepatic venules, comprises the syndrome of hepatic veno-occlusive disease (VOD) that follows high-dose chemotherapy and radiation conditioning for transplantation.^{53,54} Most often developing within the first month, this syndrome has been reported with extremely variable incidence because of differences in diagnostic stringency and specific criteria. Ten percent to 60% of patients may be affected with VOD, and this looseness in definition complicates interpretation of any and all literature about VOD.^{53,55} Generally recognized risk factors include intensive transplant conditioning or pretransplant chemotherapy (particularly including previous therapy with mylotarg), abnormal transaminase values, chronic hepatic viral infection, and other uncertain factors. Case series with more liberal definitions (reporting 30% to 50% incidence) include peritransplant liver toxicity without all the histologic and hemodynamic changes characteristic of florid VOD, whereas those with more stringent definitions (reporting 5% to 10% incidence) most often demonstrate all the clinical diagnostic features, plus hepatic reversal of flow by Doppler ultrasound and perivenular necrosis and fibrous obliteration on liver biopsy.⁵⁶ This severe VOD results in high mortality.

Prevention of VOD has been tested in several prospective trials, most frequently evaluating ursodeoxycholic acid, although corticosteroids, supplementation of hepatic glutathione, antithrombin III concentrates, prostaglandin E₁, and tumor necrosis factor- α (TNF- α) neutralization have all been studied; heparin⁵⁷ and pentoxifylline⁵⁸ were studied in modest size, prospective randomized trials.

Ursodeoxycholic acid was shown of benefit in several small trials but not confirmed in a larger Phase III prospective study.⁵⁹ Ursodeoxycholic acid is the only suggestively beneficial agent recognized to reduce VOD incidence and might be recommended, at least in high-risk patients displaying some pretransplant risk factors augmenting their hazards of VOD. The combination of ursodeoxycholic acid and heparin was not additive in its protective effect.⁶⁰

Therapy of VOD is uncertain. The thrombotic nature of its findings has led to uncontrolled testing of heparin, recombinant human tissue plasminogen activator,^{61,62} and supplementation of the anticoagulants antithrombin III and activated protein C, but no conclusive findings or comparative trials with strong evidence supporting its use are available. Defibrotide (DF) reduces the thrombogenicity of endothelium through numerous effects and has activity in reducing vascular injury and thrombosis in a variety of settings. Limited prospective noncomparative trials suggest its potential value,⁶³ although no clear evidence of efficacy is available. Other treatments supportive of liver dysfunction from other causes [plasmapheresis, intrahepatic portasystemic shunting (TIPS), and hemodialysis] have been used

without specific literature available to document their value in this setting.

Interstitial Pneumonitis

Although most lung complications following transplantation are infectious, two specific syndromes, idiopathic interstitial pneumonitis [sometimes called idiopathic pneumonia syndrome (IPS)] and diffuse alveolar hemorrhage (DAH) occur without infection.

The first, IPS, typically occurs in the first 2 to 6 weeks following transplantation, and is seen more frequently in patients with extensive pretransplant chemotherapy receiving high-dose cyclophosphamide or high-dose total-body irradiation (TBI), but it may be associated with blood transfusions, methotrexate, and GVHD.^{64,65} Some reports suggest that IPS occurs as frequently in syngeneic as allogeneic recipients, and postulate that immunodeficiency is a lesser risk factor for IPS than for infectious pneumonitis.^{66,67} Drug and radiation toxicities have been reported as major contributors, although no clear conclusions regarding this syndrome can be determined from formal trials comparing TBI or non-TBI conditioning regimens. In some trials, higher-dose TBI has been associated with more frequent IPS, although this is not consistently reported.^{68,69} Corticosteroids or anti-cytokines (etanercept or infliximab), have been proposed as cytokine shields and antiinflammatory protective agents, but their use has not been validated in prospective trials.

Diffuse alveolar hemorrhage (DAH) was initially reported in autograft recipients, but a similar syndrome occurs following allotransplantation that is, at times, included in the syndrome of IPS.^{70,71} Its specific diagnosis requires diffuse consolidation on chest X-ray, hypoxemia, and progressively bloody alveolar lavage obtained through bronchoscopy. Because bloody bronchoalveolar lavage (BAL), but not hemoptysis, is required for diagnosis, it is less frequently described in children (for whom bronchoscopy is performed less frequently), but true incidence figures are difficult to discern. Its presentation with dyspnea, hypoxemia, respiratory distress, and nonproductive cough, is usually rapid in onset and has an associated mortality of 70% to 100%. Supportive measures include correction of coagulopathy and aggressive ventilatory support. High-dose corticosteroids are regularly offered, but no controlled data and only limited, anecdotal series are available to support their use.^{70,72} Recombinant factor VIIa and other hemostatic agents have been evaluated informally, but no data beyond anecdotal reports have been published.

Posttransplant Host Defense and Infection

The initial chemotherapy and radiation insult blunts mechanical barriers to invasive infection through disruption of cutaneous mucosal and epithelial membranes.^{12,73} Neutropenia and hypogammaglobulinemia further limit defense against aerobic organisms. Severe cellular immune dysfunction, including T-cell lymphopenia and ineffective T-cell function persists for 6 to 12 months following transplantation.⁷⁴ These defects are more intense and more prolonged in patients developing GVHD. Natural killer cell recovery is early, within 4 weeks of transplant, although its importance

TABLE 88.2. Fungal prophylaxis.

Trial	Reference	Year	N	Randomized	DFS/survival	Conclusions
Goodman	77	1992	356	Placebo vs. Fluc	Superficial fungal 33% vs. 8%, $P < 0.001$ Systemic fungal 16% vs. 3%, $P < 0.001$	Prophylactic Fluc decreases the incidence of both superficial and systemic fungal infections

in host defense at that stage is undetermined.⁷⁵ In some reports, greater risks of infection follow alternative donor transplantation, even in the absence of clinical GVHD.⁷⁶

In the preengraftment 1 to 3 weeks posttransplant, neutropenia and oral/enteric mucosal disruption predominate. Fever is frequent, although only 50% of patients have specific pathogens identified. Tissue injury, transfusions, amphotericin, or other drug fevers may explain some of these culture-negative febrile episodes. Usual supportive care includes protective isolation, in many centers using high-efficiency particulate air (HEPA) filtration to reduce inhalation of airborne fungal pathogenic spores, although its use has never been formally tested. Early experience suggested reduction in febrile days for patients transplanted, using more extensive protective isolation including laminar airflow environments, broad-spectrum decontaminating antibiotics, and sterile food, but no reduction in defined infection or early mortality was observed.^{12,73} Recent experience, particularly with reduced-intensity allotransplantation and the brief neutropenia accompanying autografting, has led to abandonment of or at least diminished attention to protective isolation because many patients are cared for as outpatients.

Antibacterial prophylaxis directed toward aerobic bacteria using trimethoprim sulfa has been tested but has not been shown to be efficacious in leukemia or transplant recipients.^{73,77} Quinolones, especially those with gram-positive and gram-negative activity, have been more widely used, although definitive trials demonstrating their value in reduction in defined infection or reduced hospital days, 30-day mortality, or other proximate benefits remain uncertain. Some series suggest that their use limits febrile episodes and a need for systemic broad-spectrum antibiotic therapy, but these results have not been confirmed. Empiric broad-spectrum antibiotic therapy for neutropenic fever remains the norm, supported by numerous, although small, studies in the 1970s. Alternative

strategies, for the most part, have not been formally tested. Varying antibiotic combinations have been studied extensively, although none has emerged as superior. Attention to local hospital flora and antibiotic resistance patterns, formulary determinations, and associated other medication use (avoidance of nephrotoxic aminoglycosides in patients treated with calcineurin inhibitors) should determine choice of empiric antibiotic therapy.

Fungal infections have emerged during the past 15 years as the dominant and most frequently lethal pathogens affecting the transplant recipient (Table 88.2). Several studies documented the value of fluconazole in reducing yeast infections and overall peritransplant mortality,⁷⁷⁻⁷⁹ but concerns about inadequate prophylaxis against molds, especially *Aspergillus*, persist. Recent evaluations of itraconazole have shown promise in prophylaxis,^{80,81} but variable and uncertain absorption has limited its widespread use.

Controlled testing of voriconazole with its favorable oral absorption, pharmacokinetics, and efficacy have documented its value as empiric treatment for neutropenic fever and treatment of established aspergillosis.^{82,83} Large multicenter trials are currently assessing its efficacy compared to fluconazole for prophylaxis in allogeneic transplant recipients. Echinocandins (caspofungin, micafungin) have been recognized effective in some settings, but no formal prophylaxis trials document their utility for antimold prophylaxis in the high-risk allotransplant patient.^{84,85}

Therapy of invasive fungal infection remains imperfect despite the array of agents now available to supplement or replace amphotericin, the previous therapeutic gold standard. As above, voriconazole has proven superior in both efficacy and reduced toxicity when compared to amphotericin (conventional or lipid-based) as treatment for neutropenic fever or for established aspergillosis.^{82,83} Ongoing investigations with itraconazole, caspofungin, and several as yet unlicensed anti-

mold agents suggest that the toxicities accompanying conventional amphotericin may be undesirable because the other agents have less multiorgan toxicity and similar efficacy. Ongoing controlled study is essential for continued informed choices, recently made more difficult by the array of available antifungal agents.

Superior antimold activity of newer antibiotics may be supplemented with a change in strategy to preemptive treatment rather than broad and intensive therapy for all patients with culture-negative neutropenic fever. Serum galactomannan^{86,87} has been licensed for early diagnosis of aspergillosis and, although needing confirmation in additional multicenter trials, may prove valuable to supplement culture-negative fever, focal pulmonary infiltrates, or upper airway and sinus inflammation as early warning of the development of invasive *Aspergillus* or other mold infections.

Posttransplant Viral Infections

Three groups of viruses plague the immunocompromised transplant recipient. The herpes group viruses (herpes simplex, varicella-zoster, cytomegalovirus, Epstein-Barr virus, and possibly human herpesvirus 6) all need specific attention, screening, consideration of prophylaxis, and therapy if they reactivate following blood or marrow transplantation.^{12,73} Oral or genital herpes simplex virus (HSV) reactivates in nearly two-thirds of transplant recipients not receiving specific antiviral prophylaxis.⁸⁸ The efficacy of acyclovir or valacyclovir has been demonstrated in other set-

tings, and their use is widely applied to the HSV seropositive transplant recipient. Therapy with such antivirals is generally highly effective and is associated with limited toxicity. Disseminated HSV (pneumonitis, esophagitis, encephalitis) is uncommon with effective prophylaxis, prompt monitoring, and treatment.

Cytomegalovirus (CMV) risks are primarily determined by the patient's pretransplant exposure.⁸⁹ Highest risks of reactivation infection and disease are observed in CMV seropositive recipients, intermediate risks in seronegative allograft recipients receiving CMV seropositive donor transplants, and lowest risks in those who are CMV seronegative recipient and donor.⁹⁰ The seronegative recipient (with seronegative donor) requires protection against transfusion-associated transmission of CMV, and controlled studies have supported the value of CMV seronegative transfusion support,⁹¹⁻⁹³ leukocyte-depleted transfusion support, or the combination. The risks of CMV infection remain less than 5% in appropriately protected patients and CMV disease is rare, although one recent report highlighted the imperfect protection against transfusion-associated CMV transmission by leukoreduction.⁹⁴

The seropositive recipient or patient receiving a seropositive graft requires specific CMV management: either antiviral prophylaxis or aggressive and prolonged screening to detect early infection and initiation of preemptive therapy. Early randomized studies supported the value of acyclovir, despite its limited anti-CMV activity in vitro, as suggestively effective in preventing and delaying CMV infection after allotransplantation (Table 88.3). In many centers, its use in the

TABLE 88.3. Prevention of cytomegalovirus (CMV) reactivation.

Trial	Reference	Year	I	Randomized	Responses	Conclusions
Boeckh	97	1996	226	Preemptive ganciclovir vs. prophylactic ganciclovir	CMV disease +100 14% vs. 2.7%, $P = 0.002$ CMV disease +180 equal	Survival equal
Burns	95	2002	91	Acyclovir vs. ganciclovir	Antigenemia 41% vs. 31%, $P = 0.22$; CMV disease 17% vs. 13%, $P = 0.59$	Bacterial infection and neutropenia more common with ganciclovir
Ljungman	166	2002	727	Valacyclovir vs. acyclovir	CMV infection/disease 28% vs. 40%, $P = 0.0001$	Survival equal
Meyers	167	1988	151	Acyclovir vs. placebo for CMV seropositive	70% vs. 87% CMV infection, $P = 0.0001$; 22% vs. 38% CMV disease, $P = 0.008$	Superior 100-day survival
Prentice	168	1997	310	Acyclovir vs. placebo	Reduced risk of CMV infection	19% better survival at 1 year
Reusser	98	2002	213	Foscarnet vs. ganciclovir	CMV disease or death and EFS equal	More neutropenia, thrombocytopenia with ganciclovir
Schmidt	169	1991	104	Ganciclovir vs. placebo for asymptomatic CMV + BAL	25% vs. 70% CMV infection or death, $P = .01$	Preemptive ganciclovir prevents pneumonitis
Verdonck	180	1997	41	Risk-adapted ganciclovir	No CMV pneumonitis using ganciclovir for antigenemia or for acute GVHD	Effective strategy
Winston	99	2003	168	Valacyclovir vs. ganciclovir	CMV infection 12% vs. 19%, $P = 0.93$	Equal CMV disease
Zikos	100	1998	128	IV IgG vs. CMV-IgG	Antigenemia 71% vs. 61%, $P = 0.37$	Time to antigenemia 47 vs. 48 days, $P = 0.9$

EFS, event-free survival; BAL, bronchoalveolar lavage.

early posttransplant period continues despite only limited data supporting its value.^{95,96} Better tested is the more effective antiviral, ganciclovir, as specific CMV prophylaxis in the early posttransplant months. Its greater myelosuppressive activity confounds its superior antiviral effectiveness, and formal prospective trials⁹⁷ have suggested that its use as preemptive treatment following early detection of infection may be as effective as generally applied ganciclovir prophylaxis to the seropositive recipient. Foscarnet and valacyclovir had demonstrable efficacy as prophylaxis,^{98,99} but high-titer anti-CMV IgG did not¹⁰⁰ (see Table 88.3).

Therapy of CMV reactivation includes ganciclovir, usually in high dose for a minimum of 2 to 3 weeks induction and an extended 4- to 6-week maintenance period of antiviral suppression. Treatment of antigenemia ($n = 60$) compared to treatment of CMV isolated from alveolar lavage ($n = 58$) reduced CMV disease to 1.7% versus 12% ($P = 0.02$).¹⁰¹ This preemptive strategy led to CMV treatment in 48% versus only 13.8% of patients ($P = 0.001$), but GVHD and bacterial and fungal infections as well as survival were equivalent. Small comparative studies suggest efficacy of foscarnet for preemptive therapy as well, although its nephrotoxicity and metabolic disturbances (hypocalcemia, hypophosphatemia) complicate its general applicability and limit its efficacy for outpatient parenteral antiviral therapy. A comparison of foscarnet ($n = 110$) versus ganciclovir ($n = 113$) for antigenemia led to equivalent CMV disease and mortality, but neutropenia (4% versus 11%; $P = 0.04$) and stopping therapy for cytopenia (0% versus 6%; $P = 0.03$) was more common with ganciclovir.⁹⁸ Another smaller trial ($n = 39$) showed more CMV breakthrough with ganciclovir but similar CMV disease and treatment-related mortality.¹⁰²

Equally important as the efficacy of the antiviral preemptive therapy is regular and prolonged effective screening for CMV reactivation. CMV antigenemia (pp65 testing of circulating leukocytes) is highly sensitive although ineffective during the first few weeks of leukopenia following transplant, even though this period is rarely associated with CMV reactivation and infection. Polymerase chain reaction (PCR) assays (which may be more specific but are not available in all centers) have high specificity and sensitivity and demonstrate the same indications for preemptive antiviral therapy when detectable in posttransplant blood samples.¹⁰³ Detection of late CMV infection (beyond day 100 posttransplant) requires continuing surveillance, particularly for patients with ongoing GVHD and immunosuppression, but the strategic specifics of antiviral screening in the late posttransplant period have not been well tested.¹⁰⁴ Generally, CMV blood reactivation in a patient with ongoing chronic GVHD would be treated, although all surveillance series recognize that a small fraction of patients with low-level antigenemia or low PCR burden will fail to progress to CMV disease despite lack of effective antiviral therapy.¹⁰⁵ This anecdotal experience does not define the appropriate duration for aggressive surveillance and initiation of therapy for high-risk GVHD patients with CMV reactivation.

CMV disease, usually pneumonitis or enteritis, demands treatment, most often with high-dose ganciclovir plus IV immunoglobulin (IVIG).¹⁰⁶⁻¹⁰⁸ Studies in the 1980s defined the

high mortality of CMV pneumonitis. These risks are reduced by IV IgG, although viral neutralization but higher anti-CMV IgG titers in the infused product have not been associated with the efficacy of IVIG therapy.¹⁰⁷ Immunomodulation and reduction of lung injury through IVIG, along with effective antiviral antibiotics, can reduce the mortality of CMV pneumonitis to less than 50%, particularly if therapy is initiated before ventilator support for respiratory failure is required.

CMV enteritis has been poorly studied, and only limited prospective data support a therapeutic approach similar to that used for CMV pneumonitis. Retrospective data¹⁰⁸ emphasize the variable effectiveness of such treatment, but highlight the limited evidence upon which to choose therapeutic approaches to biopsy-documented CMV enteritis. An anti-CMV monoclonal antibody was tested prospectively,¹⁰⁹ but failed to prevent or modulate the severity of CMV disease.

Epstein-Barr virus is most often associated with posttransplant lymphoproliferative disorders (PTLD),^{110,111} which are best treated with antiviral therapy, IgG, and rituximab to lyse the virally infected CD20+ B-lymphoid neoplasm.^{112,113} No controlled data support these approaches, nor have these been formally tested in comparison, but promising retrospective series strongly suggest that rituximab, reduction in immunosuppression, and possibly antiviral treatment represent the best therapeutic approach to these otherwise highly lethal disorders. Infusion of donor lymphocytes (from allograft donors) also may be highly effective in treating PTLD.^{114,115}

Human herpesvirus (HHV) 6 has been associated with graft failure, encephalitis, enteritis, pneumonitis, and febrile posttransplant syndromes.^{116,117} Its detection through the PCR method is not always associated with notable symptomatology. Clear understanding of the HHV 6-associated syndromes and their management and therapy is still lacking. Center-specific approaches rather than evidence-based comprehension of their pathophysiology remains the norm in most transplant centers.

Respiratory viruses, including respiratory syncytial virus (RSV), parainfluenza virus (PIV), and other agents associated with upper or lower respiratory community-acquired infections, are frequent and threatening to the transplant recipient.¹¹⁸ RSV, because of its rapid diagnostic test (enzyme-linked immunosorbent assay, ELISA) and available therapy with inhaled ribavirin, has been most studied.^{119,120} Its seasonal occurrence has caused regular outbreaks in transplant units worldwide. Protection of patients from visitors and staff with upper respiratory infection (URI) symptoms (mask and handwashing) and isolation of URI-infected patients to prevent horizontal transmission is essential. A similar, nonseasonal syndrome caused by PIV has been described, but the lack of rapid testing has prevented definitive assessment of the efficacy of antiviral therapy.¹²¹ For both agents, alternative antivirals—IVIG and hyperimmune globulins—have been suggested, although no clear demonstrations of efficacy have been reported. Yearly influenza vaccine of transplant recipients and, perhaps more importantly, their immediate household contacts, is essential to reduce exposure and infection during seasonal influenza outbreaks.

Late Infections

Infections of 3 to 12 months or longer in the transplant recipient are well recognized,⁷⁶ especially in those with ongoing chronic GVHD who have defective opsonization of encapsulated bacteria (*Pneumococcus* and *Haemophilus influenza*). Poor T-cell function leaves patients at risk for *Pneumocystis carinii* or late fungal infection. Reactivation of varicella-zoster virus (VZV) or CMV are well-recognized risks. Vaccine strategies for *Haemophilus* and *Pneumococcus* have been investigated but not widely adopted.^{73,77} Donor vaccine and posttransplant recipient booster vaccines, particularly with protein adjuvant, newer-generation vaccines, are promising^{122,123} in augmenting antibody titers, although clinical efficacy has not been reported. Antibiotic prophylaxis against *Pneumocystis carinii* pneumonia (PCP) with trimethoprim sulfa, atovaquone, or dapsone is well recognized as effective in other populations. Limited reports in stem cell transplant patients, generally retrospective, support their continued use through 6 to 12 months posttransplant and 3 to 6 months after discontinuation of immunosuppression for chronic GVHD. Antipneumococcal antibiotic prophylaxis is essential for the chronic GVHD patient, but no formal reports of its efficacy are available. Widespread development of pneumococcal resistance to penicillin suggests that alternate agents (extended-spectrum quinolones) might be of value. Neither ciprofloxacin nor trimethoprim sulfa is effective as pneumococcal prophylaxis in the postsplenectomy or chronic GVHD setting. Ongoing antibiotic prophylaxis against VZV or CMV is not standardized although, as stated earlier, continuing CMV surveillance for the chronic GVHD patient under active immunosuppression is advisable, based upon the perceived risk and morbidity associated with viral reactivation.

Graft-Versus-Host Disease

Acute graft-versus-host disease (GVHD) is the most frequent life-threatening complication occurring following allogeneic transplantation.¹²⁴ Typically developing 3 weeks to 3 months after grafting, GVHD can produce a desquamative or even blistering erythematous skin rash, cholestatic hepatitis, and/or gastrointestinal (GI) involvement with nausea, vomiting, or large-volume secretory diarrhea. Its pathogenesis involves donor T-cell allorecognition, T-cell activation, and expansion in response to host alloantigens. GVHD is more frequent and more severe following partially matched or unrelated donor transplantation.¹²⁵ Some reports suggest its incidence and severity may be less in UCB transplants, despite their greater HLA donor-recipient mismatch.^{38,39,41} GVHD can be directly life threatening, can further confound host defense, and thus be complicated by infection. A chronic GVHD syndrome can develop with a sicca syndrome, hepatitis, GI involvement with esophageal dysmotility and weight loss, cutaneous scleroderma changes, contractures and arthralgias, and myopathy or genitourinary involvement.^{126,127}

GVHD requires specific prophylaxis, and numerous strategies have been studied in small and large prospective Phase III trials. Nearly three decades of experience extending from the acknowledgment that T lymphocytes are essential for initiating GVHD, led to graft manipulations to limit,

eliminate, or inactivate the donor T cells within the graft as GVHD prophylaxis.^{124,128} Varying intensities of T-cell depletion using anti-T-cell antibody plus complement, elutriation for mechanical cell fractionation, CD34 selection with resultant T-cell depletion, or anti-T-cell antisera "in the bag," have all shown variable effectiveness in limiting the frequency and severity of GVHD. Despite frequent studies of this approach, no consensus about its value, efficacy, or long-term advantage for use as GVHD prophylaxis remains. T-cell depletion regularly increases risks of graft failure, limits the allogeneic anti-tumor effect, sometimes resulting in more relapse, and may delay immune recovery, thereby augmenting risks of continuing opportunistic posttransplant infections. Despite ample evidence and extensive clinical testing, the heterogeneity of clinical settings (HLA-matched donor, unrelated donor, partial-matched haploidentical donor) and T-cell depletion strategies yields no clear evidence to conclude that T-cell depletion is either effective or ineffective at improving outcomes after transplantation. Extensive T-cell depletion can limit GVHD, but most reports demonstrate augmented alternative morbidity and similar mortality using T-cell depletion versus posttransplant immunosuppressive therapy for GVHD prophylaxis after any type of allogeneic transplant.

Pharmacologic GVHD prophylaxis is also widely studied (Table 88.4). Prevention of acute GVHD has been tested using single or combination therapies most frequently with corticosteroids, methotrexate, cyclosporine, tacrolimus, and mycophenolate mofetil (MMF). Newer anticytokine therapies (interleukin 1 receptor antagonist, anti-TNF antibodies, TNF receptor antagonists, IL-11) and newer drugs (sirolimus, pentostatin, fludarabine) have also been studied without clear conclusions as to their utility. This specific topic is the most frequent subject for prospective randomized trials in all allogeneic transplantation, yet there is continued variability across transplant centers because the evidence is uncertain.

In the 1980s, methotrexate (short course) plus cyclosporine was definitively demonstrated as superior to either cyclosporine alone, methotrexate alone, or either in combination with corticosteroids.¹²⁹⁻¹³¹ Subsequent trials suggested value for addition of low-dose prednisone, although these results are unconfirmed.^{132,133} Long-term follow-up shows no continuing advantage for the addition of prednisone. Two large trials in the 1990s (one in sibling donors, one in URD), tested tacrolimus versus cyclosporine in conjunction with short-course methotrexate as GVHD prophylaxis.^{134,135} In both studies, GVHD was less frequent using tacrolimus, but alternative morbidities and other complications yielded statistically similar survival and disease-free survival in both cohorts. Because of inhomogeneity in the randomized strata (particularly in the HLA-matched sibling trial), many centers adopted tacrolimus as superior. Frequently, lower therapeutic (5–10 ng/mL) targeted blood levels are used, although follow-up trials have not been reported to confirm its superiority.

Similarly, methotrexate, long a mainstay of GVHD prophylaxis, has had modifications to the originally reported four-dose, short-course regimen (15 mg/m² day 1, 10 mg/m² days 3, 6, and 11 posttransplant). Shorter courses and smaller doses (often 5 mg/m²) have been reported with less mucositis

TABLE 88.4. Prevention of acute GVHD.

<i>Trial</i>	<i>Reference</i>	<i>Year</i>	<i>N</i>	<i>Randomized</i>	<i>DFS/survival</i>	<i>Conclusions</i>
Antin	170	2002	186	IL1RA vs. placebo	61% vs. 59% B–D aGVHD	No effect of IL1RA on OS or DFS
Bacigalupo	171	2001	109	ATG vs. control	11% vs. 50% III/IV aGVHD with high dose ATG, $P = 0.001$; 39% vs. 50% cGVHD	OS equal; more infections with ATG
Bolwell	172	2004	40	CSA/Mtx vs. CSA/MMF	65% vs. 21% severe mucositis, $P = 0.008$; 18 vs. 11 days neutrophil engraftment, $P < 0.001$; equal GVHD	Less toxicity with MMF
Chao	133	2000	186	CSA/Mtx/Pred vs. CSA/Mtx	18% vs. 20% II–IV aGVHD, $P = 0.6$; 46% vs. 62% cGVHD, $P = 0.83$	Similar OS, DFS
Deeg	131	1997	122	CSA vs. CSA/prednisone	73% vs. 60% II/IV aGVHD, $P = 0.01$; 21% vs. 44% cGVHD, $P = 0.02$	OS equal
Locatelli	173	2000	59	Low-dose CSA vs. CSA	57% vs. 38% II/IV aGVHD, $P = 0.06$; 30% vs. 26% cGVHD, $P = \text{NS}$	Similar outcomes with low dose
Nash	135	2000	180	FK/Mtx vs. CSA/Mtx	56% vs. 74% II/IV aGVHD, $P = 0.0002$; 76% vs. 50% cGVHD, $P = 0.06$	Relapse 15% vs. 41%, $P = 0.03$; OS equal
Ratanath-arathorn	134	1998	329	FK/Mtx vs. CSA/Mtx	32% vs. 44% II/IV aGVHD, $P = 0.01$; 56% vs. 49% cGVHD, $P = \text{NS}$	More toxicity with FK
Ruutu	132	2000	108	CSA/Mtx/methylprednisolone vs. CSA/Mtx	19% vs. 56% aGVHD, $P = 0.0001$	Trend to less GVHD; equal survival
Storb	129	1989	67	Mtx vs. CSA/Mtx	53% vs. 33% II/IV aGVHD, $P = 0.012$; 80% vs. 42% cGVHD, $P = \text{NS}$	Less acute GVHD
Storb	130	1986	46	Mtx vs. CSA/Mtx	18% vs. 53% II/IV aGVHD, $P = 0.012$; 82% vs. 60% 2-year survival, $P = 0.062$	Less acute GVHD

IL1RA, interleukin 1 receptor antagonist; FK, FK506 (tacrolimus); CSA, cyclosporine; Mtx, methotrexate; MMF, mycophenolate mofetil.

and sometimes quicker neutropenia, but all studies have been too small and thus underpowered to recognize limitations in GVHD prophylaxis using these mini-methotrexate approaches.¹³⁶ They remain, however, increasingly frequently used. Individual center habits and local protocols, often thoughtfully but empirically derived from evidence-based literature, remain the norm in defining GVHD prophylaxis strategies across many centers.

Therapy of Acute Graft-Versus-Host Disease

In addition to potent immunosuppressive therapy to blunt the immunologically based tissue injury, critical elements for treatment of acute GVHD, include aggressive infection prophylaxis, nutritional support, mineral balance, and avoidance of polypharmacy and drug-associated toxicities. Specific GVHD therapy relies upon corticosteroids and has done so for more than two-and-a-half decades. Several formal trials have tested added immunosuppressive reagents for initial therapy of acute GVHD, but none has sustained a demonstrable

therapeutic advantage (Table 88.5). Antithymocyte globulin, ABX-CBL, daclizumab, and infliximab have been tested in formal prospective randomized trials with neither better GVHD symptom control nor reduced infections, lesser steroid requirements, nor improved short-term survival. Numerous other agents, including anti-TNF antibodies, pentostatin, etanercept, MMF, and denileukin diftitox (Ontax) have all showed promise in unconfirmed, single-arm, and small Phase II trials, but additional therapy evaluation in a more formal setting is required to accept any agent as promising for acute GVHD therapy.¹³⁷

Steroid dosing (1–2 mg/kg/day) of prednisone or methylprednisolone has been the most commonly applied initial therapy, with limited testing of higher doses not confirmed as superior. One formal trial compared shorter (8-week) versus longer (16-week) defined corticosteroid tapering and showed equivalent GVHD control, shorter total therapy, and no added risks of the quicker tapering schedule.¹³⁸ Little other evidence is available to strongly support the use of other reagents as primary or salvage therapy for flares of acute GVHD (anti-CD5 immunotoxin, interleukin 1 receptor antagonist, etanercept, infliximab).

TABLE 88.5. Treatment of acute GVHD.

Trial	Reference	Year	I	Randomized	Response	Conclusions
Couriel	174	2004	134	Infliximab vs. control	67% response; 62% CR	Many infections
Cragg	175	2000	100	Prednisone vs. ATG/Pred	76% responses in both groups	Equal survival; no advantage to ATG
Deeg	176	2001	27	ABX-CBL for steroid refractory GVHD	51% response; 26% CR	44% 6-month survival
Doney	177	1981	37	Prednisone vs. ATG/Pred	Equal response and survival	
Hings	138	1993	30	Long- vs. short-course prednisone	Similar control of GVHD with shorter course prednisone	Shorter therapy course preferable
Lee	178	2004	102	Daclizumab vs. prednisone	53% vs. 51% response, $P = 0.85$ 77% vs. 94% 100-day survival, $P = 0.02$ 29% vs. 60% 1-year survival, $P = 0.002$	Unsafe combination GVHD therapy
Martin	179	1996	243	CD5 immunotoxin vs. placebo	40% vs. 25% CR at 4 weeks but equal response at 6 weeks, 49% vs. 45% 1-year survival, $P = 0.68$	No net benefit of immunotoxin

ATG, antithymocyte globulin; CR, complete remission.

Chronic Graft-Versus-Host Disease

The continuing donor-derived immune attack on recipient tissues manifest as chronic GVHD develops in 30% to 40% of allograft recipients, more often in adults and recipients of mismatched transplants.^{126,127,139} Resembling scleroderma or lupus to some extent, but also including failure to thrive, intestinal dysfunction, bronchiolitis obliterans, and an ocular and oral sicca syndrome, chronic GVHD is often accompanied by autoantibody formation, hypogammaglobulinemia, and secondary infection. Its therapy requires long-term, low-dose immunosuppressive treatment with aggressive attention to hydration, nutrition, infection prophylaxis, and attempts to minimize the cumulative and chronic effects of long-term immunosuppression, including the consequences of extended steroid therapy. Diabetes, osteopenia, cataracts, and avascular necrosis of bone all complicate such extended therapy. Ongoing studies are required to minimize these toxicities.

In addition to corticosteroids, cyclosporine, azathioprine, MMF, pentostatin, hydroxychloroquine, and thalidomide have all been used as adjunct immunosuppressive therapies, most in limited single-arm Phase II trials. The promise of thalidomide was not confirmed in two prospective randomized trials.^{140,141} The first showed no advantage in disease control, infection prophylaxis, limited steroid use, duration of immunosuppressive therapy, or survival for patients treated with thalidomide, cyclosporine, and alternate-day prednisone compared to the latter two agents without thalidomide.¹⁴⁰ The other trial demonstrated intolerance of thalidomide for the majority of patients and incomplete continuation of therapy.¹⁴¹ Newer approaches to chronic GVHD show some, albeit limited, activity in a variety of small series, but no clear-cut guidelines for initiation or continuation of therapy beyond low-dose alternate-day steroids and calcineurin inhibitors have been recognized. Continuation of therapy for 6 to 9 months beyond active symptoms followed by slow withdrawal of therapy is the general recommended schedule. Several series have shown no advantage to even

cyclosporine beyond alternate-day steroids for patients with standard-risk chronic GVHD.^{139,142}

Late Complications of Transplantation

Study of late transplant complications has, for the most part, been directed toward identification of the possible toxicities, comprehension of specific risk factors, and recommendation of screening strategies to identify late toxicities. TBI, alkylating agents, and corticosteroids all contribute to cataract formation, but long-term results of TBI-sparing conditioning regimens and the incidence of such complications are not reported.¹⁴³ Hypothyroidism (30% to 50% of patients) and hypogonadism (60% to 90% of patients) develop and need periodic assessment through careful history-taking and occasional biochemical screening.^{144,145} Menopausal symptomatology and sexual dysfunction may develop requiring appropriate attention, sometimes hormone replacement and attention to prophylaxis against ongoing and progressive osteoporosis.¹⁴⁵⁻¹⁴⁹ No techniques, including gonadotropic inhibitors or pretransplant hormonal replacement for gonadal suppression, have proved effective at preventing or reducing the incidence of posttransplant gonadal failure for women. Nearly all men are azoospermic and thus infertile after transplantation. Transplantation without TBI can be fertility sparing in nearly one-third of patients, particularly in prepubertal transplant recipients, although secondary sexual development may be delayed.¹⁵⁰

The most dramatic, although not most frequent, post-transplant complication is secondary carcinogenesis as a consequence of prolonged immunosuppression, pre- and peritransplant alkylator and radiation mutagenesis, and viral-associated neoplasia.^{110,111} Greater than eightfold-higher risk of cancer for transplant recipients has been reported, most involving non-Hodgkin's lymphomas and secondary myelodysplastic syndromes or acute myelogenous leukemia (AML), but no formal studies have addressed peritransplant

techniques to reduce the incidence of posttransplant secondary neoplasia.¹⁵¹⁻¹⁵⁴ Limited use of irradiation, reduced exposure to alkylators or other DNA-damaging agents, and earlier transplantation before years of alkylator exposure (e.g., for lymphoma or chronic lymphocytic leukemia) have occurred, might be effective in these goals, but definitive evidence to support these contentions is lacking.¹⁵⁴

Recovery and Quality of Life

Stem cell transplant survivors generally return to full and complete functional status.^{148,155-157} Numerous quality of life reports have shown that, within 1 year of transplantation, the vast majority of patients return to work and nearly 90% of autologous transplant recipients show high quality of life in formal testing.¹⁵⁷ Allogeneic transplant recipients recover more slowly, especially those beyond 35 or 40 years of age, those with chronic GVHD, and those in whom physical and ongoing psychologic problems delay their return to full health and good performance status. A recent report¹⁵⁸ emphasized that full recovery after transplant requires 3 to 5 years for the majority of patients. Patients with slower physical recovery had higher medical risks and were more depressed before bone marrow transplantation. Patients with chronic GVHD, those with less pretransplant social support, and women had more posttransplant depression. Encouragingly, even patients who had extended cancer therapy before transplantation had rapid recovery from depression and overall treatment-related distress.

Summary

Overall, the life-saving potential of transplant therapy remains unchallenged by many new advances in cancer therapy. Continued efforts to reduce peritransplant morbidity and mortality require less empiricism, less reliance on experience, and additional focus on formal testing of diagnostic therapeutic and long-term supportive care approaches that can definitively improve the outcome and augment the applicability of transplantation to a larger patient population, although complex medical care in this field, as in many others, relies on expanded experience and specialty expertise. Coalescence of that expertise into defined clinical protocols, followed by testing in prospective therapeutic trials, can help remove the lore and support the physiologically based best practices in managing recipients of transplantation.

Management of Anxiety and Depression in Adult Cancer Patients: Toward an Evidence-Based Approach

Paul B. Jacobsen, Kristine A. Donovan,
Zoë N. Swaine, and Iryna S. Watson

Anxiety and depression can be viewed as part of a broader construct of psychologic distress. We chose to focus on anxiety and depression rather than on psychologic distress for several reasons. First, the literature on anxiety and depression can be more readily identified than the literature on the broader and less well defined construct of psychologic distress. Second, as described in the following, criteria have been established for the diagnosis of clinical syndromes of anxiety and depression; no similar criteria exist for the diagnosis of clinical syndromes of psychologic distress. Third, as described here, this approach allows us to build upon the findings of several previous systematic reviews and meta-analyses that also have focused on psychosocial and pharmacologic approaches to the management of anxiety and depression in adult cancer patients.

Heightened anxiety or depression in individuals diagnosed with cancer is well documented.^{1,2} Possible sources of anxiety or depression in these individuals are varied and include pre-existing psychologic problems (i.e., problems predating cancer diagnosis), reactions to the diagnosis of a severe and/or life-threatening illness, and concerns about or reactions to disruptions in life plans, diminished quality of life, and disease recurrence or progression. In addition, anxiety and depression can occur as a reaction to adverse disease symptoms or treatment side effects (e.g., pain, nausea, and fatigue) or as a direct result of the effects of disease or treatments on the central nervous system. Observational studies indicate that heightened anxiety and depression are not limited to the active treatment period but can persist for months or even years following successful treatment.³

Estimates of the prevalence of anxiety and depression in cancer patients vary widely. For example, one review reports prevalence rates for depression in cancer patients ranging from 1.5% to 50%.⁴ This variability in prevalence is most likely a reflection of differences across studies in the charac-

teristics of the samples recruited, and the methods used to assess anxiety and depression. With regard to sample characteristics, differences across studies in patient factors, such as age and disease severity, are likely to influence prevalence estimates; research consistently indicates greater anxiety and depression in younger patients and patients with more advanced disease. Concerning the methods used, differences in prevalence may reflect whether anxiety and depression were assessed using a single-symptom approach, a symptom cluster approach, or a clinical syndrome approach. The single-symptom approach refers to assessment methods that focus specifically on measuring anxious or depressed mood as a continuous variable (e.g., visual analogue scales measuring severity of anxious or depressed mood) or a categorical variable (e.g., clinical interview items measuring presence/absence of anxious or depressed mood).

The symptom cluster approach refers to assessment methods that focus on measuring constellations of anxiety or depressive symptoms theorized to reflect the construct of interest. Common symptom cluster approaches to measuring anxiety and depression in cancer patients, include self-report scales such as the State-Trait Anxiety Inventory⁵ and the Beck Depression Inventory.⁶ The content of the State-Trait Anxiety Inventory consists primarily of affective symptoms whose presence is either consistent with the presence of anxiety (e.g., "I feel frightened") or inconsistent with the presence of anxiety (e.g., "I am relaxed"); the latter are reversed coded for scoring purposes such that higher scores on the State-Trait Anxiety Inventory reflect greater anxiety. The content of the Beck Depression Inventory includes cognitive symptoms of depression (e.g., pessimism), affective symptoms of depression (e.g., sadness), and somatic symptoms of depression (e.g., changes in appetite).

The clinical syndrome approach refers to assessment methods used to detect the presence of an anxiety disorder

(e.g., generalized anxiety disorder) or a mood disorder (e.g., major depressive disorder). In the United States, this approach usually involves the application of criteria identified in the fourth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV).⁷ For example, a diagnosis of a major depressive episode requires the presence of five or more symptoms of depression, at least one of which is either depressed mood or loss of interest or pleasure in usual activities; additional symptoms may include somatic symptoms (e.g., changes in appetite) or cognitive symptoms (e.g., feeling of worthlessness or excessive or inappropriate guilt). A diagnosis of a generalized anxiety disorder requires the presence of excessive anxiety and worry, difficulty controlling the worry, plus three or more additional symptoms of anxiety (e.g., difficulty concentrating, irritability, or muscle tension). Studies of the prevalence of anxiety and depression in cancer patients have typically relied on a clinical syndrome approach. Prevalence has also occasionally been estimated using cutoff scores for clinically significant symptomatology on symptom cluster measures, such as the Hospital Anxiety and Depression Scale.⁸

Although prevalence estimates vary widely, there is general agreement that anxiety and depression are among the most common symptoms experienced by cancer patients. This assertion is supported by recent surveys of symptom prevalence among cancer patients.^{9,10} The importance of these symptoms is also reflected in the relatively large number of studies identified here that have evaluated the effects of psychosocial and pharmacologic interventions for anxiety and depression in cancer patients. Before discussing the methods used to identify these studies and reviewing their findings, we describe previous systematic reviews and meta-analyses that have examined the effects of interventions for anxiety and depression in cancer patients.

Existing Clinical Practice Guidelines for Management of Anxiety and Depression in Cancer Patients

In recent years, several organizations have proposed clinical practice guidelines that include recommendations for the management of anxiety and depression in cancer patients. Two of these guidelines are described next to illustrate different approaches to the development of such guidelines.

National Comprehensive Cancer Network Guidelines

The National Comprehensive Cancer Network (NCCN) Guidelines for Distress Management,¹¹ which were updated annually, consist primarily of recommendations for evaluation, treatment, and follow-up care organized in terms of clinical pathways. Most of the recommendations represent a uniform consensus among panel members based on lower-level evidence, such as clinical experience, as opposed to higher-level evidence, such as randomized clinical trials.

Recommendations for the management of symptoms of anxiety and depression appear primarily in the sections of the guidelines devoted to adjustment disorder, anxiety disorder,

and mood disorder. Underlying each recommendation is the assumption that, before initiating treatment, patients have been referred to a mental health team for psychologic/psychiatric evaluation. Nevertheless, the guidelines recognize that variations exist across clinical sites in the resources and personnel available to implement these recommendations. Accordingly, the guidelines stipulate that multidisciplinary institutional committees be formed to implement local standards for distress management.

The NCCN guidelines recommend an initial determination of suicide risk for patients with symptoms of adjustment disorder and mood disorder. If the patient is at risk for suicide, patient safety should first be assured and hospitalization should be considered.

For patients with a mild adjustment disorder, the initial recommendation is to initiate psychotherapy or counseling before follow-up or reevaluation. For patients with a moderate to severe adjustment disorder, the initial recommendation is to prescribe psychotropic medications and begin psychotherapy before follow-up or reevaluation. For patients with a mood disorder, the initial recommendation is for evaluation, diagnostic studies, and modification of factors potentially contributing to mood disorder symptoms, such as concurrent medications, pain, and withdrawal states. Based on findings, subsequent recommendations include initiation of antidepressant medication and psychotherapy (with or without concurrent initiation of anxiolytic medication) and consideration of referral to social work services or pastoral counseling before follow-up or reevaluation. For patients with signs and symptoms of an anxiety disorder, the initial recommendation is for evaluation, diagnostic studies, and modification of factors potentially contributing to the presenting symptoms, such as concurrent medications, pain, and withdrawal states. Based on findings, subsequent recommendations include psychotherapy (with or without anxiolytic medication and/or antidepressant medication) before follow-up or reevaluation.

National Breast Cancer Centre and National Cancer Control Initiative Guidelines

In 2003, the National Breast Cancer Centre and the National Cancer Control Initiative in Australia, published the first edition of "Clinical Practice Guidelines for the Psychosocial Care of Adults with Cancer."¹² The guidelines are presented in the form of a series of recommendations accompanied by identification of the levels and sources of research support. Numerous recommendations relevant to the present review appear throughout the document, and a complete summary of these recommendations is well beyond the scope of the current review. A table included in the document provides a succinct summary of all recommendations for psychosocial care of cancer patients that are based on systematic review of all relevant randomized controlled trials (Level I evidence) or at least one properly designed randomized controlled trial (Level II evidence). Those recommendations that relate primarily to the management of anxiety and depression are reproduced in adapted form in Table 89.1. It should be noted that the Level I evidence and Level II evidence cited in support of these recommendations, includes several systematic reviews and randomized trials that were conducted on populations other than cancer patients.

TABLE 89.1. National Breast Cancer Centre and National Cancer Control Initiative recommendations relevant to management of anxiety and depression supported by Level I or Level II evidence.

<i>Recommendation</i>	<i>Evidence level</i>
Providing question prompt sheets to patients with cancer during an initial consultation promotes patient questions, reduces anxiety, improves recall, and shortens the consultation.	II
Providing patients with information about the procedure they are about to undergo reduces emotional distress and improves psychological and physical recovery.	I
Providing patients with practical details about the procedure (procedural information), a booklet, and/or a videotape decreases anxiety and psychological distress.	II
Providing patients with information about what they are likely to experience before, during, and after a procedure (sensory information) decreases anxiety.	I
Providing patients with psychological support before undergoing surgery reduces psychological distress.	I
Cognitive behavioral, psycho-educational, and crisis interventions, as well as combinations of education and behavioral or nonbehavioral interventions and antianxiety medications, are effective in the treatment of anxiety.	I
Cognitive behavioral, psychoeducational, and supportive interventions, as well as combinations of education and behavioral or nonbehavioral interventions and cognitive behavioral interventions and antidepressants, are effective in the treatment of depression.	I
Supportive psychotherapy, in combination with antidepressants, such as selective serotonin reuptake inhibitors, is effective for the management of posttraumatic stress disorder.	I
Depression can be managed by incorporating a combination of supportive psychotherapy, cognitive and behavioral techniques, and pharmacotherapy.	I
There is no evidence that any particular antidepressant is superior to another in the management of depression in people with cancer.	I

Previous Systematic Reviews and Meta-Analyses of the Effects of Psychosocial Interventions on Anxiety and Depression

Using search methods described next, two publications^{13,14} were identified that reported the results of meta-analyses performed on studies examining the effects of psychosocial interventions on anxiety and depression in cancer patients (Table 89.2). In addition, one publication was identified that reported the results of a systematic review of studies examining the effects of psychosocial interventions on depression in cancer patients,¹⁵ and one publication was identified that reported the results of a systematic review of studies examining the effects of pharmacologic interventions on depression in cancer patients.¹⁶

Effects on Anxiety

Devine and Westlake¹³ identified 68 studies that used randomized, quasi-experimental, or single-group pretest–posttest

designs to evaluate the effects of “psychoeducational care” on anxiety in adults with cancer. The authors determined that, in 95% of these studies, a positive (although not statistically significant) treatment effect existed. The average effect size reported (0.56) was characterized as medium in magnitude. There was evidence of considerable heterogeneity among the effect sizes for the individual studies. Analyses based on type of psychoeducational care indicated that studies of progressive muscle relaxation were the major source of heterogeneity. Further analyses with corrected effect size values suggested that the effects of the different types of psychoeducational care on anxiety were not significantly different from each other. Based on these findings, the authors concluded that many types of psychoeducational care have beneficial effects on anxiety in cancer patients.

Sheard and Maguire¹⁴ identified 19 studies that featured a control condition and evaluated the effects of “psychosocial or psychiatric interventions” on anxiety in cancer patients. The average effect size reported for these studies (0.42) was characterized as being of moderate clinical significance.

TABLE 89.2. Results of meta-analyses of effects of psychosocial interventions on anxiety and depression in cancer patients.

<i>Authors</i>	<i>Reference</i>	<i>Designs of studies included</i>	<i>Types of publications included</i>	<i>Outcome</i>	<i>Mean effect size</i>
Devine and Westlake ¹³	68	Randomized, quasi-experimental, and pre–post designs	Journal articles, dissertations	Anxiety	0.56 (heterogeneous)
Devine and Westlake ¹³	48	Randomized, quasi-experimental, and pre–post designs	Journal articles, dissertations	Depression	0.54 (homogeneous)
Sheard and Maguire ¹⁴	19	Randomized and nonrandomized designs with control group	Journal articles, dissertations	Anxiety	0.42 (heterogeneous) 0.27 with positive outliers removed
Sheard and Maguire ¹⁴	20	Randomized and nonrandomized designs with control group	Journal articles, dissertations	Depression	0.36 (heterogeneous) 0.19 with positive outliers removed

Restriction of the analysis to 10 studies determined to be of more reliable design resulted in a slightly lower average effect size (0.36). As in the analysis reported by Devine and Westlake,¹³ there was evidence of considerable heterogeneity among the effect sizes for the 19 studies. Examination of potential moderator variables suggested that effect sizes were larger for group interventions (particularly group psychoeducational interventions), more time-intensive interventions, and interventions conducted by more experienced therapists. The authors note that few of the studies reviewed included patients experiencing significant distress. Characterizing most of the psychologic interventions reviewed as "preventative," they concluded these interventions may have a moderate clinical effect on anxiety.

Effects on Depression

Devine and Westlake¹³ identified 48 studies that used randomized, quasi-experimental, or single-group pretest-posttest designs to evaluate the effects of "psychoeducational care" on depression in adults with cancer. The authors determined that, in 92% of these studies, a positive (although not statistically significant) treatment effect existed. The average effect size reported (0.54) was characterized as medium in magnitude. Analyses did not suggest the presence of considerable heterogeneity among the effect sizes for the individual studies. Based on these findings, the authors reached the same conclusions for depression as they did for anxiety. That is, they concluded that many types of psychoeducational care have beneficial effects on depression in cancer patients.

Sheard and Maguire¹⁴ identified 20 studies that featured a control condition and evaluated the effects of "psychosocial or psychiatric interventions" on depression in cancer patients. The average effect size reported for these studies (0.36) was noted to be not as robust as the value these authors reported for anxiety (0.42). Limitation of the analysis to 8 studies of "more reliable design" resulted in a much lower average effect size (0.21). Analyses indicated the presence of considerable heterogeneity among the effect sizes for the 20 studies. Examination of potential moderator variables suggested that effect sizes were larger for interventions conducted by more experienced therapists and interventions provided to patients with more advanced disease. Based on these findings, particularly the lower mean effect size for studies using more reliable designs, the authors concluded that the effects of psychosocial interventions on depression in cancer patients are "weak to negligible."

Barsevick and colleagues¹⁵ conducted a systematic review of studies that evaluated "psychoeducational interventions" for depression in cancer patients. The review, which included articles published between 1980 and 2000, did not place limitations on study design. Of the 48 studies identified, 36 were randomized clinical trials, 7 were quasi-experimental studies, and 5 were descriptive studies. The authors observed that 30 of these studies (63%) provided evidence in support of the benefit of psychoeducational interventions for depression. Based on these findings, the authors concluded that psychoeducational interventions were effective in reducing depression.

Carr and colleagues¹⁶ conducted a systematic review of controlled studies that evaluated the effects of pharmacologic interventions on depressive symptoms in cancer patients.

Eleven studies dating back to 1972 were identified. These studies evaluated a variety of agents, including antipsychotics, anxiolytics, psychostimulants, and corticosteroids, as well as antidepressants. The authors observe that, with the exception of 2 studies, all medications classified as antidepressants showed benefit. In contrast, medications other than antidepressants did not appear to be effective against depressive symptoms in cancer patients.

Methodology Used in the Current Review to Identify Relevant Empirical Literature

A variety of methods were used to identify relevant published research. As an initial strategy, we sought to identify systematic reviews and meta-analyses published since 1980 that covered topics overlapping with the topic of the current study. These publications were identified through electronic searches of MedLine and PsycINFO, using search terms described next, and limits were placed on the searches to identify review papers and meta-analyses. This method identified five systematic reviews (including the one cited previously) and three publications reporting the results of meta-analyses (including the two cited previously). The systematic reviews were of psychologic treatments for cancer patients¹⁷; behavioral interventions for cancer treatment side effects¹⁸; psychologic therapies for cancer patients¹⁹; psychoeducational interventions for depression in patients with cancer¹⁵; and depression in palliative care.²⁰ The meta-analyses were of psychosocial interventions for adult cancer patients^{21,22}; psychoeducational care provided to adults with cancer¹³; psychologic interventions for anxiety in cancer patients¹⁴; and psychologic interventions for depression in cancer patients.¹⁴ In addition to these published works, we identified a systematic review of the treatment of depression in cancer patients prepared for the Agency for Health Care Research and Quality.¹⁶ All these sources were examined to identify studies that evaluated the impact of psychosocial and pharmacologic interventions on anxiety or depression in adult cancer patients. Studies identified in this manner were then obtained to determine if they met eligibility criteria (described next) for the current systematic review.

To identify studies published since the publication of the most recent systematic reviews, we also conducted electronic searches using MedLine and PsycINFO. This search was limited to studies published between January 2000 and March 2003 (MedLine) or August 2003 (PsycINFO). For MedLine, the search terms used were neoplasms AND antianxiety agents, depression, antidepressive agents, cognitive therapy, counseling, relaxation, techniques, patient education, psychotherapy, self-help groups, group psychotherapy, OR hypnosis. For PsycINFO, the search terms used were neoplasms AND tricyclic antidepressant drugs, antidepressant drugs, anxiety disorders, anxiety, anxiety management, drug therapy, benzodiazepines, depression, cognitive therapy, behavior therapy, counseling, relaxation therapy, client education, psychotherapy, support groups, self-help techniques, OR group psychotherapy.

Abstracts of studies identified through inspection of systematic reviews and meta-analyses or searches of MedLine and PsycINFO, were then reviewed to determine if they met criteria for inclusion in the current review. In the case of

studies involving psychosocial interventions, the inclusion criteria were (1) published in English in journal form since 1980; (2) focused on adults (individuals aged 18 years or older); (3) included an evaluation of a psychosocial or educational intervention; (4) involved randomization to intervention and control condition(s); (5) had a usual care, wait-list, or no treatment control condition or a design in which all forms of care other than the intervention under evaluation were administered to all participants; (6) involved use of individuals as the unit of randomization; (7) used an outcome measure labeled "anxiety" or "depression"; (8) reported results in terms of statistical significance; and (9) included comparisons of an individual intervention condition with a control condition. In the case of studies involving pharmacologic interventions, the inclusion criteria were (1) published in English in journal form since 1980; (2) focused on adults (individuals aged 18 years or older); (3) included an evaluation of a pharmacologic agent; (4) involved randomization to intervention and control condition(s); (5) had a placebo control condition or a design in which all pharmacologic agents other than the agent under evaluation were administered to all participants; (6) involved use of individuals as the unit of randomization; (7) used an outcome measure labeled "anxiety" or "depression"; and (8) reported results in terms of statistical significance. This process resulted in identification of 60 studies that examined the effects of psychosocial interventions (Table 89.3) and 12 studies that examined the effects of pharmacologic interventions (Table 89.4).

Characteristics of the Psychosocial Intervention Studies

Of the 60 psychosocial studies identified, 62% ($n = 37$) included men and women, 30% ($n = 18$) included only women, 5% ($n = 3$) included only men, and 3% ($n = 2$) did not provide sufficient information to identify the gender of participants. Among studies that included men and women, the average percentage of males was 43%.

With regard to disease site, 57% of the studies ($n = 34$) included patients with a mix of different cancers. Twenty-seven percent ($n = 16$) included only breast cancer patients. The remaining studies included samples consisting only of patients with gynecologic malignancies ($n = 2$), melanoma ($n = 2$), Hodgkin's lymphoma ($n = 2$), bladder cancer ($n = 1$), testicular cancer ($n = 1$), renal cell cancer ($n = 1$), or colorectal cancer ($n = 1$). Although some of the most commonly diagnosed cancers (e.g., lung cancer and prostate cancer) were not the focus of specific studies, these cancers were often represented in samples of patients with mixed cancers.

Stage of disease and illness progression were widely distributed across study samples. Seventy-three percent ($n = 44$) included patients diagnosed with stage I to stage IV cancer. Fifteen percent ($n = 9$) of studies limited their samples to certain stages: five included patients with stage I or II disease, one included patients with stage I, II, or III disease, one included patients with stage II, III, or IV disease, one included patients with stage II disease, and one included patients with stage IV disease. Of the remaining 12%, 3% ($n = 2$) included patients with nonmetastatic disease, 7% ($n = 4$) included patients with metastatic disease, and 2% ($n = 1$) included only patients considered to be in the terminal phase of illness.

As shown in Table 89.5, 25% of the studies ($n = 15$) included patients who were in various stages of treatment. That is, these studies enrolled patients actively undergoing treatment (e.g., chemotherapy, radiotherapy, or hormonal therapy) as well as patients not in active treatment. Seventeen percent ($n = 10$) of the studies enrolled patients just before or immediately after surgery. Of the remaining studies, 23% ($n = 14$) enrolled patients during chemotherapy, 12% ($n = 7$) enrolled patients during radiotherapy, and 10% ($n = 6$) enrolled newly diagnosed patients who had not yet begun treatment. The remaining 8% ($n = 5$) enrolled patients who were not currently receiving treatment. Of the 14 studies that enrolled patients during chemotherapy, 5 focused on patients who were experiencing anticipatory symptoms (anxiety, nausea, or vomiting). There were few studies designed specifically to include more select groups of patients. For example, only 1 study each was limited to patients reporting pain, undergoing vaccine therapy, or undergoing bone marrow transplantation.

Four studies enrolled patients based on their degree of anxiety, depression, or distress at randomization. One study included only those patients who were considered to be at high risk for psychologic distress based on their scores on a self-report questionnaire. Three studies included patients who met criteria for psychologic morbidity based on their scores on measures of anxiety and depression and a measure of adjustment to cancer.

Across studies, sample sizes for each condition ranged widely, from as few as 8 patients to as many as 158 patients. The median sample size for both experimental and control conditions was 29 patients. Four studies failed to specify the number of subjects enrolled in the control or intervention conditions.

Usual care was the most frequently employed control condition, with 87% of the studies ($n = 52$) using this control condition. Other control conditions included attentional control (2%), wait-list control (2%), and usual care accompanied by limited forms of intervention (e.g., informational brochure) (5%). One study (2%) used a pharmacotherapy-only intervention as its control condition, with comparisons made to pharmacotherapy plus psychosocial intervention.

A total of 80 interventions were evaluated in the 60 studies reviewed. The majority of interventions (71%; $n = 57$) were provided in an individual format. The group format accounted for 25% of the interventions ($n = 20$), with the remaining 4% ($n = 3$) provided in either a group or individual format, depending upon the availability of participants. The intervention most commonly evaluated was relaxation training combined with an education component and/or skills training, accounting for 33% of the interventions evaluated ($n = 26$). Relaxation training alone, typically progressive muscle relaxation, was the second most commonly evaluated intervention (20%; $n = 16$), followed by education (18%; $n = 14$), supportive-expressive therapies (13%; $n = 10$), problem-solving therapies (10%; $n = 8$), various forms of counseling (6%; $n = 5$), and provision of audiotaped music (1%; $n = 1$).

Fifty-five percent of the studies ($n = 33$) reviewed included one follow-up assessment, 27% ($n = 16$) involved two follow-up assessments, and the remaining 18% ($n = 11$) included three or more follow-up assessments. The length of time between intervention and the final follow-up assessment ranged from immediately after intervention to 2 years. Of the 60 studies reviewed, 27% ($n = 16$) conducted the final follow-

up immediately postintervention, 37% ($n = 22$) conducted it from 1 week to less than 3 months postintervention, 15% ($n = 9$) conducted it from 3 to 5 months postintervention, 8% ($n = 5$) conducted it 6 months postintervention, 13% ($n = 8$) conducted it between 7 and 12 months postintervention, and 2% ($n = 1$) conducted it more than 12 months postintervention. The median interval between intervention and the final follow-up assessment was 6 weeks.

Findings from the Psychosocial Intervention Studies

Thirteen of the 60 psychosocial studies targeted anxiety, 6 targeted depression, and 41 targeted both anxiety and depression. Outcomes were measured via patient self-report on various psychometric instruments that have been used extensively with cancer patients. Anxiety, for example, was commonly measured using the State-Trait Anxiety Inventory,⁵ the Tension-Anxiety subscale of the Profile of Mood States,²³ or the anxiety subscale of the Hospital Anxiety and Depression Scale.⁸ Measures of depression used included the Beck Depression Inventory,²⁴ the Center for Epidemiological Studies Depression Scale,²⁵ the Depression-Dejection subscale of the Profile of Mood States,²³ and the depression scale of the Hospital Anxiety and Depression Scale.⁸

The total number of anxiety outcomes, when all follow-up assessments were taken into account, was 135. Forty-nine or 36% of the total were statistically significant at P less than 0.05. As presented in Table 89.6, independent of patients' treatment status, 37% ($n = 14$) of the anxiety outcomes in studies utilizing relaxation combined with education and/or skills training (the most common type of intervention studied) were statistically significant. When compared across treatment status, the percentage of significant results ranged from 0% (0 of 1 outcome) for bone marrow transplantation (BMT) to 66% (2 of 3 outcomes) for patients receiving radiotherapy. When relaxation only was evaluated, 51% ($n = 18$) of the anxiety outcomes were significant. The percentage of significant results across treatment status ranged from 0% (0 of 1 outcome) for patients not in active treatment to 100% (7 of 7 outcomes) for newly diagnosed patients. Among those studies utilizing education-based interventions, 32% ($n = 7$) of the anxiety outcomes were significant. The percentage of significant results across treatment status ranged from 0% (0 of 7 outcomes) for patients undergoing radiotherapy to 66% (2 of 3 outcomes) for patients just before or immediately after surgery. Seventy percent ($n = 7$) of the outcomes for the supportive-expressive intervention were significant and ranged from 0% (0 of 1 outcome) for patients not in active treatment and patients receiving vaccine therapy to 100% (2 of 2 outcomes) for patients receiving chemotherapy and patients receiving radiotherapy. Twenty-five percent ($n = 3$) of the anxiety outcomes for the various problem-solving interventions were significant. The percentage of significant outcomes ranged from 0% (0 of 3 outcomes) for patients receiving chemotherapy to 40% (2 of 5 outcomes) for mixed/unspecified treatment. The percentage of significant anxiety outcomes for the counseling interventions was zero (0 of 9 outcomes for patients receiving chemotherapy and 0 of 1 outcome for patients before or immediately after surgery). There were also no significant outcomes for anxiety for

patients receiving radiotherapy who were provided with audiotaped music (0 of 8 anxiety outcomes).

The total number of depression outcomes, when all follow-up assessments were taken into account, was 102. Forty-two or 41% of the total were statistically significant at P less than 0.05. Independent of treatment status, 38% ($n = 17$) of the outcomes for the relaxation combined with education and/or skills training interventions were significant. Compared across treatment status, the percentage of significant results ranged from 0% (0 of 1 outcome) for BMT to 64% (7 of 11 outcomes) for mixed/unspecified treatment. Sixty-seven percent ($n = 10$) of the depression outcomes for the relaxation-only interventions were statistically significant. The percentage of significant outcomes across treatment status ranged from 0% (0 of 1 outcome) for patients not in active treatment to 100% (6 of 6 outcomes) for newly diagnosed patients. Forty-three percent ($n = 3$) of the outcomes for education-based interventions were significant. Across treatment status, the percentage of significant results ranged from 0% (0 of 1 outcome) to 100% (1 of 1 outcome) for newly diagnosed patients and patients before and immediately after surgery. Forty-four percent ($n = 7$) of the depression outcomes for the supportive-expressive interventions were significant. Across treatment status, the results ranged from 0% (0 of 1 outcome) for patients receiving vaccine therapy and for newly diagnosed patients (0 of 3 outcomes) to 100% (2 of 2 outcomes) for patients receiving chemotherapy and patients receiving radiotherapy. Twenty-nine percent ($n = 2$) of the outcomes for the various counseling interventions were significant. The percentage of significant results across treatment status ranged from 0% (0 of 1 outcome) for patients receiving chemotherapy to 100% (1 of 1 outcome) for patients before and immediately after surgery. Eighteen percent ($n = 2$) of the depression outcomes were significant for problem-solving interventions. Across treatment status, significant results ranged from 0% for mixed treatment/unspecified (0 of 5 outcomes) and for patients before and immediately after surgery (0 of 3 outcomes) to 100% (1 of 1 outcome) for patients receiving radiotherapy. With respect to cognitive therapy, there was only 1 depression outcome ($n = 1$), and it was statistically significant for patients receiving chemotherapy.

Characteristics of the Pharmacologic Intervention Studies

Of the 12 pharmacologic studies identified, 75% ($n = 9$) included men and women and 25% ($n = 3$) included only women. Among studies that included men and women, the average percentage of males was 51%.

With regard to disease site, 67% of the studies ($n = 8$) included patients with a mix of different cancers. Of the remaining studies, 17% ($n = 2$) included only breast cancer patients, 8% ($n = 1$) included melanoma patients, and 8% ($n = 1$) included lymphoma patients.

Stage of disease and disease status were widely distributed across study samples. Sixty-seven percent of studies ($n = 8$) included patients diagnosed with stage I to IV cancer. Eight percent of studies ($n = 1$) limited their samples to patients with stage I or II disease. Seventeen percent of studies ($n = 2$) included only patients considered to be in the terminal phase

TABLE 89.3. Randomized clinical trials of psychosocial interventions with adult cancer patients.

Investigators	Year	Reference	Patient characteristics		Control (C) groups (number of subjects at baseline)	Study design		Comparisons of intervention and control groups: number of statistically significant measures favoring intervention group ($P < 0.05$)/number of measures		
			Eligibility criteria	Percent male		Intervention groups (number of subjects at baseline)	Timing of follow-ups (F)	Anxiety	Depression	
Ali and Khalil	1989	35	Patients with bladder cancer undergoing urinary diversion surgery	77%	C1: Usual care ($n = 15$)	II: Therapist administered individual intervention (information, visit by ostomy patient, opportunity for emotional expression); 1 30- to 60-minute session 1-2 days preoperatively ($n = 15$)	F1: 3 days postoperative F2: 12 days postoperative	F1: 1/1 F2: 1/1		
Arakawa	1997	36	Patients with mixed cancers scheduled for chemotherapy	60%	C1: Attentional control ($n = 30$)	II: Therapist administered individual intervention (progressive muscle relaxation); 45- to 60-minute session 1 week before chemotherapy and guided practice once a day until chemotherapy ($n = 30$)	F1: 72 hours after first chemotherapy treatment	F1: 1/1		
Arathuzik	1994	37	Patients with metastatic breast cancer experiencing pain	0%	C1: Usual care ($n = 8$)	II: Therapist administered individual intervention (progressive muscle relaxation and guided imagery); 75-minute session ($n = 8$) I2: Therapist administered individual intervention (progressive muscle relaxation, guided imagery, and cognitive coping skills); 2-hour session ($n = 8$)	F1: postintervention (post-1)	F1: II 0/1 F1: I2 0/1	F1: II 0/1 F1: I2 0/1	
Berglund et al.	1994	38	Patients with mixed cancers within 2 months of completing chemotherapy or radiotherapy	4%	C1: Usual care with or without a single information session with an oncologist and dietician ($n = 101$)	II: Therapist administered group intervention (physical training, progressive muscle relaxation with guided imagery, information, coping skills training); 11 2-hour sessions over 7 weeks ($n = 98$)	F1: post-1 (2-6 weeks and 3 months)	F1: 0/1	F1: 0/1	
Bindemann et al.	1991	39	Patients with mixed cancers newly diagnosed	44%	C1: Usual care ($n = 40$)	II: Therapist administered individual intervention (progressive muscle relaxation and hypnosis); 12 25-minute sessions at varying intervals over 12 weeks ($n = 40$)	F1: 6 weeks F2: 12 weeks	F1: 3/3 F2: 3/3	F1: 3/3 (women only) F2: 3/3 (women only)	

Brown et al.	2001	40	Patients with mixed cancers attending initial consultation with medical or radiation oncologist	56%	C1: Usual care (n = 158)	I1: Patient provided with question prompt sheet that is actively addressed by oncologist (n = 81) I2: Patient provided with question prompt sheet that is not actively addressed by oncologist (n = 79)	F1: post-I F2: 1 week	F1: II 0/1 F1: I2 0/1 F2: II 0/1 F2: I2 0/1
Burish and Lyles	1981	41	Patients with mixed cancers undergoing chemotherapy experiencing anticipatory anxiety nausea or vomiting	13%	C1: Usual care (n = 8)	II: Therapist administered individual intervention (progressive muscle relaxation and guided imagery training); 5 45-minute sessions coinciding with chemotherapy treatment (n = 8)	F1: 4th chemotherapy treatment F2: 5th chemotherapy treatment	F1: 1/1 F2: 0/1
Burish et al.	1987	42	Patients with mixed cancers undergoing chemotherapy	?	C1: Usual care (n = 12)	I1: Therapist administered individual intervention (progressive muscle relaxation and guided imagery training); 6-8 45-minute sessions coinciding with chemotherapy treatment (n = 12)	F1: 4th chemotherapy treatment F2: 5th chemotherapy treatment	F1: 1/1 F2: 1/1
Cain et al.	1986	43	Patients with gynecologic cancer, expected to survive at least 1 year	0%	C1: Usual care (n = 28)	I1: Therapist administered group intervention (structured thematic counseling including health education and information, problem solving, coping, and relaxation); 8 weekly sessions (n = 28) I2: Therapist administered individual intervention (structured thematic counseling including health education and information, problem solving, coping, and relaxation); 8 weekly sessions (n = 21)	F1: 1-2 weeks F2: 6 months	F1: II 0/1 F1: I2 1/1 F2: II 1/1 F2: I2 1/1
Carey and Burish	1987	44	Patients with mixed cancers undergoing chemotherapy experiencing conditioned anxiety and nausea or receiving agents expected to produce nausea and vomiting	44%	C1: Usual care (n = ?)	I1: Therapist administered individual intervention (progressive muscle relaxation and guided imagery provided by professional therapist); 3 sessions of varying duration (15-45 minutes) coinciding with chemotherapy administration (n = ?) I2: Therapist administered individual intervention (progressive muscle relaxation and guided imagery provided by paraprofessional); 3 sessions of varying duration (15-45 minutes) coinciding with chemotherapy administration (n = ?)	F1: (during and following intervention)	F1: II 1/1 F1: I2 0/1 F1: I3 0/1

Sandgren et al.	2000	84	Patients with stage I or II breast cancer diagnosed within prior 3–4 months	0%	C1: Usual care ($n = 29$)	II: Therapist administered individual intervention (telephone counseling regarding support, managing anxiety and stress, and problem solving); 1 call weekly for 4 weeks followed by 1 call every 2 weeks for 12 weeks ($n = 24$)	F1: 4 months F2: 10 months	F1: 0/1 F2: 0/1	F1: 0/1 F2: 0/1	
Simpson et al.	2001	85	Patients with stage 0–II breast cancer who have completed treatment	0%	C1: Usual care ($n = 43$)	I: Therapist administered group intervention (relaxation, stress management, goal setting, planning and achieving change); 6 weekly 90-minute sessions ($n = 46$)	F1: post-I F2: 1 year F3: 2 years	F1: 1/1 F2: 0/1 F3: 1/1	F1: 1/1 F2: 0/1 F3: 1/1	
Smith et al.	2001	86	Patients with mixed cancers receiving at least 5 weeks of radiotherapy for pelvic or abdominal malignancies	100%	C1: Usual care ($n = 23$)	II: Patient access to music of their choice during radiotherapy simulation and treatment ($n = 19$)	F1: postsimulation F2: 1 week F3: 3 weeks F4: 5 weeks	F1: 0/2 F2: 0/2 F3: 0/2 F4: 0/2	F1: 0/2 F2: 0/2 F3: 0/2 F4: 0/2	
Specia et al.	2000	87	Patients with mixed cancers	17%	C1: Wait-list control ($n = 48$)	II: Therapist administered group intervention (information, practice of meditation, problem solving); 7 weekly 90- minute sessions ($n = 61$)	F1: 7 weeks	F1: 0/2	F1: 2/2	

Spiegel et al.	1981	88	Patients with metastatic breast cancer	0%	C1: Usual care (<i>n</i> = 36)	I1: Therapist administered group intervention (supportive-expressive therapy); weekly 90-minute sessions for 1 year (<i>n</i> = 50)	F1: post-I (4, 8, and 12 months)	F1: 1/1	F1: 0/1
Telch and Telch	1986	89	Patients with mixed cancers receiving outpatient care	34%	C1: Usual care (<i>n</i> = 14)	I1: Therapist administered group intervention (discussion of feelings, concerns, and problems); 6 weekly 60-minute sessions (<i>n</i> = 14) I2: Therapist administered group intervention (relaxation and stress management, communication and assertion, problem solving and constructive thinking, feelings management, and pleasant activity planning); 6 weekly 60-minute sessions (<i>n</i> = 13)	F1: 6 weeks	F1: II 1/1 F1: I2 1/1	F1: II 1/1 F1: I2 1/1
Thomas et al.	2000	90	Patients with mixed cancers receiving chemotherapy or radiotherapy	42%	C1: Usual care (<i>n</i> = 107)	I1: Patient viewed film providing preparatory information about chemotherapy and radiotherapy (<i>n</i> = 113)	F1: 3 weeks	F1: 1/1	F1: 1/1
Watson et al.	1988	91	Patients with early-stage breast cancer undergoing mastectomy	0%	C1: Usual care (<i>n</i> = ?)	I1: Therapist administered individual intervention (emotional support and facilitation of adjustment, information about physical state, and practical advice on breast prostheses); at least 4 sessions (<i>n</i> = ?)	F1: 1 week postoperative F2: 3 months postoperative F3: 12 months postoperative	F1: 0/1 F2: 1/1 F3: 0/1	F1: 0/1 F2: 1/1 F3: 0/1
Wells et al.	1995	92	Newly diagnosed patients with mixed cancers making first visit to hematology/oncology clinic	45%	C1: Usual care (<i>n</i> = 16)	I1: Brief clinic orientation (clinic tour and information and discussion session) (<i>n</i> = 17)	F1: post-I	F1: 2/2	F1: 2/2

TABLE 89.4. Randomized clinical trials of pharmacological interventions with cancer patients.

Investigators	Year	Reference	Eligibility criteria	Percent male	Design	Control groups (number of subjects at baseline)	Intervention groups (number of subjects at baseline)	Timing of follow-ups	Anxiety	Depression
Bruera et al.	1985	93	Patients with mixed cancers in terminal phase of illness (no treatment within last month)	45%	Randomized double-blind placebo-controlled crossover trial	C1: Placebo (<i>n</i> = 40)	I1: Methylprednisolone po 32 mg/day × 5 days (<i>n</i> = 40)	F1: 5 and 13 days	F1: 0/1	F2: 1/1
Bruera et al.	1986	94	Patients with mixed cancers in terminal phase of illness (no treatment within last month)	70%	Randomized double-blind placebo-controlled crossover trial	C1: Placebo (<i>n</i> = 30)	I1: Mazindol po 3 mg/day × 5 days (<i>n</i> = 30)	F1: 6 and 12 days	F1: 0/1	F2: 0/1
Clerico et al.	1993	95	Patients with mixed cancers undergoing cisplatin-based chemotherapy	85%	Randomized double-blind placebo-controlled crossover trial	C1: Placebo (<i>n</i> = 60)	I1: Lorazepam po 2.5 mg evening before chemotherapy and just before start of chemotherapy (<i>n</i> = 60)	F1: After 1st and 2nd infusion	F1: 1/1	
Costa et al.	1985	96	Patients with mixed cancers diagnosed with major depression and having depression symptoms exceeding cutoff score	0%	Randomized double-blind placebo-controlled trial	C1: Placebo (<i>n</i> = 37)	I1: Mianserin po 30 mg/day × 1 week then 60 mg/day × 3 weeks (<i>n</i> = 36)	F1: 1 week F2: 2 weeks F3: 3 weeks F4: 4 weeks	F1: 2/2 F2: 0/2 F3: 1/2 F4: 2/2	
Fisch et al.	2003	97	Patients with mixed cancers expected to survive 3–24 months and having depressed mood or anhedonia	50%	Randomized double-blind placebo-controlled trial	C1: Placebo (<i>n</i> = 80)	I1: Fluoxetine po 20 mg/day (<i>n</i> = 83)	F1: post-1 (every 3–6 weeks for 12 weeks) F2: post-1 (best change)	F1: 1/1 F2: 0/1	
González Barón et al.	1991	98	Patients with mixed cancers undergoing chemotherapy	71%	Randomized controlled trial	C1: Standardized antiemetic regimen (high-dose metaclopramide plus methylprednisolone) at each infusion (<i>n</i> = 85)	I1: Standardized antiemetic regimen at each infusion plus lorazepam 0.02 mg/kg 30 minutes before and 8 hours after each infusion (<i>n</i> = 78)	F1: first day postchemotherapy F2: third day postchemotherapy	F1: 1/1 F2: 0/1	

Musselman et al.	2001	99	Patients with melanoma treated surgically and about to be treated with interferon alfa	50%	Randomized double-blind placebo-controlled trial	C1: Placebo (n = 20)	II: Paroxetine po 10 mg/day × 1 week then 20 mg/day × 1 week then up to 40 mg/day (n = 20)	F1: 2 weeks F2: 4 weeks F3: 8 weeks F4: 12 weeks	F1: 0/1 F2: 1/1 F3: 1/2 F4: 2/2
Capuron et al.	2002	100	Patients with mixed cancers diagnosed with adjustment disorder (with depressive mood or mixed features) or major depressive disorder	20%	Randomized double-blind placebo-controlled trial with 1-week placebo run-in	C1: Placebo (n = 46)	II: Fluoxetine po 20 mg/day (n = 45)	F1: 5 weeks	F1: 1/2
Razavi et al.	1996	101	Patients with breast cancer treated with mastectomy consecutively referred for treatment of depression and poor adaptation	0%	Randomized controlled trial	C1: Behavioral intervention (n = 5)	II: Behavioral intervention plus mianserin po 30–90 mg/day (n = 5)	F1: 1 week after completion of behavioral intervention F2: 3 months after completion of behavioral intervention	F1: 0/1 F2: 0/1
Tarrier et al.	1984	102	Patients with stage I–II breast cancer and depression symptoms exceeding cutoff score	0%	Randomized double-blind placebo-controlled trial with 1-week placebo run-in	C1: Placebo (n = 27)	II: Mianserin po 30 mg/day × 1 week then 60 mg/day (n = 28)	F1: 14 days F2: 28 days F3: 42 days	F1: 0/1 F2: 1/1 F3: 1/1
Van Heeringen and Zivkov	1996	103	Patients with mixed cancers diagnosed with generalized anxiety disorder, panic disorder or adjustment disorder (with anxious mood), and having anxiety symptoms exceeding cutoff score	47%	Randomized double-blind placebo-controlled trial	C1: Placebo (n = 18)	II: Alprazolam po at dose between 0.5 mg/day and 3.4 mg/day (n = 18)	F1: 1, 2, 3, and 4 weeks	F1: 0/1
Wald et al.	1993	104	Patients newly diagnosed with lymphoma undergoing first bone marrow biopsy and aspiration (BMBA)	68%	Randomized double-blind placebo-controlled trial	C1: Placebo at first and second BMBA (n = 12)	II: Placebo at first BMBA followed by lorazepam po 2 mg and hydromorphone po 2 mg before second BMBA 1 hour later (n = 13)	F1: Difference between first and second BMBA	F1: 0/2

TABLE 89.5. Number of psychosocial studies by cancer site and treatment status.

Treatment status	Cancer site									Total
	Breast	Gynecologic	Testicular	Bladder	Colorectal	Melanoma	Hodgkin's	Renal cell	Mixed	
Newly diagnosed									6	6
During chemotherapy	2						2		10	14
During radiotherapy									7	7
Before/immediately after surgery	4	1	1	1	1	2				10
Not in active treatment	3								2	5
Mixed treatment or not specified	6	1							9	16
Vaccine therapy								1		1
Bone marrow transplantation	1									1
Total	16	2	1	1	1	2	2	1	34	60

of cancer. Eight percent of studies ($n = 1$) included patients with "advanced" cancer.

With regard to treatment status, 33% of the studies ($n = 4$) included patients who were in various stages of treatment; that is, these studies enrolled patients actively undergoing treatment (e.g., chemotherapy, radiotherapy, or hormonal therapy), as well as patients not in active treatment. Seventeen percent ($n = 2$) of the studies enrolled patients during chemotherapy and 17% ($n = 2$) of the studies enrolled patients who had undergone surgery. Seventeen percent ($n = 2$) enrolled patients who were in the terminal phase of their illness and had not had treatment within the past month. Eight percent ($n = 1$) enrolled patients who were undergoing bone marrow biopsy and aspiration, and 8% ($n = 1$) did not provide enough detail to determine patients' treatment status.

Five of the 12 studies (42%) enrolled and randomized only those patients reporting significant symptoms of depression or anxiety. With respect to depression, two studies enrolled patients who met or exceeded a cutoff score on a screening measure of depressive symptomatology. Three studies enrolled patients who met diagnostic criteria for Major Depressive Disorder. With respect to anxiety, one study enrolled patients who met diagnostic criteria for an anxiety disorder and exceeded a cutoff score on a self-report measure of anxiety. The remainder of the studies ($n = 7$) did not enroll patients based on the presence of significant depressive or anxious symptomatology.

Across studies, sample sizes for each condition ranged widely, from as few as 5 patients to as many as 85 patients.

The median sample size was 33.5 patients for the experimental conditions and 33 for the control conditions.

Ten of the 12 studies (83%) were double-blind studies. Placebo-controlled was the most frequently employed control condition, with 83% of the studies ($n = 10$) using this condition. Two of the 10 placebo-controlled studies included a 1-week placebo run-in. Three of the 10 studies utilized a crossover design. The other control conditions included a standardized antiemetic regimen (8%; $n = 1$) and a behavioral intervention (8%; $n = 1$).

Each of the 12 studies evaluated a standardized pharmacologic intervention. Six of the studies evaluated antidepressant agents, 4 evaluated antianxiety agents, 1 evaluated mazindol, a psychostimulant, and 1 evaluated methylprednisolone, a corticosteroid. Specifically, 17% ($n = 2$) evaluated fluoxetine, 8% ($n = 1$) evaluated paroxetine, 17% ($n = 2$) evaluated mianserin only, and 8% ($n = 1$) evaluated mianserin plus a behavioral intervention compared to the behavioral intervention alone. One study (8%) evaluated alprazolam, 2 (17%) evaluated lorazepam, and 1 (8%) evaluated a standardized antiemetic regimen (metoclopramide plus methylprednisolone) plus lorazepam compared to the standardized antiemetic regimen. Finally, 1 study ($n = 8$) evaluated mazindol and 1 ($n = 8$) evaluated methylprednisolone.

Fifty percent ($n = 6$) of the studies reviewed included one follow-up assessment, 25% ($n = 3$) involved two follow-up assessments, 8% ($n = 1$) included three follow-up assessments, and 17% ($n = 2$) included four follow-up assessments.

TABLE 89.6. Outcomes of psychosocial interventions studies by intervention type and treatment status [number of studies].

	Combination		Relaxation only		Psychoeducation	
	Anxiety	Depression	Anxiety	Depression	Anxiety	Depression
Newly diagnosed		1/6 [2]	7/7 [2]	6/6 [1]	3/7 [3]	1/1 [1]
During chemotherapy	4/7 [3]	3/5 [3]	9/24 [7]	3/6 [4]	1/1 [1]	
During radiotherapy	2/3 [2]	2/3 [2]			0/7 [3]	0/1 [1]

<i>Anxiety</i>	<i>Depression</i>	<i>Anxiety</i>	<i>Depression</i>	<i>Anxiety</i>	<i>Depression</i>	<i>Anxiety</i>	<i>Depression</i>	<i>Anxiety</i>	<i>Depression</i>
	0/3 [1]								
2/2 [1]	2/2 [1]	0/3 [2]	1/2 [1]	0/9 [2]	0/1 [1]		1/1 [1]		
2/2 [1]	2/2 [1]	0/1 [1]	1/1 [1]					0/8 [1]	
	1/3 [1]	1/3 [1]	0/3 [1]	0/1 [1]	1/1 [1]				
	0/1 [1]	0/1 [1]							
3/4 [4]	2/4 [4]	2/5 [3]	0/5 [3]		1/5 [1]				
0/1 [1]	0/1 [1]								
7/10	7/16	3/12	2/11	0/10	2/7		1/1 [1]	0/8	

The length of time between intervention and the final follow-up assessment ranged from immediately postintervention to 12 weeks. Of the 12 studies reviewed, 17% ($n = 2$) conducted the final follow-up immediately postintervention, 25% ($n = 3$) conducted it from 3 days to 12 days after the intervention, 33% ($n = 4$) conducted it from 4 to 6 months postintervention, and 25% ($n = 3$) conducted it 12 weeks postintervention. The median interval between commencement of the intervention and the final follow-up assessment was 4 weeks.

Findings from the Pharmacologic Studies

Three of the 12 pharmacologic studies targeted anxiety only, 4 targeted depression only, and 5 targeted both anxiety and depression. Outcomes were measured via observer report and patient self-report on various psychometric instruments that have been used extensively with cancer patients. Anxiety, for example, was most commonly measured using the observer-rated Hamilton Anxiety Scale.²⁶ Patient's self-report of anxiety was recorded using instruments, such as the State-Trait Anxiety Inventory⁵ or the anxiety subscale of the Hospital Anxiety and Depression Scale.⁸ Measures of depression used included the observer rated Hamilton Rating Scale for Depression.²⁷ Patient's self-report was recorded using instruments such as the Beck Depression Inventory,²⁴ the Zung Self-rating Depression Scale,²⁸ and the depression scale of the Hospital Anxiety and Depression Scale.⁸

The total number of anxiety outcomes, when all follow-up assessments were taken into account, was 16. Seven or 44% of the total were statistically significant at P less than 0.05. The total number of depression outcomes, when all follow-up assessments were taken into account, was 26. Thirteen or 48% of the total were statistically significant at P less than 0.05.

As presented in Table 89.7, when the six studies examining an antidepressant agent were evaluated, 52% (12 of 23 outcomes) of the depression outcomes were significant and 63% of the anxiety outcomes (5 of 8 outcomes) were significant. With respect to the agents' antidepressant effect, the percentage of significant results ranged from 0% (0 of 2 outcomes) for mianserin and fluoxetine to 67% (4 of 6 outcomes and 2 of 3 outcomes) for paroxetine and mianserin, respectively. With respect to the agents' antianxiety effect, the percentage of significant results ranged from 50% (1 of 2 outcomes) for fluoxetine and 67% (4 of 6 outcomes) for paroxetine. When the four studies examining an antianxiety agent

were evaluated, 33% (2 of 6 outcomes) of the anxiety outcomes were significant and 0% of the depression outcomes (0 of 1 outcome) were significant. With respect to the agents' antianxiety effect, the percentage of significant results ranged from 0% (0 of 1 outcome and 0 of 2 outcomes) for alprazolam and lorazepam, respectively, to 100% (1 of 1 outcome) for lorazepam. The percentage of significant results for the agents' antidepressant effect was 0% (0 of 1 outcome) for alprazolam. In the study examining the effects of mazindol, 0% (0 of 1 outcome) of the depression outcomes and 0% (0 of 1 outcome) of the anxiety outcomes were significant. In the study examining methylprednisolone, 0% (0 of 1 outcome) of the anxiety outcomes were significant and 100% (1 of 1 outcome) of the depression outcomes were significant.

Evidence-Based Recommendations for Management of Anxiety and Depression in Cancer Patients

This comprehensive review of published research provides considerable support for the use of psychosocial interventions to effectively manage anxiety and depression in adult patients with cancer. As shown in Table 89.3, the research was conducted across a broad range of cancer types, disease stages, and treatment status. The interventions were as varied as a 1-hour group-based information and orientation session, several months of weekly individual psychotherapy to explore end-of-life concerns, and self-administered relaxation. Despite the diversity of patients and the wide variety of interventions, careful reading of the research results suggests

TABLE 89.7. Outcomes for pharmacologic studies by medication type [number of studies].

TABLE 89.8. Evidence-based recommendations on the use of psychosocial interventions.

GENERAL RECOMMENDATIONS

Psychosocial interventions are effective in preventing or relieving anxiety and depression in cancer patients^{13,15}
Psychosocial interventions are effective in preventing or relieving anxiety and depression in both male and female cancer patients^{35,36,39,41,44-46,48,52,53,58,62,63,67,69,73,76,80,81,87,89,90,92,106}

RECOMMENDATIONS BASED ON DISEASE STATUS

Psychosocial interventions are effective in preventing or relieving anxiety in newly diagnosed patients^{39,73,92}
Psychosocial interventions are effective in preventing or relieving depression in newly diagnosed patients^{36,39,51,73}
Psychosocial interventions are effective in preventing or relieving anxiety in breast cancer patients with metastatic disease^{57,88}
Psychosocial interventions are effective in preventing or relieving depression for breast cancer patients with metastatic disease^{50,57}
Psychosocial interventions are effective in preventing or relieving anxiety and depression in patients in the terminal phase of illness⁶⁷

RECOMMENDATIONS BASED ON TREATMENT STATUS

Psychosocial interventions are effective in preventing or relieving anxiety in patients undergoing chemotherapy^{41,42,44,62,63,69,76}
Psychosocial interventions are effective in preventing or relieving depression in patients undergoing chemotherapy^{41,42,63,69,70,81}
Psychosocial interventions are effective in preventing or relieving anxiety in patients undergoing radiotherapy^{48,53}
Psychosocial interventions are effective in preventing or relieving depression in patients undergoing radiotherapy^{48,53,80}
Psychosocial interventions are effective in preventing or relieving anxiety in patients before and after surgery^{35,45,78,79}
Psychosocial interventions are effective in preventing or relieving depression in patients before and after surgery^{46,79,106}
Psychosocial interventions are effective in preventing or relieving anxiety following completion of active treatment⁵²
Psychosocial interventions are effective in preventing or relieving depression following completion of active treatment⁸⁵

RECOMMENDATIONS BASED ON TYPE OF INTERVENTION

Relaxation techniques are effective in preventing or relieving anxiety in cancer patients^{36,39,41,42,44,45,67,76}
Relaxation techniques are effective in preventing or relieving depression in cancer patients^{39,41,42,67}
Relaxation techniques, in combination with education and skills training, are effective in preventing or relieving anxiety in cancer patients^{43,48,52,63,69,79,89}
Relaxation techniques, in combination with education and skills training, are effective in preventing or relieving depression in cancer patients^{43,48,50,51,63,69,79,85,87,89,106}
Psychoeducation is effective in preventing or relieving anxiety in cancer patients^{35,62,73,90,92}
Psychoeducation is effective in preventing or relieving depression in cancer patients^{71,73,90}
Supportive and supportive-expressive therapies are effective in preventing or relieving anxiety in cancer patients^{53,57,69,88,89}
Supportive and supportive-expressive therapies are effective in preventing or relieving depression in cancer patients^{53,57,69,89}
Problem-solving therapies are effective in preventing or relieving anxiety in cancer patients^{58,78}
Problem-solving therapies are effective in preventing or relieving depression in cancer patients^{80,81}
Counseling is effective in preventing or relieving depression in cancer patients^{46,66}
Cognitive therapy is effective in preventing or relieving depression in cancer patients⁷⁰

RECOMMENDATIONS BASED ON INTERVENTION TYPE AND DISEASE OR TREATMENT STATUS

Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving anxiety in newly diagnosed cancer patients^{36,39}
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving depression in newly diagnosed cancer patients^{39,51}
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving anxiety in patients undergoing chemotherapy^{41,42,44,63,69,76}
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving depression in patients undergoing chemotherapy^{41,42,63,69}
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving anxiety in patients undergoing radiotherapy^{48,53}
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving depression in patients undergoing radiotherapy^{48,53}
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving anxiety in patients before and after surgery^{45,79}
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving depression in patients before and after surgery^{79,106}
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving anxiety following completion of active treatment⁵²
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving depression following completion of active treatment⁸⁵
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving anxiety in patients in the terminal phase of illness⁶⁷
Relaxation techniques, alone or in combination with education and skills training, are effective in preventing or relieving depression in patients in the terminal phase of illness⁶⁷
Psychoeducation is effective in preventing or relieving anxiety in newly diagnosed patients⁷³
Psychoeducation is effective in preventing or relieving depression in newly diagnosed patients⁷³
Psychoeducation is effective in preventing or relieving anxiety in patients before and after surgery³⁵
Psychoeducation is effective in preventing or relieving depression in patients before and after surgery⁷¹
Psychoeducation is effective in preventing or relieving anxiety in patients undergoing chemotherapy⁶²
Supportive and supportive-expressive therapies are effective in preventing or relieving anxiety in patients undergoing chemotherapy⁶⁹
Supportive and supportive-expressive therapies are effective in preventing or relieving depression in patients undergoing chemotherapy⁶⁹
Supportive and supportive-expressive therapies are effective in preventing or relieving anxiety in patients undergoing radiotherapy⁵³
Supportive and supportive-expressive therapies are effective in preventing or relieving depression in patients undergoing radiotherapy⁵³
Supportive and supportive-expressive therapies are effective in preventing or relieving depression in patients before and after surgery⁹¹
Problem-solving therapies are effective in preventing or relieving anxiety in patients before and after surgery⁷⁸
Problem-solving therapies are effective in preventing or relieving depression in patients undergoing chemotherapy⁸¹
Problem-solving therapies are effective in preventing or relieving depression in patients undergoing radiotherapy⁸⁰
Counseling is effective in preventing or relieving depression in cancer patients before and after surgery⁴⁶
Cognitive therapy is effective in preventing or relieving depression in patients undergoing chemotherapy⁷⁰

TABLE 89.9. Evidence-based recommendations on the use of pharmacologic interventions.

Recommendation:

Antidepressants are effective in preventing or relieving depression in cancer patients^{96,97,99,100,103}

Antidepressants are effective in preventing or relieving anxiety in cancer patients⁹⁹⁻¹⁰¹

a number of recommendations for preventing or relieving anxiety and depression in cancer patients. The recommendations presented in Table 89.8 are based on statistically significant, clinically relevant evidence provided by both previous systematic reviews and meta-analyses and our systematic review of randomized controlled trials.

The review of published research designed to evaluate pharmacologic interventions for the management of anxiety and depression in cancer patients is considerably narrower in scope. Nevertheless, the best available evidence supports the use of pharmacologic interventions in adult patients with cancer. The recommendations presented in Table 89.9 are based on statistically significant, clinically relevant evidence provided by our systematic review of randomized controlled trials.

Limitations of Existing Research Base for Developing an Evidence-Based Approach to Management of Anxiety and Depression in Cancer Patients

The relatively large number of randomized clinical trials listed in Tables 89.3 and 89.4, provides a strong foundation for developing an evidence-based approach to the management of anxiety and depression in cancer patients. The recommendations listed in Tables 89.8 and 89.9, which follow directly from the results of these many studies, address numerous aspects of the psychologic and psychiatric care of cancer patients. It should be noted, however, that several recommendations listed in Tables 89.8 and 89.9, are based on a very few studies. In addition, important gaps in the existing research literature can be identified that limit the type and scope of recommendations that can be offered.

Limitations in Research on Psychosocial Interventions

Inspection of the evidence and recommendation tables included in this chapter, suggests several areas where evidence regarding the use of psychosocial interventions to manage anxiety and depression in cancer patients is sparse. With respect to patient characteristics, we noted that in only 5% of the studies were the samples limited to male cancer patients. Although these studies and studies of samples including both men and women suggest that psychosocial interventions are effective in male patients, important questions regarding the relative effectiveness and acceptability of psychosocial interventions in male and female cancer patients remain unanswered. Clinicians often report that male cancer patients can be more difficult to engage in psychosocial interventions and, once engaged, are more likely to benefit from educational interventions than interventions focusing on expression of emotions and group support.

Clearly, more research is needed to either confirm or disconfirm beliefs that male cancer patients are less likely than female cancer patients to benefit from psychosocial approaches to the management of anxiety and depression.

Limitations in the evidence base also exist regarding the effectiveness of psychosocial interventions in specific forms of cancer. We noted that 57% of psychosocial intervention studies were based on patient samples that included more than one form of cancer. Although breast cancer was the focus of 27% of the remaining studies, no other single form of cancer was the focus of more than two studies. The significance of this issue lies in the possibility that the sources of anxiety and depression and the methods needed to treat it psychologically, may vary considerably across different cancers. For example, the psychologic issues raised by having a disease in a part of the body closely related to sexual functioning (e.g., breast cancer) are likely to differ from those associated with having a disease linked to smoking behavior (e.g., lung cancer) or a disease that may lead to significant changes in facial appearance (e.g., head and neck cancer) or cognitive abilities (e.g., brain cancer). To address this gap, more studies are needed that focus on forms of cancer other than breast cancer, as well as studies that examine whether generic interventions (e.g., relaxation training) are more effective if adapted or tailored for different forms of cancer.

A similar situation exists with regard to disease stage or status. Most of the studies identified (73%) did not focus on patients at a specific stage of disease. Information included in many of these studies suggests that they were composed primarily of patients with early-stage disease. Of those studies in which eligibility was limited by disease stage or status, just 9% focused on patients with stage IV or metastatic disease and only 2% focused on patients in the terminal phase of their disease. Although these studies provide preliminary evidence that psychosocial interventions are effective in patients with more advanced disease, the issue merits closer study in light of evidence suggesting the presence of more severe psychologic symptoms in patients with more advanced disease.²⁹

Examination of treatment status also leads to identification of gaps in the research base. In general, studies of psychosocial interventions for anxiety and depression have focused on patients in the period during which they are being actively treated with surgery, chemotherapy, and/or radiotherapy. Just 8% of the studies identified were limited to patients not currently receiving treatment. A growing body of research has documented the presence of anxiety and depression in patients who have successfully completed treatment for cancer.^{30,31} Although preliminary evidence suggests that psychosocial interventions are effective in the posttreatment period, a number of important issues have yet to be examined. For example, no randomized clinical trials could be identified that have evaluated interventions designed specifically to address symptoms of posttraumatic stress in patients who had completed treatment for cancer.

Another consideration involves the types of interventions that have been evaluated. Our systematic review found that 53% of the psychosocial studies evaluated the effectiveness of relaxation training, either alone or in combination with education and skills training. Other forms of psychosocial intervention, such as problem-solving therapy, were found to be effective in a limited number of studies and merit further evaluation. In addition, there are several major forms of psychotherapy found to be effective against anxiety and depression in outpatient psychiatric settings that received little or no attention in research with cancer patients. These approaches, which include interpersonal therapy³² and cognitive therapy,³³ may be particularly well suited to cancer patients experiencing more severe symptoms of anxiety and depression.

The issue of symptom severity is one that has received relatively little attention in prior psychosocial research with cancer patients. Our systematic review found that only 5% of studies restricted eligibility to patients experiencing heightened levels of psychologic distress. As a consequence, the average pretreatment levels of anxiety and depression in these studies are likely to have been relatively low. In contrast, clinical practice guidelines, such as those developed by NCCN,¹¹ recommend the use of psychosocial interventions for cancer patients experiencing the heightened distress characteristic of adjustment, mood, or anxiety disorders. By evaluating psychosocial interventions with patients experiencing more severe symptoms of anxiety and depression, future research is likely to yield results of greater relevance to the evaluation of current clinical practice.

Limitations in Research on Pharmacologic Interventions

The primary limitation in the evidence base for pharmacologic interventions is the relative paucity of randomized clinical trials. Only 12 such studies could be identified, and these studies encompassed the evaluation of several different classes of pharmacologic agents, including antidepressants, anxiolytics, psychostimulants, and corticosteroids. Five of the studies were of an antidepressant agent and included eligibility criteria based on level or presence of depressive symptomatology. These studies yield evidence that supports the NCCN guideline recommendation that antidepressants be prescribed for cancer patients experiencing severe adjustment reactions or mood disorders.¹¹ The principal gap in the evidence base is the lack of research on the effectiveness of anxiolytic agents in cancer patients experiencing heightened anxiety. Although 4 studies were identified that evaluated anxiolytic agents, 3 of these studies focused on the use of lorazepam in combination with antiemetic or analgesic medications for relief of treatment-related symptoms. Another important gap in the evidence base is research on the effectiveness of psychostimulants for the treatment of depression in cancer patients. Although nonrandomized studies suggest that psychostimulants, such as methylphenidate, are effective as antidepressants in patients with advanced disease,³⁴ evidence from randomized clinical trials is lacking.

In addition to the need for more research on pharmacologic interventions for anxiety and depression in cancer patients, there is a need for research about the relative efficacy of pharmacologic and psychologic approaches with

cancer patients. One type of research needed is studies that evaluate whether the combined psychosocial and pharmacologic intervention results in better management of anxiety and depression than the use of psychosocial or pharmacologic interventions alone. This type of research would allow for evaluation and possible refinement of recommendations, such as those contained in NCCN guidelines,¹¹ that patients with mood disorders be treated initially with antidepressant agents plus psychotherapy, as well as recommendations that patients with anxiety disorders be treated initially with psychotherapy with or without psychotropic medication. Another type of research needed is studies that directly compare the effectiveness of pharmacologic and psychosocial approaches in treating anxiety and depression in cancer patients. This type of research would allow for evaluation of recommendations, such as those contained in NCCN guidelines,¹¹ that patients with mild adjustment disorders be treated initially with psychotherapy alone.

Summary

Anxiety and depression, which are among the most common symptoms experienced by cancer patients, have been the focus of considerable attention and research. In recent years, clinical practice guidelines have appeared that include specific recommendations for the management of anxiety and depression in cancer patients. These efforts have been limited, however, by reliance on a consensus-based approach rather than an evidence-based approach,¹¹ or by inclusion of evidence from studies conducted on populations other than cancer patients.¹² To address these issues, the present chapter focused on evidence from randomized clinical trials of psychosocial and pharmacologic interventions with cancer patients, in which anxiety or depression was measured as outcomes.

Aided by previous systematic reviews and meta-analyses, we were able to identify 60 randomized clinical trials of psychosocial interventions and 12 randomized clinical trials of pharmacologic interventions. The relatively large number of psychosocial studies yielded numerous evidence-based recommendations regarding the use of psychosocial interventions in the management of anxiety and depression. Indeed, the quantity and quality of the research permitted not only general recommendations, but recommendations based on disease status, treatment status, type of intervention, and the combination of type of intervention and disease or treatment status. Because of the much smaller number of studies, far fewer evidence-based recommendations could be offered regarding the use of pharmacologic interventions for anxiety and depression in cancer patients.

Despite the relatively large number of psychosocial intervention studies that have been conducted, several important gaps in this evidence base could be identified: these include the limited number of studies that have focused on male patients, patients with cancers other than breast cancer, patients with more advanced disease, patients who have completed cancer treatment, and patients with more severe symptoms of anxiety and depression. The primary limitation in the evidence base for pharmacologic interventions is the relative paucity of randomized clinical trials. Notable gaps in the evidence base include the lack of placebo-controlled studies of

anxiolytic agents in the treatment of anxiety symptoms and of psychostimulant agents in the treatment of depressive symptoms. In addition to these types of pharmacologic studies, there is a need for studies that evaluate the relative and combined efficacy of psychosocial and pharmacologic interventions with cancer patients. These types of studies will allow for the evaluation of patterns of care for which there appears to be a general clinical consensus, as suggested by NCCN guidelines,¹¹ but no direct empirical evidence. This approach would also allow us to proceed from individual evidence-based recommendations to a more comprehensive evidence-based approach to treatment selection and delivery of care for the management of anxiety and depression in cancer patients.

Reproductive Complications and Sexual Dysfunction in the Cancer Patient

Leslie R. Schover

Defining the Population at Risk for Reproductive Complications

This chapter will review risk factors and management for three types of reproductive complications of cancer treatment: infertility, menopausal symptoms, and sexual dysfunction. Each problem area affects unique, albeit overlapping, populations of cancer patients and survivors.

Risk Factors for Cancer-Related Infertility

The demographics of cancer survivorship and delayed childbearing ensure that increasing numbers of patients will have their family-building disrupted by cancer treatment. The success of cancer treatment for malignancies that affect young people, such as pediatric cancers, testicular cancer, and Hodgkin's Disease, has yielded a large population of cancer survivors. According to the National Health Information Survey of 2001,¹ 2.2% of adults aged 18 to 44 in the United States have been diagnosed with cancer. Extrapolating based on statistics for this age group from the United States 2000 Census,² approximately 2.5 million adults of childbearing age are cancer survivors. It is more difficult to specify how many have faced infertility, but most probably had treatment with gonadotoxic chemotherapy, and smaller numbers would be at risk for infertility because of surgery or radiation therapy affecting the reproductive system.

Another trend that increases the salience of cancer and fertility is delayed childbearing in American families. Birth rates for women in their thirties have been climbing steadily, reaching a high in 2001 of 95.6 per 1,000 women aged 30–34 and 41.4 per 1,000 women aged 35–39.³ Births to women aged 40–44 have more than doubled since 1981 to 8.1 per 1,000 women. According to the United States Census report for 2000, the percentage of childless women age 30–34 has jumped from 19.8% in 1980 to 28.1% in 2000, and for women aged 35–39 from 12.1% in 1980 to 20.1% in 2000.⁴ When these women are ready to conceive, some will receive the unwelcome news of a malignancy. Data on paternal age are

not readily available, but in 1995 in the United States, men at marriage were on the average 2.7 years older than their brides so that men, too, would be more at risk currently to have cancer interfere with their fertility.⁵

Infertility Related Directly to a Malignancy

For a few types of malignancy, for example testicular cancer, the risk of infertility and risk of cancer are related. In a cohort of 3,530 Danish men who were born between 1945 and 1980 and developed testicular cancer from 1960 to 1993, the standardized fertility rate was significantly lower (ratio 0.93) than for all 1,488,957 Danish men born in the same era.⁶ Fertility was particularly reduced in the two years leading up to cancer diagnosis, and for men with nonseminomatous tumors (ratio 0.87). Furthermore, men who developed testicular cancer were less likely than men in the general population to conceive male children, possibly indicating a genetic or environmental factor.

Skakkebak and his colleagues believe that a testicular dysgenesis syndrome (TDS) is increasing in frequency in Western countries because of environmental influences in utero, perhaps combined with a genetic susceptibility factor. The syndrome includes testicular cancer, undescended testes, hypospadias, and decreased semen quality.⁷ Although the evidence for TDS, and in particular the influence of endocrine disrupting pollutants, remains controversial, it is clear that men with testis cancer have a high percentage of abnormalities in the contralateral testis suggesting abnormal fetal development of these tissues.⁸ The standardized incidence ratios of testis cancer in 32,442 men who had a semen analysis at the laboratory in Copenhagen between the years of 1963 and 1995 were compared with rates in the general population of Danish men.⁹ Parameters of poor semen quality, including low count, poor motility, and abnormal morphology, were all associated with increased risk of testis cancer (standardized incidence ratios of 2.3–3.0).

In women, a recent evidence-based review of the link between infertility and cancer risk concluded that borderline ovarian tumors are slightly more common in women

diagnosed with infertility.¹⁰ It is less clear whether infertile women are at increased risk for invasive ovarian cancer, but rates may be elevated in those who never achieve a pregnancy or among women with endometriosis. In contrast, infertility does not appear to be a risk factor for breast cancer.¹⁰ Although most cohort and case-control studies have not demonstrated a link between using ovarian stimulating drugs to treat female infertility and subsequent cancer risk for any site,¹¹ a recent comparison of 4,575 women with breast cancer and 4,682 controls found that women who used human menopausal gonadotropin for at least 6 cycles had a greater relative risk of breast cancer (2.7–3.8).¹²

Infertility Caused by Cancer Treatment

Many cancer patients are put at risk for infertility by the therapies used to eradicate or control their malignancy. Surgical treatment for pelvic cancer may remove a critical part of the reproductive organ system, e.g. bilateral orchiectomy for prostate cancer or for asynchronous testicular tumors, or bilateral oophorectomy as part of treatment for gynecological malignancies or as prevention for breast or ovarian cancer in women with BRCA mutations.¹³ Treatment of prostate or bladder cancer may entail removal of the prostate and seminal vesicles and the vagina or uterus may be removed to treat vaginal, cervical, or uterine cancer. Nerves controlling antegrade ejaculation of semen may be damaged in retroperitoneal lymphadenectomy for testicular cancer¹⁴ or in surgery for colorectal cancer.¹⁵

Radiation therapy to the pelvis damages fertility because developing gametes and ovarian follicles, like cancer cells, are more likely to be in the genetically vulnerable, proliferative state.¹⁶ Patients treated for prostate or cervical cancer, or those who have total body irradiation as preparation for bone marrow transplant, are the most common groups to experience radiation-associated infertility.

Chemotherapy drugs also interfere with gametogenesis because maturing sperm and oocytes are vulnerable to the toxins that damage rapidly-growing cancer cells.^{17,18} Alkylating drugs (including the platinum-based chemotherapies) are most likely to damage fertility. The likelihood of permanent ovarian failure in women increases with cumulative dose and age, and is manifested as decreased numbers of follicles, atretic follicles, and fibrotic changes in the ovary.¹⁹ Spermatogenesis is even more vulnerable to disruption by chemotherapy, with a similar pattern of risk factors in terms of dosage and type of drugs.²⁰ The impact of male age on fertility after cancer is unclear, but in general men over age 45 take longer to establish a pregnancy and have decreased conception rates.²¹

Preventing and Managing Cancer-Related Infertility

Preserving fertility is highly important to men and women diagnosed with cancer before completing their families. Although research on the psychosocial aspects of cancer-related infertility is limited, surveys and qualitative interview studies concur that most survivors feel healthy enough to be good parents, believe that their experience of cancer has increased the value they place on family closeness, are par-

ticularly distressed about infertility if childless, and are not getting enough information on options to spare or treat fertility.^{22–26}

Utilization of infertility services in the United States is limited even for the population at large. Less than 50% of women with infertility seek medical consultation and only 1.6% use assisted reproductive technology.²⁷ Although male factors explain roughly half of infertility, no statistics are available on men's use of infertility services.²⁸ This gives some context for help-seeking among cancer survivors with infertility.

Preventing Cancer-Related Infertility

Obviously it is preferable to prevent cancer-related infertility rather than to try treating it after the fact. Hormonal manipulation during chemotherapy may be used to try to minimize damage to the gonads. In addition, when treatment of a particular malignancy has become highly successful, efforts have been made to spare fertility in younger patients by using less toxic chemotherapy drugs or by limiting cancer surgery. Several options are available to cryopreserve gametes or embryos before cancer treatment for later use in conception, although assisted reproductive technology is typically required. Each of these options will be reviewed, and the level of evidence for its efficacy examined.

HORMONAL PREVENTION

In men, efforts during chemotherapy to protect the spermatogonia A cells that produce mature spermatozoa have included prescribing GnRH analogues with or without accompanying testosterone. Despite promising results in animals, human trials have been uniformly disappointing.²⁹ Howell and Shalet speculate that continuing hormonal treatment for several months after finishing chemotherapy might have more success, allowing surviving stem cells to recover and renew spermatogenesis. If no spermatogonia survive chemotherapy or radiation therapy, however, continuing hormonal treatment will be fruitless. Even in the prepubertal testis, cancer therapies damage fertility because the Leydig, Sertoli, and germ cells are not truly quiescent, but continue to develop,³⁰ making them vulnerable to toxic cancer therapies

Efforts at hormonal protection of the ovaries during chemotherapy in women have had more promising results, but double-blind randomized trials are still lacking. The largest case-control cohort has been followed by Blumenfeld in Israel.³¹ An injectable GnRH agonist was administered, beginning 1 to 2 weeks before chemotherapy and continuing for up to 6 months, to a group of 60 women aged 15 to 40 being treated for lymphoma. All but 3 of the surviving women resumed menstruation by the end of the first year, compared to only 45% of 60 women treated with chemotherapy alone, without hormonal protection. Inhibin -A and -B levels decreased during GnRH administration, normalizing only in the women who resumed menstruation.¹⁸ Although the GnRH and comparison groups did not differ on age, tumor type, cumulative dose of chemotherapy drugs, or exposure to radiation therapy, the comparison group consisted either of historical controls or women who were not seen in time to start the GnRH-agonist before chemotherapy.³¹ Obviously, selection bias is possible.

The use of a GnRH-agonist during adjuvant chemotherapy for breast cancer is attractive because it not only may protect against ovarian failure in young women, but could potentially add to cancer control. In a Phase II pilot study, a group in Rome administered the long-acting GnRH analog goserelin for one year during adjuvant chemotherapy to 64 newly diagnosed women with breast cancer, aged 18 to 50 and without distant metastases.³² Dosage and drug regimen depended on cancer stage. At a median follow-up time of 55 months, 86% of women had resumed menstruation after chemotherapy, including five who had stem cell transplantation. Although this was a lower rate of ovarian failure than would be expected, no comparison group was provided.

Chemoprotection Strategies

Even if hormonal protection helps preserve a greater number of primordial follicles during chemotherapy, many of those remaining would be damaged.³³ Another type of chemoprotection is suggested by advances in understanding how toxins like chemotherapy influence signaling pathways in the testis and ovary. A small lipid molecule, sphingosine 1-phosphate, may be able to prevent damage to the follicles as well as protecting against genetic damage to the oocyte.³⁴ Even more tantalizing is the recent discovery of stem cells in the human ovary, suggesting that females are not limited to the number of oocytes that survive fetal development, but have ongoing replenishment of primordial follicles.³⁵

Cryopreservation of Reproductive Tissue for Future Conception

The most well established form of reproductive tissue cryopreservation in cancer patients is sperm banking. Measures of the effectiveness of sperm banking include the success of using sperm cryopreserved by cancer patients in conceiving

healthy offspring and the utilization of stored samples by cancer survivors.

Conception rates from banked sperm have increased radically since the advent of intracytoplasmic sperm injection (ICSI) in 1992. In this technique, only one live sperm is injected into each oocyte retrieved from in vitro fertilization (IVF). Rates of fertilization with ICSI do not differ when using sperm that was cryopreserved versus from a fresh ejaculate, nor has the use of cryopreserved sperm resulted in increased birth defects.³⁶

Although many men diagnosed with cancer have impaired semen quality, samples from patients with suboptimal semen parameters survive freezing and thawing just as well as sperm from men of normal fertility.^{37,38} Several prospective case series of men who cryopreserved sperm are presented in Table 90.1. Only about 6% to 18% of cancer patients are azoospermic and unable to bank at the time of attempted semen collection.^{39,41,42,44} The most efficient use of stored samples is to attempt to conceive with IVF-ICSI,^{41,43} unless the semen quality is unusually good.

It appears that less than 10% of men who store semen actually use their samples to try to conceive, but this rate may be accelerating with the availability of IVF-ICSI.⁴²⁻⁴⁴ The percentage of couples who use their cryopreserved sperm with assisted reproductive technology (ART) and actually have a live birth varies widely from center to center, but is comparable to results for the general population of infertile couples.^{41,43} With all cohorts in Table 90.1 combined, 37 healthy babies were born, with only one pregnancy terminated because a major fetal malformation was detected.⁴²

Although specific rates of impaired fertility have been reported for a variety of chemotherapy combinations or radiation therapy doses and fields,²⁹ it is not possible to accurately predict recovery of fertility in any one man treated for cancer.³⁶ Therefore, sperm banking should be routinely offered when men are about to begin treatments that put fertility at risk. An adequate number of specimens can be banked without delaying cancer treatment in all but the most

TABLE 90.1. Long-term Follow-Ups of Cohorts of Consecutive Cancer Patients Who Cryopreserved Sperm.

Reference	Year	No. of Patients	Years follow-up	% able to store sperm	% using samples	Cycles of ART	Pregnancies per cycle	Live births	% couples attempting conception who achieved parenthood	Birth defects
Lass et al. ³⁹	1998	191	8	83%	3%	IUI: 2 IVF: 9 ICSI: 4	100% 22% 50%	7	83%	0

**Only N cryopreserving sperm was reported

***Rates increase with duration of follow-up to 12% at 12 years

emergent cases. A study of 95 cancer patients found that acceptable post-thaw semen quality could be obtained when men abstained for only 24 to 48 hours between collecting ejaculates.⁴⁵

Despite low rates of usage of stored sperm, men do not appear to regret the trouble or expense. Hallak and colleagues examined the reasons that 56 (16%) of 342 cancer men who had banked sperm before cancer treatment in their clinic discarded their cryopreserved specimens.⁴⁶ Out of the 56 men, 21 had died and the families discarded the samples, 23 had already conceived all the children they wanted without using their stored sperm, 8 had a return of good semen parameters, and 4 had decided not to have children. The cost of banking sperm was not a factor in these decisions.

Unfortunately, recent surveys of oncologists reveal that many fail to give men information about sperm-banking, underestimating its importance to their male patients and overestimating the barriers of cost and availability of sperm banking facilities.⁴⁷⁻⁴⁹ For those cancer patients interested in having future children, the most common reason cited for failure to bank sperm is lack of timely information. In our recent survey of young male survivors, only half recalled their oncology health care providers discussing the possibility of banking sperm.²³

The pediatric oncology community has shown an increasing interest in giving teens with cancer the option of banking sperm. Out of 238 boys aged 12 to 19 referred to one center in London, 87% were able to produce an ejaculate for semen storage, with semen quality similar to that in adult cancer survivors.⁵⁰ A new experimental technique uses testicular biopsies to obtain spermatogonia from prepubertal boys for cryopreservation before cancer treatment, in the hope that they can be replaced through autografting to restore fertility later. Attempts at replacement in adult men have been disappointing, however, since it is not possible to inject the thawed suspension of cells directly into the fibrous seminiferous tubules.²⁹ Cryopreserved human spermatogonial stem cells have been transplanted into mouse testes and survived for up to 6 months, suggesting that xenotransplantation could some day be another option for producing mature sperm cells for IVF-ICSI, or at least for providing a research model.⁵¹

In women, progress is also being made with the use of a rapid freezing technique called *vitrification* to freeze mature, unfertilized oocytes, although pregnancy rates still do not approach those with cryopreserved embryos.⁵² Another promising avenue is the use of sugars as cryoprotectants during freezing.⁵³ To have a true analogue to sperm banking in men, it would be necessary to cryopreserve primordial follicles and then to mature them in the laboratory. Although such techniques remain years away,⁵⁴ researchers are having some preliminary success with *in vitro* maturation of freshly retrieved antral follicles that are approaching full maturity.⁵⁵

A number of centers around the world are removing and cryopreserving ovarian tissue for women about to undergo cancer treatment that could impair fertility.⁵⁴ Several cases of auto-transplantation have taken place, with promising results.^{56,57} Technical problems include minimizing injury to ovarian tissue during the freezing itself and ischemia causing damage to follicles while the graft grows a new vascular system.⁵⁸ For some malignancies, concern about reintroducing cancer cells along with the ovarian tissue may limit this

option.⁵⁸ An alternative use of the tissue could be in xenotransplantation to immunodeficient mice with subsequent harvest of mature oocytes. Recently an embryo was produced using an oocyte retrieved from transplanted ovarian tissue in a female cancer survivor, but no pregnancy resulted when the embryo was transferred to the woman's uterus.⁵⁹ Furthermore, the first primate has been born using this technique—a rhesus monkey.⁶⁰ Still, an ethical dilemma is that women facing cancer treatment and desperate to protect their future fertility are paying several thousand dollars in out-of-pocket costs to harvest, freeze, and store ovarian tissue with very low odds that a pregnancy will ever result.

Ovarian Transposition During Pelvic Radiation Therapy

When radiation therapy fields include the pelvis, the ovaries can be moved surgically to a more protected location. Although both medial positioning behind the uterus and lateral movement to the pelvic sidewall have been used, currently the most common procedure is to use laparoscopy to move the ovaries laterally just prior to starting radiotherapy. Although ovarian transposition can be performed during a staging laparotomy, it is less effective because the ovaries tend to migrate back to their original position.⁶¹ The ideal position is above the pelvic brim, with the fallopian tubes remaining attached to the uterus.⁶²

A recent literature review of the outcome of laparoscopic lateral ovarian transposition included only 44 cases of women under age 40 with a variety of malignancies. However, 89% had preserved menstrual function.⁶² Oophoropexy can be complicated by vascular injury, infarction of the fallopian tube, or ovarian cyst formation. IVF is often required to conceive. Women with adenocarcinoma of the cervix or with more advanced stage disease may be at some risk for metastasis to a transposed ovary or to the site of trocar insertion for the laparoscopy.⁶³ Successful transposition may still be followed by early menopause because of reduced ovarian reserve after radiation therapy.⁶⁴

Fertility-Sparing Surgery for Early-Stage Gynecological Malignancies

Young women diagnosed with early stage cervical or ovarian cancer may opt for conservative surgical procedures that allow them to retain fertility. For women with squamous cell carcinoma of the cervix that is invasive but still early stage, a trachelectomy can be substituted for a radical hysterectomy.⁶⁵⁻⁶⁸ After the majority of the cervix is removed, the vaginal cuff is sewn back to the cervical remnants. As long as lymph nodes and surgical margins are clear, recurrence rates are comparable to those after radical hysterectomy. Although many women are able to become pregnant after trachelectomy, rates of miscarriage and prematurity are higher than normal. The cervical mucous plug that prevents infection of the amniotic membranes may be inadequate and there is an increased risk of cervical incompetence.

Women with adenocarcinoma of the cervix that is either *in situ* or very early stage can be treated with conization alone to preserve fertility, as long as surgical margins are clear.^{69,70} Adenocarcinoma of the cervix is often multifocal or located high in the endocervical canal, however, and about 20% of

women with negative margins at the time of conization will have local recurrences.

In conservative surgery for young women with borderline or germ cell ovarian tumors, only the affected ovary is removed, preserving the uterus and contralateral ovary.⁶⁶ Results have been good, both in terms of fertility and cancer control, but only small case series have been published.^{71,72} Recurrence rates after conservative surgery for borderline tumors are higher than after radical surgery, but survival rates remain similar.⁷¹ Conservative surgery has also been utilized for Stage I epithelial tumors.⁷³ The largest cohort study included women treated for germ cell tumors with a median follow-up of 122 months.⁷⁴ Of those who tried to conceive ($N = 38$), 76% have become pregnant.

Other Fertility-Sparing Modifications of Cancer Treatment

Other modifications made to cancer treatment to spare fertility have not been evaluated in randomized clinical trials, but instead have been compared to historical controls. Examples include the less gonadotoxic chemotherapy regimens for Hodgkin's disease⁷⁵; surveillance protocols and nerve-sparing retroperitoneal lymphadenectomy for early stage testicular cancer⁷⁶; and orthotopic bladder reconstruction with fertility preservation for men with bladder cancer.⁷⁷

The Safety of Pregnancy After Cancer Treatment

It would be of little utility to promote fertility in women after cancer if pregnancy were a risk factor for cancer recurrence. However, evidence has accumulated that becoming pregnant after successful cancer treatment does not affect women's survival, even those who have had breast cancer.⁷⁸ Women diagnosed with breast cancer during pregnancy often have more advanced disease but do not have a survival disadvantage when matched to nonpregnant controls on medical factors such as cancer stage and histology.⁷⁹

An area much in need of study is the psychosocial impact of experiencing cancer during pregnancy, and the development of supportive interventions for women in this predicament.⁸⁰ One recent survey found that reproductive concerns remain salient in women successfully treated for gestational trophoblastic disease and that 75% would have attended support groups if they had been available during treatment.⁸¹ Young survivors often lack accurate information about pregnancy after cancer. In our pilot survey, 20% of breast cancer survivors and 18% of women with other cancer sites worried at least "a fair amount" that pregnancy could trigger a recurrence of cancer. Only 53% of women recalled any discussion by their oncology team of pregnancy after cancer.²²

Survivors also lack knowledge about potential pregnancy complications related to impaired cardiac, pulmonary, or uterine function after cancer treatment. Few would plan evaluation by a high-risk obstetrician before trying to conceive.²² In the largest study to date, 4,029 pregnancies of participants in the Childhood Cancer Survivor Study were reviewed.⁸² A woman's history of chemotherapy was not associated with adverse outcomes, but women who had pelvic irradiation were more likely to have low birthweight infants. A higher than expected rate of voluntary pregnancy termination was observed, again suggesting that women may be worried about

the safety of pregnancy or about the likelihood of having healthy offspring. Some women may also have been told in error that they were infertile, and thus did not use contraception to prevent an unwanted pregnancy. Higher rates of miscarriage and prematurity have also been observed in women with uterine exposure to radiotherapy as young adults, although the damage from childhood exposure is more severe.⁸³

The Use of Assisted Reproductive Technology (ART) and Cancer

Although cryopreservation of embryos is far more successful than freezing unfertilized oocytes or ovarian tissue, undergoing IVF before cancer treatment presents some difficulties.^{84,85} Women with a very aggressive malignancy such as acute leukemia may not have time to delay chemotherapy for several weeks of ovarian stimulation. Women who do not have a committed male partner have to use an anonymous sperm donor to create embryos. Women recently diagnosed with cancer often do not produce many mature oocytes in response to IVF. Women with untreated breast cancer risk exacerbating their disease by taking hormones for IVF. One alternative is natural cycle IVF, in which the one or two oocytes that mature without exogenous hormones are harvested and fertilized. Recently Oktay and colleagues developed an IVF protocol especially for women newly diagnosed with breast cancer, using tamoxifen for ovarian stimulation. The average number of embryos per cycle was 1.6 compared to 0.6 with a natural cycle, yielding a higher chance of an eventual pregnancy.⁸⁶ Ovarian stimulation regimens combining tamoxifen and follicle stimulating hormone (FSH) are yielding even better results.⁸⁷

Women who wait until after chemotherapy to try IVF typically have a suboptimal response to the hormone stimulating drugs.⁸⁵ Creating embryos with oocytes from a donor is another option for the woman who has diminished fertility or is in ovarian failure after cancer treatment, but can still carry a pregnancy.^{88,89} The cancer survivor herself does not undergo the risks of ovarian stimulation. If she is in ovarian failure, she may need some hormonal support to prepare her uterus for embryo transfer, as well as during the first weeks of a pregnancy, until the placenta begins to produce its own hormones. The hormone levels during these intervals are similar to those in a natural pregnancy. Pregnancy rates per cycle with donated oocytes are high, especially when both egg donor and recipient are under age 35. Women who have had pelvic irradiation still suffer the risk of prematurity and miscarriage, however. Along with survivors who have lost their uterus to cancer but have stored embryos or ovarian tissue, they may work with a gestational carrier to have a child. Only isolated case reports are available in the literature, however.⁹⁰

For men with poor semen quality after cancer, IVF with ICSI is the preferred method of treatment. Some men do not have any mature spermatozoa in their semen, or no longer ejaculate seminal fluid after their cancer treatment. If they did not bank sperm before treatment, some options are still open to them. Men who do not ejaculate after node dissection for testis cancer or surgery for colorectal tumors may respond to medications that temporarily restore antegrade ejaculation. Viable sperm may also be retrieved from urine voided just after orgasm. Perhaps the most reliable means of

obtaining sperm from these men is via electrical stimulation of ejaculation with a probe in the anal canal.⁹¹ This procedure must be performed under anesthesia, but yields samples that typically can be used for IVF with ICSI.⁹² Some urologists have used electroejaculation to obtain ejaculates from young teens who are unable to collect semen through masturbation due to anxiety or religious constraints.⁹³

About half of men with no sperm in their semen after chemotherapy do have islands of spermatogenesis in their testes. A few viable sperm can be retrieved in testicular biopsies and used for successful IVF with ICSI.^{94,95} Although increased aneuploidy has been observed in the sperm of men recently treated for cancer,⁹⁶ and aneuploidy has been associated with poorer fertilization rates with ICSI,⁹⁷ the pregnancy rates using ICSI with testicular sperm from cancer survivors have been comparable to those with other causes of male factor infertility, with a quarter to a third of cycles resulting in a healthy baby.^{94,95} In a recent case series of 33 male childhood cancer survivors, only 33% of had normal semen quality but the integrity of DNA in their spermatozoa did not differ from that in a group of control men, suggesting that offspring would not be at increased risk of birth defects or other health problems.⁹⁸

Health of Offspring of Cancer Survivors

Despite concerns that children born to men or women who had been treated for cancer would have unusual rates of genetic abnormalities or fetal malformations,⁹⁹ the available data suggest reasonable cause for optimism. Karyotypes of 2,630 live-born children with a parent who had survived childhood cancer were available from the Danish Cytogenetic Registry.¹⁰⁰ The rate of abnormal karyotypes was not significantly greater than those in the children born to the siblings of the childhood cancer patients. No study has thus far documented an excess rate of birth defects in children born after one parent's cancer treatment, with the caveats that 1) a limited number of offspring have been studied; and 2) the nature and duration of follow-up of offspring has been limited.

Genetic damage from cancer treatment may impact rates of early miscarriage or the gender of surviving infants. In addition to the results of pregnancies from the females in the Childhood Cancer Survivor Study,⁸² 2,323 pregnancies sired by the male cancer survivors were documented. The live birth rate of 69% was significantly less than that for the survivors' brothers, and a deficit of male offspring born to the survivors was also observed.¹⁰¹ Partners of men exposed to more than 5,000 mg/m² of procarbazine had an increased risk of miscarriage. A large Scandinavian registry study did not document any increased lifetime cancer risk in offspring, except in families with known, autosomal dominant inherited cancer syndromes.¹⁰² Most offspring in these studies have been born to childhood cancer survivors long removed from their active treatment when they conceived. On the other hand, some types of chemotherapy can be administered to pregnant women in the second and third trimesters without causing fetal malformations.¹⁰³

A new issue is the impact on young adults' childbearing decisions of knowing they carry a mutation that increases lifetime cancer risk. For example, women with BRCA mutations increase their risk of breast cancer by having a pregnancy before age 40 and decrease their risk by early

oophorectomy without estrogen replacement.^{104,105} Technologies such as prenatal diagnosis and preimplantation genetic diagnosis are also available to identify known autosomal dominant mutations responsible for hereditary cancer syndromes,¹⁰⁶ bringing potential ethical dilemmas, especially whether they should be used for those syndromes with a relatively late onset.

Risk Factors for Cancer-Related Menopausal Symptoms

Since the incidence of cancer increases with aging, menopausal symptoms are probably of high concern for more survivors than infertility. Women treated for breast cancer and men receiving hormonal therapy for advanced prostate cancer are particularly at risk for troublesome hot flashes. Vaginal atrophy and dyspareunia are the major sexual consequences of menopause for women¹⁰⁷ and will be discussed in the sections on sexual function. Menopause-related risks for cardiovascular disease and osteoporosis fall outside of the scope of this chapter.

Psychosocial Factors and Hot Flashes

It is unclear whether cancer survivors experience more severe menopause symptoms than women in the community without a cancer history. The prevalence of menopausal symptoms has generally been overestimated. The Massachusetts Women's Health Study followed a large cohort of women through the transition to menopause.^{108,109} Most women did not have hot flashes or depression, had neutral or positive attitudes to menopause, and did not seek any medical attention for menopausal symptoms. Women who had hysterectomy were a more distressed group, with indications that women with pre-existing psychological problems are more likely to have this surgery.¹¹⁰ An analysis of sexual function in 200 of the participants found that estrogen levels were significantly correlated with reports of dyspareunia, but not with any other sexual problem. A woman's perceptions of her overall health and the quality of her dyadic relationship were stronger predictors of her sexual function than was her menopausal status.¹¹¹

Psychosocial factors play an important role in women's menopause complaints. The best predictors of depression, general health, and utilization of medical services after menopause are a woman's physical and psychological health and history of medical consultation before menopause.^{109,110,112,113} Hot flashes and the use of hormone replacement therapy (HRT) are both correlated with psychological distress.^{114,115} More educated women are consistently less likely to report hot flashes,^{114,115} and cultural beliefs and expectations about menopause affect women's symptom reporting.¹¹⁶

The Prevalence of Hot Flashes After Breast Cancer

Women with breast cancer are the group most at risk for troublesome hot flashes after cancer treatment because they are advised not to use systemic estrogen replacement. No large case-control study has compared hot flashes in breast cancer survivors and other women. Carpenter and colleagues

surveyed breast cancer survivors from a tumor registry, with about a third responding (N = 69), and compared them to a convenience sample of women with no history of breast cancer but similar age. Hot flashes were more frequent, severe, and distressing for the breast cancer sample. This finding may reflect selection bias in women who chose to participate, as well as the fact that women in the breast cancer group were significantly more likely to be menopausal and less likely to be using estrogen replacement.¹¹⁷ Within the breast cancer group, hot flash severity and indices of emotional distress were related, parallel to findings in the general population of postmenopausal women.^{117,118}

Among 860 breast cancer survivors surveyed by Ganz and colleagues at an average of 3 years post-diagnosis, 55% reported problems with hot flashes, a higher rate than expected from similar studies in healthy postmenopausal non-users of HRT.¹¹⁹ Women who are premenopausal at breast cancer diagnosis and become menopausal because of cancer treatment are at highest risk to have hot flashes.¹¹⁹⁻¹²¹ Although women taking tamoxifen experience hot flashes, they decrease after therapy ceases if women resume menses.^{122,123} When adjuvant chemotherapy causes permanent menopause, however, hot flashes, vaginal dryness, and decreased quality of life persist even at long-term follow-up.^{122,124}

Menopause Symptoms After Other Malignancies

Very little information is available on the prevalence and severity of menopausal symptoms in young women treated for other malignancies with chemotherapy or pelvic radiation that causes ovarian failure, although hot flashes and vaginal dryness are classic symptoms in women who become menopausal after treatment for gynecological cancer^{125,126} or after intensive chemotherapy for hematological malignancies.¹²⁷ Women whose tumors are not hormone-sensitive may be less reluctant than breast cancer survivors to use estrogen replacement,¹²⁷ although publicity about the results of the Women's Health Initiative¹²⁸ has many women questioning the benefits of estrogen to manage all but the most short-term menopausal symptoms.

Hot Flashes in Male Cancer Survivors

A final group of cancer survivors at risk for menopausal symptoms are men who have androgen ablation to treat prostate cancer or take hormonal therapy for male breast cancer. Whether prostate cancer treatment involves orchiectomy or administration of a gonadotropin-releasing-hormone (GnRH) agonist, half to three-quarters of men report troublesome hot flashes.¹²⁹ As in the literature on menopausal women, there is not convincing evidence that androgen ablation increases depression in men, although sexual dysfunction is quite common.¹²⁹ Although in the year 2002, 189,000 new cases of prostate cancer were expected compared to only 1,500 men diagnosed with breast cancer,¹³⁰ the symptoms of hot flashes and sexual dysfunction are also common when men are treated with tamoxifen for advanced breast malignancies.¹³¹

Managing Menopausal Symptoms in Cancer Survivors

A variety of treatments are available for menopausal symptoms, ranging from relaxation treatment to antidepressant medication or hormonal replacement therapy. Only a few have been validated in double-blind randomized trials, a crucial design given the large and enduring placebo effect observed when breast cancer survivors are presented with a credible treatment for hot flashes.¹³² Most intervention studies have used breast cancer survivors, the principal group at risk because of their concern about using estrogen replacement and their high rates of hot flashes. Men on hormonal therapy for prostate cancer have been another target group.

Estrogen Replacement for Hot Flashes

Estrogen replacement has consistently been shown to reduce hot flashes in 80% to 90% of postmenopausal women.¹³² Nevertheless, an estimated 56% of all American women on HRT tried to stop within the first 8 months after publication of the Women's Health Initiative findings.¹³³ This randomized trial not only failed to confirm health benefits of HRT¹²⁸ but showed that HRT increases the risk of breast cancer.

The literature on using estrogen replacement after treatment for breast cancer also showed clear benefits in alleviating menopausal symptoms.¹³⁴⁻¹³⁶ Case control studies failed to find an impact on survivors' cancer recurrence or decreased survival,^{134,135,137-143} including a meta-analysis comparing 717 breast cancer survivors using some form of HRT to 2,545 nonusers. The relative risk of recurrence for women on HRT was 0.72 (95% confidence interval 0.47-1.10).¹⁴⁴ The relative risk of death for women on HRT after breast cancer was 0.18 (95% confidence interval, 0.10-0.31).

The first randomized trial¹⁴⁵ to be conducted confirmed these results, but included only 56 women in the estrogen-treated group. Women who agree to participate in such a trial may be a very select sample, since most survivors of breast cancer are highly anxious about the risks of taking estrogen.^{145,146} More recently, the HABITS trial of the safety of hormone replacement therapy after breast cancer was stopped after 345 women had been followed for a median of about 2 years. An excess of new breast cancer events showed up in the hormone-treated group.¹⁴⁷

One alternative hormonal therapy for hot flashes is to use progestins alone. Depomedroxyprogesterone acetate was effective in reducing hot flashes in a randomized clinical trial of breast and prostate survivors, and 45% continued using the medication for up to three years, despite some side effects.¹⁴⁸

Nonhormonal Therapies for Hot Flashes

Trials of nonhormonal approaches to treating hot flashes are summarized in Table 90.2, with a focus on trials that include cancer survivors. Newer antidepressants appear to be the most promising nonhormonal therapy for both breast and prostate cancer survivors with hot flashes, producing greater relief and fewer side effects than older treatments such as progestins, clonidine, or bellergal.¹³² Some other widely touted remedies such as isoflavones, black cohosh, and magnetic therapy have proved disappointing when tested in placebo-controlled trials.^{153-155,158,159}

TABLE 90.2. Trials of Nonhormonal Therapies for Hot Flashes.

Reference	Year	Type of trial	No. of patients	Type of treatment	Type of patients	Average length of follow-up	Impact on hot flashes
Pandya et al. ¹⁴⁹	2000	Randomized, double-blind trial	194	Oral clonidine, 0.1 mg./day	Postmenopausal women on tamoxifen for breast cancer	12 weeks	38% reduction on clonidine vs. 24% on placebo
Stearns et al. ¹⁵⁰	2003	Randomized, double-blind trial	165	Paroxetine, 12.5 or 25.0 mg./day	Postmenopausal women without active cancer or cancer treatment	6 weeks	62% reduction on 12.5-mg./day and 65% on 25.0 mg./day
Loprinzi et al. ¹⁵¹	2000	Randomized, double-blind trial	191	Venlafaxine, 75 mg./day or 150 mg/day	Breast cancer survivors or women scared to use HRT	4 weeks	37% reduction on 75 mg./day, 49% on 150 mg./day and 27% on placebo
Quella et al. ¹⁵²	1999	Pilot trial	16	Venlafaxine, 25 mg./day	Prostate cancer patients on androgen ablation with hot flashes	4 weeks	54% reduction in hot flashes
Quella et al. ¹⁵³	2000	Randomized, double-blind trial	149	50 mg. soy isoflavone/day	Breast cancer survivors with severe hot flashes	9 weeks	24% of women had 50% reduction on soy, 36% on placebo
Tice et al. ¹⁵⁴	2003	Randomized, double-blind trial	246	57 mg. or 82 mg. of isoflavone/day	Recently postmenopausal with severe hot flashes	12 weeks	No significant group differences
Nikander et al. ¹⁵⁵	2003	Randomized, double-blind trial	62	114 mg. isoflavone/day	Postmenopausal breast cancer survivors with hot flashes	12 weeks	No significant group differences
Muñoz et al. ¹⁵⁶	2003	Random, open-label trial	136	20 mg. <i>Cimicifuga racemosa</i>	Premenopausal breast cancer survivors on tamoxifen	52 weeks	Treatment group improved significantly more than usual care group in number and frequency of hot flashes
Wuttke et al. ¹⁵⁷	2003	Randomized, double-blind placebo-controlled	62	40 mg. <i>Cimicifuga racemosa</i> vs. 6 mg. conjugated estrogens vs. placebo	Postmenopausal women	13 weeks	Herbal preparation and estrogen gave equal symptom relief and both were better than placebo
Jacobson et al. ¹⁵⁸	2001	Randomized placebo-controlled, stratified on tamoxifen use	69	Black cohosh	Breast cancer survivors who had completed primary treatment	8 weeks	No significant group differences
Carpenter et al. ¹⁵⁹	2002	Randomized, placebo-controlled crossover study	11	Magnetic device	Breast cancer survivors	3 days	Placebo group improved more than magnet group
Porzio et al. ¹⁶⁰	2002	Pilot trial	15	Acupuncture	Breast cancer patients on tamoxifen	26 weeks	Emotional distress and hot flashes decreased significantly

Given the magnitude of the placebo effect, promising results using herbal remedies or acupuncture must be confirmed with randomized, placebo-controlled trials. For example, acupuncture using clinically recommended points could be tested against acupuncture using sites judged inactive according to traditional Chinese medicine. The duration of therapies tested has also been quite short, particularly given the stubborn nature of hot flashes in breast and prostate cancer survivors. Since some studies focused on cancer survivors with severe symptoms while others used unselected samples, the efficacy of various treatments cannot be directly compared. Although not yet tested in cancer survivors, behavioral modalities such as relaxation training^{132,161} and engaging in regular aerobic exercise¹⁶² show promise in decreasing hot

flashes in postmenopausal women unselected for cancer history.

One small, randomized trial has examined the efficacy of a brief, nursing intervention in reducing menopausal symptoms in 76 postmenopausal breast cancer survivors chosen because they had at least one severe problem of hot flashes, vaginal dryness, or urinary stress incontinence.¹⁶³ Women were randomized to receive usual care or to have a special session with a nurse practitioner to assess symptoms and apply treatment algorithms such as prescribing medication or advising on the use of vaginal lubricants and moisturizers. Telephone follow-up calls were included. All three target symptoms improved in the treated group compared to the usual care group. This type of inexpensive, brief intervention

should be replicated, and then tested in further studies to evaluate its effectiveness and dissemination into a variety of health care settings.

Risk Factors for Cancer-Related Sexual Dysfunction

To understand the prevalence of sexual dysfunction after cancer, it is important to realize how common these problems are in otherwise healthy adults.

Prevalence of Sexual Dysfunction in the General Population

The National Health and Social Life Survey (NHSLs) conducted in 1992 still provides the best estimates of the prevalence of sexual problems in American adults 18 to 59, because the researchers used probability sampling and achieved a high response rate (79%).^{107,164} Thirty-one percent of men and 43% of women had experienced a sexual dysfunction in the past year. Factors associated with sexual problems included poor physical and mental health, aging, past sexual trauma, and relationship satisfaction.

More recently, the Pfizer Global Study of Sexual Attitudes and Behaviors has used similar interview techniques to sample over 26,000 men and women aged 40 to 80 in 28 countries around the world. Although response rates were much lower than in the NHSLs, the sheer volume of data is impressive. Again, one-third to one-half of men and women reported having sexual dysfunctions during the past year.¹⁶⁵ In the data subsets from the United States, Canada, Australia and New Zealand, lack of sexual desire was the most frequent female problem (29%) whereas premature ejaculation was the most common male dysfunction (26%).¹⁶⁶ Overall, women were twice as likely as men to experience difficulty with sexual desire, experiencing pleasure, and reaching orgasm. Most large surveys agree that erectile dysfunction (ED) increases dramatically with age and cardiovascular risk factors in men, so that by age 70, about half of men experience it.¹⁶⁷⁻¹⁶⁸ In contrast, sexual problems in sexually active women (other than vaginal dryness) do not increase consistently with age or ill health.^{107,166} Elderly women are more likely than men of the same age to be without a sexual partner, however.¹⁶⁹

Risk Factors for Sexual Dysfunction After Cancer

Within groups of cancer survivors, sexual dysfunction is usually related to the impact of cancer treatment, rather than being a function of the cancer itself, with a few notable exceptions. Prostate cancer that is locally advanced may damage nerves essential for erection.¹⁷⁰ Women with gynecological cancer, especially cancer of the cervix, vagina, or vulva, may experience pain and bleeding with sexual activity as a presenting symptom of their malignancy.¹⁷¹ Cancer survivors most at risk for treatment-related sexual dysfunction are those with pelvic tumors and/or those whose treatments damage the hormonal systems mediating sexual desire and pleasure.

Psychosocial factors are also crucial. The risk of sexual dysfunction for any individual cancer survivor is heightened

by overall emotional distress, relationship conflict, and having a partner who is sexually dysfunctional. It is also important to remember that medications used to treat depression, anxiety, pain, and nausea during and after cancer treatment frequently have sexual side effects.¹⁶⁷⁻¹⁶⁹

Treatment-Related Sexual Problems in Men

Men treated for prostate cancer are the group at highest risk for sexual dysfunction. In a prospective study of 31,742 non-physician health professionals aged 53 to 90, rates of ED for the 2,109 men who had been diagnosed with prostate cancer were 10 to 15 times higher than for men of comparable age.¹⁶⁸ Despite attempts to modify surgery or radiation therapy for prostate cancer to spare sexual function, recent large cohort studies suggest that 75% to 85% of men treated for localized disease have long-term problems with ED.¹⁷²⁻¹⁷⁵ Rates of ED are similar after radical cystectomy¹⁷⁶ but somewhat lower with treatment for colorectal cancer.¹⁷⁷ Men on hormonal therapy for advanced prostate cancer have even more severe sexual dysfunction because of the impact of androgen ablation on sexual desire and arousability.^{129,175}

Men treated for testicular cancer are often assumed to be at increased risk for sexual problems. Two extensive recent reviews of the literature on this topic concur that few studies of high quality are available.^{178,179} Nevertheless, both reviews conclude that the only clear sexual morbidity of treatment for testicular cancer is the interference of retroperitoneal node dissection with antegrade ejaculation. When the lymph nodes are fully dissected along the bifurcation of the aorta, nerves are disrupted that control the smooth muscle contractions of the prostate and seminal vesicles during the emission phase of male orgasm. The result is that men experience the pleasure of orgasm, but with no expulsion of semen. Most retroperitoneal lymphadenectomies now spare crucial nerves by limiting the dissection, preserving normal ejaculation of semen in 75% to 90% of patients.^{180,181}

Prospective data on sexual function from a very recent Norwegian randomized trial of chemotherapy for 666 men with metastatic germ cell tumors found that sexual problems rose somewhat 3 months after treatment began, but by 2-year follow-up had subsided to normal levels.¹⁸² The quality of the sexual relationship with a partner had also not suffered. In the longer term, however, testicular cancer survivors who had higher doses of external beam radiation therapy may have an increased risk of ED with aging¹⁷⁸ because of the potential for reduced blood flow in an irradiated pelvic vascular bed.

Higher than expected rates of sexual dysfunction have been reported in longer-term survivors of renal cell carcinoma¹⁸³ and bone marrow transplantation.¹⁸⁴ Low-normal to frankly low levels of testosterone are common in young men treated with high-dose chemotherapy for lymphoma or Hodgkin's Disease, which could be a factor in loss of sexual interest and arousal.²⁹

Treatment-Related Sexual Problems in Women

Breast cancer is often assumed to be the site most associated with female sexual dysfunction. Although sexual problems are present in about half of long-term survivors of breast cancer, rates are comparable to those in age-matched women who have not had cancer.¹¹⁹ Frequency of sexual activity is

also similar to that of community-dwelling women of similar age.^{119,123,185} Premenopausal women whose chemotherapy results in ovarian failure cancer do have unusually high rates of sexual dysfunction, however,^{119,123,186} including a long-term loss of desire for sex, increased vaginal dryness, and dyspareunia. In a sample of 153 women interviewed 20 years after having chemotherapy for premenopausal breast cancer, 29% attributed current sexual problems to past cancer treatment.¹⁸⁷ In contrast to chemotherapy, tamoxifen is not associated with decreased desire for sex or impaired lubrication with sexual arousal.^{119,186-188} Breast loss is not a crucial factor in these problems, contrary to conventional wisdom. Comparisons of women after various breast surgeries have been highly consistent in showing that breast conservation and reconstruction are not superior to mastectomy in preserving women's sexual function or satisfaction.^{119,123,188,189}

Indeed, young women treated for leukemia or Hodgkin's disease are as likely as breast cancer survivors to report sexual dysfunction.¹⁸⁷ About a quarter to a third of women have sexual dysfunction after treatment for hematological malignancies. Although both psychosocial trauma and ovarian failure can contribute to their sexual problems,^{190,191} in at least one, small randomized trial, a less gonadotoxic chemotherapy was not superior in sparing sexual function.¹⁹²

A gender difference in sexual function seen both in unselected, healthy women¹⁹³ and in cancer survivors^{119,194} is that women's sexual satisfaction is not tightly linked to physical functioning like men's, but rather to overall well-being and the quality of intimacy and affection with the sexual partner. For example, in women treated for vulvar cancer, the extent of the tissue excised is less important than relationship happiness in predicting sexual satisfaction.¹⁹⁴ Among breast cancer survivors, those who had found new partners after their cancer treatment had the happiest sex lives.¹¹⁹

Nevertheless, it is clear that treatment for gynecological malignancies, including cancer of the cervix, vulva, or uterus, does increase the prevalence of sexual dysfunction beyond that seen in healthy, community-dwelling peers, particularly rates of vaginal dryness and pain with sexual activity.¹⁹⁵ In women treated for localized cervical cancer, pelvic radiation therapy has a more negative impact than radical hysterectomy in reducing vaginal lubrication and expansion with sexual arousal, as seen in two small, but carefully monitored, prospective studies.^{196,197} The literature on hysterectomy for benign disease also demonstrates no detriment of surgery to sexual function, even when the cervix is removed, as long as the woman's hormonal status remains unchanged.^{198,199} The risk of painful sex and loss of erotic pleasure increases when bilateral oophorectomy is included, or if pelvic surgery affects vaginal caliber or depth, as in abdomino-perineal resection,¹⁷⁷ radical cystectomy,²⁰⁰ or total pelvic exenteration.²⁰¹

Management of Sexual Symptoms in Cancer Survivors

Despite increased attention in the past 20 years to sexual dysfunction as a consequence of cancer treatment, pitifully little progress has been made in developing cost-effective treatment programs to alleviate these symptoms. The entire field of behavior therapy for sexual dysfunction has seen scant innovation in techniques or new outcome research since the

1970s.²⁰² Although standard sex therapy programs have been modified for cancer patients,²⁰³ prospective studies of efficacy are lacking.

In 1987 we published a retrospective chart review of detailed clinical notes on consultations in a sexual rehabilitation program within a cancer center over a 4-year period.²⁰³ Out of 384 individuals or couples, 73% were seen only once or twice. Of the index patients seen, 308 were men and 76 were women. Male cancer patients were older, and were more likely to include a partner in their visits (56%) than were the women (28%). Seventy-nine percent of the patients had pelvic malignancies, but this probably reflected referral bias, since the program was located within a urology department and also had strong ties to gynecology. According to their retrospective reports, the prevalence of sexual dysfunctions had increased after cancer treatment in the index patients, but not in their partners. Most men sought help for ED whereas women typically had a combination of loss of desire and vaginal dryness/dyspareunia.

About half of patients were seen prior to or during cancer treatment, and half were first evaluated after treatment had been completed. Follow-up data on outcome were available for only 118 cases. The therapist rating of improvement was "somewhat to much better" for 63% of this group. Factors correlated with better outcome included having more counseling sessions, younger age, absence of depression, and absence of marital conflict.

Prospective clinical trials of sex therapy for specific types of sexual dysfunctions after cancer, using standardized outcome measures, should have followed this report. They are strikingly absent from the literature, however. The majority of people with sexual dysfunction after cancer never seek professional help. In the Pfizer Global Study of Sexuality, less than 20% of men or women unselected for health who had sexual problems consulted a physician about them, although roughly half discussed the problem with a partner, friend, or family member.²⁰⁴

Physicians are often urged to initiate discussions of sexuality with all patients, but an analysis of data from the same survey on 5,250 men aged 40 to 80 from 7 countries in Europe revealed that less than 7% had a physician who initiated an assessment of sexual function in the past year, although the majority of men believed such dialogues should be routine.²⁰⁵ Medical schools in North America only devote an average of 3 to 10 hours to sexuality in the entire 4-year curriculum,²⁰⁶ so that a physician who wants to counsel patients on sexual rehabilitation must be essentially self-taught. Qualitative interviews of nurses and physicians on an ovarian cancer treatment unit in England confirmed that less than a quarter ever discussed sexuality with patients,²⁰⁷ despite knowing that sexual problems were prevalent.

We will discuss evidence-based management of sexual problems after cancer using the minimal empirical evidence that exists in the literature on treatment of dysfunctions in men and women unselected for health, and in the literature on sexual rehabilitation after cancer.

Modifying Cancer Treatment to Spare Male Sexual Function

One approach to managing cancer-related sexual dysfunction is to modify cancer treatment to prevent damage to

hormonal, vascular, or neurologic systems needed for a healthy sexual response.

In men, hormonal therapy for advanced prostate cancer results in a profound loss of desire for sex, as well as erectile dysfunction and difficulty reaching orgasm.^{175,208,209} Tactics to avoid this morbidity have included delaying treatment in asymptomatic men, using intermittent hormonal therapy to keep prostate specific antigen (PSA) values close to zero while allowing improved sexual function during intervals off treatment, or prescribing an androgen-blocker such as bicalutamide either alone or in combination with finasteride. Unfortunately, delayed treatment may compromise ultimate survival time,²¹⁰ and both androgen production and sexual function appear to be permanently impaired by a period of months on androgen ablation.^{175,211} Bicalutamide is more promising, but considerable sexual morbidity still occurs.²¹²

Perhaps the best-validated attempt to preserve sexual function after cancer is the nerve-sparing modification of radical prostatectomy, cystectomy, and colorectal cancer surgery.²¹³ Although avoiding damage to the nerves near the prostate and posterior urethra helps preserve penile hemodynamics and erection in some men, up to 80% do not recover erections firm enough to allow vaginal penetration on most attempts.^{172–175,214} Success depends on the skill of the surgeon, the ability to spare nerves bilaterally, and younger patient age. Although nerve-sparing may not restore normal erections, it does increase the percentage of men who can effectively use oral medications such as sildenafil.^{175,214} Similarly, using brachytherapy instead of external beam irradiation to treat localized prostate cancers is only slightly more successful in preserving erectile function.^{175,215}

Modifying cancer surgery to conserve or reconstruct pelvic organs does appear superior in terms of impact on sexuality. For example, conserving the bladder by using a combination of transurethral resection, chemotherapy, and radiation leaves men with better sexual function compared to radical cystectomy.²¹⁶ Procedures to reconstruct a continent, internal urinary pouch combined with nerve-sparing also appear to result in better sex lives for men compared to the traditional, radical cystectomy with ileal conduit.^{217,218}

Modifying Cancer Treatment to Spare Female Sexual Function

In women, the main approaches that spare hormonal function are aimed at fertility, i.e. the conservative surgical approaches to gynecologic cancers.^{66,71–74} The sexual consequences of such modifications have not been examined. Likewise, researchers have not studied the sexual impact of efforts to spare ovarian function by using ovarian transposition prior to radiation therapy, or GnRH agonists during chemotherapy.

In contrast to results after radical cystectomy, women who have orthotopic bladder reconstruction with preservation of the anterior vaginal wall do not report sexual dysfunction.^{176,219} Surgery for colorectal cancer that avoids creation of an ostomy also results in better quality of life and sexual satisfaction.²²⁰ Despite some controversy about the value of vaginal reconstruction after total pelvic exenteration for cervical cancer, the majority of women stay sexually active with their neovagina²⁰¹ and the use of myocutaneous flaps helps fill in the surgical defect and promotes healing.

Unfortunately, these reports focus on small series of highly selected patients treated at academic centers. It would be virtually impossible to conduct randomized trials of more vs. less radical surgical procedures, keeping patient age, education, socioeconomic status, and tumor variables equal between groups. Yet, when several randomized trials did compare mastectomy to breast conservation, researchers were surprised to find that neither sexual variables nor quality of life differed according to the extent of breast surgery.^{119,188}

Treatment of Desire Disorders

Loss of desire for sex is one of the most common sexual problems seen in both male and female cancer survivors. The efficacy of androgen in alleviating these problems is controversial. Decreased androgen levels are an important factor in men on androgen ablation, some men treated for testicular cancer, or men who have sustained gonadal damage from high-dose chemotherapy.²²¹ Ovarian failure in women and chronic use of opioid therapy²²² in both genders also can reduce circulating androgens and sexual desire.

Unfortunately, androgen replacement therapy remains more of an art than a science. In young men who are clearly hypogonadal, testosterone replacement restores sexual motivation and pleasure.^{223,224} Only two double-blinded, randomized, placebo-controlled trials of the newer testosterone gel or patch formulations have been published, however, with contrasting outcomes.^{225,226} Androgens were administered to hypogonadal men unselected for cancer history. The study showing no benefit focused on men over age 65 with testosterone in low-normal range.²²⁵ Men in the more successful trial were more hypogonadal.²²⁶

In men, loss of desire for sex is often linked to frustration and low self-esteem when erectile function is impaired.¹⁷⁵ One research group has had success in treating ED by combining testosterone with sildenafil for men with low circulating androgen levels.²²⁷ The same strategy was helpful to eight severely hypogonadal men who had testicular failure after bone marrow transplant.²²¹ Whereas testosterone replacement is a viable option for young, hypogonadal, cancer survivors, men treated for prostate cancer are obviously not candidates. Although elevated luteinizing hormone levels combined with low-normal testosterone levels are common in young men after high-dose chemotherapy, a recent trial of the testosterone patch in 35 such survivors failed to document positive changes in mood or sexual function.²²⁸

Loss of desire for sex is common after systemic treatment for breast cancer,^{119,124,188} As reviewed in the previous section of this chapter, there is reasonable evidence for the safety of short-term estrogen replacement in breast cancer survivors, but no studies have examined the impact of androgen replacement in this population, despite suggestions that such treatment might improve women's sexual function.²²⁹ Yet, high androgen levels are clearly associated with breast cancer risk in postmenopausal women, and have also been observed post-diagnosis.²³⁰

In fact, the level of androgens needed to maintain normal sexual function in women, particularly after menopause, is unknown.²³¹ Several methodologically sound studies have not found any correlation between endogenous androgen levels and sexual function in naturally postmenopausal

women.²³²⁻²³⁴ The only randomized, placebo-controlled trials that have shown a sexual benefit of testosterone replacement in women have studied surgically menopausal women and have raised testosterone above the normal physiological level.²³⁵⁻²³⁷ No published trials of testosterone replacement have focused on female cancer survivors, although studies of safety and efficacy would be appropriate in women in ovarian failure after treatment for tumors that are not hormone sensitive. However, female survivors of Hodgkin's disease exposed to radiation would be poor candidates because of their already elevated risk of breast cancer, which appears to be potentiated by ovarian hormones.²³⁸

In the future, selective androgen receptor modifiers may provide a safer modality to treat desire problems in women with abnormally low testosterone. A recent randomized, double-blind cross-over trial of tibolone vs. placebo in 44 postmenopausal women who did not have sexual complaints found in a laboratory paradigm that women taking tibolone had increased sexual desire, fantasies, and arousability, as well as improved vaginal lubrication.²³⁹ Unfortunately, tibolone also appears to increase the risk of breast cancer in postmenopausal women.²⁴⁰

Loss of sexual desire after cancer treatment is often multifactorial, rather than a purely hormonal problem, particularly in women. Risk factors can include lingering post-treatment fatigue, pain, or nausea; perceiving oneself as less attractive after cancer; loss of sexual pleasure because of changes in skin sensitivity or genital blood flow; dreading sex because of dyspareunia; medication side effects; mild depression; and relationship conflict exacerbated by cancer treatment. Empirical studies suggest that sexual desire and arousability are linked in women, not only with each other, but with chronic mood disorders, low self-esteem, and guilt about sexuality.²⁴¹ Andersen developed a questionnaire to measure negative sexual self-image and found women's scores correlated with failure to resume sex comfortably after gynecological cancer.²⁴² Treating low desire in women may involve cognitive-behavioral psychotherapeutic interventions rather than a simple, pharmaceutical approach. Such treatment programs should also be evaluated in randomized, controlled trials.^{243,244}

Treatment of Erectile Dysfunction (ED) After Cancer

Most efforts at sexual rehabilitation for men after cancer have had the goal of mechanically restoring erectile rigidity. Despite the revolution in treating ED in the past 20 years, yielding not only the various types of penile prosthesis, medications to inject into the penis, vacuum devices, urethral suppositories, and more recently several oral prostaglandin E5-inhibiting drugs (PDE5-inhibitors), the majority of men who seek help for ED are not satisfied in the long term. In three studies of outcome in impotence clinics where men were not selected for health or the etiology of their ED, only 30% to 40% of men were sexually active and considered their problem resolved by one to five years after their initial evaluation despite trying a mean of two treatment modalities.²⁴⁵⁻²⁴⁷

Men prefer noninvasive, "natural" therapies, such as oral medication, and often will not try more invasive treatments for ED if PDE-5 inhibitors do not restore reliable, firm erec-

tions. Men's adherence even to taking a pill is limited. In two case series of men prescribed sildenafil for ED of varied etiology, over half were no longer taking it by 2-year follow-up.^{248,249} In a cohort of 197 consecutive patients, the most significant correlate of discontinuing sildenafil was a history of radical prostatectomy, primarily because the drug was less effective for these men.²⁴⁹ Only 56% of the men who stopped using sildenafil tried a second treatment.

The importance of encouraging men who fail a first-line treatment to try a more invasive method is reinforced by data from 89 men with ED prospectively followed over 12 months.²⁵⁰ Men tried an average of two treatments for ED, and those who found an effective medical treatment for ED reported better quality of life and less emotional distress about ED. Prostate cancer survivors were more likely to report trying more than one ED treatment.

In our own retrospective cohort study of men in the prostate cancer registry at the Cleveland Clinic Foundation, half of consecutive men surveyed filled out questionnaires.²¹⁴ At an average of 4.5 years after cancer treatment, 59% of 1,188 respondents with ED had tried at least one treatment for it. Only 38% of men found a medical treatment that was at least somewhat helpful in improving their sex lives, however, and just 30% of respondents were still using an ED treatment at the time of the survey. Seventy-nine percent of men had stopped using intraurethral prostaglandin suppositories, 66% no longer used penile injections, 61% stopped taking sildenafil, 59% discarded a vacuum erection device, and 19% no longer had sex with their implanted penile prosthesis. The most important factor in men continuing to use a treatment for ED was that it worked effectively. As in the case series above, men who tried a greater number of treatments were more likely to have positive scores on the International Index of Erectile Function.

A man's motivation to progress from taking a pill to trying a more invasive therapy may be a particularly important factor in the ultimate success of sexual rehabilitation. Penile injection therapy is one of the most effective treatments for men after prostate cancer.^{214,250} Other correlates of a good sexual outcome in our survey included younger age, having a sexual partner who still enjoyed sex, having a cancer treatment that was more likely to spare some erectile function (e.g. bilateral nerve-sparing prostatectomy or brachytherapy), and no historical or current use of anti-androgen therapy.^{175,214}

Surgeons who perform radical prostatectomy frequently encourage men to begin attempts within 6 weeks to get an erection through use of penile injections, a vacuum device, or a PDE5-inhibitor.²⁵¹ The theory is that regular increases of blood circulating to the penis will oxygenate the tissues of the cavernous bodies, preventing fibrosis and atrophy and enhancing the chance of nerve regeneration. This popular theory is based on one very small randomized trial using early penile injection therapy after prostatectomy, published in 1997.²⁵² Despite a number of attempts to replicate the results using oral medication or vacuum devices, no other peer-reviewed randomized trial has been published.

Treating Female Sexual Arousal Disorder (FSAD)

Men can observe their erections, but women are often unaware of vaginal expansion and lubrication, and subjective ratings of sexual arousal do not always correlate well with

physiological measures.²⁵³ When women complain of poor sexual arousability after cancer, they typically report a loss of desire for sex, along with a lack of subjective excitement and symptoms of vaginal dryness and tightness. Ovarian failure is a frequent medical factor.

In recent years, researchers testing pharmacological treatments for women's sexual problems have created the "diagnosis" of female sexual arousal disorder (FSAD), an isolated sexual complaint characterized by lack of genital vasocongestion. Nine randomized, placebo-controlled trials of therapies for FSAD in postmenopausal women have been published, including those reviewed above on androgen replacement.²⁵⁴⁻²⁵⁷ None focus on cancer populations. Two randomized, placebo-controlled clinical trials of sildenafil for FSAD have not produced convincing results on its efficacy,^{255,258} and Pfizer no longer intends to seek approval of the drug for women.²⁵⁹ Another trial examined the efficacy of alprostadil cream applied to the vulva before intercourse. This is the same medication most commonly used in penile injection therapy, but no significant impact on female sexual function was observed.²⁵⁶ The remaining trial compared a proprietary vulvar herbal lotion to placebo oil.²⁵⁷ Only 20 women participated. The outcome measure was a sexual diary created for the study, which was conducted by the company marketing the lotion.

Thinking that FSAD might be caused by inadequate blood flow to the clitoris, researchers created a special vacuum device, the Eros, to increase clitoral engorgement.²⁶⁰ In a sample of 19 women, use of the Eros over 6 weeks significantly increased reports of erotic sensation, lubrication, ability to reach orgasm, and overall sexual satisfaction, regardless of whether a woman had sexual dysfunction at baseline. The device has received FDA approval and has been shown to increase genital engorgement on repeated use.²⁶¹

Women's subjective pleasure as well as objective changes in genital blood flow should be measured in a randomized trial comparing the Eros device to a handheld vibrator, or even to a woman's own manual self-stimulation. Although a placebo-controlled trial may not be possible, these two other conditions would presumably also induce sexual arousal and increased genital blood flow, as well as giving the woman tacit permission to enjoy genital stimulation. It is possible that these are the active components of the Eros intervention, rather than the vacuum-induced clitoral vasocongestion.

Managing Sexual Pain After Cancer Treatment

For women, pain with sexual activity is one of the most frequent problems after cancer treatment. Postmenopausal vaginal atrophy is frequently the cause. As noted in the previous section on managing menopausal symptoms, systemic or local estrogen replacement is highly effective in reversing vaginal atrophy as well as decreasing hot flashes. Although many female cancer survivors have concerns about using systemic estrogen, new forms of topical estrogen may be safer options.

The Estring® is a vaginal ring delivering a low dose of estradiol time-released over three months. It is effective in reversing vaginal atrophy with little impact on plasma estrogen levels.²⁶²⁻²⁶⁴ In the dosage that would be used in breast cancer survivors, the Estring® may not reduce hot flashes but has been shown in randomized, placebo-controlled trials to

reduce urinary incontinence in about 50% of women.²⁶⁴ A higher dose could be used in women who had not had a history of hormone-sensitive tumors. Women prefer the Estring® to vaginal suppositories²⁶⁵ or creams. Many can insert the Estring® themselves but others may need a medical visit to replace the ring. Women with significant vaginal prolapse may not be able to tolerate the ring. Another form of vaginal estrogen replacement that is superior to estrogen cream in patient acceptance and does not elevate plasma estradiol is the Vagifem® suppository²⁶⁶ which contains 17beta-estradiol.

Trials of these localized estrogen therapies should be conducted specifically in cancer survivors. One goal would be to ascertain the safety of long-term use in women prematurely menopausal after breast cancer. Another would be to test efficacy in women whose vaginal atrophy is not just the result of estrogen deficiency, but is complicated by tissue damage from pelvic radiotherapy²⁶⁷ or post-transplant graft vs. host disease.²⁶⁸ These women are particularly vulnerable to dyspareunia. Recently a case report has described successful treatment of vaginal agglutination after allogeneic bone marrow transplant, using a combination of surgical dissection of adhesions, estrogen cream, and vaginal dilation.²⁶⁹

Although regular vaginal stretching by intercourse or use of a dilator has been assumed to prevent loss of depth and caliber after pelvic radiation therapy, remarkably little evidence exists to demonstrate this effect. A recent Cochrane Library review of interventions for female sexual dysfunction after pelvic radiotherapy²⁷⁰ found only two references on dilators. Both were retrospective case series, although they presented evidence that dilators could help maintain or restore vaginal patency. The most recent reference was published in 1999. Furthermore, most women are probably not adherent with the classic recommendation to have sexual intercourse or use a dilator three times weekly. In one small study, 32 cervical cancer survivors were randomized to one session of counseling plus a booklet on sex and cancer, or to a 3-hour psychoeducational group designed to increase adherence to vaginal dilation.²⁷¹ Group participation increased the percentage of women under age 41 who met the criterion of dilator/intercourse use from 6% to 44%. About half of the older women met the criterion, whether they were in the intervention or control group. For all women, rates of dilation decreased over the year of the study. Since the fibrosis after radiation therapy continues to progress for several years,²⁶⁷ long-term adherence to vaginal stretching would be necessary to ensure continued ability to enjoy sexual intercourse and to allow adequate pelvic examinations—assuming that vaginal stretching is indeed physiologically effective.

Perhaps the simplest and most conservative intervention for dyspareunia after cancer is instruction on the use of water-based lubricants during sexual activity. Yet, the only study that evaluates the outcome of giving advice on lubricants is Ganz' nursing intervention, which did reduce vaginal pain and dryness.¹⁶³ This trial and several others also included the use of Replens®, a polycarbophil-based vaginal moisturizer that adheres to the vaginal mucosa and is designed to be used three times weekly, independent of any sexual activity. One double-blind, crossover, randomized clinical trial compared 4 weeks of Replens® to a "placebo" water-based lubricant²⁷² in 45 postmenopausal breast cancer survivors. Although both preparations relieved vaginal dryness, Replens® was signifi-

TABLE 90.3. Treatment Algorithms for Common Reproductive Problems after Cancer.

Level of Intervention	Hot Flashes	Loss of Sexual Desire	Erectile Dysfunction	Vaginal Dryness/Dyspareunia
Written pamphlet, video, internet, or nurse	Education about diet, dress, sleep, hygiene	Assessment of depression, fatigue, and medications with sexual side effects	Education about impact of cancer treatment and availability of medical treatments	Education on use of water-based lubricants and vaginal moisturizers ²⁸⁰
Peer counseling or counseling by a mental health professional	Stress management with focus on relaxation training	Promote positive body image, permission to have sexual fantasies, activities that increase desire, and erotic material such as stories or films ²⁸⁰	Intervention to enhance couple's sexual communication, improve partner's sexual satisfaction ²⁸⁰	Education on positioning, Kegel exercises to gain voluntary control over circumvaginal muscles ²⁸⁰
Intervention by a physician	Prescription of antidepressant medication, and consideration of risk/benefit ratio of using estrogen replacement	Change medications that may be interfering with desire; Consideration of androgen replacement, but only if survivor's levels are in the clinically hypogonadal range and the survivor is not at high risk for breast or prostate cancer as a recurrence or second primary tumor	Try medical treatments that are acceptable to both partners, starting with least invasive ²⁸¹	Prescription of graduated vaginal dilators with instructions on use to maximize control over vaginal muscles ²⁸⁰ ; Prescription of local vaginal estrogen replacement if appropriate; Consideration of vaginal reconstructive surgery in rare cases

cantly more effective in reducing dyspareunia scores. In two open-label studies of women unselected for cancer history, Replens® was just as effective as estrogen cream in treating vaginal atrophy and dyspareunia.^{273,274}

In women with chronic pelvic pain and dyspareunia unrelated to a history of cancer treatment, successful comprehensive treatment programs have combined sexual counseling with specific biofeedback and physical therapy modalities designed to increase awareness of and control over muscle tension in the pelvic floor.²⁷⁵ Trials applying these techniques are needed with women who have dyspareunia related to surgical adhesions or anatomic changes, radiation damage to the vagina, or vaginal complications of graft vs. host disease.

Similar treatments have been helpful in a pilot study of men with chronic pelvic pain.²⁷⁶ Pelvic pain has been reported to be more common than usual after treatment for testicular cancer²⁷⁷ or after radical prostatectomy.^{175,278} This type of pain is very recalcitrant to treatment and may include aching in the testes or groin, and/or urethral pain exacerbated by urination or ejaculation. Non-steroidal anti-inflammatory or alpha-blocking drugs, low-dose antidepressants, and nerve blocks are occasionally helpful, but more extreme surgical procedures do not produce results that justify routine use.²⁷⁹ Randomized trials of treatments for male pelvic pain have not been published.

Table 90.3 presents treatment algorithms for the most common reproductive symptoms seen in cancer survivors: hot flashes, loss of sexual desire, erectile dysfunction, and vaginal dryness/dyspareunia. The first level of intervention involves giving patient education materials in written, video, or interactive computerized format. If more help is needed, brief counseling can be provided either by a trained peer counselor or by a member of the oncology team, such as a nurse clinician or social worker. At the third level, a health care provider specialist is consulted. Many brief counseling interventions can be found in a self-help format²⁸⁰ and algorithms for treating ED are also available.²⁸¹

Conclusions

Reproductive health problems, including sexual dysfunction, menopausal symptoms, and infertility are common, long-term consequences of cancer treatment for both men and women. Until targeted cancer therapies are more common, systemic chemotherapy is likely to entail considerable gonadal toxicity. Efforts to modify pelvic surgery and radiation therapy to spare the reproductive system are ongoing, but remain limited in applicability and efficacy. Because sexuality and childbearing are such sensitive issues, psychosocial counseling and education may increase the efficacy of purely physiological interventions. As this review highlights, very little evidence-based knowledge is available to guide oncology clinicians in remediating reproductive health issues. For many problems, pilot studies of efficacy of innovative treatments are needed before randomized trials can be justified. Hopefully our increasing knowledge about the prevalence, causes, and impact on quality of life of reproductive health problems will soon generate more research.

The Care of the Terminal Patient

Andrew Putnam

According to the Institute of Medicine, “at the beginning of the 21st century, half of all patients diagnosed with cancer will die of their disease within a few years.”¹ This statistic does not fully explain the reality of the illness and its repercussions for the individuals living with cancer and their families and friends.² Many patients live through a final period of life when health professionals, in concert with the patient, must acknowledge that there are no reasonable treatments that remain untried. The patient will most probably die of complications of the cancer. This is a stressful period when health professionals must continue their efforts to treat the patient’s suffering and alleviate onerous symptoms.

Palliative care, as part of good medical practice, is delivered in various amounts throughout the disease process, but at different times the goals of care may differ. This chapter discusses palliative care as delivered by oncologists, palliative care teams, and hospice, concentrating on adult cancer patients in the United States. In the interest of brevity, there is very little discussion pertaining to palliative care outside the United States. There also is no discussion of pediatric palliative care. Palliative care in that population faces many of the same challenges as in adults, but also others that pertain specifically to the pediatric population.

Palliative care has been defined as follows: “The active total care of patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms, and of psychological, social and spiritual problems, is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families. Many aspects of palliative care are also applicable earlier in the course of the illness in conjunction with anticancer treatment.”³

Although all oncologists must have some skills in palliative care, an expert team often has a role. A key aspect of palliative care is that it should be integrated throughout the course of illness and not only at the end of life. Symptom management, family support, skilled communication, and other aspects of palliative care clearly have important roles throughout the care of a patient with cancer. An important tenet of palliative care is taking care of the whole person and the family, not only the disease. Whether an oncologist or a palliative care specialist is taking care of the patient, treating the *entire* patient requires considering how to identify and best care for the patient’s medical, physical, psychologic, spiritual, and social concerns. With this wide spectrum of concerns in mind, the aspects of medicine and care that are embraced under the “umbrella” of palliative care cover a very broad area.

This chapter focuses on reviewing research in some key areas of palliative care: the role of the palliative care team, shifting goals in cancer care, aspects of communication, symptom management, systems of care, end-of-life care, and also discussions of some ethical questions. Because palliative care is a broad topic, a full review of all evidence related to the many aspects of palliative care is beyond the scope of this chapter. That stated, key evidence is reviewed for many aspects of care; where the evidence for aspects of care is highly complex or detailed, the reader is referred to specialized reviews of particular topics.

Palliative medicine is the medical specialty whose practitioners specialize in treating symptoms throughout a patient’s illness, but certainly their focus is commonly on the later phases of illness. One of the goals of the palliative care team is to improve or maintain the patient’s quality of life, making the end of that person’s life as comfortable as possible. There is evidence to show that specialized palliative care teams can improve patient care in a number of different domains, including patient and caregiver satisfaction, number of inpatient hospital days, and overall cost to the system.⁴

Because no single healthcare professional can be an expert in all the necessary areas of palliative care, the skills of members of an interdisciplinary team are required to address the array of needs that arise in patients with cancer. These teams usually include physicians, nurses, social workers, chaplains, and sometimes physical therapists, music therapists, and other paramedical practitioners.

Research in Palliative Medicine

Before proceeding with this chapter, it is important for the reader to be aware that much of our understanding of optimal approaches to end-of-life care to date has been based on anecdote or case reports. In fact, some people believe that careful research, which may affect a patient’s comfort, defies the spirit of palliative care.⁵ Researchers might even be concerned about charges of experimentation on the dying.⁵ Recently, however, investigators are turning increasingly to evidence-based studies to research the efficacy of palliative care interventions and improve the understanding of the care of the patient near the end of life.

In attempting research on seriously ill palliative care patients, there are several problems that have to do with the complicated nature of the end of life. Steinhauser wrote that

“end-of-life is a complex multidimensional experience in which understanding of the interrelatedness of domains is unclear.”⁶ Even the most basic question of what defines “the end of life” does not have a satisfactory answer.⁷ It is not easy in a given patient to predict the date of death, which makes it difficult to find patients who fit criteria for a study but who are also still able to participate.⁸ This restriction adds to the problem of clinicians’ lack of comfort in labeling a patient “terminal.” Another problem is the interconnectedness of patient and family, which makes research at this time more complicated as the experience of each person affects the other in ways that are unclear.⁶ It is not always easy to sort out the feelings of the patient from those of the family.

Research in end-of-life care has often seemed to be a low priority for funding agencies, but often also for those patients who are close to dying, as they have other concerns. In addition, it is often difficult to retain the seriously ill patients who do decide to enroll. The numbers of patients who complete palliative care studies are often low, and those patients who do survive to that point may be the healthier ones as compared to the entire population.⁸

Other problems for palliative care research that have been suggested have to do with study design, such as (1) possible suboptimal care, (2) biased results, and (3) enrollment and retention.⁹ There is also the problem that patients often find it difficult to communicate effectively during the last days to weeks of life.⁶

Many palliative care studies use death as a marker. This criterion complicates the results of a study, as any heterogeneity of diagnoses and problems can lead to a wide variety of results, thus reducing its applicability.⁹ This difficulty, as well as the other problems already mentioned, has caused research into end-of-life care to lag as a scientific discipline.

Active Treatment to Palliative Care

At diagnosis, or as cancer progresses, a patient may run out of realistic options to prolong life. Life-sustaining goals are often a priority even at the very end of life, but for many, there comes a time when the likely burdens of any remaining treatments may far outweigh the benefits. Some patients may still wish to participate in clinical trials, feeling that any chance of sustaining life is better than no chance at all. Other patients may not desire to participate with such a small likelihood of success.

Certainly, however, in many cases, a physician might reasonably advise an end to active treatment and a change to a purely palliative mode of care. Despite this, many patients and physicians are, however, reluctant to shift, or recommend a shift, to care in which the primary focus is quality of life and comfort. The reasons behind physicians’ apparent hesitancy to discuss these topics are complex, and some of these are discussed next.

One of the common barriers to shifting to palliative care is acknowledging when to begin it.¹⁰ Often a patient has undergone multiple different therapies, and the time to make the switch to therapies focused on patient comfort may not be obvious. At other times, the barrier may be that it is difficult for the oncologist to actually suggest this change to a dying patient. This difficulty may be greater in a patient who

has progressed through many treatments but wishes to continue with another treatment. There is evidence demonstrating that the longer a physician knows a patient, the more likely it is that the physician will be overly optimistic in predicting the patient’s prognosis.¹¹

There is some evidence to suggest that patients welcome discussions of end-of-life care^{12–14}; however, most of these discussions took place with relatively healthy patients. There is little evidence involving a population of sick cancer patients, but a recent study by Straton et al., provided evidence that individuals with significant functional impairment may be more likely than those without impairment to endorse the use of “high-burden” treatments.¹⁵

Helping the patients to reframe their hopes once significant life extension seems no longer possible is very important. This is a process that takes time and is not linear. Reframing hope may include focusing on the present and specifics that can be done in the present, rather than vague uncertainties about the future. This refocusing may create the form of encouraging the patient to create a legacy to leave behind, resolving conflicts with friends or relatives, or creating special memories with one’s spouse. Patients may hope for improved quality of life and, as death approaches, possibly for release from suffering or for a painless death. Clinicians may find it helpful to discuss the idea of hope with their patients early in treatment because that discussion can become more threatening later if the disease does progress. Physicians and patients alike consider it important that the physician be comfortable discussing death and dying as part of end-of-life care.¹⁶

Some patients interpret their individual culture or religion¹⁷ as requiring a continued fight for life instead of a peaceful death.⁶ It may be necessary to request a chaplain or an authority figure for that culture or religion to discuss the patient’s views. These views may serve as another barrier when trying to move from care aimed at cure, to care or sustaining life, to care where the primary focus is quality of life.

The Importance of Communication

One area of importance in terminal care is consistent open communication among the medical team, the patients, and their caregivers (Table 91.1). There is evidence that different patients^{18,19} and families want varying amounts and types of information from their physicians. While also receiving active treatment, these individuals often have many psychosocial needs, but the number of these needs often increases once the main focus shifts to palliative care.²⁰ Patients whose needs are

TABLE 91.1. Six areas of central importance in communicating with dying patients.

1. Talking with patients in an honest and straightforward way
2. Being willing to talk about dying
3. Giving bad news in a sensitive way
4. Listening to patients
5. Encouraging questions from patients
6. Being sensitive to when patients are ready to talk about death

not met may later report higher levels of distress²¹ and possibly dissatisfaction with care received.

Patients are thought to suffer through a number of losses as their illnesses advance (Table 91.2). The first loss is usually that of physical health when an illness that may end life at some time in the future is diagnosed. As illness progresses, many people are faced with having to give up their work, their identities in society, and even their independence once they need others to assist them with even the most basic activities of daily living.²² Patients may also struggle with thoughts of leaving everything behind, or from finding that despite all the medical advances, they are still going to die.²³ Patients frequently want open and honest discussion about their end-of-life concerns.^{24,25} Detmar et al., found, however, that often clinicians missed opportunities to address those concerns.²⁶ There may be a desire not to upset the patient, but this minimizes the patient's needs and feelings. Patients want physicians who are sensitive to these needs.^{16,27}

Family and close friends also need opportunities to communicate their suffering, which is often overlooked because of the necessary focus on the patient.²⁸ Lederberg has referred to family caregivers as second-order patients. Although they in essence have been part of the healthcare team, they need as much support and care as the patient.²⁹ While taking into account the importance of patient trust and privacy, clinicians should consider the role of discussing such desires with patients and, with permission, facilitating these discussions. Lilly et al. found that when caregivers spent more time meeting with patients and families, they were more effective at meeting the goals of the patient.³⁰

Communication may become more difficult when bad news must be given to the patient and/or family. While there is little evidence about the best way to deliver bad news, there are a variety of ways that seem to be effective.^{31,32} How the news is presented may affect how the patient and others interpret the news. However it is presented, it is optimal to find a quiet comfortable place to deliver the news³³; this will help those present feel that there is enough time for discussion. Prefacing the bad news with "forewarning words" such as "I'm afraid I have some bad news" or "This result is not as good as we had hoped for" is speculated to help listeners

prepare mentally for what is to follow.³⁴ Such words also help the physician gauge whether the patient and/or family members wish to hear more. Lilly et al. found that when caregivers spent more time meeting with patients and families they were more effective at meeting the goals of the patient.³⁰ The physician's skill at communicating can greatly assist in the care of the patient and family. One crucial skill is being able to explain the situation in everyday language. Patients and families often misunderstand the meaning of any discussion if there is too much medical jargon.³⁵ A clear and careful explanation by the clinician, in terms that are understood by the patient and family will facilitate a better understanding of what to expect and how to act during such a sad situation.

Symptom Management

Treating symptoms should be a priority throughout the course of cancer. As a patient's condition worsens, the causes of symptoms may become more complex, and there may be limits on clinicians' ability to treat the primary etiologic factors. In certain situations, an approach that directly treats the cause of the symptom and provides relief may still be obvious. Examples include the draining of a pleural effusion to treat dyspnea or the use of whole-brain radiation to shrink brain metastases and eliminate the disability that had resulted from the lesion. Often, however, the cause of a symptom may be multifactorial or unclear and/or the cause may not be amenable to treatment. In these cases, the best course may be to bring the patient relief by treating the symptom itself, whether it is caused by the disease or is a side effect of a necessary medication. It is beyond the scope of this chapter to provide a comprehensive guide to the treatment of all the symptoms that patients experience. Table 91.3 provides a brief list of some of the more frequently encountered symptoms and some common treatments in the terminal patient.³⁶⁻⁶² Evidence for the different treatments varies, but use is often the result of anecdote or clinical experience.

TABLE 91.3. Frequently encountered symptoms and some common treatments in the terminal patient.

<i>Symptom</i>	<i>Class</i>	<i>Examples of agents</i>	<i>Comments</i>
Anorexia	Corticosteroids Cannabinoid derivative	Megestrol ³⁶ Dronabinol ³⁷	
Anxiety	Benzodiazepines Neuroleptics ³⁸	Lorazepam Clonazepam diazepam Quetiapine olanzapine Haloperidol	IV formulation
Asthenia/ fatigue	Corticosteroids ³⁹ Psychostimulant	Dexamethasone Methylphenidate Dextroamphetamine	Also used for opioid-induced sedation ³⁹
Bowel obstruction	Opioids Corticosteroids Somatostatin analogue	Morphine Others Dexamethasone Octreotide ^{40,41}	For pain Uncertain effectiveness ⁴² Dries out GI tract
Constipation	Stool softeners Bulking agents Stimulants	Docusate sodium Polyethylene glycol Lactulose Senna Casanthranol	No conclusive evidence to determine if any medications for constipation are more effective than any others ^{43,44}
Cough	Opioids Tetracaine derivative	Codeine Morphine Benzonatate ⁴⁵	
Delirium	Neuroleptics ⁴⁶ Benzodiazepines	Quetiapine Risperidone Haloperidol <i>Not recommended</i>	Risk of paradoxical agitation
Depression	Selective serotonin reuptake inhibitor (SSRI) antidepressants Psychostimulant	Sertraline Citalopram Escitalopram Methylphenidate ⁴⁷	Depression is common in terminal patients ^{48,49} Effective for short periods of time
Dyspnea	Open window or a fan blowing on the face ^{50,51} Oral or parenteral opioids ^{53,53} Benzodiazepines ^{50,54}	Morphine Others Lorazepam	Dyspnea is compatible with normal O ₂ saturation ⁵⁴ Poor evidence for their use in most patients
Hiccups		Metoclopramide, baclofen chlorpromazine nifedipine ^{55,56}	There is little good evidence for any pharmacologic therapy
Myoclonus		Clonazepam ⁴⁴	
Nausea/ vomiting		Metoclopramide hydroxyzine Haloperidol Octreotide ⁴⁰	
Pain	Opioids NSAIDs Tricyclic antidepressants Anticonvulsants	Many choices Many choices Amitriptyline Desipramine Gabapentin Carbamazepine	Neuropathic pain Neuropathic pain
Pruritus	Corticosteroids ^{57,58} Antihistamines ^{57,58}	Various Various	Symptomatic treatment depends on cause
Restless legs syndrome	Catecholamine precursor Benzodiazepines	Levodopa ⁵⁹ Clonazepam	Some evidence Nighttime symptoms
Somnolence	Stimulant	Methylphenidate ⁶⁰	
Terminal restlessness	Benzodiazepines ⁶¹ Antipsychotics ⁶¹ Barbiturates ⁶¹	Lorazepam Haloperidol Pentobarbital	Sedation may be necessary
Xerostomia	Sialagogues Saliva replacements Vaseline	Pilocarpine ⁶² Various	If saliva glands have residual function Symptomatic Keeps lips moist

Hospice and Palliative Care

The term *hospice* has been used in Europe since medieval times. The first known hospice specifically for the dying was begun in Lyons, France, in 1842. The Irish Sisters of Charity

opened hospices in Dublin in 1879 and London in 1905.⁶³ There were other important efforts, but the first modern hospice is generally considered to be St. Christopher's in London, which opened in 1967.⁶³ The first modern hospice in the United States is frequently considered to have opened

in 1974, in Branford, Connecticut.⁶³ The hospice movement in the United States has expanded so that in 1999 about 25% of all deaths in the United States involved hospice.⁶⁴

When the likely burdens of any remaining life-prolonging options outweigh the likely benefits, the clinician may refer the patient to hospice, depending on that patient's care needs and resources. The term hospice can be confusing for patients because it has been used in several different ways. An inpatient hospice can be a free-standing building or beds in a hospital reserved for end-of-life care. A home hospice program supports terminal patients in the home or in institutions, such as nursing homes.

Although there are few data for the United States, it is generally thought that most people would prefer to die at home.⁶⁵ In 2002, 25% of Americans died at home, whereas 50% died in hospitals and another 25% died in other institutions, such as nursing homes.⁶⁶ Wherever they die, patients, their families and other caregivers often experience economic, physical, and social burdens imposed by the terminal illness.^{67,68} Hospice can assist in many ways to overcome those burdens.

The philosophy of hospice involves interdisciplinary care, as already mentioned. To relieve suffering in all aspects of the patient's life, the hospice team may include doctors, nurses, physical therapists, chaplains, social workers, volunteers, and many others. The goals of care are to preserve the patient's dignity, function, and control for as long as possible. Encouraging realistic personal goals is an important aspect of care. Caregivers can help fit the goal to the current condition of a patient, for example, whether the patient has the stamina for a long-desired trip or for making a videotape for children or grandchildren.

A cancer patient's spiritual beliefs can be a major source of support. Many patients are actively supported by members of their faith group during their disease. It is important to explore patients' beliefs because they can be important indicators of how patients will manage the terminal phase of their lives.¹⁷

Under the original rules, the Medicare hospice benefit did not allow payment for any antineoplastic treatment for a hospice patient. Over the past decade, many hospices have moved more toward a palliative care model, getting involved earlier in the disease process. This shift means that in some instances, hospices may accept patients who are still undergoing chemotherapy or radiation, especially if the treatment is palliative. Sometimes a patient's insurance may contribute to the payment for such treatments in addition to covering hospice services. The total time in hospice still remains short; however, as in 2002, the median length of stay in hospice was only about 21 days.⁶⁹

A home hospice referral is appropriate when a patient requires symptom management or support and there is a likely possibility of death from the disease within 6 months, as required by the Medicare Hospice Benefit. The advantages of being in a home hospice program include home visits by hospice nurses who specialize in symptom control and other hospice professionals, such as social workers and chaplains. The hospice program also usually covers all medications used to treat symptoms related to the terminal disease.

When a home hospice program cares for a patient, family members remain the primary caregivers, taking care of the patient for more than 90% of each day. In general, although

it varies, a hospice program in the United States supplies regular short nursing visits a few days a week and possibly a home health aide who will come to the house for 1 to 2 hours a day to provide patient care.

A hospice program's psychosocial and emotional support can be very helpful to a family's success in caring for a patient at home because many families find it hard to take care of a dying family member. For some, the trauma of the disease or discomfort with performing various intimate aspects of care can be significant barriers to caring for the patient at home.

Living at home and ultimately dying there is usually the hospice patient's goal, but in certain cases, inpatient hospice referral is appropriate. These situations include patients with symptoms that are difficult to treat, such as severe pain or dyspnea. Another instance is when caregivers are exhausted and need a break. Admitting the patient for a few days of inpatient "respite care" allows the caregivers necessary rest.

Whether directed beds in a hospital or a free-standing building, inpatient hospices usually are small and have few beds. These are normally held for patients who are thought to be in the final 2 weeks of life or for whom staying at home can mean great suffering. If a patient is nearing death and has accepted that idea, an inpatient hospice may be a better place than an acute care hospital. In such a case, the goals of the hospice are often in line with those of the dying patients and decrease the possibility of unwanted aggressive workups or treatments. If a patient's symptoms are severe and require around-the-clock professional nursing, remaining at home can put the patient at risk for a very uncomfortable death. At those times, admission to inpatient hospice can be the best option for both patient and caregivers.

The discomfort with conversations about death and the stigma of hospice may prevent referrals early enough for the patient to benefit fully from hospice services.⁷⁰ Although receiving an accurate prognosis is important to many patients, medical professionals have a bias toward overly optimistic predictions.⁷¹ This attitude reduces a patient's ability to make informed choices regarding quality of life. Patients may, however, also wish to continue antineoplastic treatments until they are dying, which is another important barrier to hospice referrals. If the goals of care are frequently revisited with patients and concerns and ways of addressing those concerns are defined, patients and caregivers may take more advantage of what hospice programs have to offer. In addition, another change that could affect the timing of referrals would occur if the ability of hospices to accept patients receiving anticancer treatment for the relief of symptoms were more widespread.

The Final Days

When a patient is dying, clear communication with the patient, if possible, and with caregivers is crucial. Time used by clinicians to explain the dying process can make an important difference in end-of-life care, both for the patient and also in how the family is affected by the experience.^{72,73} Manfredi et al. showed that discussions about goals of care were helpful in implementing advanced directives and making decisions to forgo specific interventions.⁷³ The medical community generally focuses on the patient, but the caregivers, many of

TABLE 91.4. Concerns important at the end of life.^a

1. Be kept clean
2. Name a decision maker
3. Have a nurse with whom one feels comfortable
4. Know what to expect about one's physical condition
5. Have someone who will listen
6. Maintain one's dignity
7. Trust one's physician
8. Have financial affairs in order
9. Be free of pain
10. Maintain sense of humor
11. Say goodbye to important people
12. Be free of shortness of breath
13. Be free of anxiety
14. Have a physician with whom one can discuss fears

^aThese concerns were rated very important by more than 90% of patients and more than 70% of bereaved family members, physicians, and other care providers.

whom may not have seen someone die before, in the midst of their own suffering also need support.

Unspoken fears and anxieties are often close to the surface for both patient and family (Table 91.4). Some patients fear that their lives will be technologically prolonged at the expense of quality of life.⁷⁴ Other patients fear being a financial drain on their families,⁷⁵ as well as the loss of independence.⁴⁴ The Support Study showed that as cancer patients approached the end of life, increasing numbers preferred care that focused on quality of life.⁴⁴ Other studies have found that the opposite can be true. In these studies, as the patients' conditions worsened, they became more likely to choose more aggressive treatments.^{15,76} These thoughts and others are often what the patient wishes to discuss, but they often need encouragement from family or clinicians to do so.

"Comfort measures only" is often written by physicians to describe care provided near the end of life that focuses on quality of life. This description means that clinicians must weigh the benefits against the burdens of any proposed intervention to determine the effect on patient comfort. As a person nears death, certain interventions are less likely to be beneficial than they might be for a healthier patient. For example, blood draws and other needle sticks are obviously painful. Unless the result might direct a change in treatment, such as demonstrating hypercalcemia as a treatable cause of delirium, blood draws can usually be discontinued as they are more burdensome than beneficial to the patient. The decrease in pain from stopping unnecessary needle sticks is fairly clear, but other changes that may provide increased comfort to dying patients are not always so easily recognized.

It is usually necessary at this time to reevaluate the patient's goals. As death approaches, patients often will not benefit from various interventions in the way they might have earlier in the disease process. These medical interventions, although necessary in sick patients, can increase discomfort in the dying. Although medical nutrition, gastric tube feedings, and even intravenous fluids can be important in some settings, such as in a patient with an obstructed bowel and in some instances of delirium, they do not necessarily increase a dying person's comfort. These medical inter-

ventions not only are capable of prolonging the dying process but also have the potential to increase patient suffering. Typical rates of intravenous fluids may cause increased rates of vomiting, urination, and defecation that may require painful moving and cleaning of the patient.⁷⁷ The fluid also commonly does not stay intravascular and so it may cause or even worsen peripheral and pulmonary edema. Vullo-Navich et al. found that dehydration near the end of life causes fairly benign symptoms and, by decreasing the risk of all the factors just mentioned, often leaves the patient more comfortable.⁷⁸ In one study, almost all discomfort caused by the lack of nutrition or hydration was relieved with either small amounts of food or appropriate mouth care.⁷⁹

Medical nutrition in the dying patient can also be counterproductive. In most cultures, feeding the sick is part of normal care of that person. This concept may lead to the concern that a patient near the end of life might "starve" unless given proper nutrition. One study appeared to show that allowing dying patients to eat and drink as they wish, but not attempting artificial life-prolonging therapies, usually leads to more comfortable and peaceful deaths.⁷⁹ Stopping medical feedings may also be beneficial because the body then produces ketones, which can provide an additional sense of well-being as a patient approaches death.⁷²

Patients with diminished renal function are often more comfortable with decreased amounts of various medications as well as fluids. Decreasing body mass or dehydration can lead to increasing side effects that may require lowering the doses of medications, including the pain medications that a dying patient receives. However, if the patient is already comfortable, options include changing to as-needed dosing or treating the side effects rather than risking increased pain from a dose reduction.

One common end-of-life intervention in the hospital setting is a "morphine drip." Continuous intravenous morphine may be indicated to treat existing pain or dyspnea, but it is not necessary for all dying patients. The fact that a person is close to death is not a sufficient reason to start intravenous morphine if pain is not already a problem. Patients, who have not experienced pain as a major problem during their disease rarely develop severe pain near the end. Morphine and other opioids, although important for comfort, can also cause side effects. Somnolence, myoclonus, and urinary retention can become problems as the dose of opioid is increased. However, use of an opioid at high doses, if indicated for relief of symptoms, is generally considered to be acceptable. The use of morphine and other opioids at this time are governed by the principle of double effect. This principle holds that it is the clinician's intention of providing comfort that determines the ethics of appropriate opioids use at the end of life and not any possible unintended hastening of the patient's death.⁸⁰

Bereavement

An important but often-overlooked aspect of caring for the family of a terminal patient is following up with them after their loved one dies.⁸¹ After the intensity of the final days of a patient's life, the family will often benefit from and be grateful for communication from the physician. An early phone call or letter of sympathy to family members from the physician or some other known member of the medical team can

mean a great deal. Later on, verbal contact can be helpful in distinguishing normal from pathologic grief.⁸¹

Studies have demonstrated the possibility of significant morbidity during the bereavement period.^{82,83} So far, however, there is little evidence that lends support to any specific intervention. Hospices are required to offer bereavement follow-up to anyone who lives in the areas they serve even if the deceased loved one was not involved with hospice.

Ethical and Legal Issues

Decision Making

Difficult ethical issues can arise while taking care of a terminal patient. The range of issues includes requests to withhold information from the patient, requests for futile treatment, withholding or withdrawing life-sustaining treatments, and requests for physician-assisted suicide.

One issue that can arise is a request by the family to withhold distressing information from the patient. In the United States, the patient "of sound mind and adult years" holds the legal right to make medical decisions.⁸⁴ The patient does have the option to delegate that responsibility to someone else and request not to be told, but that ought to be an explicit decision.

One approach to a request to withhold information from the patient is to explore with the family their reasons.⁸⁵ Often clinicians can allay their fears of the patient losing hope or not wanting to know. Using open-ended statements allows patients to ask questions or to express the desire not to know. Occasionally there may be a valid reason for concern, such as a patient's suicide threat following previous distressing news. Although cultural differences can have a great impact in this area, specific cases are beyond the scope of this chapter.

Medical Futility

Another ethical issue involves the concept of *medically futile treatment*. The medical team may view certain procedures or treatments as futile for an end-stage patient while the family's view may be quite different. The reverse may also occur. There may be a point at which the treating team should decide that they have done everything medically indicated to support a patient's life. Determining that any specific treatment is futile and needs to be stopped requires careful communication and possibly an ethics consult if the family and medical team disagree.

Withholding or withdrawing any life-sustaining treatment can lead to major disagreement, whether the medical team views it as futile or the patient does not want it. In most states, stopping a treatment or never starting it are legally equivalent and also viewed as ethically equal.⁸⁶ Once a patient starts receiving intravenous fluids or a feeding tube, however, the experience of stopping the treatment often appears far more difficult emotionally. It is best to try to discuss those possibilities long before they may become reality.

Physician-Assisted Suicide

"Doctor, will you help me end my suffering?" According to one study in 1998, this is not a rare question. Of a national

TABLE 91.5. Requirements for physician-assisted suicide.

1. The person must be a capable adult resident of Oregon.
2. The person must have a terminal disease.
3. There must be less than 6 months to live.
4. The person must make two oral requests for assistance in dying.
5. The person must make one written request for assistance in dying.
6. The person must convince two physicians that he or she is capable, acting voluntarily, and making an informed decision.
7. The person is not making the decision because of a depression or other psychiatric or psychologic disorder.
8. The person must be informed of the diagnosis, prognosis, potential risks of medication, probable result of taking the medication, and "the feasible alternatives, including but not limited to, comfort care, hospice care, and pain control."
9. The person must wait 15 days.

Source: From The Oregon Death with Dignity Act of the Oregon Revised Statutes.

sample of 1,902 physicians, 18.3% had received a request for a prescription to end suffering by ending life, with a median of three requests per physician since entering practice.⁸⁷ Of these physicians, 3.3% had written at least one of these prescriptions.

Well-respected leaders have expressed support both for and against physician-assisted suicide (PAS). As of this writing, the state of Oregon is the only American jurisdiction that has legalized PAS. There are formal criteria that must be met before the act may occur (Table 91.5). Valid arguments exist both for and against the legalization of PAS, and it would require more than the space allowed here to do full justice to the topic. Some of the arguments for each side are listed in Table 91.6 and are also briefly described next. For more complete presentations on the subject, there are several good references.⁸⁸⁻⁹⁰

Although there is some disagreement as to the exact meaning of the term physician-assisted suicide, here the meaning of PAS is as used in the Oregon law. PAS occurs if a person commits suicide using a method supplied by a physician specifically for that purpose (Table 91.7). In Oregon, the physician supplies a prescription for medication, which the patient fills and later uses to commit suicide either with the doctor present or not. This is not the same as euthanasia, which is when the physician physically performs the action that ends the life of the patient, such as with a lethal injection. Euthanasia is considered murder in all parts of the United States today.

TABLE 91.6. Arguments in favor of and against physician-assisted suicide.

Arguments in favor of physician-assisted suicide:

1. Respect for patient autonomy
2. Relief of suffering
3. Legalization allows controls
4. Society allows some killing

Arguments against physician-assisted suicide:

1. Intrinsic value of life
2. Legalization would reduce efforts at palliative care
3. Slippery slope
4. Professional ethics

TABLE 91.7. Some definitions of terms.

Suicide signifies that a person knowingly performs an action that takes his or her own life.

Physician-assisted suicide is suicide as above in that the person commits the act of knowingly ending his or her own life, but has been assisted by a physician in obtaining the means, usually a medication.

Euthanasia is the ending of a person's life by another. In the medical sense, usually the patient has expressed a wish to die and someone else performs the act.

Execution is commonly used in the setting of a government-sanctioned act as a form of capital punishment.

Murder is involuntary euthanasia, which is illegal everywhere in the United States.

Turning off a ventilator or stopping some other form of life-sustaining treatment at the patient's or family's request, with the intention of allowing life to end, is not usually considered PAS. Benjamin Cardozo, a New York judge, in 1914, ruled that "every human being of adult years and sound mind has the right to determine what shall be done with his own body."⁸⁴ If a ventilator, or other life-sustaining treatment, is determined by the patient or other legal decision maker to be excessively burdensome, then removing it is not PAS but a legal request in most states that ought to be respected. In these cases, the life-sustaining treatment is considered as holding back death and, when stopped, the patient dies of his disease or medical problem, not from the withdrawal of the treatment. In some states, the law limits the ability of a decision maker, but not the patient, to withdraw certain treatments.

Although not a legal part of end-of-life care in most of the country at this time, PAS is an ongoing question. Below are presented some of the arguments supporting PAS followed by some that oppose it.

THE CASE IN FAVOR OF PHYSICIAN-ASSISTED SUICIDE

Some of the arguments for PAS are based on respect for patient autonomy, which is generally considered to be the preeminent principle in American medical ethics today. Respect for autonomy is the basis for informed consent, which is necessary for any procedure performed on a patient. If a patient wishes to die to escape uncontrollable suffering, or being an extreme burden on the family, some would argue that the patient's physician has a responsibility to try all possible legal means to achieve patient comfort. Various forms of suffering are, however, extremely difficult to control. Even the provision of excellent palliative care may not relieve all types of psychologic, emotional, existential, or even physical pain. Proponents of PAS argue that duty requires that the physician not abandon the patient whose suffering remains intolerable, claiming that there are no other palliative treatments. This argument continues that the logical continuation of a physician's responsibility, after ensuring that the patient neither is depressed nor has otherwise compromised decision making, is to provide the means for a comfortable death.

Many are afraid that dying must be a painful experience. When a clinician is unable to prevent unbearable suffering in a dying patient, proponents would argue that PAS should be an option on the continuum of total care of a patient. They would say that a physician is responsible for treating that suf-

fering by any possible means and that refusing to explore what may be the only way to prevent that suffering could be viewed as abandoning the patient. Proponents could also argue that giving a patient control over the process of dying would reduce some suffering. Most of the requests for PAS in Oregon have been made to try and control the circumstances of dying, not because of physical symptoms, which are more easily treated.⁷⁵

To some extent PAS or even euthanasia is widespread already. A national survey in 1998 reported that 4.7% of physicians stated that they had given at least one patient a lethal injection.⁸⁷ These situations already exist in the privacy of the doctor-patient relationship, and some would say that they should be allowed to continue without interference. This argument continues that legalizing PAS would allow society to acknowledge and regulate these actions, thereby providing protections for all involved parties. Currently, in all states except Oregon, any physician involved in PAS is legally at risk, whereas the patient, if interrupted or unsuccessful in the act, is at risk for unwanted aggressive measures and increased physical handicaps.

Intentionally ending the life of a person, while usually proscribed by society, is allowed in a few specific instances. Killing another human being while fighting for one's country is often defended as a responsible act, or even a required one for a member of the military. Capital punishment is legal in 38 states for those whom society has deemed deserving of that ultimate punishment. Some say that PAS should be included in this class of "justifiable killing."

THE CASE AGAINST PHYSICIAN-ASSISTED SUICIDE

The case against PAS also follows several avenues, a few of which are presented below. Two of the main arguments involve the effect of PAS on society as a whole.

The first argument states that life has intrinsic value and that physicians are viewed as guardians of those lives. They attempt to heal the sick, but when cure is not possible, proponents would say that their role is to comfort the sick until a patient succumbs to his or her inevitable death. Their role is either trying to prolong life or bearing witness to the end of patients' lives they cannot prolong because of the value of those lives. It would follow that they are not charged by society *intentionally* to shorten life. Many argue that the public's views of the profession would change were physicians allowed to intend death while supplying the means. It is certainly possible for a physician to hasten a patient's death while struggling to make a dying patient comfortable with opioids and benzodiazepines, but the intention here is to relieve suffering. The alternative is uncontrolled pain and suffering followed by a difficult death. Proponents would argue that the role of physicians is to protect the lives of patients and not purposely try to end them.

Opponents of PAS might also say that legalizing PAS could allow the medical profession not to work so hard to provide the best palliative care. Instead, if comfort were not achieved easily, there would be an alternative to continued serious efforts. Currently, with the choice of either increasing or decreasing levels of comfort, the only option is to continue trying to reduce any patient's suffering. PAS would serve as an "easy way out" for some physicians if they found end-of-life care too challenging.

Some would argue that legalizing PAS could be the beginning of a slippery slope. It might begin as a way for people with a serious illness to avoid a bad end and could proceed to a time when people with serious disabilities or the very old would be encouraged to end their lives and cease being a burden to their families or to society. PAS could become viewed as the way to rid society of those who were no longer capable of being contributing members. Some might even argue that it could eventually open the door for euthanasia.

PAS could also lead to decisions burdened by conflicts of interest. Patients who may not be ready to die, but who also do not wish to deplete their family's resources, might feel pressure not based on the medical situation. On the other side, physicians in certain situations might eventually find financial incentives involved in the decision. Legalizing PAS could lead to society having serious questions about how the decisions are influenced.

Physicians are not required to provide care that they believe is unethical, and many people feel that killing a human being under any circumstances is evil in itself. Legalizing PAS would cause some physicians to be seen as not helping those who suffer because of their beliefs. This could cause a difficult split within the community of physicians. Of course, there is also the question of whether humans should decide when to end their own lives. At this time, American society has not fully resolved this larger question.

End-of-life care in the United States is changing rapidly as palliative care and hospice both develop and become more well known. Oncologists and other physicians are becoming more aware of the needs of terminal patients and their families, and there is more literature about those situations. Palliative care specialists and teams are becoming more widespread, and hospice now takes care of about 50% of the dying people in the United States. One common idea is that good palliative care will prevent the need for PAS. Although this concept seems as though it might be valid, there is little evidence to prove it. As terminal care continues to improve, it will be interesting to watch what happens to the debate over PAS.

Metastatic Cancer to the Central Nervous System

Douglas B. Einstein

Epidemiology

Brain metastases are the most common intracranial solid tumors identified in adults, with 150,000 to 170,000 newly diagnosed cases of brain metastases per year in the United States.¹ Ten percent to 30% of adult cancer patients develop brain metastases in their lifetime with an incidence of up to 25% to 40% at time of autopsy.^{2,3} The mean age of patients diagnosed with brain metastases is 60 years.⁴ Brain metastases are much less frequent in children, affecting approximately 3% of children with localized solid tumors and 7% of those with known metastatic disease.⁵ The most common primary tumor giving rise to brain metastases is non-small cell lung cancer, followed by small cell lung cancer and breast cancer (Figure 92.1).⁶ The median time from diagnosis of the primary tumor to development of brain metastases is approximately 8 months.⁷

The number of brain metastases identified at diagnosis is highly dependent on the imaging modality utilized. Multiple brain metastases were identified in 47% of newly diagnosed patients using computed tomography (CT) studies. This percentage increases to 75% with gadolinium contrast-enhanced magnetic resonance imaging (MRI).⁶⁻¹¹ Patients with prostate, unknown primary, and gastrointestinal cancers present with a higher proportion of single brain metastases than multiple metastases (Figure 92.2).⁶

Brain metastases appear to preferentially localize to certain portions of the brain in relationship to their relative blood flow. Brain metastases are usually found at gray-white matter *watershed* areas because of decreases in superficial artery sizes at these junctions that trap metastatic emboli.⁹ Approximately 80% of brain metastases are supratentorial, with 15% to 17% in the cerebellum and 3% to 5% in the brainstem.⁷ Patients with single brain metastases from pelvic primaries (prostate, uterine, ovarian) appear to have a predilection for the posterior fossa 50% of the time, whereas single nonpelvic primary metastases localize to the supratentorial region 80% to 90% of the time.^{6,7}

Diagnosis

Two-thirds of patients present with neurologic symptoms at diagnosis, with the majority of the remainder diagnosed incidentally at time of staging evaluation. The most common neurologic symptoms are headaches or changes in mental status (Figure 92.3).⁶ Five percent to 10% of patients present

symptoms of secondary hemorrhage or infarction at time of diagnosis.¹² Melanoma, choriocarcinoma, renal cell carcinoma, and thyroid carcinoma brain metastases have a higher than average risk of associated hemorrhage.^{6,12,13}

Twenty percent of brain metastases are diagnosed synchronously with a new extracranial malignancy; 80% are diagnosed metachronously after the primary diagnosis.² In the absence of a known primary, a metastatic workup should be performed, including history and physical examination, CT of the chest, abdomen, and pelvis, and bone scan. Sixty percent to 70% of synchronously diagnosed brain metastases originate from a primary lung cancer.¹⁴⁻¹⁶ In a study of patients without an initially detectable primary at the time of brain metastasis diagnosis, prospective surveillance screening shows the primary to be of lung origin 82% of the time.¹⁷

Contrast-enhanced MRI has supplanted CT as the imaging modality of choice for the diagnosis of brain metastases because of its higher sensitivity, as previously mentioned. Figure 92.4 shows typical gadolinium-contrast enhanced T₁ and T₂ sequences from the MRI of patients with single and multiple brain metastases. Brain metastases are typically identified as spherical, multiple ring-enhancing lesions on T₁ images with surrounding edema often larger than the lesion on T₂ images.^{10,11} Increased doses of gadolinium (double or triple dose) appear to be more beneficial than single doses in identifying smaller lesions.^{18,19} Diffusion-weighted MRI imaging and MR spectroscopy may also aid in identifying hemorrhage within a brain metastasis and differentiate it from an abscess.²⁰

Despite characteristic imaging features, a differential diagnosis should be considered for a suspected brain metastasis in the absence of a known malignancy. This is especially critical for patients with a solitary brain metastasis (a single brain lesion representing the only evidence of metastatic disease throughout the body) versus a single brain metastasis (a single brain lesion in addition to other known extracranial metastases). This differential includes primary brain tumors, abscesses, infarctions, nonmalignant hemorrhage, demyelinating diseases, or leukoencephalopathy.¹³ As shown by selected randomized trials in Table 92.1, the surgically proven false-positive rate of suspected single brain metastases detected by CT or MRI in patients with known malignancies, ranges from 2% to 11%, supporting the role of biopsy for any questionable lesion before treatment.²¹⁻²³ Treatment of presumed brain metastases without a brain biopsy has routinely been delivered at most centers and on national protocols for patients with multiple suggestive lesions on MRI and known

CT, computed tomography; MRI, magnetic resonance imaging.

extracranial biopsy-proven metastatic disease diagnosed within 5 years.^{21–25} However, any patient with MRI imaging-equivocal single or multiple lesions should have a stereotactic biopsy or resection of the brain lesion before treatment.

Prognostic Factors

The largest study to date investigating the pretreatment prognostic factors affecting the survival of patients with brain metastases was performed by the Radiation Therapy Oncology Group (RTOG),²⁶ a study of 1,200 patients from three large RTOG trials. Several prognostic factors were found to be significant by univariate analysis (Table 92.2). Recursive partitioning analysis (RPA), a statistical methodology that creates a regression tree according to factors identified as significant in univariate analysis, was used to further analyze these data. Three RPA classes of patients were identified stratified by Karnofsky Performance Score (KPS), age, and extent of extracranial disease, with significantly different expected survival times (Table 92.3). These RPA classes have been borne out on analyses of other large (more than 500 patients) patient data sets (Table 92.4). It has also been proposed in a study of 916 patients²⁷ that RPA class 3 patients be segregated into 3A (age less than 65, controlled primary, single brain metastasis), 3B (not B or C), and 3C (age greater than 65, uncontrolled primary, multiple brain metastasis) as

these three subsets have low but different median survivals of 3.2, 1.9, and 1.2 months, respectively (P less than 0.0001). The RPA classification scheme has been utilized to aid in determining which patients may benefit from more aggressive treatment of their brain metastases.

The number of lesions identified by CT imaging was also shown to have prognostic significance in an analysis of a large RTOG database of 779 patients.²⁸ For patients with characteristics similar to RPA class I patients (age less than 60, KPS 70 or greater, controlled extracranial disease), those patients with fewer than four lesions had a statistically significantly prolonged survival over those with four or more lesions (4.0 months versus 3.2 months; $P = 0.001$). Mass effect as evidenced by midline shift was also found to be a prognostic factor in this study. These patients, however, were imaged by CT rather than MRI, raising the possibility that the number of larger, CT-identifiable metastases may be a more important prognostic factor than the absolute number of lesions.

The Mini-Mental State Examination (MMSE), a rapid 10-question examination tool with a maximum score of 30, has also been shown to have prognostic significance for patients with brain metastases. In a study of 445 patients in a RTOG trial,²⁹ a decline in pretreatment MMSE score (especially less than 23) was associated with a decrease in time to death from brain metastases ($P = 0.003$). The only other factor in this study associated with an improved survival by multivariate analysis was a breast primary, which may explain some reports of gender as a prognostic factor.

TABLE 92.2. Prognostic factors identified in Radiation Therapy Oncology Group (RTOG) trials by univariate analysis.

Factor	<i>P</i> value
Solitary brain metastasis	<0.0001
KPS >70	<0.0001
Age <65 years	<0.0001
Controlled primary lesion	<0.0001
Squamous or small cell histology	<0.0001
No neurologic dysfunction	<0.0001
Total radiation dose >52 Gy	<0.0001
Breast primary	0.001
No headache	0.003
More than 2 years after primary diagnosis	0.004
Surgical resection	0.005
Complete tumor response	0.019
Noncerebellum or brainstem location	0.033
Nonmidline brain lesion	0.038

KPS, Karnofsky Performance Status.

Management and Outcomes

Symptomatic Therapy

Initial management of the patient with brain metastases consists of symptomatic therapy that is often first focused at treating peritumoral edema, resulting in increased intracranial pressure and associated neurologic symptoms. Cortico-

TABLE 92.3. Recursive partitioning analysis (RPA) classes identified in RTOG trials.

RPA class	RPA class	Median survival

Sanghavi ⁹⁷	502	16.1	10.3	8.7

steroids have historically been utilized because of their ability to reduce the permeability of tumor capillaries.¹³ Dexamethasone is used preferentially to other steroids because of its minimal mineralocorticoid effect, lowering the potential for fluid retention; its long half-life (plasma, 2–5 hours; biologic, 24–36 hours), allowing for twice-daily dosing; and equivalent dosing by po or IV route.^{13,15,30} Typically, for the symptomatic patient, loading doses of 10 to 20 mg IV are given followed by 16 to 24 mg/day in bid or qid divided doses. For the neurologically unstable patient, higher dexamethasone doses up to 100 mg/day have been utilized.^{7,15,30} Sixty-five percent to 70% of patients have symptomatic relief within 6 to 24 hours after their first dose of dexamethasone.^{30,31} Steroids used as a single treatment modality increases the median survival of patients with brain metastases from 1 month, if left untreated, to 2 months.^{15,31,32}

After a patient is clinically stabilized, dexamethasone should be tapered to the lowest dose necessary to maintain neurologic status because long-term steroid use can be associated with well-known side effects, such as oral candidiasis, gastritis, myopathy, hyperglycemia, fluid retention, weight gain, sleep and personality disorders, acne, osteoporosis, and immunosuppression.^{7,13} In a double-blinded randomized study of patients with stable but symptomatic brain metastases treated with 16, 8, or 4 mg dexamethasone per day, 4 mg per day was found to be equally effective as 16 mg per day in maintaining neurologic status as measured by KPS.³³ Steroid taper is often started after initiation of definitive therapy, such as surgery or radiotherapy, and typically is reduced over a 3- to 4-week period by 2 mg per 5 to 7 days to avoid steroid withdrawal symptoms and adrenal insufficiency if utilized.^{7,30} To minimize acute effects of gastritis, patients should be routinely placed on prophylactic H₂ blockers. *Pneumocystis carinii* pneumonia prophylaxis can also be considered for otherwise immunocompromised patients. Patients with small (less than 1 cm), asymptomatic lesions with minimal peritumoral edema often identified during staging evaluation may require no steroids or a brief course of steroids that can be discontinued within 14 days without need for tapering.^{7,30}

Anticonvulsants are recommended by the American Academy of Neurology for patients presenting with seizures

at time of brain metastases diagnosis.³⁴ Phenytoin, carbamazepine, valproic acid, and phenobarbital are the most commonly used anticonvulsants.^{7,34} Anticonvulsant side effects include cognitive impairment, myelosuppression, liver dysfunction, and dermatologic reactions (ranging from minor rashes to life-threatening Stevens–Johnson syndrome), which appear to be increased in brain tumor patients.^{13,34} Phenytoin, carbamazepine, and phenobarbital can also stimulate the cytochrome P-450 system, increasing the metabolism and decreasing the efficacy of many medications, including dexamethasone.³⁴ Newer anticonvulsants, such as levetiracetam may be a better choice for patients with brain metastases as they have a decreased risk of dermatologic reactions and do not interfere with the P-450 system.^{35,36}

For patients with newly diagnosed brain metastases who have not had a seizure, the role for prophylactic anticonvulsants is controversial. A meta-analysis of four randomized trials involving the use of prophylactic anticonvulsants was performed by the American Academy of Neurology.³⁴ As summarized in Table 92.5, there was no statistically significant benefit to the use of prophylactic anticonvulsants. The Academy concluded, “In patients with newly diagnosed brain tumors, anticonvulsant medications are not effective in preventing first seizures. Because of their lack of efficacy and their potential side effects, prophylactic anticonvulsants should not be used routinely in patients with newly diagnosed brain tumors.” With regard to postoperative anticonvulsant duration, they concluded that “In patients with brain tumors who have not had a seizure, tapering and discontinuing anticonvulsants after the first post-operative week is appropriate, particularly in those patients who are medically stable and who are experiencing anticonvulsant-related side effects.”

Whole-Brain Radiotherapy

Whole-brain radiotherapy (WBRT) has been the historical standard treatment for brain metastases. WBRT is a technique by which megavoltage irradiation is delivered to the entire brain and meninges via two opposing lateral 4- to 6-MV photon beams with custom blocking to include the retina but exclude the lenses, oral/nasal cavities, and pharynx (Figure 92.5). This technique allows for the treatment of both gross and microscopic tumor within the brain. WBRT is given in fractionated form (small doses per day for a period of several weeks) to increase the therapeutic ratio by allowing normal cells to repair radiation-induced DNA damage between fractions with much greater efficacy than tumor cells, thus minimizing normal tissue toxicity.³⁷

TABLE 92.5. Randomized trials of prophylactic anticonvulsant use in patients with brain tumors.

Study	N	No. (%) of drug	Patients with seizures/placebo	Odds ratio (95% CI)
Forsyth ⁹⁸	100	11/46 (24)	15/54 (28)	0.82 (0.33–2.01)
Glantz ⁹⁹	74	13/37 (35)	9/37 (24)	1.69 (0.61–4.63)
Franceschetti ¹⁰⁰	63	3/41 (7)	4/22 (18)	0.36 (0.07–1.76)
North ¹⁰¹	81	9/42 (21)	5/39 (13)	1.85 (0.56–6.12)
Total	318	36/166 (22)	33/152 (22)	1.09 (0.63–1.89)

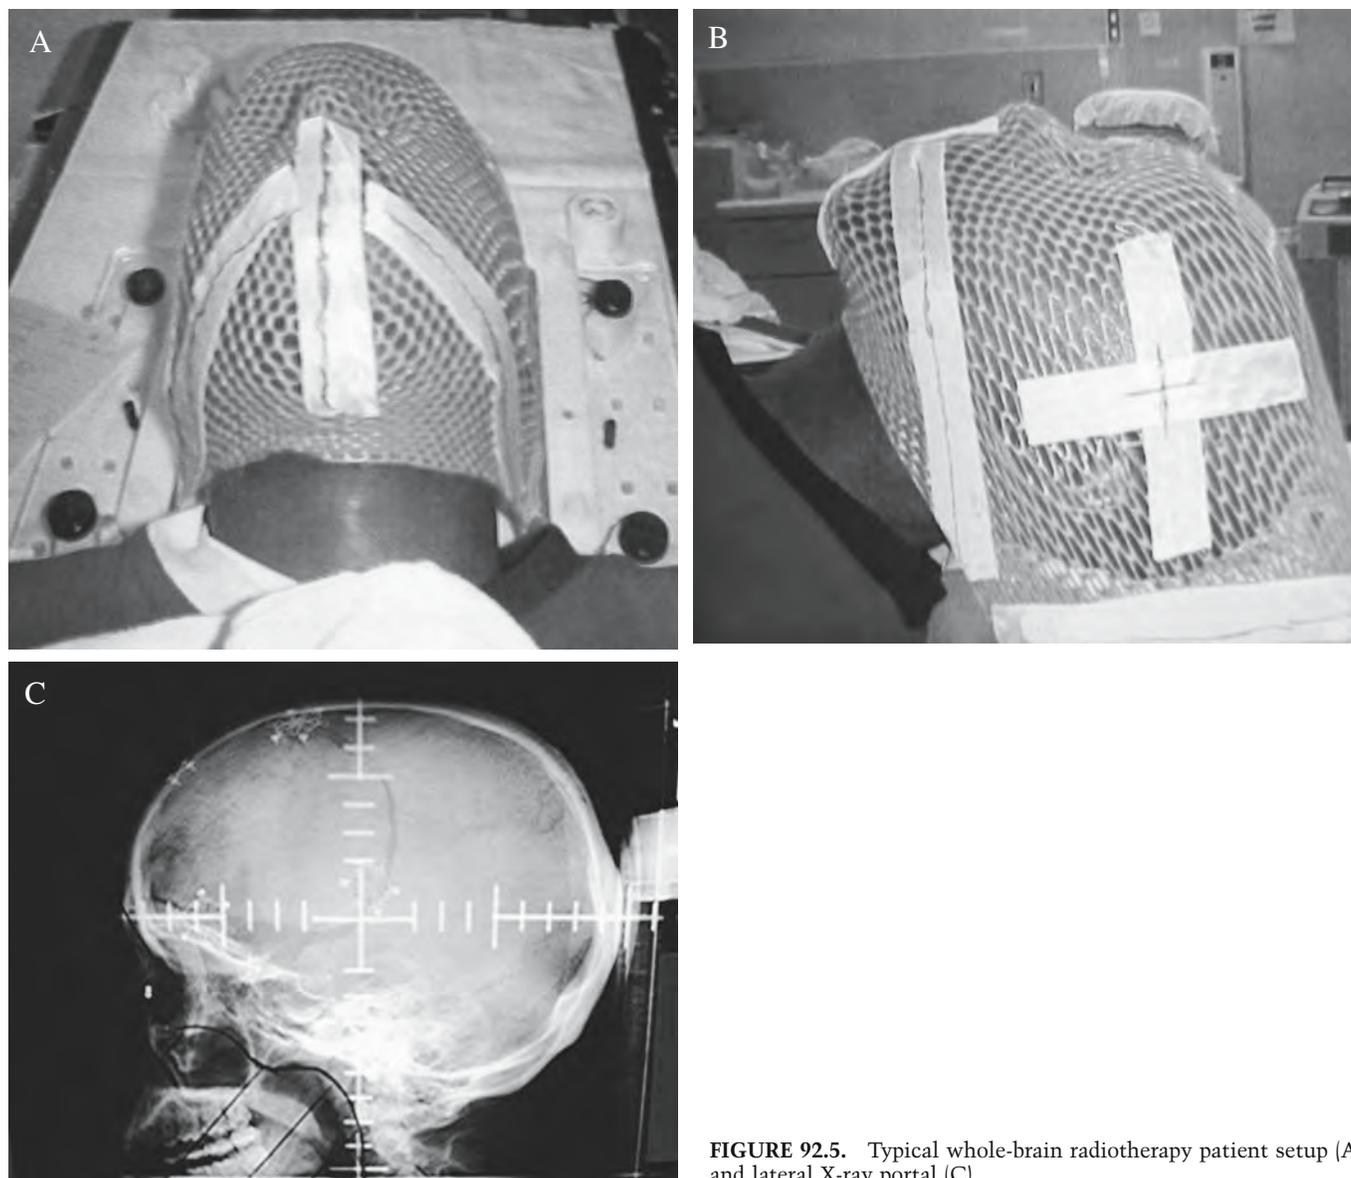

FIGURE 92.5. Typical whole-brain radiotherapy patient setup (A, B) and lateral X-ray portal (C).

Acute side effects of WBRT commonly include fatigue, a scalp skin reaction (reddening, tanning, or irritation), and hair loss. Uncommonly observed are radiation parotitis with dry mouth and change in taste sensation; otitis externa and serous otitis media with possible ear plugging, tinnitus, and drainage; possible transient increased intracranial pressure symptoms of headaches, nausea, vomiting, or seizures that may be related to increased capillary permeability; and a rare somnolence syndrome 4 to 10 weeks after WBRT with spontaneously recovering increased fatigue. Late side effects of WBRT include effects of radiation necrosis with increased peritumoral inflammation; neurocognitive impairment with decreased memory or concentration; cerebellar dysfunction with ataxia; and cataracts with a rare risk of blindness.^{7,12,24}

WBRT improves the median survival of patients with brain metastases over steroid use alone to 3 to 6 months.^{2,7,13,15,38} The RTOG performed the largest series of randomized trials to date investigating the optimum dose/fractionation schedule for WBRT (Table 92.6).³⁹⁻⁴² There was no statistically significant difference in median survival

of patients treated with fractionation schemes ranging from 10Gy in 1 fraction to 70.4Gy in 1.6 bid fractions, with the exception of patients with solitary brain metastases treated on RTOG 85-28. Patients with solitary brain metastases treated with boost doses higher than 48 Gy had an improved median survival compared to patients treated to 48 Gy or less, although there was no dose-response differential between the three higher doses.⁴³ This finding led to a Phase III trial of standard WBRT versus accelerated fractionated (twice-daily) WBRT with a dose-escalated local radiation boost (RTOG 91-04).⁴⁹ This trial did not find any difference in median survival of patients treated with the dose-escalated local boost compared to lower-dose conventional daily fractionation delivered to the entire brain, supporting the use of conventional fractionation WBRT.

Although no significant differences in median survival have been produced by varying WBRT dose-fractionation schedules, there do appear to be dose-fractionation-dependent differences in quality of life and toxicity parameters. Neurologic quality of life as measured by symptom relief was ulti-

TABLE 92.6. Randomized trials of whole-brain radiotherapy alone performed by the Radiation Therapy Oncology Group (RTOG).

^aWhole brain treated to 32 Gy with a reduced-field size boost beyond 32 Gy.

mately observed in 60% to 90% of patients treated in the aforementioned RTOG randomized trials. A high palliative index was also produced by WBRT alone, with patients spending 75% to 80% of their remaining life in an improved or stable neurologic state.³⁹⁻⁴² There was a dose-fractionation-dependent difference in the promptness of neurologic improvement. Patients receiving larger daily fraction doses reported a quicker response to neurologic improvement by the second week than those patients receiving lower daily doses (Table 92.7).³⁹ For patients presenting with the highest pretreatment neurologic function, total doses greater than 30 Gy were associated with a longer duration of neurologic improvement compared to lower total dose schedules (19 weeks versus 13 weeks; $P = 0.05$).³⁹

Neurocognitive function also may be dependent on the daily fraction dose of WBRT. In 1 year, of long-term survivors from a widely quoted retrospective analysis of 79 patients receiving postoperative WBRT (20–40 Gy total dose in 2- to 6-Gy daily fractions) after resection of a single brain metastasis,⁴⁵ 17% of patients who received more than 3 Gy per fraction (4/23) experienced dementia versus 0% of patients who received 3 Gy per fraction or less (0/15), supporting the use of lower daily fraction size to decrease late toxicity in patients with the highest potential for long-term survival. WBRT fraction sizes of 2.5 Gy or less have also been associated with a decreased risk of late neurocognitive side effects.⁴⁶ Hyperfractionation (twice-daily radiotherapy), which has

TABLE 92.7. Impact of daily fraction size on promptness of neurologic response after whole-brain radiation therapy (WBRT).

WBRT Dose per daily fraction	Percent with neurologic improvement by week 2	P value
<3 Gy/day	43%	$P = 0.06$
>3 Gy/day	55%	
<4 Gy/day	54%	$P = 0.01$
>4 Gy/day	64%	

TABLE 92.8. Proposed dose-fractionation schedule for whole-brain radiotherapy (WBRT) alone stratified by RPA class.

RPA class	RPA class	Dose per fraction	Total dose
I	KPS 70 or more, age less than 65 years, controlled primary, no active extracranial metastases	2.5 Gy	37.5 Gy
II	Not class I or III	2.5-3 Gy	30–37.5 Gy
III	KPS less than 70	3-4 Gy	20–30 Gy

been utilized in other sites to decrease radiation side effects, did not affect neurocognitive outcome as measured by the MMSE for patients in RTOG 91-04 receiving twice-daily versus once-daily WBRT doses. The neurocognitive outcome proved to be highly dependent on tumor control with an average drop in MMSE score of 0.5 for patients with controlled brain metastases versus a drop of 6.3 in patients with uncontrolled brain metastases ($P = 0.02$).⁴⁷ Tumor growth, rather than WBRT treatment effect, was also found to be the primary factor resulting in neurocognitive decline assessed by a battery of neurocognitive tests administered before and after WBRT in another prospective trial.⁴⁸

The more rapid neurologic symptom improvement with higher daily fractionation schemes, combined with the longer duration of neurologic response with higher total dose and decreased late neurotoxicity in suspected longer-term survivors with lower daily doses, supports the use of stratified WBRT dose-fractionation schemes based on prognostic factors. One proposed dose-fractionation stratification based on recursive partitioning analysis (RPA) classes used at our institution is described in Table 92.8.

Surgery

Surgical intervention is indicated for patients requiring a histologic diagnosis with no known extracranial cancer, for patients requiring rapid relief from metastases causing symptomatic mass effect or obstructive hydrocephalus, and for improvement of local control.^{15,49} Surgical morbidity and mortality have been improved through the use of newer advanced techniques, such as intraoperative MRI and ultrasound, functional cortical mapping, and frameless stereotaxis.^{15,50} In the largest reported retrospective cohort study to date of 13,685 patients undergoing craniotomy for the resection of brain metastases from 1988 to 2000, in-hospital mortality rates decreased from 4.6% between 1988 and 1990 to 2.3% between 1997 and 2000. Mortality was dependent on hospital and surgeon volume, with lower-volume sites/surgeons associated with higher mortality rates.⁵¹ Although surgical morbidity/mortality has been significantly reduced using advanced neurosurgical techniques, surgical therapy is often not offered for patients with extensive progressive extracranial disease, as this factor removes patients from RPA class I status and is associated with a poorer than average prognosis.^{12,13}

For patients with a single brain metastasis with stable extracranial disease, surgical resection has been shown to improve survival over WBRT alone. Three randomized trials of patients with single brain metastases compared preradiotherapy surgical resection of the metastases to WBRT alone

TABLE 92.9. Randomized trials of surgical resection in addition to whole-brain radiotherapy (WBRT) for patients with a single brain metastasis.

Trial	Randomization	N	WBRT dose (Gy)/dose per fraction	Median survival with progressive extracranial disease (ED)	P value	Median survival with stable ED	P value	Recurrence rate at original site	P value
Patchell ⁵²	Surgery + WBRT	25	36/3	Not stated		40 weeks		20%	
	WBRT	23	36/3	Not stated	<i>P</i> = NS	15 weeks	<i>P</i> < 0.01	52%	<i>P</i> < 0.02
Noordjik ⁵³	Surgery + WBRT	32	40/2 bid	20 weeks		43 weeks		Not stated	
	WBRT	31	40/2 bid	20 weeks	<i>P</i> = NS	26 weeks	<i>P</i> = 0.02	Not stated	
Mintz ⁵⁴	Surgery + WBRT	41	30/3	12 weeks		24 weeks		Not stated	
	WBRT	43	30/3	12 weeks	<i>P</i> = NS	27 weeks	<i>P</i> = 0.24	Not stated	

(Table 92.9). None of the trials showed a survival advantage for patients undergoing surgery in the presence of progressive extracranial disease, again demonstrating the importance of this prognostic factor. The first two trials^{52,53} found a significant increase in overall survival for patients with stable extracranial disease whose single brain metastasis was resected before WBRT. The third trial⁵⁴ failed to show a benefit for surgical resection. This may be secondary to the inclusion of patients with a KPS above 50 rather than 70 in the other trials, and a higher proportion of patients with progressive extracranial disease (45% versus 38% and 32%).⁵²⁻⁵⁴

The necessity of immediate adjuvant WBRT after surgical resection for patients with a single brain metastasis, has been investigated in several retrospective analyses with varied results,^{45,55-59} but in only one prospective, randomized trial.⁶⁰ This trial randomized 95 patients with a single brain metastasis to either immediate WBRT or WBRT upon recurrence.⁶⁰ There was no difference in overall survival between the immediate WBRT group (48 weeks) and the delayed WBRT group (43 weeks). There were, however, several benefits of immediate WBRT. Immediate WBRT decreased the risk of recurrence anywhere in the brain from 70% to 18% (*P* less than 0.001); decreased the risk of recurrence at the site of the initial metastasis from 46% to 10% (*P* less than 0.001); increased the time to brain recurrence from 27 weeks to 52 weeks; and decreased death from neurologic causes from 44% to 14% (*P* = 0.003). Although delayed WBRT resulted in the same overall survival as immediate WBRT, the authors recommended the routine use of immediate WBRT to decrease brain recurrences and associated neurologic symptoms that can affect quality of life and neurologic death.

For select patients with a solitary brain metastasis from non-small cell lung cancer and resectable thoracic disease, aggressive surgical resection of gross disease at both sites has been attempted with encouraging results. In retrospective trials of patients with complete resection of both solitary brain metastases and limited (stage I or II) non-small cell lung cancer, combined resection has yielded median survivals ranging from 13 to 24 months and 5 year survival rates of 10% to 30%.⁶¹⁻⁶⁴ Thoracic lymph node tumor involvement was found to be the most significant negative prognostic factor for patients undergoing combined resection of their cranial and thoracic disease.^{62,64}

For patients with multiple brain metastases, surgical resection has been generally limited to resection of a

dominant single lesion, causing symptomatic mass effect. However, with advanced surgical techniques, the ability to resect multiple lesions has improved. Although there have been no randomized trials investigating the benefit of surgical resection of multiple brain metastases, retrospective studies of patients with multiple resected brain metastases have been reported.^{65,66} The largest of these studies⁶⁵ subdivided patients undergoing resection of multiple brain metastases into three groups: group A (30 patients) had remaining metastases after resection, group B (26 patients) had all brain metastases resected, and group C patients (26 patients) were case-controlled matched patients to those in group B who underwent resection of a single brain metastasis for comparison. All patients received WBRT (30Gy in 3-Gy daily fractions) either pre- or postoperatively. The median survival of group B patients (with all metastases resected) was 14 months, which was equivalent to those patients in group C (with a single resected metastasis), but significantly higher than the 6-month median survival of group A (with remaining unresected lesions). These authors concluded that removal of all lesions in selected patients with multiple brain metastases improves survival time, and gives a prognosis similar to that of patients with a single resected brain metastasis combined with WBRT. Although supporting surgical resection of multiple brain metastases that can be resected within a single operation, these data await validation by a prospective, randomized trial.

Stereotactic Radiosurgery

Stereotactic radiosurgery (SRS) has produced significant advances in the treatment of brain metastases over the past decade. SRS is a technique using single-fraction, high-dose megavoltage radiation directed at a discrete target identified in three-dimensional stereotactic space. Brain SRS is delivered via collimator-modified linear accelerators using multiple arcing beams intersecting at the defined target (LINAC-SRS), or via a gamma knife machine using 201 fixed cobalt sources, with the target moved into the intersection (focal point) of the beams (GK-SRS). Head position must also be fixed using stereotactic frames attached to the skull. SRS head frames, devices, and typical SRS isodose curves for brain metastases are shown in Figure 92.6.

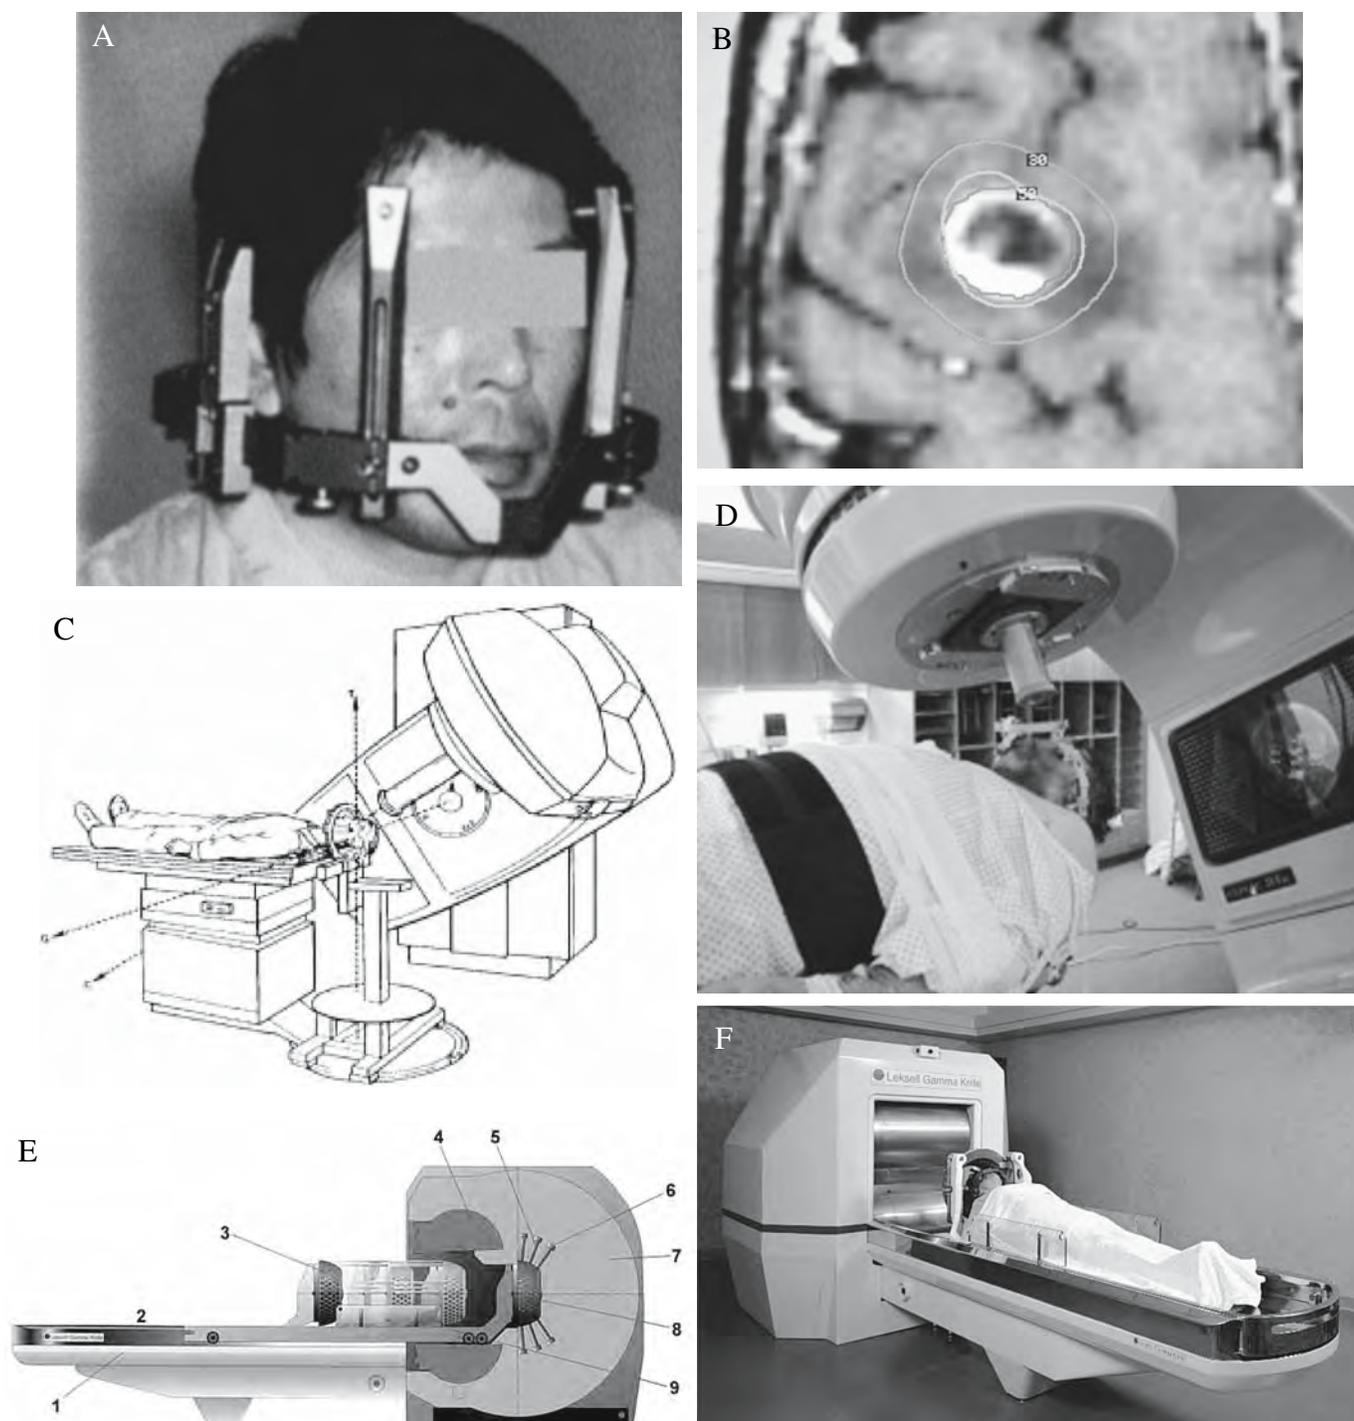

FIGURE 92.6. (A) Stereotactic radiosurgery (SRS) head immobilization frame. (B) SRS isodose curves (inner 50%, outer 30%). (C, D) LINAC stereotactic radiosurgery treatment. (E, F) Gamma knife stereotactic radiosurgery treatment.

The radiobiology of single-fraction high-dose radiation treatments allows for maximal DNA damage with minimal sublethal damage repair that normally occurs during the interfraction interval of fractionated radiotherapy treatments. Because normal tissue repair is minimized, SRS targets must be exquisitely defined to minimize the amount of normal

tissue within the SRS field. Therefore, SRS is utilized, in a manner similar to surgical resection, to treat gross brain metastases that can be identified on imaging studies and is not used to treat nonvisualized microscopic metastases.

Side effects of SRS include stereotactic frame pin site issues, including transient facial swelling and rare risks of

TABLE 92.10. Radiation Therapy Oncology Group (RTOG) central nervous system (CNS) toxicity criteria.

Grade	Definition
1	Mild neurologic symptoms; no medication necessary
2	Moderate neurologic symptoms; outpatient medication required (e.g., steroids)
3	Severe neurologic symptoms; outpatient or inpatient medication required
4	Life-threatening neurologic symptoms (e.g., uncontrolled seizures, paralysis, or coma); includes clinically or radiographically suspected radionecrosis and histologically proven radionecrosis at the time of an operation
5	Death

bleeding or infection; radiation-induced peritumoral inflammation with risk of increased intracranial pressure symptoms, such as headaches, nausea, vomiting, or seizures within 24 to 48 hours of the radiosurgical procedure; and risk of symptomatic radiation necrosis, which can cause peritumoral edema 3 to 24 months after radiosurgery.²⁴ Dexamethasone and anticonvulsants delivered on the day of the procedure can decrease the risk of increased intracranial pressure (ICP) symptoms. The risk of symptomatic radiation necrosis is highly dose-volume dependent. The largest Phase I multi-institutional trial investigating the risk of symptomatic necrosis from radiosurgery is RTOG 90-05,⁶⁷ in which 168 patients with recurrent primary brain tumors or brain metastases after large-field radiotherapy (WBRT or conformal brain radiotherapy), were entered on the protocol. Tumor diameter-dependent doses were escalated to the maximum tolerable dose (MTD) based on the incidence of acute (less than 3 months) and chronic (more than 3 months) central nervous system (CNS) toxicity as measured by RTOG CNS toxicity criteria (Table 92.10). The MTDs identified are summarized in Table 92.11. These MTDs have been used as guidelines in all subsequent RTOG radiosurgery protocols. Radiosurgical toxicity for unirradiated brain has also been investigated by the University of Pittsburgh group in their large study of 332 patients treated with SRS for arteriovenous malformations (AVMs).⁶⁸ They found a dose-volume relationship between the volume covered by the 12-Gy isodose curve and risk of symptomatic necrosis.⁶⁸

Advantages of SRS over surgical resection include outpatient treatment with rapid recovery time, no need for general anesthesia, lower side-effect profile, easier accessibility of more eloquent regions of the brain, and less cost with the median reported cost of WBRT plus SRS of \$15,102 compared to \$22,018 with WBRT plus surgery.^{49,69} Surgical resection remains the treatment of choice for patients who require

TABLE 92.11. Radiosurgery maximum tolerable doses (MTDs) from RTOG 90-05.⁶²

Maximum tumor diameter	Maximum tolerable radiosurgical dose	Comments
0–2.0 cm	24 Gy	MTD not reached at 24 Gy
2.1–3.0 cm	18 Gy	18 Gy based on chronic toxicity, 21 Gy based on acute toxicity
3.1–4.0 cm	15 Gy	15 Gy based on acute toxicity

rapid decompression of symptomatic brain metastases causing substantial mass effect, for patients requiring tissue diagnosis before treatment, and for patients with radiosurgery-ineligible tumors, that is, those larger than 4 cm, inseparable from the optic nerves or chiasm, or involving the brainstem (relative contraindication).⁴⁹

Two randomized trials of the addition of SRS to WBRT (Table 92.12) have been conducted in a similar manner to those for the addition of surgical resection to WBRT (see Table 92.9).^{70,71} The first trial by the University of Pittsburgh group⁷⁰ included 27 patients with two to four brain metastases less than 2.5 cm in diameter with a median KPS of 100 and a median age of 59 years. Most patients had active systemic disease (62% in WBRT + SRS versus 71% in WBRT alone). The trial was stopped after a planned analysis at 60% accrual that showed an improvement in 1-year local control from 8% in WBRT to 100% in WBRT + SRS ($P = 0.002$). At that level of accrual, the group found a trend in improved median overall survival from 7.5 months in the WBRT group to 11 months in the WBRT + SRS that did not reach statistical significance ($P = 0.22$). However, in the group of patients with stable extracranial disease, there was a significant improvement in overall survival from 5.5 months (with pulmonary metastases) to 7.5 months (without pulmonary metastases) to 14 months ($P = 0.02$). The difference was still significant without the pulmonary disease stratification ($P = 0.05$), emphasizing the importance of stable extracranial disease on the prognosis of patients with brain metastases.

The second trial, RTOG 95-08, is the largest multi-institutional trial of WBRT versus WBRT + SRS to date, randomizing 333 patients with one to three brain metastases with diameters less than 4.0 cm and a KPS of 70 or more.^{71,72} SRS improved survival over WBRT alone for patients with a single brain metastasis (4.9 to 6.5 months; $P = 0.04$); RPA class I patients (9.6 to 11.6 months; $P = 0.05$); and patients with non-small cell lung cancer or any squamous cell carcinoma (3.9 to 5.9 months; $P = 0.05$). All patients receiving SRS were more likely to maintain a stable or improved performance status

TABLE 92.12. Randomized trials of stereotactic radiosurgery (SRS) in addition to whole-brain radiotherapy (WBRT).

Trial	Randomization	N	WBRT dose (Gy)/dose per fraction	Median survival (months) with stable extracranial disease (ED)	P value	One-year SRS in-field recurrence rate	P value
Kondziolka ⁷⁰	SRS + WBRT	14	30/2.5	14 months	$P = 0.05$	8%	$P < 0.02$

RTOG 95-08 ^{71,72}	SRS + WBRT	16	37.5/2.5	11.6 months	$P = 0.045$	18%	$P = 0.01$
		4		9.6 months		29%	
	WBRT	16	37.5/2.5				
		7					

TABLE 92.13. Retrospective studies of SRS alone versus SRS + WBRT.

<i>Trial</i>	<i>Initial treatment</i>	<i>N</i>	<i>Local control</i>	<i>P value</i>	<i>% requiring salvage therapy</i>	<i>P value</i>	<i>Median survival (months) with stable ED</i>	<i>P value</i>
Sneed ⁸⁹	SRS alone	268	NA	NA	37%	$P > 0.01$	8.2 months	$P = \text{NS}$
	SRS + WBRT	301	NA		7%		8.6 months	
Flickinger ¹⁰²	SRS alone	51	53%	$P = 0.004$	NA	NA	NA	NA
	SRS + WBRT	65	81%		NA		NA	
Pirzkall ¹⁰³	SRS alone	158	72%	$P = 0.13$	NA	NA	5 months	$P = \text{NS}$
	SRS + WBRT	78	86%		NA		6 months	
Sneed ¹⁰⁵	SRS alone	62	42%	$P = 0.008$	40%	$P = 0.02$	11.3 months	$P = \text{NS}$
	SRS + WBRT	43	63%		19%		11.1 months	
Chidel ¹⁰⁴	SRS alone	78	52%	$P = 0.034$	NA	NA	10.5 months	$P = 0.079$
	SRS + WBRT	57	80%		NA		6.4 months	
Shehata ¹⁰⁶	SRS alone	228	87%	$P = 0.0001$	NA	NA	NA	NA
	SRS + WBRT	240	97%		NA		NA	
Robinson ¹⁰⁷	SRS alone	68	74%	$P = 0.01$	NA	NA	5.8 months	$P = \text{NS}$
	SRS + WBRT	51	84%		NA		6.1 months	

(KPS) at 3 months (50% versus 33%; $P = 0.02$) and at 6 months (43% versus 27%; $P = 0.03$).

Thus, SRS has a proven survival benefit in addition to WBRT for all RPA class I patients and for select RPA class II patients with stable extracranial disease, young age, or single brain metastases. The benefit of SRS for RPA class III patients (KPS less than 70) has not been proven, as these patients have a historically poor prognosis and have been excluded from the aforementioned randomized trials.

Attempts have been made to delay or exclude WBRT for patients receiving initial SRS for the treatment of brain metastases to minimize treatment-related side effects of WBRT. To date, there have been no randomized trials comparing SRS alone versus SRS + WBRT, although one by the American College of Surgeons Oncology Group (ACOSOG) has recently begun accrual.⁷³ Based on the only randomized trial comparing surgery alone with surgery + WBRT for patients with single brain metastases,⁶⁰ one would expect similar conclusions substituting SRS for surgical resection; namely, no difference in overall survival with immediate WBRT versus WBRT upon recurrence, a decrease in future CNS failure rate with immediate WBRT, and a resultant improvement in neurologic quality of life by decreasing the

risk of further symptomatic brain metastases.⁶⁰ Several retrospective studies have shown an improvement in local control with the addition of WBRT over SRS alone (Table 92.13). None of these studies, however, demonstrated a significant difference in overall survival between the SRS alone versus SRS + WBRT, presumably due to the ability to salvage recurrences with delayed WBRT or repeat SRS.

Radiosensitizing Agents

Several trials of radiosensitizing agents in conjunction with WBRT have been performed. Radiosensitizing agents, by definition, are compounds that increase the lethal effects of radiotherapy but have little activity in the absence of radiation.³⁷ Agents tested in trials include misonidazole (an oxygen mimetic; a hypoxic cell sensitizer), BrdU (bromodeoxyuridine; a halogenated pyrimidine), lonidamine (inhibits cellular respiration), RSR13 (increases oxygen release by hemoglobin; a hypoxic cell sensitizer), and, most recently, motexafin gadolinium (depletes reducing metabolites that may inhibit radiation-induced DNA damage). A summary of Phase II/III radiosensitizer trials is found in Table 92.14. Unfortunately,

TABLE 92.14. Phase II/III trials of WBRT with or without radiosensitizing agents.

<i>Trial</i>	<i>Phase</i>	<i>N</i>	<i>Treatment</i>	<i>Median survival</i>	<i>P value</i>
RTOG 79-16 ¹⁰⁸	Phase III	190	WBRT + misonidazole	3.9 months	$P = \text{NS}$
		193	WBRT alone (3.0 Gy × 10 fractions)	4.5 months	
RTOG 79-16 ¹⁰⁸	Phase III	196	WBRT + misonidazole	3.1 months	$P = \text{NS}$
		200	WBRT alone (5.0 Gy × 6 fractions)	4.1 months	
RTOG 89-05 ¹⁰⁹	Phase III	30	WBRT + bromodeoxyuridine (BrdU)	4.3 months	$P = \text{NS}$
		34	WBRT alone (2.5 Gy × 15 fractions)	6.1 months	
DeAngelis ¹¹⁰	Phase III	31	WBRT + lonidamine	5.4 months	$P = \text{NS}$
		27	WBRT alone (3.0 Gy × 10 fractions)	3.9 months	
Mehta ¹¹¹	Phase III	193	WBRT + motexafin gadolinium	5.2 months	$P = \text{NS}$
		208	WBRT alone (3 Gy × 10 fractions)	4.9 months	
Shaw ¹¹²	Phase II	57	WBRT + RSR13	6.4 months	$P = 0.174$
		1,070	WBRT alone (historical from RTOG database)	4.1 months	

TABLE 92.15. Histology-specific brain metastasis response rates to chemotherapeutic agents.

Primary histology	Response rate	References
Small cell lung cancer	21%–76%	82, 83, 89
Breast cancer	38%–59%	84, 85
Non-small cell lung cancer	23%–33%	85, 86, 88
Melanoma	0%–38%	85, 87, 91

none of the randomized trials showed a benefit of the radiosensitizing agent in addition to WBRT. There was a suggestion of a benefit of RSR13, although this was only a Phase II trial, and Phase III trial results (RT-009) are pending.

Chemotherapy

Many different chemotherapeutic agents have shown activity in the treatment of brain metastases, including etoposide, cisplatin, temozolomide, thalidomide, teniposide, topotecan, vinorelbine, gemcitabine, carboplatin, IL-2, BCNU, and methyl-CCNU (chloroethylnitrosurea).^{74–86} Chemotherapy has historically had limited success in the treatment of brain metastases, presumably because of blood–brain and blood–tumor barriers maintained by tight endothelial junctions and p-glycoprotein-mediated active efflux transport of chemotherapeutic agents away from the CNS.^{15,74,76} Reports that some CNS-penetrating drugs, such as methyl-CCNU have failed to improve survival over WBRT alone in a randomized trial,⁷⁵ suggest that there are other factors involved in brain metastasis response to chemotherapy besides the ability to penetrate the CNS. Inherent tumor histology-specific chemosensitivity also appears to play a role in the differential response rates seen with the use of different agents in the treatment of brain metastases. Chemosensitive small cell lung cancer shows the highest response rates (Table 92.15).

One promising newer chemotherapeutic agent utilized in the treatment of brain metastases is temozolomide, an alkylating agent similar to dacarbazine (DTIC) with CNS-penetrating properties used in the treatment of malignant gliomas. A summary of Phase II/III trials of temozolomide with WBRT for newly diagnosed brain metastases is shown in Table 92.16.

Although most trials have shown an increased response rate with the addition of temozolomide to WBRT in the treatment of brain metastases, none has shown a statistically significant increase in overall survival. Larger multiinstitutional trials are ongoing.

Salvage for Recurrent Brain Metastases

Options for patients with recurrent brain metastases after surgical resection/SRS, and an initial course of WBRT, include further surgical resection, repeat SRS, repeat WBRT, and chemotherapy. Surgical resection tends to be reserved for those patients with significant mass effect symptoms from their recurrent brain metastases. Several retrospective studies of patients undergoing surgical resection for recurrent brain metastases have shown encouraging median survival times after resection, ranging from 6 to 11 months.^{86–88} Of the remaining options, repeat SRS to the new, previously untreated, metastasis offers the highest control rate of 60% to 90%, similar to control of initial lesions.^{89–92} Lesions previously treated with SRS have been retreated with no apparent added toxicity at cumulative doses up to 39Gy with a minimum interdose interval of 4 months.⁹² The largest reported study of reirradiation of recurrent brain metastases, using a repeat course of WBRT, comes from the Mayo Clinic.⁹³ In this retrospective study of 2,658 patients who received initial WBRT for brain metastases (median dose, 30Gy), 86 received a repeat course of WBRT (median dose, 20Gy in 10 fractions). Seventy percent of reirradiated patients had partial or complete resolution of neurologic symptoms, with a median survival of 4 months after reirradiation. Retreatment appeared to be the well tolerated, with 6% of patients developing radiographic changes consistent with reirradiation and 1 patient developing dementia believed to be secondary to reirradiation. Systemic chemotherapy for recurrent brain metastases appears to be the least successful treatment, with partial responses in 20% to 50% of patients with recurrent brain metastases. The blood–brain barrier-penetrating systemic agent temozolomide appears to have the highest activity.^{73,76,94} A potentially promising chemotherapeutic treatment of recurrent brain metastases involves intraarterial delivery of chemotherapy, with regional blood–brain barrier disruption. In preliminary studies using intraarterial carboplatin and intravenous etoposide, response rates of 79% were obtained with predominantly hematologic toxicities and rare angiographic complications.⁹⁵

TABLE 92.16. Phase II/III trials of WBRT with or without temozolomide for patients with newly diagnosed brain metastases.

Trial	Phase	N	Treatment	Overall response	P value	Median survival	P value
Antonadou ¹¹³	Phase II	25	WBRT + temozolomide	96%	$P = 0.017$	8.6 months	$P = 0.45$
		23	WBRT alone (2.0 Gy × 20 fractions)	67%		7.0 months	
Antonadou ¹¹⁴	Phase III	67	WBRT + temozolomide	53%	$P = 0.039$	8.3 months	$P = 0.18$
		67	WBRT alone (3.0 Gy × 10 fractions)	33%		6.3 months	
Verger ¹¹⁵	Phase II/III	24	WBRT + temozolomide	45%	$P = NS$	18.4 weeks	$P = NS$
		20	WBRT alone	44%		12.5 weeks

Metastatic Cancer to Lung

Jessica S. Donington

Metastasis is the major cause of death in cancer patients. The lungs are the second most frequent site of metastatic disease for all histologies and the sole site of metastasis in 20% of autopsy cases.¹ The presence of pulmonary metastasis implies systemic dissemination of disease and was once considered beyond the realm of surgical cure. It was widely accepted that surgery could provide nothing beyond palliation. We now recognize that metastases that are isolated to the lungs are not consistently associated with the same dismal survival as metastases to multiple sites.² During the past 40 years, surgical resection has become a standard approach for the treatment of pulmonary metastasis in selected histologies. A multitude of series have documented the survival benefits of pulmonary metastasectomy in selected patients.

Despite the vast number of series that propose the benefit of pulmonary metastasectomy, they all share a similar weakness; data in this area are all retrospective. There are no controlled randomized trials comparing surgical metastasectomy to medical therapy or best supportive care. The definitive benefit of surgery has never been proven because no group of unresected patients has clearly been shown to be comparative. Critics of metastasectomy state that only clinically detectable disease is resected and therefore, the majority of patients will recur. This is true: more than 50% of patients will have their disease recur following resection. Critics also argue that only highly selective patients with good performance status and favorable tumor biology undergo resection and these patients would have a prolonged survival with or without surgery. Proponents of metastasectomy counter these arguments by pointing out the universally poor outcome in patients with pulmonary metastases who undergo other curative or palliative therapy.

Following metastasectomy, most patients die of recurrent pulmonary disease, but 20% to 40% of patients survive 5 years. The generally accepted selection criteria for pulmonary metastasectomy include (1) control of the primary tumor, (2) absence of extrathoracic metastasis, (3) the ability to completely resect all metastatic disease, (4) sufficient cardiopulmonary function to tolerate resection, and (5) lack of effective systemic therapy. Advancements in systemic therapy, molecular profiling of tumors, and our understanding of tumor biology continue to mold our treatment strategy.

History

Weinlecher is credited with the first pulmonary metastasectomy in 1882, when he removed a metastatic lung deposit during a chest wall resection for a rib sarcoma.³ Divis performed the first pulmonary metastasectomy as an independent operation in 1927 in Czechoslovakia.⁴ The first such resection in the United States was performed by Barney and Churchill, who performed a right lower lobectomy for metastatic kidney cancer.⁵ The patient survived disease free for 23 years before dying of coronary artery disease. The success of this case and other isolated reports gave credibility to the concept of curative pulmonary metastasectomy. In 1947, Alexander and Haight published a series of 24 pulmonary metastasectomies and formally addressed appropriate selection criteria for the procedure.⁶ In 1965, the Mayo Clinic published a series of more than 200 pulmonary metastasectomies and pointed out the limitations of preoperative radiologic studies in predicting the extent of metastatic disease.⁷ In 1979, Memorial Sloan-Kettering Cancer Center (MSKCC) stressed the prognostic significance between metastases from sarcomas, and those from other histologies, in their series of 622 pulmonary metastasectomies.⁸ Efforts to better refine selection criteria and better define prognostic variables led to the development of the International Registry of Lung Metastasis (IRLM) in 1997. The registry consists of more than 5,000 patients from major thoracic surgery groups around the world and provides the most definitive analysis of clinical prognostic factors for pulmonary metastasectomy to date.⁹ Their findings guide our current treatment protocols.

Surgical Techniques

When discussing techniques for pulmonary metastasectomy, we must address the approach used to access the chest cavity and the mode of removal of the lesion from the lung parenchyma. There are a wide variety of options in surgical approach, including posterolateral thoracotomy, median sternotomy, clamshell thoracotomy (bilateral anterior thoracotomy), or, most recently, by the video-assisted thoracoscopic surgery (VATS) approach (Table 93.1).

TABLE 93.1. Approach for metastasectomy.

<i>Approach</i>	<i>Advantage</i>	<i>Disadvantage</i>	<i>Reference</i>
Posterior lateral thoracotomy	Excellent exposure	Unilateral access Staged operations Postoperative pain	Hazelrigg ⁵⁹ Ponn ⁶⁰ Rusch ¹⁰
Median sternotomy	Bilateral access Single procedure Decreased pain	Poor exposure to left lower lobe and posterior lung fields	Hazelrigg ⁶¹ Johnston ⁶² Roth ¹¹
Clamshell (bilateral anterior thoracotomies)	Excellent exposure Bilateral access Single procedure	Increased postoperative pain Increased chest tube drainage Increased OR time	Cooper ¹² Bains ¹⁴ Shimizu ¹³
Video-assisted thoracoscopic surgery (VATS)	Decreased pain Decreased hospital stay	Unilateral access Staged operations No manual palpation Decreased detection of nodules	Dowling ⁶³ Hazelrigg ⁶⁴ Landrenau ¹⁵ McCormack ¹⁶

Posterior lateral thoracotomy is the standard approach for the majority of pulmonary resections and the original approach used for pulmonary metastasectomy. The main advantage of this approach is excellent exposure to the lung and hilum. Almost any pulmonary procedure can be performed through this incision. The downside of this approach for metastasectomy is that it provides access to only one lung. Unfortunately with access to only one thoracic cavity, patients with bilateral disease are committed to two procedures. Most surgeons stage the thoracotomies from 3 days to 3 months apart. Postoperative pain issues also hamper posterior lateral thoracotomies. Pain issues are handled in the same manner as pain from posterior lateral thoracotomies for other reasons with the use of epidural analgesia and with muscle-sparing procedures. The surgeons at MSKCC advocate performing bilateral thoracotomies at a single setting and believe it can be done safely with these techniques.¹⁰

The median sternotomy was popularized in the 1980s as an approach for pulmonary metastasectomy. It has the advantages of access to both lung fields through a single, well-tolerated incision. The downside of this approach is that it does not provide good access to the posterior lung fields or the left lower lobe. Although most metastasectomies are performed as wedge resections, which are easily performed through a sternotomy, lobectomies can also be performed through this incision. Median sternotomy has the advantage of manual palpation of both lungs. In patients with unilateral disease on preoperative studies, up to one-third of patients can have disease on the opposite side at operation.¹¹

In the 1990s, Cooper and colleagues popularized the clamshell thoracotomy (simultaneous, bilateral anterior thoracotomies) for bilateral lung transplants.¹² It provides excellent exposure to both pleural cavities while being surprisingly safe and well tolerated in even the most debilitated patients. It provides better exposure to lesions in the posterior lung fields and left lower lobe than median sternotomy. Clamshell thoracotomy has been shown to lengthen operative time and increase chest tube drainage and postoperative pain compared to median sternotomy,¹³ but it has not been associated with a significant increase in morbidity or mortality compared to median sternotomy.¹⁴

Most recently, VATS has been advocated for pulmonary metastasectomy. VATS has the advantage of decreased pain and hospital stay compared to standard posterior lateral thoracotomy.¹⁵ The largest disadvantage of the VATS approach is the lack of manual palpation of the lung. VATS for metasta-

sectomy was prospectively evaluated by the MSKCC in the early 1990s.¹⁶ Patients with one or two ipsilateral metastases on preoperative computed tomography (CT) scan were eligible for evaluation. They underwent complete resection by VATS, which was immediately followed by a thoracotomy for manual palpation of the lung. Over half of the patients had additional malignant lesions found at the thoracotomy. This study questioned the utility of VATS for metastasectomy because of the inaccuracy of preoperative staging to accurately identify all nodules. Manual palpation was thought to be vital to detecting and resecting all lesions. As radiographic technology advances with fine-cut helical CT scans, we are able to more accurately detect smaller and smaller lesions preoperatively. A more recent study found that helical CT scans are more sensitive than older scans and can accurately detect 82% of lesions and with 61.5% sensitivity for lesions less than 6mm.¹⁷ Although a VATS trial similar to the one from MSKCC has not been repeated, many surgeons believe that as our radiographic technologies improve, VATS resection may be a viable alternative in certain histologies. Renal cell carcinomas and colorectal cancers tend to produce a smaller number of large nodules. Other histologies, especially sarcomas, may never be good candidates for VATS resection as they have a tendency to present with multiple small nodules, and may always require manual palpation to assure complete resection. It is important for the surgeon to remember that complete resection is the most important prognostic factor in patients undergoing pulmonary metastasectomy and therefore, a complete oncologic resection should never be sacrificed for the short-term benefits of a VATS approach.

Pulmonary metastasectomy should be done with the assistance of single-lung ventilation whenever possible. The lung should be thoroughly palpated, both inflated and completely deflated, to avoid missing any small nodules. The lungs should be completely examined and palpated before and after the resections by both members of the operating team. Although there is no formal margin required, 1 cm circumferentially of grossly normal lung is recommended. Most metastasectomies are performed as a simple wedge resection with standard stapling device. Lesions on the flat surface of the lung, which do not lend themselves to stapled wedge resection, can be removed with precision electrocautery. With this technique, the lesion is cored out with a healthy margin, clipping and ligating large vessels during the dissection. Patients with deep lesions may require segmentectomy, lobectomy, or even pneumonectomy for complete resection.

TABLE 93.2. Long-term survival following complete resection according to disease-free interval (DFI).

DFI	N	Five-year survival (%)	Ten-year survival (%)	Median survival (months)
Overall	4,572	36	26	35
0–11 months	1,384	33	27	29
12–35 months	1,662	31	22	30
36+ months	1,416	45	29	45

Source: International Registry of Lung Metastasis (IRLM).

The value of concurrent lymph node dissection with pulmonary metastasectomy has not been well investigated. Mediastinal lymphadenectomy is a standard procedure for lung cancer resections but is not routinely performed during pulmonary metastasectomy. Mediastinal lymph node metastases, along with pulmonary metastases, carry a poor prognostic value,¹⁸ but it is impossible to determine the true impact of lymphatic metastases on patients with resected pulmonary lesions, because lymphadenectomy has been performed in a small number of patients. If preoperative studies identify mediastinal lymph node involvement, most surgeons would agree that metastasectomy is not indicated. It is likely that PET scanning will help identify some radiographic occult lymph node metastases preoperatively to help provide improved patient selection.

International Registry of Lung Metastases (IRLM)

Over the past 40 years, pulmonary metastasectomy has become recognized as a potentially curative treatment for selected patients. To date, no controlled trial exists comparing metastasectomy to chemotherapy, radiation therapy, or best supportive care for patients with isolated pulmonary metastases, but historical data suggest that unresected lung metastases are uniformly fatal within 2 years.^{19,20} IRLM pooled large numbers of unselected patients and obtained extensive follow-up from the major thoracic oncology centers worldwide. The meta-analysis of these data has helped to clarify the therapeutic benefit of pulmonary metastasectomy.

The ILMR project was launched in 1990 to combine and analyze the experience of major European and American thoracic surgery centers during the past 50 years. It created a database using a single form for each patient. The record included (1) patient identification, (2) features of the primary neoplasm, (3) description of each metastasectomy performed (sequential or staged thoracotomies were treated as a single metastasectomy), and (4) follow-up. Between 1991 and 1995, 5,290 patients were enrolled. Only 84 cases were excluded for

TABLE 93.3. Long-term survival following complete resection according to number of pathologically proven metastases (IRLM).

No. of metastases	N	Five-year survival (%)	Ten-year survival (%)	Median survival (months)
Overall	4,572	36	26	35
1	2,169	43	31	43
2–3	1,226	34	24	31
4+	1,123	27	19	27
10+	342	26	17	26

incomplete data, leaving 5,206 evaluable patients. The largest series is from MSKCC, which submitted their consecutive series of all pulmonary metastasectomies performed in their institution from 1945 to 1995. Variables that were tested for significance included gender, age, number of resected and pathologically proven metastases, disease-free interval (DFI), histology, and site of the primary tumor. Survival was calculated from the time of the initial metastasectomy to the date of last follow-up.

Data from the registry confirmed that the morbidity from metastasectomy is very low and overall perioperative mortality was only 1%. The accuracy of preoperative radiologic testing was only 61%, with 25% of patients having more metastases at the time of resection and 14% having fewer lesions than suspected preoperatively. The accuracy of preoperative evaluation varied among histologies, with osteosarcoma frequently having a higher number of occult lesions, whereas colon cancer had the highest frequency of false-positive lesions.

Completeness of resection was the single most important prognostic factor following pulmonary metastasectomy. The actuarial survival after complete metastasectomy was 36% at 5 years, 26% at 10 years, and 22% at 15 years, with a median survival of 35 months. The median survival for patients with incomplete resections was 15 months; survival at 5 years was 13% and 7% at 10 years.

Disease-free interval (DFI) is the time between the treatment of the primary tumor and the appearance of metastases. Table 93.2 demonstrates 5- and 10-year survival according to DFI. The surprisingly good survival in patients with DFI less than 1 year is mainly due to the patients who presented with synchronous pulmonary metastases. Table 93.3 reports survival by the number of pathologically proven metastases. There was significant survival benefit for solitary lesions compared to multiple lesions. The probability of survival tends to decrease with the number of resected nodules, but very little survival difference was seen between patients who had 4 or more lesions and those with 10 or more lesions.

Table 93.4 reviews survival by primary diagnosis. Germ cell tumors had by far the best survival, 68% at 5 years and 63% at 10 years. It was apparent from the registry data that these represented a separate clinical entity because of the high frequency of complete pathologic response to chemotherapy. These patients were therefore excluded from the multivariate analysis of prognostic factors. Melanomas had the worst survival, 21% at 5 years and 14% at 10 years,

TABLE 93.4. Long-term survival following complete resection according to histology (International Registry of Lung Metastasis, IRLM).

Primary tumor	N	Five-year survival (%)	Ten-year survival (%)	Median survival (months)
Overall	4,572	36	26	35
Osteosarcoma	734	33	27	40
Soft tissue sarcoma	938	30	22	27
Colorectal	653	37	22	41
Breast	411	37	21	37
Renal cell	402	41	24	41
Melanoma	282	21	14	19
Germ cell	318	68	63	Not reached

with a median survival of 19 months. There was no significant difference in survival between epithelial tumors (37% at 5 years, 21% at 10 years) and sarcomas (31% at 5 years, 26% at 10 years). There were survival differences among the specific histologies of sarcoma and the various sites of epithelial cancers.

Of completely resected patients, 53% had a documented recurrence. Sarcomas (64%) and melanomas (64%) recurred more frequently than epithelial (46%) or germ cell tumors (26%). The majority of sarcomas relapsed in the lungs (66%), whereas 73% of melanoma relapses were extrathoracic. An intermediate pattern of relapse was seen in epithelial and germ cell tumors. The median time to recurrence was 10 months and was shorter in sarcomas (8 months) than epithelial tumors (12 months).

Twenty percent of patients underwent multiple metastasectomies. Repeat pulmonary metastasectomy was more common in sarcomas (53%) than in other histologies, as one might predict from their pattern of relapse. The median interval between first and second metastasectomy in sarcomas was 10 months. Long-term survival for patients who underwent repeat pulmonary metastasectomy was 44% at 5 years and 29% at 10 years. These survivals are better than those seen in patients who underwent a single operation (34% at 5 years and 25% at 10 years). Better survivals can be attributed to both the improved selection criteria of patients offered redo surgery (good performance status and limited disease) and the real salvage benefit of repeat resection.

One of the goals of the IRLM was to establish a new staging system that would be simple, discriminant, and valid across histologies. Complete resection was the single most important prognostic factor. The new classification system combined the DFI, number of nodules, and completeness of resection into a simplified reliable system that could be used to predict long-term survival across histologies. Among resectable lesions, a DFI greater than 36 months and solitary metastases were seen as independent risk factors for improved outcome. Table 93.5 demonstrates the four distinct prognostic groups based on these factors. The median survival for group I was 61 months, 34 months for group II, 24 months for group III, and 14 months for group IV (P less than 0.00001). The prognostic grouping was highly significant for the entire group and in each specific tumor histology. The log rank χ^2 was 131.8 for epithelial tumors, 118.8 for bone sarcomas, 77.4 for soft tissue sarcomas, and 29.6 for melanomas.

By combining data from the leading thoracic surgical centers, the IRLM was able to collect a large number of metastasectomies from a broad spectrum of primary diseases

TABLE 93.5. International Registry of Lung Metastasis (IRLM) system of prognostic grouping.

Group	Description
I	Resectable, no risk factors: DFI > 36 months and single metastasis
II	Resectable, one risk factor: DFI < 36 months <i>or</i> multiple metastases
III	Resectable, two risk factors: DFI < 36 months and multiple metastases
IV	Unresectable

and with extensive follow-up. The analysis verified the low morbidity and mortality associated with metastasectomy and the inaccuracy of radiology studies to accurately stage patients. Thorough intraoperative staging by an experienced thoracic surgeon is required to optimize resection of all nodules. The proposed prognostic groups are based on easily available clinical data and represent a simple and discriminate system to classify these patients. Further confirmation of the validity of the system is planned.

Osteosarcoma

The disease model for surgical removal of pulmonary metastases is osteogenic sarcoma. High-grade osteosarcoma is a malignant bony tumor with a peak incidence in the second decade of life. Historical data demonstrate that although 80% of patients present with localized disease, 80% of those treated with amputation alone will develop pulmonary metastases within 2 years and none of those untreated will survive to 5 years.^{21,22} In the absence of effective chemotherapy or radiotherapy, MSKCC led the way in developing a strategy for pulmonary metastasectomy in these young patients. In a series from 1971, 29 patients were treated with surgical metastasectomy; they demonstrated a 32% 5-year survival in the 22 patients who had a complete resection.²³

Over the past two decades, the prognosis for patients with localized osteosarcoma has improved considerably with the development of effective chemotherapeutic regimens. The event-free survival for patients who present with localized disease, treated with neoadjuvant chemotherapy and resection, is estimated to be 44% to 78% at 5 years.^{24,25} The lungs remain the most frequent site of recurrence, but an increased frequency of bony metastases is seen following chemotherapy.²⁶⁻²⁸ Complete resection remains the most important prognostic factor following metastasectomy (Table 93.6).²⁵

DFI and number of metastases found at resection have proven to be significant in numerous series. Neoadjuvant chemotherapy has led to an increased time to the development of lung metastases and a reduction in the number of lung lesions, helping to facilitate complete surgical resection.^{26,27} The combination of effective systemic therapy and the refinement of surgical indication and techniques have greatly enhanced the outlook for these young patients. The role of second-line, salvage chemotherapy for recurrence is an area still being investigated.²⁹

Soft Tissue Sarcoma

Soft tissue sarcomas are relatively uncommon, with 8,000 new cases and 4,600 deaths annually in the United States.³⁰ The lung is the most common site of metastases in patients with extremity soft tissue sarcomas; 20% of patients will develop isolated pulmonary metastases, and the majority of metastases occur in the first 2 years following diagnosis with a median time to development of 14 months.³¹ Features of soft tissue sarcomas that are associated with a propensity to metastasize include extremity location, large size, and high grade.³² The most common soft tissue tumors to develop pulmonary metastases are malignant fibrous histiocytoma (MFH) (23%), synovial-cell sarcoma (19%), and leiomyosarcoma (15%).²⁴

Approximately one-third of patients are symptomatic at diagnosis.³³ The most common symptoms are cough and hemoptysis. The majority of patients are asymptomatic at diagnosis and have lesions detected on an abnormal chest radiograph or CT scan. Patients with soft tissue sarcomas are 10 times more likely to develop pulmonary metastases than a primary lung cancer,³⁴ and therefore, any new pulmonary

lesions should be considered metastatic until proven otherwise.

Many series have documented survival benefit following metastasectomy in soft tissue sarcoma (Table 93.7). Complete resection is the most significant predictor of long-term survival. Attempts have been made to further identify prognostic markers in resectable patients. Factors that appear to be associated with improved survival include prolonged DFI, low histologic grade, young age, tumor depth, doubling time, number of nodules, MFH, and unilateral disease. Features associated with poor prognosis include liposarcoma, malignant peripheral nerve sheath tumor, and large tumor size.

Renal Cell Carcinoma

Renal cell carcinomas affect approximately 25,000 patients yearly in the United States, representing about 3% of all malignancies.² Up to one-third of patients have metastatic disease at the time of diagnosis,³⁵ and half of the remaining patients will develop metastases following nephrectomy.³⁶ The lungs are the second most common site of metastatic spread. The lack of effective chemotherapy, radiation therapy, or immunotherapy for metastatic renal cell carcinoma justifies an aggressive approach to surgical resection. Five-year survival for patients with unresected metastatic renal cell cancer is 2.7%.³⁷ Numerous series have been published on pulmonary metastasectomy for renal cell carcinoma, and 5-year survival rates range from 30% to 60% (Table 93.8). The studies are unanimous in the recognition that the completeness of resection is the most important factor affecting survival. The DFI, number of lesions, and lymph node involvement have less of a prognostic impact. Survival after

Pfannschmidt ⁷⁸	2002	Heidelberg	191	42%	22%

repeat thoracotomy for recurrent pulmonary metastases does not differ from survival following first complete resection. Pulmonary metastasectomy is a safe and effective treatment for metastatic renal cell carcinoma.

Colorectal Cancer

Colorectal cancer is one of the most common malignancies in the United States. It is the third most common cancer in both American men and women.³⁸ The lungs are the second most common site of metastases from colorectal cancers, but only 10% of patient with pulmonary disease have isolated pulmonary metastases and are possible candidates for resection.³⁹ The first pulmonary resection for metastatic colorectal cancer was performed by Blalock in 1944.⁴⁰

There are numerous series of patients undergoing resection of pulmonary metastases from colorectal cancers with 5-year survivals ranging between 16% and 56% (Table 93.9). The most important prognostic factor in all series is the completeness of resection. Other significant predictors of survival in selected series include the number of metastases,⁴¹⁻⁴³ DFI,⁴⁴ and serum levels of carcinoembryonic antigen (CEA).^{41,45} The location, stage, and grade of the primary tumor do not appear to have any influence on survival following metastasectomy.

Spread of colorectal cancers to the liver is very common, occurring in approximately 50,000 patients per year in the United States.⁴⁶ Similar to lung metastases, only a small proportion of patients with liver metastases are candidates for resection, but also similar to pulmonary metastases survival after hepatic metastasectomy is 25% to 40% at 5 years.⁴⁷ Colorectal cancer provides a unique therapeutic dilemma where patients can have surgically curable metastases in two different organs. Untreated, survival is dismal for either isolated pulmonary or hepatic metastases. Limiting surgical resection to patients with single-organ metastases may be denying some patients a chance for long-term survival. Several studies have been published addressing combined liver and lung resection for metastatic colorectal cancers (Table 93.10). The most common sequence of presentation is to have hepatic metastases that are resected and then develop lung metastases,⁴⁸ but these series also contain patients who presented with lung lesions first or simultaneous metastases. Survival following resection from both sites is comparable to survival from either site alone.

Melanoma

Melanoma is widely recognized as the most lethal skin cancer. The lungs are the most common site of initial presentation of metastatic disease,² and 30% to 50% of patients

TABLE 93.9. Pulmonary metastasectomy for colorectal carcinoma.

Author	Year	Institution	No. of patients	Complete resection: 5-year survival

Saeter ⁶⁶	2002	Kansai	165	40%

with stage IV disease have pulmonary metastases.⁴⁹ Long-term survival for melanoma patients with pulmonary metastases is dismal with less than 5% surviving for 5 years.⁵⁰ Unfortunately, no effective chemotherapy, radiation, or immunotherapy exists. Surgery offers a small chance for control of disease. Numerous small series have documented occasional long-term survivors among patients who have undergone pulmonary resection for isolated metastases from melanoma (Table 93.11). The overall outcome for patients who undergo complete metastasectomy remains poor, and therefore, surgeons have continued to seek factors that will better identify patients who are likely to benefit from resection. Data from both Harpole et al.⁵⁰ and IRLM suggest that patients with complete resections, longer DFI, and solitary metastases do better overall. Progrebniak's series from the National Cancer Institute (NCI), demonstrated an important aspect of care in these patients in that 30% of patients in their series with new pulmonary nodule on serial studies were found to have nonmetastatic lesions at exploration.³⁶ The majority of these were benign. They thought that melanoma patients with a new pulmonary nodule who are surgical candidates should be explored for diagnosis and to attempt complete resection.

New and Evolving Treatments

Only a small proportion of patients with pulmonary metastases are candidates for metastasectomy. Many patients have disease isolated to the lungs but are either not fit candidates for thoracic surgery or have unresectable lesions. Many new and evolving treatments are being investigated for patients who are not candidates for standard resection.

Isolated Lung Perfusion

In general, systemic toxicity limits the amount of chemotherapy that can be given to an individual. New drug delivery systems, such as isolated pulmonary perfusion, may enhance chemotherapeutic treatment effects by increasing drug concentrations in the lung tissue and decreasing systemic toxicity. Isolated limb perfusion with hyperthermia and chemotherapy has become an accepted treatment strategy for locally advanced malignant melanoma. Animal studies have demonstrated that, with pulmonary artery and vein cannulation, the pulmonary vascular system can be isolated from the systemic system and chemotherapeutic agents can be infused at higher levels than systemically tolerable. This technique results in higher tissue concentrations within the lung.^{51,52} Isolated pulmonary perfusion has been performed in clinical trials by using continuous infusion techniques. These procedures are cumbersome, but safe, producing elevated tissue concentration of drugs without associated systemic toxicity. Unfortunately, clinical responses have been variable (Table 93.12). Acute and late lung injury was noted in most series with a decrease in FEV₁ and diffusion capacity (DLCO). The pathophysiology of the lung injury may be secondary to elevated drug levels or to ischemia associated with the procedure. Modifications in perfusate solution could help to limit this injury.

Isolated lung perfusion may prove to be a useful system for gene delivery to the lung. Animal models have been used to study human tumor necrosis factor (TNF)-alpha gene delivery for the treatment of pulmonary sarcoma metastases.⁵³ The technique of isolated lung perfusion is still experimental. The ability to modulate the drug dose, concentration, and perfusate composition will help to provide safer and more effective outcomes. There remains a paucity of effective treatment for pulmonary metastases and, despite the lack of overwhelming clinical benefit to date, isolated lung perfusion warrants further clinical investigation.

Inhalation Therapy

Inhalation therapy has been used most commonly in the treatment of patients with pulmonary metastases from renal cell carcinoma. Inhaled interleukin 2 (IL-2) is given in doses of 18 to 36 million IUs, alone or in combination with other systemic therapy. It is associated with a decrease in the progression of pulmonary metastases in renal cell, ovary and breast carcinomas, and melanomas.⁵⁵ Therapy is well tolerated, the main toxicity being a dose-dependent cough. High-dose IL-2 (36 million IUs/day) with single-agent dacarbazine was studied in 27 patients with malignant melanoma.⁴⁸ Five patients had complete response and partial response was seen in 8 patients. Extrapulmonary metastases do not respond to treatment. Inhalational IL-2 appears to be a promising strategy that will allow prolonged therapeutic response and a potential long-term survival advantage to patients with isolated pulmonary metastasis with low toxicity.

Radiofrequency Ablation

Radiofrequency ablation (RFA) applies thermal energy via a catheter delivery system, resulting in coagulation necrosis. Its use is widely accepted for the treatment of unresectable liver tumors, and is now being explored for destruction of solid tumors in other locations, including the lung. Animal models investigating the histologic effects of RFA on pulmonary parenchyma revealed that tumors can be effectively ablated with minimal damage to surrounding lung.⁵⁶ A pilot study from the University of Pittsburgh, evaluated RFA in patients with unresectable lung tumors [5 with non-small cell lung cancer (NSCLC) and 13 with pulmonary metastases]. There was 1 death following treatment. A better radiographic response was seen in lesions smaller than 5 cm. After a mean follow-up of 6 months, lesions that had radiographic treatment effect did not demonstrate regrowth, but 9 of the 13 developed new sites of metastatic disease, and 6 (46%) died.⁵⁷

TABLE 93.12. Isolated lung perfusion for pulmonary metastases.

Author	Year	No. of patients	Agents	Complications	Response
Johnston ⁵⁴	1995	8	Doxorubicin/CDDP	25%	0%
Ratto ⁸⁵	1996	6	Resection + CDDP	33%	N/A
Pass ⁸⁶	1996	15	TNF + interferon	20%	33%
Burt ⁵²	1998	8	Doxorubicin	0%	0%
Putnam ⁸⁷	2000	16	Doxorubicin	19%	6%

CDDP, cisplatin; TNF, tumor necrosis factor.

Pulmonic RFA is still new but it appears to be a promising treatment option for patients with isolated pulmonary metastases who are not resection candidates.

Stereotactic Radiosurgery

Stereotactic radiation is a method of delivering highly focused external-beam radiation using a compact fractionation schedule. The techniques are well established for intracranial neoplasms and have replaced surgical resection for many intracranial neoplasms but are a novel approach to treating tumors in the lung. Treatment uses a 6-Me LIAC (6 megavolt linear accelerator) on a robotic arm. A gold fiducial is percutaneously placed within pulmonary lesions to guide treatment and decrease treatment to surrounding tissue secondary to respiratory motion. Results from a Phase I trial at Stanford University, in patients with solitary lung tumors who were not candidates for resection (14 NSCLC, 9 metastases) show 25% stable disease, 40% partial response, and 35% complete response at median follow-up of 8 months.⁵⁸ Long-term follow-up is necessary to determine the overall toxicity and efficacy of treatment.

Conclusion

There is a wealth of retrospective data demonstrating the benefit of pulmonary metastasectomy compared to other treatment modalities for isolated pulmonary metastases, but there remains a lack of randomized clinical trials demonstrating the benefit. The IRLM has provided us with a large database with extensive follow-up to evaluate this issue. Data from the IRLM and countless smaller series demonstrate that metastasectomy can be performed with minimal morbidity and low mortality. In selected histologies, metastasectomy provides a survival advantage over other therapies. The completeness of resection is the single most significant prognostic variable across all histologies. The DFI and number of metastases appear to be the next most significant variables. Using these three variables, prognostic groups have been constructed, with patients with respectable single lesion and DFI greater than 36 months having the greatest chance for cure. The majority of patients treated with pulmonary metastasectomy will eventually die of their metastatic disease, and therefore work continues to refine selection criteria and on new treatment modalities.

Surgical and Regional Therapy for Liver Metastases

Kenneth K. Tanabe and Sam S. Yoon

The liver is a frequent site of metastases from solid tumors and the most common site of distant metastases from colon and rectal cancer. Death from colon and rectal cancer is usually a result of metastatic disease. In one study, more than one-half of patients who died of colon and rectal cancer had liver metastases at autopsy, and the majority of these patients died as a result of their metastatic liver disease.¹ Unlike many types of cancer, however, the presence of distant metastases from colon and rectal cancer does not necessarily preclude curative treatment. Nearly 40% of patients with colon and rectal cancer and hematogenous metastases have disease that is predominantly in the liver.² Moreover, in a subpopulation of patients, the number of lesions is limited. Accordingly, there exists a strong rationale for regional therapies directed specifically against colon and rectal cancer liver metastases. This pattern of metastases is rarely observed in other cancers.

Resection is the most effective regional therapy for patients with colon and rectal cancer liver metastases, and this treatment leads to long-term survival in a defined subset of patients. Other regional therapies, such as cryosurgery, radiofrequency ablation (RFA), and hepatic artery infusion (HAI) chemotherapy, have been used, mainly for patients whose liver metastases are unresectable. Although ablative therapies and HAI chemotherapy hold promise, their ability to either improve quality of life or overall survival has not been convincingly demonstrated in prospective trials. Regional hepatic therapies are of much less value for patients with liver metastases from other types of cancer. Accordingly, this chapter focuses mainly on regional therapies for patients with colon and rectal cancer.

Natural History of Colon and Rectal Cancer

Understanding the natural history of colon and rectal cancer liver metastases sets a framework from which to assess the value of various treatments. Natural history data are increasingly more difficult to come by, as the vast majority of patients with this condition are treated with some form of therapy. Thus, many of the data on natural history come from studies conducted primarily in the 1960s and 1970s. Median survival for patients with colon and rectal cancer liver metastases was found to be between 5 and 9 months.³⁻⁸ However,

in these older studies, the majority of patients had advanced disease diagnosed without the advantage of modern-day imaging techniques. A few retrospective studies have assessed the survival of patients with potentially resectable colon and rectal cancer liver metastases that were left untreated. Wilson and Adson reported no 5-year survivors among patients with untreated but potentially resectable liver metastases compared to a 28% 5-year survival for patients with resected liver metastases.⁹ A subsequent study found 5-year survival rates in similar groups of patients to be 2% and 25%, respectively.¹⁰ In another study, patients with untreated but potentially resectable liver metastases had a mean survival of 21.3 months with only 1 of 13 patients surviving 5 years.¹¹ Wanebo et al. found that patients with an untreated single liver metastasis had a median survival of 19 months and no patients survived 5 years, whereas patients with a resected single liver metastasis had a median survival of 36 months and 25% of patients survived 5 years.¹²

Conclusions that can be reached from these studies are limited because of their retrospective patient identification and relatively insensitive methods for assessment of extent of disease. However, one can conclude that patients with a limited number of liver metastases survive longer than patients with more extensive liver metastases. Another conclusion is that 5-year survival is highly uncommon for patients with untreated liver metastases from colon and rectal cancer. Improvements in the quality of imaging in more recent years combined with more widespread use of imaging has led to earlier detection of liver metastases in the years since these original studies on natural history. Accordingly, recent "improvements" in the natural history of colon and rectal carcinoma liver metastases are expected solely as a result of earlier diagnosis.

Patient Evaluation

One of the greatest challenges to the decision-making skills of a surgeon comes with intraoperative detection of colon or rectal cancer liver metastases. The decision whether to include regional therapy during surgery for the primary tumor is a function of many variables: the surgeon's experience, the anatomic location of the liver lesions, the thoroughness and quality of intraoperative assessment of the distribution of

liver metastases, the location of the primary tumor and the difficulty of the operation to remove the primary tumor, the anticipated morbidity of adding a regional therapy to the operation, and an understanding of the values and goals of the patient and family based on preoperative discussions. A decision whether or not to intraoperatively biopsy a liver lesion should be made with careful consideration of the consequences. In patients with clinically obvious liver metastases that are clearly not candidates for curative hepatectomy, core biopsy or incisional biopsy of one lesion to histologically confirm its nature is indicated. In contrast, in a patient with potentially resectable liver metastases, biopsy is not justified if the lesions appear to be obvious metastases based on clinical inspection. The risk of implanting tumor cells into the abdominal cavity or abdominal wound after an incisional biopsy, represents an unnecessary risk in a patient that has the opportunity to undergo potentially curative hepatectomy.

For patients who will undergo systemic chemotherapy rather than regional therapy as their treatment, mere confirmation of the presence and volume of metastases on computed tomography (CT) scan is sufficient. But when considering regional treatment strategies, patient evaluation necessarily focuses on evaluation of the extent and anatomic distribution of anatomic disease, the presence or absence of extrahepatic disease, underlying liver function, and medical comorbidity.

Candidates for regional therapies, including liver resection, should undergo a detailed history and physical examination, hematology and chemistry panels, liver function tests, chest X-ray, and abdominal and pelvic CT scans. Physical findings and clinical symptoms are the least reliable and least sensitive method of diagnosing liver metastases. An elevated carcinoembryonic antigen (CEA) value may be the first sign of colon or rectal cancer liver metastases and may hold prognostic value.^{13,14}

In recognition that 5% of patients with colon and rectal cancer develop metachronous primary colon and rectal cancers,¹⁵ strong consideration should be given to colonoscopy if not done within the past 12 to 24 months to exclude recurrence of the original primary colon and rectal cancer or development of a second primary colon and rectal cancer.

Chest CT scans in patients considered for regional therapy of liver metastases are of small but defined benefit in the setting of a normal chest X-ray. A retrospective study of patients with colon and rectal cancer liver metastases, without evidence of pulmonary metastases on chest X-ray, demonstrated that chest CT had a positive yield of only 4% and a positive predictive value of 36% for lung metastases.¹⁶ However, if one modifies the manner in which these data are integrated into patient management decisions, the value to improving patient care is greater than that suggested by the authors of this study. If one sets a higher threshold for chest CT findings that alter management, the specificity will consequently improve. Along those lines, the writers of this chapter routinely obtain chest CT scans in patients considered for hepatic regional therapy. Treatment decisions are altered for findings that have a high probability of representing pulmonary metastatic disease. In patients with indeterminate findings, such as small, nonspecific lesions, management is not altered and the study serves as a baseline for future comparison.

For liver resection and ablation therapies, precise anatomic localization of liver tumors is important. Magnetic resonance imaging (MRI), CT, and intraoperative ultrasound are used frequently for this purpose and have been compared in numerous studies.¹⁷⁻³¹ Positron emission tomography (PET) studies provide a physiologic survey for hypermetabolic tumors to complement these anatomic imaging studies. Imaging technology continues to rapidly improve. For example, faster image acquisition times, greater numbers of detectors on CT scanners (e.g., multidetector CT), postprocessing algorithms, and MRI contrast agents have dramatically improved image quality.

Abdominal CT scans remain the most commonly used modality for the assessment of the number, size, and anatomic distribution of liver metastases. Although normal liver is perfused primarily by the portal vein, liver metastases are perfused principally by the hepatic artery.³² Therefore, on CT images obtained during the portal venous phase following intravenous contrast administration, hypoattenuated liver metastases are more easily recognized.³³

MRI is being increasingly utilized for the diagnosis and characterization of liver lesions, particularly now that liver-specific contrast agents and dynamic scanning have been incorporated. Additional improvements in MRI, include availability of high field strength magnets, use of phased array coils, multiplanar capability, breath-hold acquisition, fat saturation, and three-dimensional imaging. Liver-specific contrast agents increase the imaging window for evaluation of liver and thus permit acquisition of high-resolution thin sections through liver. One liver-specific contrast agent, manganese pyridoxyl diphosphate (Mn-DPDP), is a paramagnetic agent taken up preferentially by hepatocytes and excreted in the bile. Normal liver parenchyma is markedly enhanced on T₁-weighted images, whereas metastases do not enhance.³⁴

PET imaging has improved markedly over the past decade, and many centers routinely incorporate PET imaging results into their decisions on whether to pursue regional therapy. Many studies have focused on the diagnostic yield of fluorodeoxyglucose (FDG)-PET in staging patients with liver metastases from colon and rectal cancer, but have generally suffered from retrospective analysis concerning clinical management decisions.²⁴⁻³¹ In a prospective study of 51 patients analyzed for resection of colon and rectal cancer liver metastases by conventional diagnostic imaging and FDG-PET, clinical management decisions based on conventional diagnostic imaging were changed in 10 (20%) of 51 patients after FDG-PET findings were known. Eight patients were spared unwarranted liver resection or laparotomy, and 2 other patients were identified as candidates for liver resection. One patient was falsely upstaged.³⁵

Transabdominal ultrasound is a relatively inexpensive modality but misses up to 50% of liver metastases.³⁶ It has essentially no role in the preoperative evaluation of potential liver resection candidates. However, many studies have shown the superiority of intraoperative ultrasound (IOUS) in the detection of liver lesions as compared to helical CT or MRI.³⁷⁻⁴³ In addition, IOUS findings have been observed to change surgical management in 11% to 33% of patients.³⁷⁻⁴³ The proportion of patients in which IOUS changes management may be dropping as a result of improvements in MRI imaging.^{44,45} In a study of 79 patients treated at the Massachusetts General Hospital (MGH) who underwent

FIGURE 94.1. Intraoperative ultrasound image demonstrating the relationship between the tumor (*T*) located in segment VII and the inferior vena cava (*IVC*) and right hepatic vein (*RHV*). (By permission of Yoon SS, Tanabe KK. In: *Cancer of the Lower Gastrointestinal Tract*. London: Decker, 2001.)

contrast-enhanced MRI examination within 6 weeks of surgery, 10 had unsuspected liver metastases detected by IOUS examination. Surgical management was altered in only 3 of these patients by these findings.⁴⁴ Although the likelihood of new findings with IOUS examination is low, this imaging modality has other advantages. IOUS defines the location of hepatic vessels to allow segmental localization and accurately assesses the anatomic relationship between hepatic lesions and blood vessels (Figure 94.1). Additionally, small subcentimeter hepatic lesions, which could not be characterized on preoperative MRI, can be characterized on IOUS. IOUS guidance is required for RFA (see following) and aids with biopsy of small liver lesions. Most liver surgeons perform IOUS in all patients who undergo resection of colon or rectal carcinoma liver metastases.

Angiograms were once required preoperatively for patients who may undergo placement of a hepatic artery infusion pump. However, recent studies have demonstrated the accuracy of CT angiograms in which the hepatic arterial anatomy is reconstructed from either MRI or CT scans.^{46,47}

Laparoscopy, sometimes combined with laparoscopic ultrasound, is increasingly used for preoperative evaluation of metastatic disease. Because the quality of liver imaging with CT or MRI scan has improved so dramatically over the past decade, the principal value of laparoscopy is now for detection of radiographically occult peritoneal metastases. Laparoscopy with laparoscopic ultrasound may change the intraoperative treatment plan.⁴⁸ In one study of 24 patients with liver tumors judged preoperatively to be resectable by conventional imaging studies, laparoscopy, combined with laparoscopic ultrasound, identified 6 patients who were in fact unresectable and avoided laparotomy in these patients.⁴⁹ The frequency with which laparoscopic findings alter intraoperative management is clearly a function of the quality of

other imaging used before laparoscopy. The writers of this chapter have found a much lower incidence of unresectable metastases during laparotomy, when MRI with Mn-DPDP is used as the primary preoperative imaging study.⁴⁴

Liver Resection

Techniques

Liver resections are performed based on the liver's functional anatomy as described by Couinaud,⁵⁰ who described anatomic division of the liver into eight segments defined by hepatic veins and portal vessels (Figure 94.2). In addition to the main hepatic veins, small hepatic veins drain directly from the posterior surface of the liver (including the caudate) directly into the inferior vena cava. The left and right triangular ligaments, coronary ligament, and the falciform ligament secure the liver to the diaphragm. Precise knowledge of the surgical anatomy of the liver, its blood vessels, and its biliary drainage system are mandatory for liver surgery.

The commonly performed major hepatic resections (Figure 94.3) include right hepatectomy, left hepatectomy, right trisegmentectomy (sparing segments II and III), left trisegmentectomy (sparing segments VI and VII), and left lateral segmentectomy (resection of segments II and III).^{51,52} There is no advantage to performing a major resection when removal of one or more segments can eradicate all metastases with an adequate margin. In fact, often one or more segmental resections can spare more normal liver than a major resection or allow resection of metastases not encompassed by a traditional major resection. Anatomic segments of the liver can be delineated intraoperatively to allow removal of individual segments. In the absence of underlying liver dysfunc-

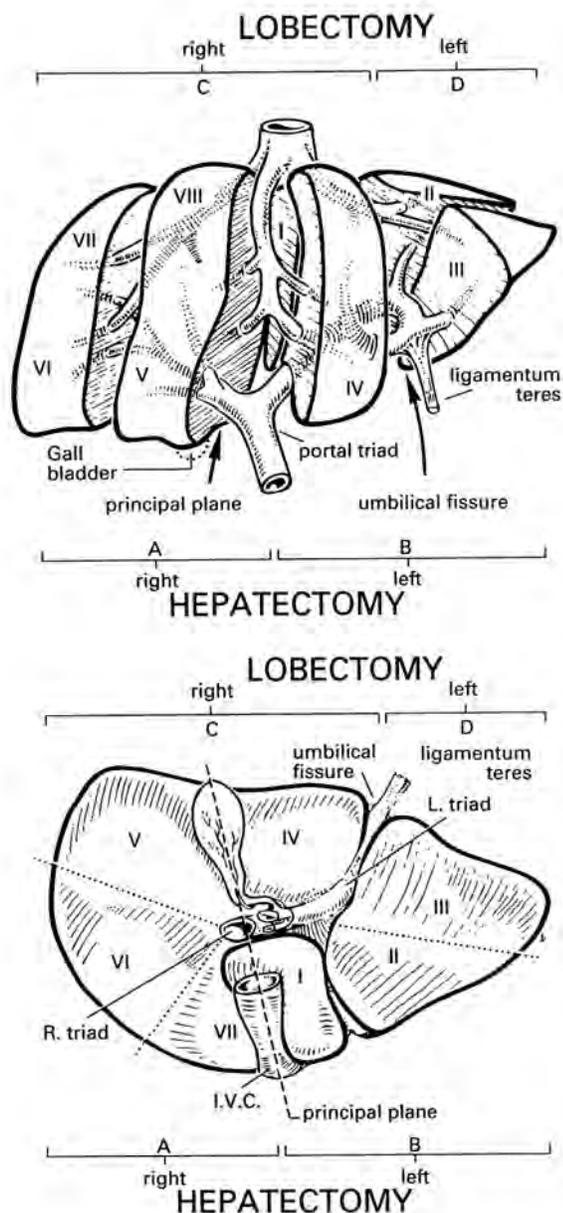

FIGURE 94.2. Functional anatomy of the liver. A schematic view of the liver demonstrates segments I–VIII, as described by Couinaud. (Adapted from Blumgart,⁵¹ by permission of Churchill Livingstone.)

tion, up to 75% of the liver can be removed without subsequent hepatic failure.⁵³

The operation to resect liver metastases starts with an exploratory laparotomy. Attention is paid to possible extrahepatic sites of disease, such as portal lymph nodes and peritoneum, and any suspicious areas are biopsied for frozen section analysis. The liver is then fully mobilized by dissection of its supporting ligaments and palpated to identify lesions. Intraoperative ultrasonography is performed to identify unsuspected metastases and to determine the anatomic relationship between metastases and major vascular structures.^{44,45}

In situations where the tumors are located well away from the porta hepatis, the entire right or left portal pedicle may be ligated en masse away from the hepatic duct confluence,

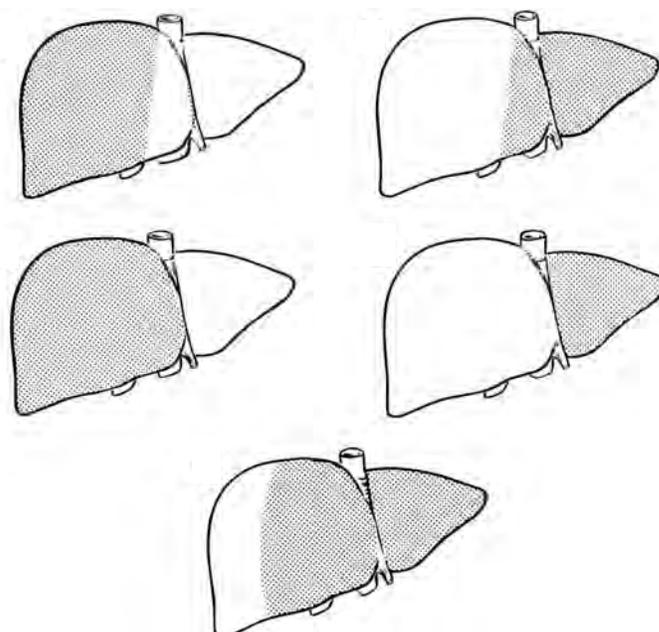

FIGURE 94.3. Commonly performed liver resections.

thus avoiding problems with anatomic variations in this area.⁵⁴ Following liver mobilization, the hilar plate is lowered with sharp dissection. To isolate the main right portal pedicle, incisions into the liver are made in the gallbladder fossa and in the caudate lobe immediately parallel to and 5 mm to the right of the inferior vena cava (Figure 94.4). An umbilical tape is passed around to completely encircle the portal pedicle, which may be either clamped or stapled with a TI-30 or Endo GIA stapler with a vascular cartridge (Figure 94.5). It is important to keep the umbilical tape between the stapler and the confluence of the hepatic ducts to avoid injury to the left hepatic duct. It is also important to have the right liver fully

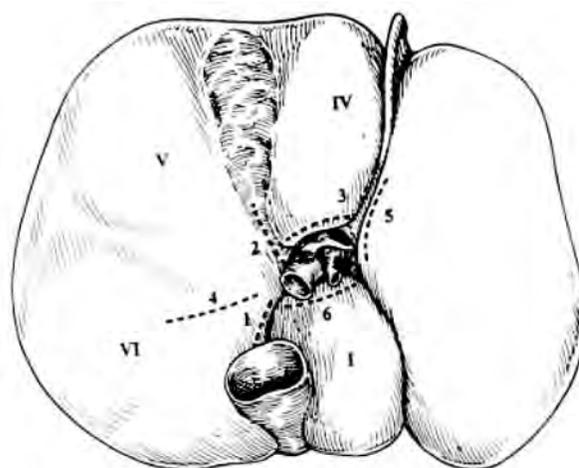

FIGURE 94.4. Sites for hepatotomy in portal pedicle isolation. The undersurface of the liver is illustrated. The *dotted lines* indicate sites for hepatotomy if control of the intrahepatic portal pedicles is desired. Incision at 3 allows lowering of the hilar plate. Incisions at 1 and 2 allow control of the main right pedicle. Incisions at 1 and 4 allow control of the right posterior pedicle. Incisions at 2 and 4 allow control of the right anterior pedicle. Incisions at 3 and 5 allow control of the left pedicle. (From Fong and Blumgart,⁵⁴ by permission of *Journal of the American College of Surgeons*.)

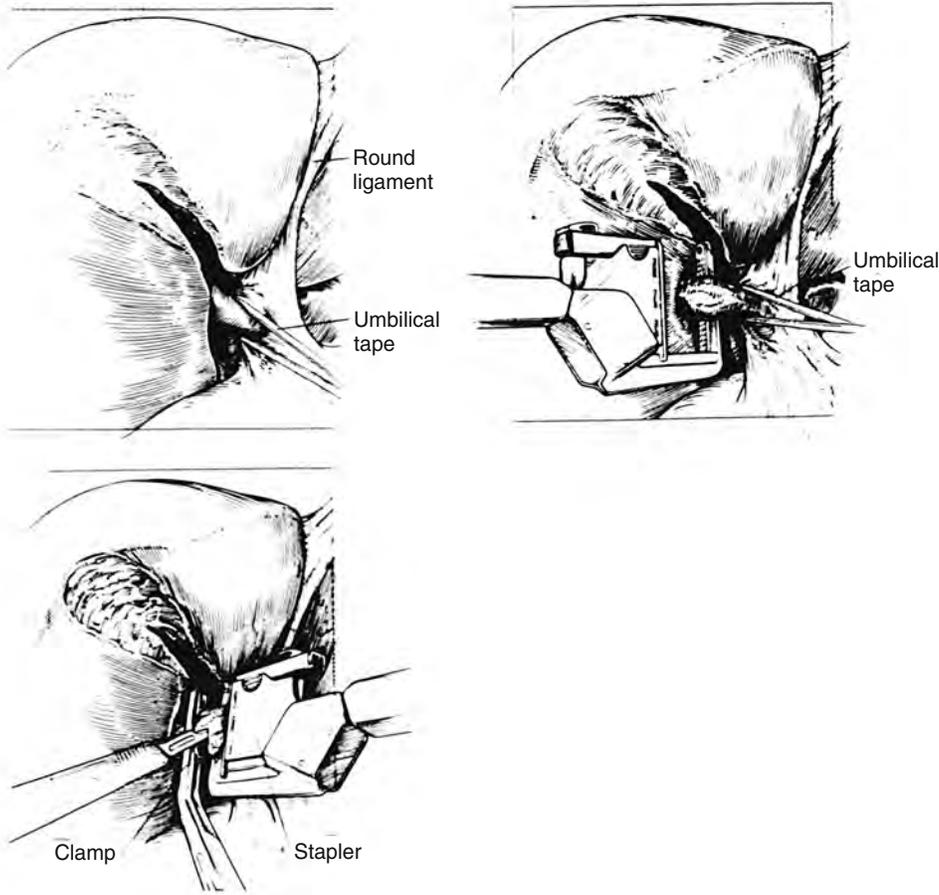

FIGURE 94.5. Control of the right portal pedicle. After an umbilical tape is passed around the main pedicle, it is retracted medially and the stapler is placed away from the bifurcation to avoid injury to the hilus. A clamp is subsequently placed to control bleeding from the specimen side. (From Fong and Blumgart,⁵⁴ by permission of *Journal of the American College of Surgeons*.)

mobilized before performing this maneuver, as it is possible to inadvertently injure a hepatic vein. The left main portal pedicle may be similarly ligated en masse by incising the liver at the base of segment IV anterior to the left portal pedicle and incising the liver in the caudate lobe posterior to the left portal pedicle.⁵⁴

Following control of liver inflow, the liver outflow can be controlled by division of the hepatic veins. For right hepatectomy, before division of the right hepatic vein, short hepatic veins that drain directly from the caudate lobe into the vena cava are first divided. It is important to identify and avoid injury to the right adrenal vein. A ligament from the right lobe of the liver arching across the lateral aspect of the vena cava just inferior to the right hepatic vein is identified and sharply divided to gain full access to the right hepatic vein. It is safe and usually simple to divide the right hepatic vein itself using a laparoscopic Endo GIA 30 stapler with a vascular cartridge (Figure 94.6). For left hepatectomy, the left lateral segment is rotated to the right and the gastrohepatic ligament and ligamentum venosum are divided close to its entry to the left vein. A tunnel is then formed to incorporate the left hepatic vein. The laparoscopic Endo GIA 30 stapler may also be used to transect the left hepatic vein (Figure 94.7). Vascular control of the suprahepatic and infrahepatic vena cava should be obtained before isolation of the hepatic veins if the size and location of metastases reduces visualization and exposure of the hepatic veins.

Whether performing a traditional major resection or one or more segmental resections, the goal of the operation is

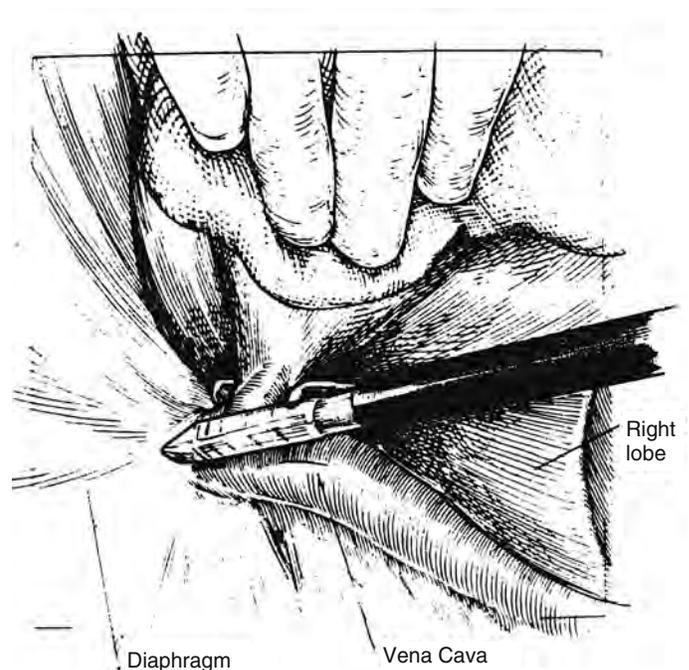

FIGURE 94.6. Stapling the right hepatic vein. The liver is rotated clockwise to provide exposure to place an Endo GIA 30 vascular stapler to the junction of the right hepatic vein and vena cava. (From Fong and Blumgart,⁵⁴ by permission of *Journal of the American College of Surgeons*.)

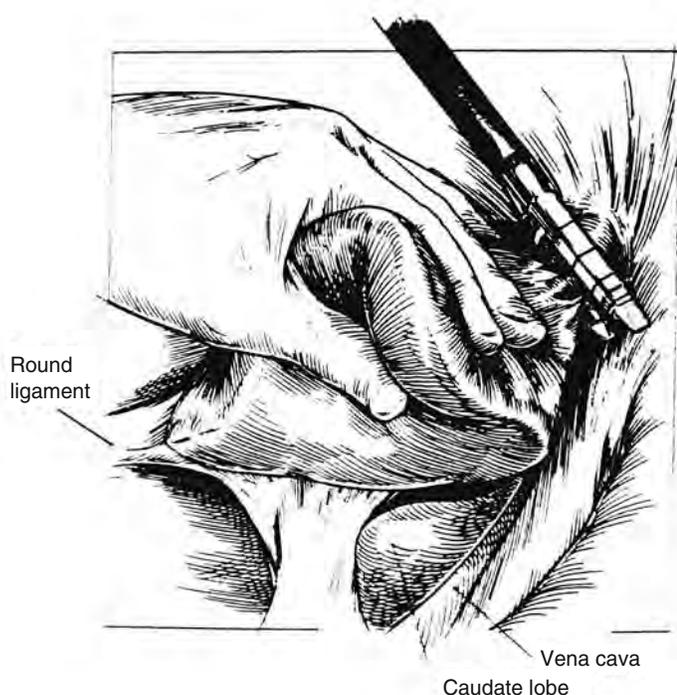

FIGURE 94.7. Stapling the left hepatic vein. The liver is rotated to the right and an Endo GIA 30 vascular stapler is applied at the junction of the left hepatic vein and the vena cava. (From Fong and Blumgart,⁵⁴ by permission of *Journal of the American College of Surgeons*.)

complete removal of all metastases with at least a 1 cm tumor-free margin. Recognition of hepatic veins is critical in determining which segments may be surgically excised. A large inferior right hepatic vein is present in approximately 20% of individuals and is usually identified on preoperative MRI or CT images (Figure 94.8). The presence of this vein permits resection of segments VII and VIII without sacrifice of segments V and VI. With the use of IOUS, the anatomic segments are quickly and accurately delineated.

There are various techniques to divide hepatic parenchyma (Table 94.1). The manner with which liver tissue is divided should achieve several objectives. The method ideally should allow visualization of blood vessels and bile ducts before their transection to allow their ligation. The method should be hemostatic and avoid bile leaks. The method should avoid devascularization of large zones of remnant liver and should allow creation of a crisply defined transection plane. Clamp fracture, ultrasonic surgical aspiration, water-jet dissection, and focused RFA dissection are methods that achieve all these goals. Finger fracture is effective but cannot create the precise transection plane that is sometimes necessary. A prospective randomized trial of clamp fracture versus ultrasonic dissection demonstrated no significant difference between the two methods in blood loss or transection time.⁵⁵

The skill with which the liver parenchyma is transected is an important factor that influences blood loss. In addition, several surgical maneuvers can be used to minimize blood loss. Transient portal inflow occlusion during parenchymal transection is well tolerated and reduces blood loss.⁵⁶ Surgery

FIGURE 94.8. under low central venous pressure to reduce hepatic venous bleeding has also been demonstrated to be safe and reduces blood loss.⁵⁷ Although some anesthesiologists may feel more secure keeping the central venous pressure high during an operation that could be associated with high blood loss, this maneuver will only increase blood loss. Additionally, placement of the patient in 15° Trendelenburg position during hepatic transection will lower the hepatic vein pressure. Hemodilution is another strategy that reduces blood loss. This strategy involves removing 1 to 2 L blood in the operating room just before liver resection, with simultaneous replacement with crystalloid or colloid. The blood lost during liver transection is then more dilute. The removed blood is then reinfused following completion of the portion of the operation that is associated with blood loss. Compression of the liver edge with either a Penrose drain or a Lin liver clamp during transection reduces blood loss. Total vascular isolation is another technique that has been used to reduce intraoperative blood.⁵⁸ With this technique, vascular clamps are used to stop vascular inflow, as well as to isolate the hepatic veins from the inferior vena cava (Figure 94.9). Liver transection may then be performed with minimal blood loss.

Improvements in preoperative evaluation and imaging, surgical technique, and postoperative care have allowed liver surgeons to expand the boundaries of liver resection for colon and rectal cancer liver metastases. Liver metastases that were previously considered unresectable, such as multiple, bilobar metastases, are often now resected with multiple segmentectomies or trisegmentectomy. Strategies also have been developed to increase the volume of liver tissue that can be safely resected; these include use of sequential hepatic resections, which allows hypertrophy before removing more liver, as has been championed by Adam and Bismuth.⁵⁹ Preoperative portal vein embolization to induce hypertrophy before liver resection has been demonstrated to be safe and permits resection of larger volumes with less risk of postoperative hepatic insufficiency.^{60,61}

Outcomes

The operative mortality for major hepatic resections has declined with improved operative techniques and postoperative care, but morbidity remains significant. Table 94.2 summarizes the operative mortality, morbidity, median survival, and 5-year survival in 10 published series.^{14,62-70} It is important to point out that these studies all reported 5-year *actuarial* overall survival rates. Rare reports of *actual* 5-year survival rates suggest that 5-year actual survival rates are gen-

erally lower than actuarial 5-year survival rates. Operative mortality in these studies ranges from 2.8% to 7%, and causes of death include hemorrhage, sepsis, and hepatic failure. Morbidity is observed to range between 11% and 34%, and common causes of morbidity include hemorrhage, biliary leak or fistula, hepatic failure, perihepatic abscess, wound infection, pneumonia, and myocardial infarction. Median survival ranges from 28 to 46 months, and 5-year survival was between 24% and 38%.

Criteria for patient selection for liver resection have been influenced significantly by numerous retrospective studies conducted to identify prognostic factors. Hughes et al.^{70a} published a multicenter retrospective review of 859 patients who had undergone resection of colon and rectal cancer liver

metastases. The overall actuarial 5-year survival was 33%. No patients with portal or lymph node metastases or with extrahepatic disease survived 5 years, and few patients with four or more metastases survived 5 years. Other less significant prognostic factors associated with a worse outcome were a surgical resection margin of less than 1 cm, advanced stage of the primary colon and rectal cancer, and short disease-free interval. Many other studies have examined prognostic factors, which are summarized in Table 94.3.^{14,63-70,71}

In a large single-institution retrospective study of 456 consecutive patients with colon and rectal cancer liver metastases who underwent resection, perioperative mortality was 2.8%, perioperative morbidity was 24%, median hospital stay was 10 days, median survival was 46 months, and 5-year survival was 38%.⁶⁸ The authors concluded that the only factors that are absolute contraindications to resection are the presence of extrahepatic metastases and tumors larger than 10 cm in diameter. These factors were associated with only 13% and 14% 5-year survival rates, respectively. A reasonable percentage of patients with other negative prognostic factors, such as bilobar tumor distribution and four or more tumors, survived 5 years, and thus, the authors concluded that these factors should not be considered absolute contraindications to surgical resection. In an attempt to account for numerous prognostic factors in a formula to estimate outcome following liver resection, some investigators have developed mathematical formulas. One such example is shown in Table 94.4.

Despite careful selection, a majority of patients who undergo resection of colon and rectal cancer liver metastases

will have recurrence of their cancer. The most common sites of recurrence following resection of colon and rectal cancer liver metastases are the liver and lung (Table 94.5).¹⁴ Repeat liver resections for colon and rectal cancer liver metastases are feasible and have been reported by several groups.⁷²⁻⁸⁰ In a large series, median survival reported following repeat hepatic resection in 170 patients was 34 months and 5-year survival was 32%. The only significant negative prognostic factor was an incomplete resection. Median follow-up, however, was only 25 months.⁸⁰ The number of patients who have undergone repeat hepatectomies for metastases is far fewer than the number who have had only one hepatectomy, and so the available literature is limited. In general, prognostic factors that predict outcome following repeat resection are similar to those which predict outcome following the initial liver resection. Thus, indications for repeat hepatectomy are similar to the indications for initial hepatectomy.

A few groups have reported on the resection of initially nonresectable colon and rectal cancer liver metastases following tumor regression from chemotherapy given by either systemic administration or hepatic intraarterial administration.⁸¹⁻⁸³ In a series of 53 patients with a mean follow-up of greater than 2 years, 5-year survival was 40% with 15 cases of repeat liver resection for liver recurrence.⁸³ In a subsequent publication, these authors reported 87 patients followed 5 years after liver resection following neoadjuvant chemotherapy, and the overall survival is 35% from the time of resection.⁸⁴ The value of this strategy for improving resectability rates or survival is currently under prospective examination in a randomized trial sponsored by the European Organiza-

tion for Research and Treatment of Cancer (EORTC), in which patients with resectable colon or rectal carcinoma liver metastases are randomized to undergo resection or neoadjuvant chemotherapy followed by resection.

Adjuvant Therapy Following Resection of Colon or Rectal Carcinoma Liver Metastases

As evidenced by 5-year survival rates averaging 35% following resection of liver metastases, two-thirds of patients develop some type of recurrence following hepatic resection. Although several retrospective studies have examined the utility of systemic chemotherapy in patients following resection of colon and rectal cancer liver metastases, most prospective studies have focused on regional, liver-directed chemotherapy.⁸⁵⁻⁹¹ Four small, single-arm studies have examined hepatic artery infusion (HAI) chemotherapy after liver resection.⁸⁵⁻⁸⁷ In addition, one small⁸⁸ and three large randomized studies⁸⁹⁻⁹¹ of HAI chemotherapy after liver resection have been completed (Table 94.6). The largest study of adjuvant therapy following liver resection was a multicenter European study comparing HAI of 5-fluorouracil (5-FU) and folinic acid (leucovorin) to observation.⁹¹ No differences in survival were observed between patients in these two arms, but there were several problems with this study. The use of 5-FU rather than floxuridine (FUDR) did not capitalize on the

TABLE 94.5. Patterns of first recurrence after liver resection.

Site	% of recurrences	% of all patients

significant regional exposure advantages of FUDR (see following). In addition, the use of subcutaneous ports rather than pumps and technical problems led to termination of adjuvant therapy before completion of the planned treatment courses in many patients. Only 84 of 107 patients randomized to adjuvant chemotherapy received any chemotherapy, and only 34 finished the planned treatment.

The Eastern Cooperative Oncology Group (ECOG) and the Southwest Oncology Group (SWOG) sponsored a study in which 77 patients with fewer than four liver metastases resected were randomized to treatment with HAI FUDR and systemic 5-FU versus observation.⁸⁹ Although disease-free survival was improved by adjuvant therapy ($P = 0.03$), mainly as a result of reduced relapses in the liver, the difference in overall survival was not statistically significant.

A recently completed, single-center study randomized 156 patients to systemic 5-FU and leucovorin or to HAI FUDR and dexamethasone combined with systemic 5-FU after resection of liver metastases from colon or rectal cancer.⁹⁰ The study was designed to examine 2-year survival and patterns of recurrence at 2 years. Local recurrences in the liver were significantly reduced by regional plus systemic chemotherapy. Survival at 2 years was improved in patients randomized to combined HAI and intravenous chemotherapy; however, differences at 5 years were not statistically significant.

Newer combinations of HAI and systemic chemotherapy may be more active, such as the combination of HAI FUDR plus systemic irinotecan (CPT-11).⁹² However, such newer combinations will have to be assessed in relation to newer systemic regimens for metastatic colon and rectal cancer, such as the FOLFOX (5-FU, leucovorin, oxaliplatin) and FOLFIRI (5-FU, leucovorin, and irinotecan) regimens, which have demonstrated better efficacy than systemic 5-FU and leucovorin alone.

Hepatic Tumor Ablation

Several techniques of in situ liver tumor ablation by local destruction have been developed, including cryosurgical ablation, RFA, microwave ablation, laser ablation, and alcohol injection. These techniques are used mainly in patients whose tumors are considered unresectable, although some have used cryosurgical ablation for resectable colon and rectal cancer metastases.⁹³ Real-time imaging of the zone of ablated tissue is typically accomplished with MRI or ultrasound; however, the inability of these techniques to accurately assess areas of incompletely ablated tumors remains problematic.

Cryosurgical Ablation

Hepatic cryosurgery involves the freezing and thawing of liver tumors by means of a cryoprobe inserted into the tumor. Liquid nitrogen is circulated through the cryoprobe, and the subsequent iceball formation is observed by ultrasound. Freezing is continued until the iceball is at least 1 cm beyond the tumor. During freeze-thaw cycles, intracellular and extracellular ice formation occurs, leading to tumor destruction.⁹⁴ Some centers perform two or three freeze/thaw cycles or combine freezing with hepatic inflow occlusion to increase tumor destruction and iceball size.^{94,95}

Hepatic cryosurgery is generally reserved for patients with colon and rectal cancer liver metastases in whom one or more lesions are not surgically resectable, although certain centers have offered hepatic cryosurgery as an alternative to surgical resection.⁹³ Cryosurgery can treat multiple lesions and salvages more uninvolved liver parenchyma than surgical resection. Cryosurgery may also be used to treat tumors intimately associated with major blood vessels, but large blood vessels may serve as "heat sinks" and prevent adequate freezing of immediately adjacent tumor.⁹⁶ Hepatic inflow occlusion or hepatic vein occlusion may reduce the incidence of inadequate freezing of tumor adjacent to blood vessels,⁹⁷ but recurrence of tumor adjacent to large blood vessels remains a problem.⁹⁸ In addition, many surgeons avoid hepatic inflow occlusion for fear of blood vessel wall destruction and subsequent hemorrhage. Cryosurgery may also help in treating patients who are left with a positive surgical margin after hepatic resection, as well as patients in whom underlying illness or hepatic insufficiency precludes surgical resection.

Complications associated with cryosurgery include arrhythmia, cracking of frozen liver with subsequent hemorrhage, right-sided pleural effusion, subphrenic or hepatic abscess, bile collection, biliary fistula, thrombocytopenia, myoglobinuria, acute renal failure, and cryoshock phenomenon (multisystem organ failure and disseminated intravascular coagulation).^{93,97,99,100} Measures to reduce complications include packing the cryoprobe site with Gelfoam to prevent hemorrhage and postoperative administration of lasix, mannitol, and sodium bicarbonate to promote diuresis and alkalize the urine. Overall morbidity rates range widely, from 6%⁹³ to 49%¹⁰⁰ with aggressive treatment. Mortality rates range from 0% to 8% with an overall mortality rate in reported series of 1.6%.⁹⁸ Median survival in reported series has ranged from 8 to 33 months.⁹⁸

Hepatic cryosurgery is clearly an option for patients with isolated colon and rectal cancer liver metastases that are not surgically resectable, but limited enough to allow cryoabla-

tion of all lesions. In general, these patients' tumors usually have unfavorable tumor biology, and it is unclear whether cryoablation improves survival. It is also unclear whether hepatic cryosurgery will lead to equivalent survival in patients with more limited disease who currently undergo surgical resection. Well-controlled studies are required to address these questions. Although this technique gained popularity in the 1980s and 1990s, its usage has become much more restricted with the development of RFA.

Radiofrequency Ablation

Among the more promising experimental therapies for colon and rectal cancer liver metastases is RFA. This technique involves percutaneous or intraoperative insertion of a RFA electrode into the center of a hepatic tumor under ultrasound or CT guidance. RFA energy is then emitted from the electrode and absorbed by the surrounding tissue. This process generates extreme heat leading to coagulative necrosis of treated tissue.¹⁰¹

The initial limitation of this therapy was the small (1.5-cm) diameter of necrosis achievable with a single RF electrode. Strategies to increase this treatment area include multiprobe arrays,¹⁰² saline infusion with RFA application,¹⁰³ and internal cooling of the tip of the RFA electrode.¹⁰³ One type of multiprobe array deploys multiple curved stiff wires in the shape of an umbrella from a single 14- or 16-gauge cannula. Studies using a 12-hook "umbrella" array in porcine liver in vivo produced spherical regions of coagulation necrosis measuring up to 3.5 cm in diameter.¹⁰⁴ Another type of RFA probe allows infusion of low volumes of saline during RFA that increases the volume of coagulation necrosis.^{103,105,106,107} Injection of ethanol has also been demonstrated to increase the volume of coagulation necrosis achieved by RFA in animal models.¹⁰⁸ Another tactic to increase coagulation volume has been the development of internally cooled RF electrodes. With internal electrode tip cooling, which avoids desiccation of tissue adjacent to the electrode and rises in impedance, radiofrequency-induced coagulation necrosis is greater than that achieved with noncooled electrodes.¹⁰⁹

Blood flow serves as a "heat sink," such that tumors located in vascular environments are less susceptible to thermal destruction as perfusion-mediated tissue cooling reduces the extent of coagulation necrosis. Greater coagulation is observed in vivo when radiofrequency energy is delivered during occlusion of the portal vein than when energy is delivered during normal blood flow.^{110,111} Finally, pulsed current may increase the extent of coagulation necrosis as compared to continuous current.^{112,113}

TECHNIQUES

Radiofrequency ablation can be performed percutaneously by means of interventional radiology or surgically, either by laparoscopic or open techniques. When performing RFA during open laparotomy, careful planning of ablation zones is necessary to achieve complete necrosis of the target lesion. Current technology allows for effective ablation of tumors up to 3 cm with an adequate margin. Tumor sizes larger than 4 to 5 cm are associated with increased incidence of local recurrence.^{114,115} The location of a tumor near the main portal pedicles is considered a relative contraindication to RFA. In

addition to the inability to achieve an effective ablation because of the high blood flow, ablation near the porta hepatis can result in stricture and liver failure from injury to a central bile duct.¹¹⁶

Once the target lesion is identified, the RFA electrode needle is inserted under ultrasound guidance. Optimally, the electrode is advanced in a track parallel and within the plane of the transducer, so the entire path of the needle can be visualized. When using a multielectrode needle, the array is deployed within the tumor and position is confirmed ultrasonographically. Monitoring during thermal ablation can be performed using a variety of methods. Some RFA devices have the capacity to measure tissue temperatures using thermistors located at the tips of the electrodes. Alternatively, tissue impedance and current can be monitored during treatment. With some devices, the power output is adjusted automatically to control impedance and maintain tissue temperature between 70° and 105°C. The ablation zone is visualized by ultrasound during treatment (Figure 94.10). Typically, local minuscule gas bubble formation results in hyperechogenicity within the treated tissue.

Laparoscopic RFA offers the advantage of a minimally invasive procedure with the ability to visualize the abdominal cavity and perform the therapy using IOUS. With this approach, patients are treated under general endotracheal anesthesia, typically in the supine position. In most cases, the procedure can be done with two or three ports.¹¹⁷ The liver is typically partially mobilized, and viscera within 2 cm of the intended ablation zone are mobilized out of the way. The RFA electrode is placed into the abdominal cavity through a percutaneous approach and does not require the placement of an additional port. The needle is placed within the tumor under US guidance, and ablation is performed and monitored as with the open technique.

Serial follow-up imaging of the liver is recommended after RFA treatment. However, as with other ablative approaches, interpretation of these images can at times be difficult, as a hypoattenuating lesion may persist for months to years despite complete tumor destruction. In most cases, a local recurrence is characterized by an increase in the lesion size

on serial scans, or evidence of new areas of contrast enhancement.¹¹⁸ CT or MRI is the most useful method for follow-up imaging, emphasizing the importance of comparing images to previous ones.^{119,120} The role of FDG-PET in assessing local residual or recurrent disease following RFA is yet to be defined.

OPERATIVE VERSUS PERCUTANEOUS RADIOFREQUENCY ABLATION

Many of the published reports evaluating RFA of liver metastases have relied upon percutaneous electrode insertion under image guidance.^{103,121} The principal advantage of the percutaneous approach compared to operative approaches is the lower associated morbidity and cost. A second advantage of a percutaneous approach is the ability to use either ultrasound, MRI, or CT guidance, whereas imaging of RFA performed during laparotomy or laparoscopy is for the most part limited to ultrasound guidance (Figure 94.11).

However, there are several advantages to performance of ablation during laparotomy or laparoscopy. The first benefit is that of enhanced staging, as laparotomy and laparoscopy afford the opportunity to identify both hepatic and extrahepatic metastases not visualized on preoperative imaging. Ten percent to 20% of patients who undergo exploration for intent to resect colorectal cancer liver metastases are found at laparotomy to have additional metastases that either preclude or significantly alter the planned resection. Many of these operative findings can be detected via laparoscopy as well. In addition, IOUS can frequently detect lesions that are not seen with transabdominal ultrasound, CT, or MRI.

Second, laparotomy affords the opportunity to combine ablation with surgical resection. It is important to point out that following ablation of tumors larger than 5 cm, the local recurrence rate is unacceptably high.¹²² Accordingly, a significant fraction of patients with "unresectable" liver tumors can be fully treated only by the combination of resection of larger lesions and ablation of smaller lesions. For example, a patient with a 7 cm tumor occupying the left hepatic lobe and a 2 cm tumor straddling segments 6 and 7 is an ideal candi-

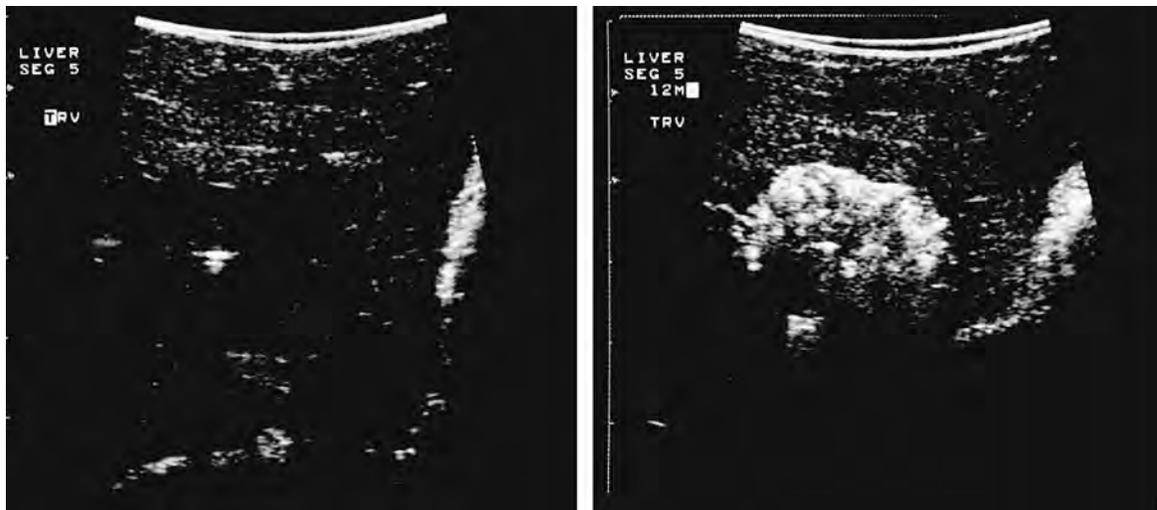

FIGURE 94.10. Placement of an electrode into the center of a liver tumor intraoperatively under ultrasound guidance (*left*). Delivery of radiofrequency (RF) energy to the tumor is associated with significantly increased echogenicity in the treated area (*right*). This typically resolves within 15 minutes. FIGURE 94.11. CT scan of a colon carcinoma liver metastasis in the right lobe before (A), during (B), and following (C) RF ablation. The tumor was resected several days later (D), and coagulation necrosis was observed throughout the tumor.

date for treatment with a combination of left hepatic lobectomy for the larger left lobe tumor and RFA of the smaller right lobe tumor.

Third, hepatic blood flow creates a “heat sink” that reduces the efficacy of thermal ablation. Ablation during laparotomy or laparoscopy can be performed with a vascular clamp occluding hepatic arterial and portal venous blood flow. This technique has been demonstrated to safely and reproducibly increase the size of the zone of ablation.^{110,111,123,124} Although this can also be accomplished using percutaneous techniques, it adds negligible morbidity when performed during laparotomy or laparoscopy.

Fourth, laparotomy or laparoscopy affords excellent access to tumors in the dome of the liver or in other locations that are difficult to accurately target percutaneously. This location is difficult to access with precision using a path for the electrode that does not violate the pleura. In addition, motion of the liver caused by respiration creates further problems that can be better managed during an open laparotomy.

Fifth, operative approaches permit mobilization of structures away from a surface tumor that may be thermally injured during RFA. For example, the transverse colon may be adherent to a tumor in the inferior portion of the liver. Effective thermal ablation of the entire tumor would risk injury to the colon unless it was first dissected free from the tumor.

Finally, laparotomy affords the opportunity to implant a hepatic arterial infusion pump for postoperative administra-

tion of regional chemotherapy. The most common pattern of relapse following treatment of both primary and secondary hepatic malignancies is within the liver. A prospective, randomized trial comparing intravenous chemotherapy to HAI chemotherapy combined with intravenous chemotherapy following curative liver resection, demonstrated enhanced survival at 2 years in patients treated with the combination of hepatic arterial infusion and intravenous chemotherapy.⁹⁰ The majority of the benefit was obtained by marked reduction in hepatic recurrences observed in patients who received hepatic arterial infusion chemotherapy. This study remains the only prospective randomized trial to demonstrate a survival benefit to adjuvant therapy following curative resection of colon or rectal carcinoma liver metastases. The American College of Surgeons Oncology Group is currently conducting a clinical trial of operative RFA combined with hepatic arterial infusion of floxuridine and intravenous administration of CPT-11.

OUTCOMES

The analysis of clinical results achieved by RFA for the treatment of hepatic colorectal metastases has been hampered by lack of appropriate controls and relatively short follow-up times. As technical improvements have occurred, investigators have used different devices and techniques. In addition, inclusion of heterogeneous patient populations, the difficulty in defining true local recurrences, and the significant impact

of distant recurrence on survival have made assessment of the efficacy of RFA challenging.

Curley et al. reported the largest series to date of operative RFA of unresectable primary and metastatic hepatic malignancies in 123 patients.¹¹⁵ In these patients, RFA was used to treat 169 tumors with a median diameter of 3.4 cm. Primary liver cancer was treated in 48 patients and metastatic liver tumors were treated in 75 patients. Percutaneous and intraoperative RFA was performed in 31 patients and 92 patients, respectively. No treatment-related deaths occurred, and the complication rate was only 2.4%. All treated tumors were completely necrotic on imaging studies after completion of the RFA treatments. With a median follow-up of 15 months, tumor had recurred in 3 of 169 treated lesions (1.8%), but metastatic disease had developed at other sites in 34 patients. Based on these results, these investigators concluded that RFA is a safe, well-tolerated, and effective treatment in patients with unresectable hepatic malignancies. RFA may not cure most patients with primary or malignant metastatic disease, as witnessed by the 34 patients with disease found at extrahepatic sites, but initial disease-free rates of 20% to 50%, justify continued investigation into aggressive treatment of isolated hepatic disease with a multimodality approach including RFA. Another large series was reported by Wood et al., in which 231 tumors in 84 patients were treated in 91 procedures.¹²⁵ Thirty-nine procedures were performed via laparotomy and 27 were performed via laparoscopy. Of note, intraoperative ultrasound detected intrahepatic tumors that were not evident on preoperative scans in 38% of patients who underwent either laparotomy or laparoscopy. In 45% of patients, RFA was combined with resection or cryosurgical ablation. Median hospital stay overall was 3.6 days. Eight percent of patients had complications, and 1 patient died as a result of the procedure. With a median follow-up of 9 months, 18% of patients experienced a local recurrence at a RFA site.

In a large series from Italy of 117 patients with colorectal cancer, 179 liver metastases were treated with RFA.¹²² The tumors ranged in size from 0.9 to 9.6 cm and all were percutaneously treated using internally cooled 17-gauge electrodes under image guidance. The estimated median survival was 36 months, with 1-, 2-, and 3-year survival rates of 93%, 69%, and 46%, respectively. Two-thirds of patients developed recurrences at a median time of 12 months following treatment. Seventy (39%) of 179 treated lesions developed local recurrence, and of these, 54 were observed by 6 months and 67 by 1 year. No local recurrence was observed after 18 months, although the median follow-up time for the entire study population is not reported. As expected, the incidence of local recurrence differed by size of lesion. The local recurrence rates were 22%, 53%, and 68% for lesions measuring less than 2.5 cm, 2.6 to 4.0 cm, and more than 4.1 cm, respectively.

Hepatic Arterial Infusion Chemotherapy

In patients with liver metastases from colon and rectal cancer that are not amenable to surgical resection, HAI chemotherapy can be used. HAI chemotherapy has received considerable attention over the years, and is based upon two primary concepts: (1) liver metastases larger than a few millimeters derive

most of their blood supply from the hepatic arterial circulation, whereas the normal liver derives most of its blood supply from the portal circulation,¹²⁶ and (2) clearance of chemotherapeutic agents by first pass through the liver can increase drug level in the liver and limit systemic toxicity.¹²⁷ FUDR is the most commonly used agent for HAI chemotherapy. Hepatic venous levels of FUDR have been documented to be four times higher following hepatic intraarterial administration than following systemic administration, whereas systemic FUDR levels following hepatic intraarterial administration are one-fourth FUDR levels following intravenous infusion.¹²⁸ It is estimated that hepatic intraarterial administration of FUDR allows a level of liver exposure 100 to 400 times greater than with intravenous administration.¹²⁹

HAI chemotherapy is generally reserved to patients without evidence of extrahepatic metastases. Rare exceptions are made for patients with a good performance status who have minimal extrahepatic metastases, but have substantial liver tumor burden. In the past, patients considered for HAI chemotherapy would first undergo a preoperative angiogram to define arterial anatomy because about 37% of patients have variant arterial anatomy.¹³⁰ In recent years, CT angiography has largely replaced conventional hepatic arteriography in many centers. Subsequently, an operation is performed in which a cannula is placed into the hepatic arterial circulation and attached to an infusion pump. The pump is implanted into a subcutaneous pocket in the abdominal wall.

Once appropriate hepatic perfusion is verified and the patient has recovered from the operative procedure, HAI chemotherapy is initiated. A typical infusion regimen involves a 28-day cycle of continuous infusion of FUDR for 14 days at a dose of 0.15 mg/kg/day, leucovorin 8 mg/m²/day, and decadron 20 mg/14 days, followed by a 14-day continuous infusion of heparinized saline.¹³¹ Hepatic toxicity is not uncommon with HAI FUDR, and liver function tests should be obtained every 2 weeks to allow dose adjustments that will reduce the chances of biliary sclerosis. FUDR infusion is generally withheld for any liver function test that exceeds twice the baseline value and resumed at one-half or one-third the original dose when the liver function tests return to baseline.^{131,132} After three cycles of HAI chemotherapy, an abdominal CT scan is obtained to assess response. In patients with stable disease or disease regression, cycles can be continued and reevaluated periodically for response. Patients with disease progression during therapy should have treatment discontinued.

There have been several randomized trials comparing HAI chemotherapy with FUDR to systemic chemotherapy with FUDR or 5-fluorouracil (5-FU) (Table 94.7).^{133,134-139} Median survival ranged from 12.6 to 17 months. Response rates for HAI chemotherapy ranged from 43% to 62% compared to 10% to 21% for systemic chemotherapy. The increased response rate for HAI chemotherapy did not translate into significantly increased survival in any of the studies. There are several reasons that may explain why no difference between treatment arms was observed in survival in these studies. First, colon and rectal cancer may be a systemic disease in many patients such that regional therapy will not affect survival. Second, some of the trials allowed cross-over.^{134,136} Third, the high incidence of biliary sclerosis precluded full and prolonged HAI therapy in the earlier trials. Fourth, complications related to pump placement were common in the

TABLE 94.7. Selected published prospective randomized clinical trials of HAI chemotherapy compared to systemic chemotherapy.

Trial author	Year	No. of patients	Randomized	Stage	Intervention/design	P value	Median survival (months)	Comments
Kemeny ¹³⁴	1987	99	Yes	IV	HAI FUDR or systemic FUDR	0.424	17 vs. 12	Crossover allowed

early trials, and this problem prevented many patients from receiving HAI therapy.¹³³ Subsequent improvements in surgical technique, combined with improvements in HAI chemotherapy regimens, have resulted in renewed interest in this approach in recent years.

A meta-analysis of six prospective randomized trials published by Harmantas et al.,¹⁴⁰ demonstrated a statistically significant survival advantage of HAI chemotherapy over systemic chemotherapy, but this analysis included one study in which some patients in the control group received no treatment.¹³⁹ Two randomized trials evaluating HAI therapy have been conducted and recently reported. A multicenter trial was recently reported in which the one group received IV leucovorin followed by HIA 5-FU every 2 weeks and the control group received systemic 5-FU and leucovorin.¹⁴¹ Thirty-seven percent of patients randomized to HAI chemotherapy did not receive therapy because of technical complications. HAI chemotherapy was not associated with better median progression-free survival (7.7 versus 6.7 months) or overall survival (14.7 versus 14.8 months).

The Cancer and Leukemia Group B recently reported results of a randomized trial comparing patients treated with HAI chemotherapy with FUDR, leucovorin, and dexamethasone to patients treated with systemic 5-FU and leucovorin (Mayo regimen).¹⁴² The trial was closed before achieving its accrual goals due to poor enrollment. An early analysis demonstrated that HAI chemotherapy was associated with a significantly higher response rate (48% versus 25%) and median survival (22.7 versus 129.8 months).

Despite better disease control in the liver, about 56% of patients receiving HAI chemotherapy, subsequently develop extrahepatic disease compared to 37% of patients receiving systemic FUDR.¹³⁴ One approach has been to combine HAI chemotherapy with systemic chemotherapy. Several centers are presently exploring the combination of FUDR-based HAI chemotherapy and intravenous CPT-11.¹¹³ Similar to the use of HAI chemotherapy in the adjuvant setting, HAI chemotherapy for unresectable colon and rectal liver metastases needs to be compared to newer systemic regimens for metastatic colon and rectal cancer, such as the FOLFOX and FOLFIRI regimens, which have demonstrated better response rates for liver metastases than older systemic regimens.

Resection of Liver Metastases from Tumors Other Than Colon and Rectal Carcinoma

The paradigm of resection for liver metastases was established with colon and rectal cancer metastases, principally to take advantage of the known biology of this cancer, where it

is not uncommon to harbor a limited number of liver metastases in the absence of extrahepatic metastases. Surgeons have exploited this knowledge to cure patients with colon and rectal cancer liver metastases. For patients with liver metastases from other cancers, the statistical likelihood that a patient actually has isolated liver metastases in the absence of extrahepatic metastases is much lower.

In one selected report concerning resection of breast cancer metastases from Duke University, 17 patients underwent resection of breast cancer liver metastases following neoadjuvant high-dose chemotherapy over a 10-year period.¹⁴³ The 5-year actuarial survival rate was calculated at 22%, and 7 of 17 patients are alive with follow-up of up to 12 years. Four of these survivors had no measurable disease and were 6 months, 17 months, 6 years, and 12 years out from their resections. This report is not an outlier, as is shown in Table 94.8, demonstrating that several centers have reported 5-year actuarial survivals of 18% to 51% following resection of breast cancer liver metastases. Probably the most important information from these studies is gained by noting the interval over which these patients were accumulated; each center reports on average 1 or 2 patients per year. This finding underscores two points. First, a favorable tumor biology for liver resection (i.e., isolated liver metastases) is rare with breast cancer. And second, such tumor biology does indeed exist in some patients with breast cancer.

Retrospective reports in the literature also address the issue of resection of neuroendocrine cancer liver metastases. Chen et al. reported on 15 patients over an 11-year period who underwent complete resection of their liver metastases from neuroendocrine tumors. Following complete surgical resection, patients were noted to have an actuarial 5-year survival of 73%.¹⁴⁴ Yao et al. identified 16 patients over a 9-year period with neuroendocrine carcinoma liver metastases who underwent resection for whom a 70% actuarial 5-year survival is reported.¹⁵² These reports originate from a high-volume tertiary care institution, and yet they report on average 1 or 2 patients per year whom they have selected for resection. Similar patterns are observed in an analysis of published

TABLE 94.8. Selected published series of resection for breast cancer liver metastases.

reports of surgery for patients with sarcoma liver metastases (Table 94.9).^{153–155}

The tumor biology involving isolated liver metastases that justify regionally intensive therapy is even more rare (possibly nonexistent) for gastric cancer, esophageal cancer, pancreatic cancer, and melanoma. Although metastases from ocular melanoma commonly manifest in the liver, patients with this disease commonly also harbor metastases in other sites, such as the bone, lung, or lymph nodes.¹⁴⁴

Hyperthermic Isolated Liver Perfusion

Isolated hepatic perfusion has been under clinical evaluation for four decades.¹⁴⁵ In this procedure, the circulation of the liver is isolated completely from the systemic circulation using an extracorporeal circuit driven by a heart–lung bypass machine. This approach has not gained widespread or consistent clinical application, because it is a complex treatment to administer, has been associated with significant morbidity, and has not demonstrated adequate efficacy to justify such aggressive treatment.

The Surgery Branch at the National Cancer Institute initiated clinical trials of isolated hepatic perfusion with several refinements and modifications to improve the potential safety and efficacy of this treatment technique. Over 200 patients have been treated on protocols designed to systematically evaluate refinements in this treatment strategy using tumor necrosis factor, melphalan, and hyperthermia as the therapeutic components of treatment. Initially, a Phase I study of escalating dose of tumor necrosis factor (TNF) alone was conducted, and the maximum safe tolerated dose defined as 1.5 mg/kg TNF administered into the perfusate during a 60-minute hyperthermic perfusion.¹⁴⁶ Subsequently, patients were treated on a Phase I trial of alternating escalating dose melphalan and TNF for unresectable malignancies confined to the liver.¹⁴⁶ In that trial, the maximum safe-tolerated dose of the agents used in combination was 1 mg TNF and 1.5 mg/kg melphalan. The dose-limiting toxicity of TNF was coagulopathy and the dose-limiting toxicity of melphalan was hepatic veno-occlusive disease. Subsequently, a Phase II trial of isolated hepatic perfusion was performed using the maximum safe-tolerated doses of these agents in patients with malignancies confined to the liver.¹⁴⁷ The overall response rate in that trial was approximately 75% and was consistently observed in patients with colorectal cancer, ocular melanoma, and other histologies. In addition, the response rates were observed in patients who had failed previous systemic or regional therapy, patients who had large (greater than 10 cm) lesions, patients who had multiple (more than nine) lesions, and patients who had greater than 30% hepatic replacement by tumor. Although the median duration

of response was only 8 months, some patients had sustained responses that are ongoing at 3 years of follow-up. Subsequent to these studies, pharmacologic grade TNF became unavailable in the United States. Another study designed to incorporate postperfusion hepatic intraarterial FUDR and leucovorin following hyperthermic isolated liver perfusion with melphalan alone, demonstrated that hepatic arterial infusion of FUDR lengthened the duration of response.¹⁴⁸ Objective response rates of 75% and a median duration of response of 8 to 14 months were observed following treatment of liver metastases from a variety of cancers, including colon and rectal cancer, ocular melanoma, islet cell cancers, and cholangiocarcinomas.^{146–148}

Metastatic Cancer to Bone

Patrick J. Getty, Jeffrey L. Nielsen,
Thomas Huff, Mark R. Robbin,
and Beth A. Overmoyer

Metastatic disease to bone is the most common malignancy of bone. The American Cancer Society estimated that in 2004 there will have been 1,368,030 new cases of cancer in the United States.¹ Of these, they estimated that approximately 2,400 will be new cases of primary bone malignancy; that is, compared with over 230,000 new cases of prostate carcinoma, 217,000 cases of breast carcinoma, and 173,000 cases of lung carcinoma. Those three diagnoses, along with kidney cancer and thyroid carcinoma, represent 80% of metastases to the skeleton.² Autopsy studies have shown that 50% to 70% of patients with prostate cancer develop metastases and 85% of patients with breast cancer develop skeletal metastases. The skeleton is surpassed only by the lungs and liver for incidence of metastatic disease. Any bone of the skeleton can be involved; however, the axial skeleton is most commonly involved. Involvement of the appendicular skeleton most commonly involves the proximal portion of the lower extremities. Within the spine, it is primarily the anterior and middle columns that are involved.³

Presentation of patients with skeletal metastases takes many forms. Metastases may be found on routine staging studies, including bone scan. They typically become clinically evident as a result of pain and dysfunction. Spinal metastases can present because of pain with or without pathologic fracture as well as spinal instability or compression of the spinal cord. Metastases to the long bones of the extremities typically present secondary to pain or pathologic fracture.

Diagnosis of metastatic disease to bone requires an organized approach and, if necessary, a well-planned biopsy. Appropriate treatment options, including medical management, radiation therapy, and surgical treatment, can then be considered.

Mechanisms of Osseous Metastases

The development of metastatic disease to bone is a complex interaction between the neoplastic cells and the host organism. In 1889, Paget described the seed and soil hypothesis of tumor metastasis.⁴ Although the exact mechanisms remain elusive, increased understanding of the mechanism of metastasis has occurred via both anatomic and molecular studies.

The mechanism of metastasis to bone involves both the generalized steps required at the primary site for all metastases as well as specialized interactions at the bone end organ.⁵ At the primary site of disease, the tumor cells must induce neovascularization, following which there must be alterations in the expression of cell adhesion molecules, followed by the expression of collagenases and metalloproteinases to allow the tumor cell to leave the primary site and invade the bloodstream for hematogenous spread. The tumor cells must then evade the host immune mechanisms to arrive intact at the bone end organ.

The most common sites of skeletal metastasis are the spine, pelvis, and proximal femur.⁶ It is believed that these represent receptive anatomic sites due to the presence of hematopoietic marrow, which contains vascular sinuses that allow circulating tumor cells to pass from the bloodstream into the bone marrow space. Another site of valveless blood flow was described by Batson with reference to the venous plexus surrounding the spine and high incidence of spinal metastasis.⁷ Once within bone, the tumor cells must adopt a mechanism for bone lysis to create the space needed for tumor growth. It is believed that tumor cells do not cause direct bone lysis, but rather induce the host osteoclasts to perform lysis of bone.⁵ It is thought that tumor cells do this primarily by producing parathyroid hormone-related protein, possibly under the stimulation of transforming growth factor-beta (TGF- β .) The parathyroid hormone-related protein then stimulates the osteoclasts to perform lysis of bone. This exogenous stimulus places the normal homeostatic mechanism of bone metabolism out of balance to produce overall bone lysis and allow for increased tumor growth.

Pathophysiology of Osseous Metastasis

Both osteolytic and osteoblastic bone metastasis can be viewed as part of the spectrum of dysregulation of bone remodeling that occurs with the development of osseous metastasis. Occasionally, both types of metastasis occur in association with the same malignancy, such as with breast cancer; however, in general, breast cancer is associated with primarily osteolytic disease, contrasting with prostate cancer that has primarily osteoblastic features.⁸ The skeleton is a

common site of metastasis because of significant access to blood flow, and the ability of marrow stromal cells to bind to circulating tumor cells via the presence of adhesion molecules, for example, integrin $\alpha_v\beta_3$, which also function to bind osteoclasts to bone surfaces.⁹⁻¹² The microenvironment of the bone matrix facilitates tumor expansion via the paracrine production of growth factors, such as TGF- β , platelet-derived growth factor (PDGF), insulin-like growth factor I and II, and calcium. The favorable combination of these factors enhances the capacity of solid tumors to use bone as a frequent target for metastasis.¹³

Understanding the metabolic functions involved in the balance of osteoclast and osteoblast activity within the marrow stroma will help support the rationale behind newer therapies in the treatment of bone metastasis discussed later in this chapter. Osteoclasts arise from the monocyte-macrophage lineage, and are induced by macrophage colony-stimulating factor (M-CSF), and by binding to the receptor activator of nuclear factor- κ B (RANK) ligand (RANKL) present on the surface of osteoblasts and stromal cells.^{10,14} Osteoblastic secretion of cytokines, such as interleukin 6 (IL-6), IL-1, and prostaglandin E₂, also aids in the induction of osteoclast formation. Osteoclasts adhere to the surface of the bone via integrins, where they control osseous resorption by protease secretion. Osteoblasts arise from mesenchymal cells, and their differentiation is controlled by several of the growth factors produced by the stromal cells, such as TGF- β and PDGF.⁹

Within the bone matrix, most metastatic solid tumors secrete parathyroid hormone-related peptide, which binds to the parathyroid hormone receptor (PTH1R) and stimulates osteoclast development.^{15,16} The activation of PTH1R also stimulates expression of RANKL on stromal cells, which has been shown to induce formation of osteoclasts. Osteoclast-induced resorption of bone results in the local increase in calcium concentration, which in turn stimulates tumor growth and parathyroid hormone-related protein production. Therefore, a significant relationship appears to exist between bone destruction and metastatic tumor growth mediated through cell signaling involving the microenvironment. This phenomenon has been viewed as a "vicious cycle."^{9,10}

This "vicious cycle" may also exist in the development of osteoblastic metastasis, such as that seen with prostate cancer; however, the mechanisms related to osteoblastic metastasis are less recognized. Paracrine factors, such as endothelin 1 and PDGF, also appear to stimulate osteoblastic metastasis and tumor growth.^{8,9,10,17} In addition, prostate cancer cells secrete both prostate-specific antigen (PSA) and urokinase-type plasminogen activator (u-PA), which activate growth factors within the marrow stroma, such as TGF- β and insulin-like growth factors I and II that, in turn stimulate osteoblastic activity.⁹

Clinical Presentation

The principal presenting symptom of metastatic cancer to the bone is pain. The pain can have both biologic and mechanical components.¹⁸ The biologic component refers to pain associated with growth of the tumor itself. Tumor growth must be accompanied by angiogenesis and hyperemia. Along with the increased blood flow come cytokines, which are thought

to be important mediators of the pain response.¹⁹ This biologic component to the pain is often described as a deep, dull, ache in the bone that is unrelated to activity. This type of pain is often responsive to nonsurgical management, such as radiation and chemotherapy.²⁰

The mechanical aspects of the pain, on the other hand, are strain related. This pain is aggravated by weight-bearing activities and is relieved by rest. This pattern of pain results from the loss of structural integrity of the bone.²⁰ As already stated, for the metastatic tumor to grow within the bone there must be a mechanism for bone lysis, which is thought to occur secondary to effects on the host osteoclasts and osteoblasts, rather than by a direct effect of the tumor cells themselves. Typically, osteoclast stimulation outweighs osteoblast stimulation, and a lytic lesion of bone results.²¹ This net bone loss reduces bone strength and stiffness, thereby leading to pain with weightbearing. Pain of this character is less likely to be immediately responsive to medical management. Increasing mechanical symptoms may signal impending pathologic fracture and warrant protected weight-bearing as well as a consideration of prophylactic operative stabilization.

Many metastatic tumors to bone have no presenting symptoms. These lesions may come to medical attention as an incidental finding on plain radiographs or, more commonly, by bone scintigraphy in the setting of staging of a known primary tumor.

Radiologic Evaluation of Skeletal Metastases

Radiography

The sensitivity of plain radiographs to detect metastatic lesions is low. Studies have shown that more than 50% to 70% of cancellous bone must be destroyed to be reliably detected by plain radiographs.²² Although involvement of the cortex may be detectable much earlier (i.e., with a lesser degree of destruction), it is an uncommon site of early metastatic involvement. Cortical bone, which is much denser than cancellous bone, masks subtle foci of abnormal trabecular bone, leaving them much less conspicuous (Figure 95.1).

Appearance of the metastatic lesion also affects its detectability by radiography. Permeative lesions can be particularly difficult to detect until a large area of medullary bone is involved. Similarly, purely lytic metastases may be radiographically occult until large unless they involve the cortex (Figure 95.2). Cortical involvement of a trabecular lesion can be perceived as endosteal scalloping along the inner margin. In lesions of mixed lytic/blastic appearance, adjacent areas of sclerosis depict reaction of the adjacent normal bone in an attempt to "wall off" the metastasis. Purely blastic lesions are often more readily detectable, with areas of sclerosis often demonstrating ill-defined margins. These lesions are likely caused by reaction to osteoblast-like factors made by the tumor, attempts by the surrounding normal bone to isolate the abnormal focus, or a combination of the two processes. In the event of a direct cortical metastasis, a well-defined focal cortical defect can be seen, which can give the false impression of a benign lesion.

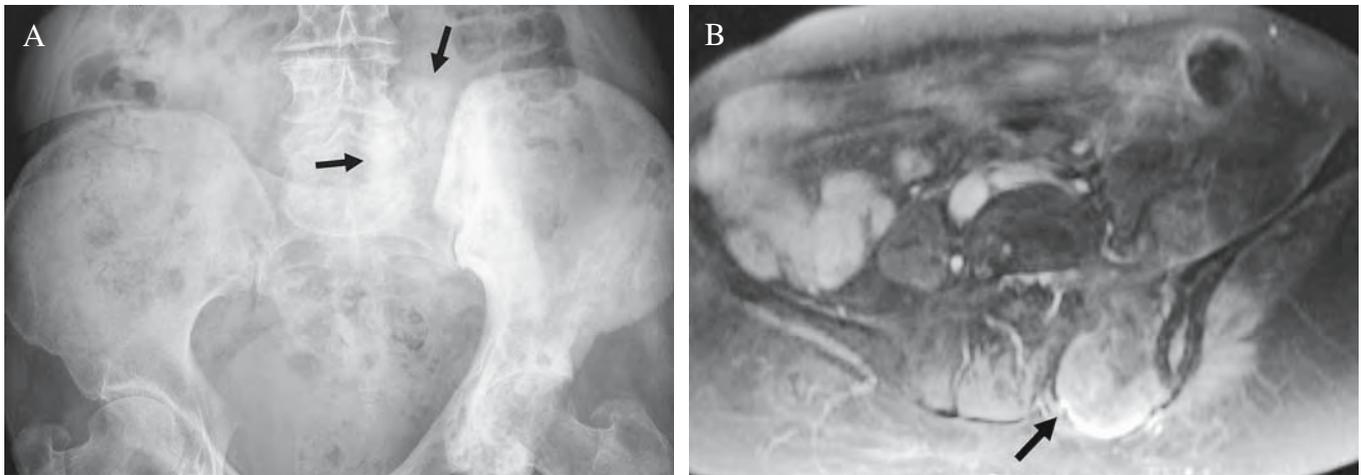

FIGURE 95.1. Anteroposterior (AP) view of the pelvis (A) in a 76-year-old patient with a history of Paget's disease shows bony expansion and trabecular thickening involving the right hemipelvis, consistent with this history. Additionally, the superior margin of the left sacrum is not seen, and there is suggestion of a soft tissue mass in this location. Dense osteoid matrix is identified within the soft

tissue mass. In this setting, findings are suggestive of sarcomatous transformation in the setting of Paget's disease. (B) Axial post-gadolinium T₁-weighted magnetic resonance imaging (MRI) of the pelvis better demonstrates the extensive involvement of the left sacrum by the heterogeneously enhancing soft tissue mass.

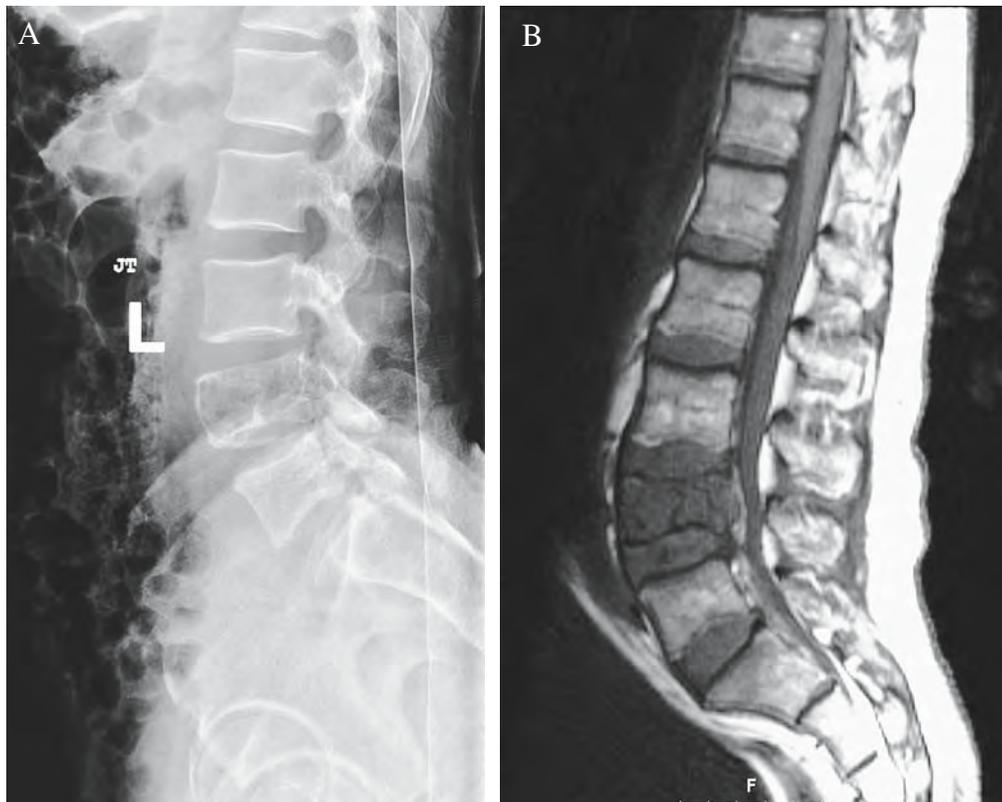

FIGURE 95.2. Lateral view of the lumbar spine (A) demonstrates lytic replacement of the L4 vertebral body in this 53-year-old patient. Sagittal T₁-weighted MRI of the spine (B) shows diffuse marrow replacement. Subsequent computed tomography (CT)-guided biopsy (not shown) confirmed the presence of a plasmacytoma.

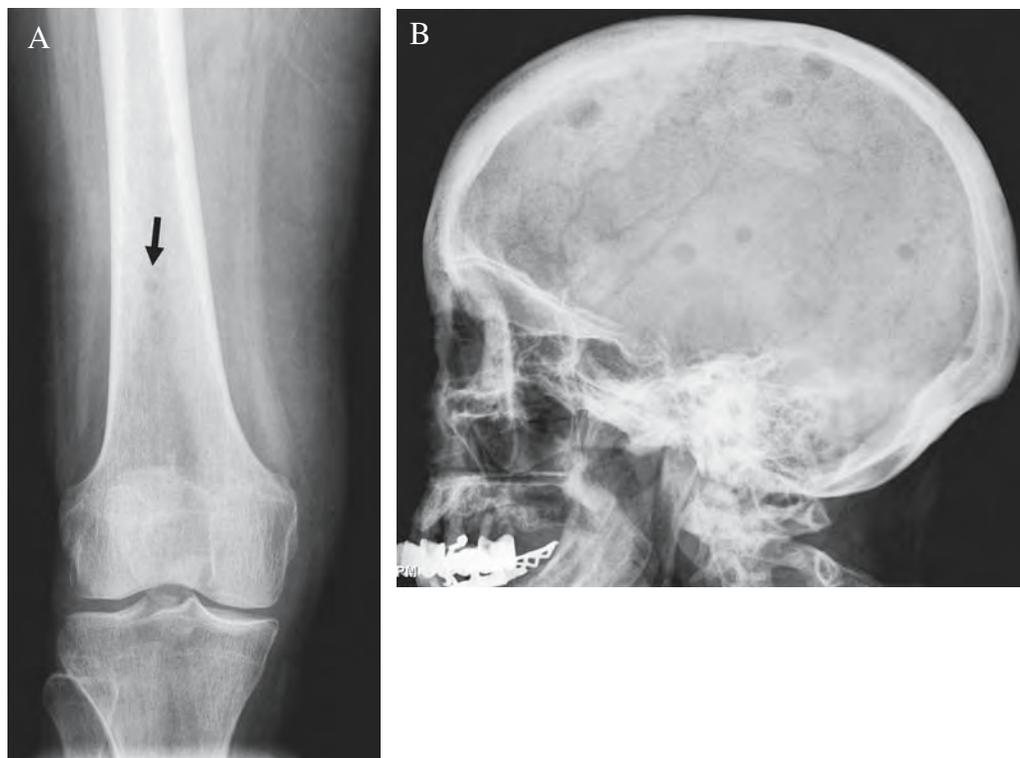

FIGURE 95.3. AP view of the right femur (A) and lateral view of the skull (B) in a patient with a history of multiple myeloma demonstrate the classic “punched-out” lytic lesions associated with this malignancy.

Because of its low sensitivity for most metastatic lesions, radiography is best used as an adjunct to other imaging modalities. Plain films can also be helpful in the evaluation of symptomatic sites. Additionally, radiography has been used in an attempt to assess the risk of pathologic fracture in long bone metastases. Fidler et al. proposed that pathologic fracture was unlikely if less than 50% of the cortex was destroyed, likely if 50% to 75% was destroyed, and expected if greater than 75% was destroyed.²³ Given the limitations of plain film radiography, this is likely only an approximation.

A related clinical presentation in which radiography is still the imaging modality of choice is multiple myeloma. Lesions associated with myeloma are notorious for their low conspicuity on conventional bone scintigraphy, such that the bone survey is still used for staging and evaluation in this disease. Plain film usually demonstrates a “punched-out” lytic lesion (Figure 95.3). Nevertheless, evaluation of these surveys is difficult, with the inherent limitations of radiography meaning that significant disease can be missed.

Nuclear Medicine

In most cases, nuclear medicine scans using Tc-99m phosphate compounds represent the preferred method of evaluating skeletal metastases in both symptomatic and asymptomatic patients. Although they represent a powerful tool in the staging of metastatic disease due to their high sensitivity, a basic understanding of their mechanism of action is important when interpreting results. The radioactive complexes are incorporated into areas of bone formation or

increased osteoblast activity. This process can lead to areas of increased radiopharmaceutical activity in the presence of tumor, with a sensitivity reported at 50% to 80% greater than radiography. However, virtually any pathologic process can yield a similar appearance.²⁴ Foci of abnormally increased activity can be seen in the presence of fracture, infection, inflammation, surgery, and degenerative changes. Plain film correlation is indicated in situations or at sites where these processes may give the false impression of tumor spread.

In bone scintigraphy, the pattern of abnormal foci of activity may suggest the diagnosis of skeletal metastases. Multiple areas of increased activity of varying size, with a propensity for the axial skeleton, most likely represent metastatic disease (Figure 95.4). However, clinical correlation with the patient’s symptoms is necessary because the aforementioned mimics can coexist with metastatic disease. It has been estimated that only 50% of solitary “hot” lesions on bone scan indicate metastasis, even in the setting of a known malignancy²⁵; this underscores the importance of plain film correlation in characterizing bone scan abnormalities. Because plain film findings of metastasis can lag behind scintigraphic abnormalities, a negative plain film in the presence of an abnormality on nuclear scanning does not exclude the possibility of a metastasis.

Among metastases shown by bone scintigraphy, 39% were seen in the vertebrae, 38% in the ribs and sternum, 12% in the pelvis, with only 10% in the skull and long bones.²⁶ This propensity for the axial skeleton makes bone scanning particularly attractive as an initial evaluation, as it simplifies the evaluation of those parts of the skeleton that are more dif-

difficult to visualize by plain film: the scapula, sternum, ribs, and spine. Evaluation of the pelvis is sometimes complicated by pooling of the excreted radiopharmaceutical in the bladder.

The ribs are also sometimes difficult to evaluate. Areas of increased activity that parallel the long axis of the rib likely indicate metastasis, whereas more focal lesions, especially when arranged in a linear orientation in adjacent ribs, often indicate fracture. Although 80% of solitary foci of activity in a series of proven metastatic disease to bone were found to correspond to true metastatic lesions, only 17% of solitary "hot spots" in the ribs were the result of metastasis.²⁷

As tracer activity is dependent on the presence of bone turnover, photopenic or "cold" lesions can be seen in the presence of particularly aggressive tumors, where the growth is

too rapid for sufficient reactive bone growth. This presentation can be seen in metastases from carcinoma of the breast or lung. Additionally, diffuse metastatic involvement throughout the skeleton can lead to a relatively homogeneous appearance, yielding a false impression of a normal scan. This entity, termed the "super scan," should be suspected in the setting of intense skeletal activity in the absence of renal, bladder, or soft tissue uptake. The appearance is due to the increased extraction of the radiopharmaceutical by the reactive bone compared to the soft tissues and kidneys.

Bone marrow scanning has been advocated as an alternative to phosphate compound methods in the evaluation of some malignancies. In one study, bone marrow scanning with a monoclonal antibody complex detected almost twice the

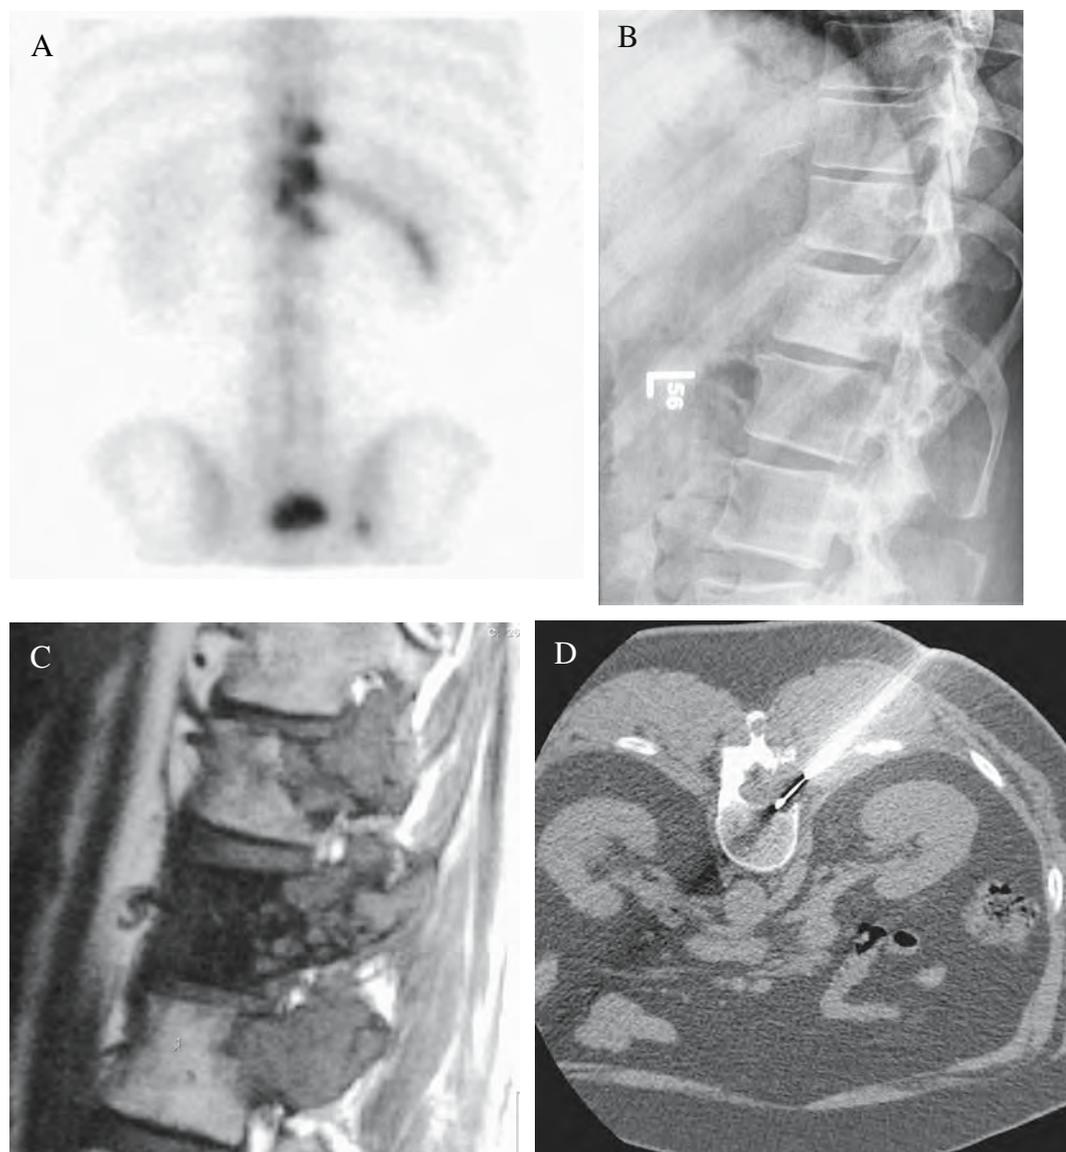

FIGURE 95.4. (A) Posterior tomographic image from a technetium-99m-MDP bone scan in a 55-year-old patient with a history of breast carcinoma, shows abnormally increased radiopharmaceutical activity on the right at the T11, T12, and L1 vertebral body levels. (B) Lateral film of the thoracolumbar spine in the same patient demonstrates lytic lesions at the same levels, which appear centered at the junction

of the pedicles with the vertebral bodies. (C) Sagittal T₁-weighted non-contrast MRI through the same region demonstrates abnormal marrow replacement centered at the vertebral body–pedicle junction. This case illustrates the improved marrow resolution of MRI relative to plain film. (D) Axial CT image in the same patient showing CT-guided core biopsy of the T12 lesion via a transpedicular approach.

number of metastases as conventional bone scanning. However, the number of patients identified as having skeletal metastatic involvement was the same with both methods, suggesting that management would not have been changed.²⁸

For screening in patients with papillary and follicular variants of thyroid carcinoma, ¹³¹I whole-body scans are preferred over Tc-99 studies. One study found that 78% of thyroid metastases visualized by radiography or ¹³¹I scans were undetectable or "minimally abnormal" on technetium bone scans.²⁹

Positron emission tomography (PET) scanning has gained widespread acceptance in the evaluation and staging of metastatic disease in recent years, having lately been approved for the evaluation of breast and lung carcinomas. PET has been shown to be moderately sensitive in the detection of prostatic carcinoma metastatic to the spine (sensitivity, 65%), but with high specificity (98%).³⁰ PET appears to be useful in separating Paget's disease and other benign entities (which demonstrate low uptake) from bone metastases or sarcomatous degeneration of Paget's.^{31,32}

Evaluation of Response to Therapy

Skeletal metastases may respond to chemotherapy, radiation therapy, and bone agents, such as the bisphosphonate class of drugs. This response may be detected through imaging studies. On plain radiographs, an increase in sclerosis may be seen, with progression of the sclerosis from the periphery toward the center of the lesion. Increasing sclerosis may make previously undetectable lesions visible radiographically. This misleading appearance may give the false impression of worsening disease. An increase in size of either a sclerotic or lytic lesion, as well as increased lysis in a previously blastic site, suggest failure of therapy and progression of metastatic disease.³³

Similarly, radioisotope bone scans may show an increase in tracer activity shortly after administration of chemotherapeutic drugs.³⁴ This so-called flare phenomenon is believed to represent increased radionuclide deposition secondary to bone healing and a resultant increase in bone formation. Additionally, an increase in the number of "hot spots" in the setting of therapy may represent previously undetectable lesions being made visible by the increase in bone formation. Such appearances must be correlated with the clinical history of therapy in order to avoid a false impression of worsening disease. If followed, healing lesions will eventually demonstrate decreased radiopharmaceutical uptake and should eventually take on a normal or near-normal appearance. In equivocal cases, radiographs can offer evidence of subtle changes that may not be manifest on bone scanning.³³

Computed Tomography

Computed tomography (CT) is useful as an adjunct to other imaging modalities in the evaluation of metastases. While CT is capable of demonstrating abnormalities before they are seen on radiography, it is a cumbersome tool for screening the skeleton. CT can delineate abnormalities seen on bone scan when they cannot be corroborated by plain film evaluation. CT can also depict subtle areas of cortical involvement in long bones better than radiography. It can demonstrate spinal metastases better than plain film, and can be used in con-

junction with nuclear medicine scans to more clearly elucidate specific sites of involvement, such as the pedicles.^{35,36} Similarly, the complex bony anatomy of the pelvis is better evaluated by CT. Quantitative CT has been used to detect marrow replacement in long bones before bone destruction is noted. Increased attenuation compared with the normal fatty marrow suggests the abnormality. A difference between the right and left sides of 20 Hounsfield units is considered abnormal.³⁷

Perhaps the most potentially useful aspect of CT in the evaluation of metastatic disease is as a means of directing biopsy. CT-guided biopsy of suspected areas of tumor involvement has been shown to be a safe and effective means of reaching a diagnosis and, in the setting of metastatic disease, provides staging information as well.^{38,39} Although image-guided biopsies of bone lesions have been performed for over 60 years, CT allows improved precision of needle placement over previous fluoroscopic techniques (Figure 95.4D). Modern techniques allow most procedures to be performed on an outpatient basis and under local anesthesia, thereby decreasing the cost and potential morbidity compared with surgical biopsy.³⁹⁻⁴²

Most skeletal lesions can be reached under CT guidance. This ability to make a tissue diagnosis has wide-ranging implications in guiding subsequent management. CT-guided biopsy can also identify alternative diagnoses, such as infection and primary tumors of bone. Percutaneous biopsy of metastatic lesions has been shown to have a higher accuracy than biopsies of infections and primary tumors.⁴³ Nonetheless, this information can drastically alter management.

Image-guided biopsy of spinal lesions under CT guidance has been shown to have an overall accuracy of 71% to 100%.³⁹ In an early study, 78% of clinically or histologically confirmed bone malignancies were correctly identified by CT-guided fine-needle aspiration.⁴⁰ More recent studies have reported successful diagnoses by CT-guided bone biopsy in 71% to 89% of cases.^{38,39,40,44} CT-guided biopsy has also proven useful in the diagnosis of benign lesions, which can give the false impression of malignancy.⁴⁴

In addition to CT-guided biopsy as a means of diagnosis and staging, recent work has studied the potential for percutaneous treatment of lesions. Techniques have involved alcohol injections and ablation, for the purpose of palliation. In one study, 25 patients with painful skeletal metastases that were previously unsuccessfully treated, received image-guided injection of 95% alcohol; 74% of these patients reported decreased analgesic requirements within 2 days of the procedure.⁴⁵ Painful vertebral body fractures have also been treated by vertebroplasty under fluoroscopic or CT guidance.

Magnetic Resonance Imaging

Skeletal metastases lead to infiltration or replacement of normal marrow. This propensity for marrow involvement underlies the usefulness of magnetic resonance imaging (MRI) in the identification of metastatic lesions. The fact that the majority of red marrow in adults is located within the axial skeleton, where metastases most commonly occur, makes this an ideal technique.

MRI is used most often to evaluate metastatic disease of the spine, where it has proven superior to CT and myelography.^{46,47} The superior soft tissue detail of MRI allows it to

demonstrate paravertebral extension of tumor as well as canal involvement, whether the spinal cord is compressed or not. In the setting of extradural masses, MRI is more sensitive than CT myelography.⁴⁸ The excellent marrow detail achievable by MRI also makes it a useful adjunct to conventional bone scans. MRI has been shown to be more sensitive to spinal metastases than bone scintigraphy, although bone scanning is probably more practical as an initial screening method at this time, with MRI used to further evaluate equivocal nuclear medicine findings.^{49,50}

Faster MRI sequences under development may make screening with MRI feasible, obviating the need for scintigraphy in many circumstances. These methods employ sequences designed to highlight sites of marrow infiltration. Early studies comparing MRI marrow screening of the axial skeleton to whole-body bone scintigraphy, showed no significant difference in accuracy when evaluating breast and prostate cancer patients for skeletal metastases. In this study, 2% had isolated metastatic involvement of the appendicular skeleton. Nevertheless, 75% of patients with isolated peripheral involvement experienced pain, with subsequent plain films showing the metastatic lesions.⁵¹ A more recent study used turbo-STIR (short tau inversion recovery) imaging of the whole body to evaluate metastatic involvement in a small group of patients with breast cancer. Comparison showed an 88% concordance rate between the two modalities, with MRI showing an additional lesion not evident on scintigraphy and subsequently shown by biopsy to be malignant.⁵² MRI techniques, such as these, provide the additional potential benefit of evaluating the liver and brain. While initial results appear promising, larger studies will be required before scintigraphy is likely to be replaced.

Normal bone marrow (including hematopoietic marrow) contains a high percentage of fat, making it high in signal on T₁-weighted spin echo images. Metastatic foci in adults characteristically demonstrate areas of decreased signal on T₁-weighted images relative to the high signal of normal fatty marrow (see Figure 95.2B). These lesions often demonstrate increased signal on STIR or T₂-weighted spin echo images, owing to their high water content, and often have a surrounding area of bright T₂ signal (known as the "halo" sign).⁵³ Variable enhancement is seen following gadolinium administration, and different metastatic foci within the same patient can demonstrate vastly different enhancement patterns. Lesion conspicuity on gadolinium-enhanced scans can be improved by employing fat suppression techniques (see Figure 95.1B). Use of fat suppression on precontrast images can actually lower sensitivity, however, because of the loss of the otherwise noticeable fat-soft tissue interface.

MRI can be useful in distinguishing osteoporotic vertebral body compression fractures from those arising secondary to metastases. In the setting of an osteoporotic compression fracture, marrow signal intensity should follow that of normal marrow in adjacent vertebral bodies. Metastatic foci will demonstrate findings of marrow replacement, as already noted, and may show enhancement following gadolinium administration. Additional findings suggestive of metastatic compression fracture on MRI include a convex posterior border of the vertebral body, abnormal signal intensity involving the pedicle or posterior elements (Figure 95.4B,C), and the presence of an epidural or paraspinal mass.⁵⁴ The presence of multiple lesions also suggests metastatic involvement.

Acute benign compression fractures can have a similar appearance to metastatic lesions, making this differential diagnosis particularly difficult.⁵⁵ Findings suggestive of acute osteoporotic compression fracture are low signal intensity on both T₁- and T₂-weighted images, spared bone marrow signal within the vertebral body, retropulsion of bone fragments, and the presence of multiple compression fractures.⁵⁴ The use of gadolinium also may be helpful, with metastatic lesions expected to show enhancement relative to the adjacent marrow.⁵⁵

Many of the techniques employed in MR imaging lack specificity with respect to the evaluation of metastases. Infection, as well as several benign tumors, can mimic the appearance of metastases on imaging studies. MRI is also subject to decreased sensitivity in the setting of diffuse metastatic involvement, similar to the so-called "super scan" encountered in nuclear medicine.

Diagnostic Evaluation

In general, patients presenting for evaluation of a metastatic lesion to bone fall into three categories.⁵⁶ The first category is a patient with a known primary tumor who presents with bone pain and a lesion on plain radiographs or with pathologic fracture. The second category is the asymptomatic patient with a known primary lesion who is found to have areas of increased uptake on scintigraphic evaluation. The third category is a patient who does not have a known diagnosis of cancer and presents with pain or pathologic fracture and a suspicious lesion on plain radiographs. Each patient deserves an organized approach to their management. A systematic approach can shorten the time to and improve the accuracy of the diagnosis and eliminate pitfalls in treatment.

The evaluation of the patient should begin with a thorough history and physical examination. Focused questioning in the history of present illness will often reveal symptoms of mechanical pain before pathologic fracture, which can be particularly helpful in the patient with an unknown primary. Patients should be asked directly whether they have had a diagnosis of cancer. Often patients with a history of cancer followed by a prolonged disease-free interval do not consider the previous diagnosis as pertinent. However, bone metastases may present after a decade or more of remission from, for example, breast cancer. Social and occupational history should be focused to reveal any exposure to possible carcinogens. The sexual history may also be contributory, as human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) carries an increased risk of certain neoplasms. A thorough review of systems should include specific questions regarding respiratory, endocrine, genitourinary, and integumentary systems. Patients should be asked directly about persistent cough or hemoptysis that may be associated with a lung carcinoma. The patients should be questioned directly about flank pain or hematuria, which may be related to a renal cell carcinoma. Symptoms typically associated with prostate enlargement, such as voiding hesitancy, frequency, and nocturia may be secondary to prostate carcinoma. Patients should be asked about suspicious lesions found on their skin or any history of biopsy. Patients should be asked whether they have ever had a breast mass or biopsy. All these

areas should be covered directly, because the association is often not apparent to the patient.

Physical examination, as always, should be complete. If the patient is presenting without an underlying diagnosis of a primary tumor, the physical examination should not be limited to the musculoskeletal system. Breast, intraabdominal, or prostate masses may indicate the primary site of disease.

Laboratory evaluation can be diagnostic in some cases of metastatic bone disease. Serum and urine protein electrophoresis studies can be diagnostic of multiple myeloma. A markedly elevated prostate-specific antigen (PSA) can lead to the diagnosis of prostate cancer. In most cases, however, laboratory workup is relatively nonspecific and therefore nondiagnostic. Nonetheless, a general laboratory workup, including complete blood count with differential, serum chemistries, and erythrocyte sedimentation rate, can help guide the management of the patient with suspected metastatic bone disease. Elevated white count may be indicative of infection or lymphoma. Leukocytosis may also be present in other marrow cell tumors, such as Ewing's sarcoma, multiple myeloma, histiocytosis, or leukemia. Erythrocyte sedimentation rate may also be elevated in these settings.⁵⁷ The utility of serum tumor markers has been established in the setting of known primary disease; however, they are of little value in the diagnostic workup of suspected metastatic disease to bone in the setting of an unknown primary tumor.⁵⁸

After a thorough history and physical examination and the appropriate laboratory studies, an algorithmic approach to the evaluation of suspected metastatic bone disease splits into two categories based on whether the patient has a known primary or not. Asymptomatic patients with a known primary malignancy typically present following a bone scan that demonstrates an area of increased metabolic activity. If this is the case, the next study obtained should be a plain radiograph of the area in question. If plain radiographs reveal a lesion that is nonaggressive in appearance and demonstrates diagnostic characteristics, it may represent an enchondroma or other benign bone tumor. The lesion can be followed with serial radiographs over time. Experience in recognizing such lesions may save the patient an unnecessary biopsy.⁵⁶

If the plain radiograph reveals a suspicious lesion, then bone scans should be reviewed to determine whether the patient has monostotic or polyostotic involvement. Metastatic disease to bone is commonly polyostotic; therefore, a monostotic lesion warrants advanced imaging before further workup. Advanced imaging would consist of CT and/or MRI. These studies can be diagnostic for certain primary tumors of bone and also are helpful in planning a biopsy.⁵⁹⁻⁶¹ Options for biopsy include CT-guided core needle biopsy, incisional biopsy, and excisional biopsy.

The issue of biopsy technique is important. The biopsy tract must be placed in such a way that it can be resected with the tumor in cases in which the final diagnosis is primary sarcoma of bone. Also, excessive dissection and tissue contamination should be avoided while meticulous hemostasis must be maintained. Mankin et al. have shown that poorly placed and poorly performed biopsies can result in a higher incidence in the need for amputation.^{60,61} Pathologic analysis is necessary to determine definitively whether a lesion represents a primary bone tumor, such as sarcoma, or metastatic disease. It must be remembered that patients with a history of cancer elsewhere can have a second primary

malignancy. The clinician must be particularly concerned about the patient with monostotic disease and no previous history of metastasis. However, in the setting of metastatic disease, pathologic analysis of the biopsy specimen is often unable to provide the primary diagnosis.⁶² Once the diagnosis has been established, treatment can proceed as indicated.

The patient with a known primary malignancy who presents with a bone scan that demonstrates polyostotic disease, should obtain plain radiographs of each involved area. If there is no area of impending pathologic fracture identified on plain radiograph, the patient can be followed with observation or treated medically and/or with radiation. If the diagnosis is in doubt, biopsy can be performed at the most accessible site. If radiographs do reveal an impending fracture, surgical treatment should be considered.

Diagnosing the patient with an unknown primary can present a more daunting clinical dilemma. However, an organized approach can produce a diagnosis of the primary site of disease in the majority of cases.⁶² A thorough history and physical, along with laboratory evaluation, in some cases will reveal the primary diagnosis. Serum or urine protein electrophoresis may lead to a diagnosis of myeloma. In these cases, a skeletal survey should be obtained and the patient should be referred to a medical oncologist. If history, physical, and laboratory findings fail to identify a primary diagnosis, the workup should proceed with a bone scan to look for polyostotic disease. CT images of the chest, abdomen, and pelvis also should be obtained as a screening for primary tumors.^{56,62} If the CT scan identifies a primary tumor, the patient should then be staged and treated as indicated. If the CT scan fails to identify a primary tumor and the bone scan reveals polyostotic disease, biopsy should then be performed on the most appropriate and accessible site. Treatment can then proceed as indicated. If the CT scan is negative and the bone scan reveals monostotic disease, the lesion should be assumed to be sarcoma until proven otherwise, and the patient should be referred to an orthopedic oncologist.

Rougraff et al. conducted a study of 40 consecutive patients with metastasis of unknown origin.⁶² The patients were evaluated with history and physical, routine serum laboratory studies, plain radiographs of the involved bones and chest, whole-body bone scintigraphy, and CT of the chest, abdomen, and pelvis. The most accessible bone lesion was then biopsied. Serum laboratory studies were nondiagnostic. History and physical revealed the primary site in 3 patients (1 each with carcinoma of the breast, kidney, and bladder). Plain chest radiographs established the diagnosis of lung carcinoma in 17 patients whereas chest CT made that diagnosis in an additional 6 cases. CT of the abdomen and pelvis established the diagnosis in 5 patients (3 with kidney carcinoma and 1 each with carcinoma of the liver and colon). Examination of the bone biopsy specimen established the diagnosis in 3 additional patients (1 with melanoma and 1 each with carcinoma of the lung and thyroid) and confirmed the primary diagnosis in 11 others. Therefore, with this strategy, the authors were able to identify the primary site of disease in 34 of 40 patients who presented with metastasis of unknown origin. Of interest, the most common primary site of disease was the lung (24 cases) followed by the kidney (3 cases). Breast carcinoma only accounted for 1 case, whereas prostate carcinoma accounted for no cases. Also of interest, histologic review of the biopsy specimen alone was able to

identify the primary site in only 14 cases, whereas the pre-biopsy workup identified the primary site in 31 cases.

Once the diagnosis has been established, there are three primary modes of treatment: medical management, radiation, and surgical treatment. These modes of treatment are addressed in the following sections.

Treatment Options

Radiation Treatment

EXTERNAL-BEAM RADIATION THERAPY

Although the specific cause of cancer-related bone pain may differ, that is, mechanical, inflammatory, muscle spasm, or nerve compromise, more than 75% of patients with osseous metastasis will develop pain as their most important cause of reduced quality of life.⁶³ Radiation therapy has been the mainstay of relieving pain associated with bone metastasis. Unfortunately, this modality is used for localized palliation and is often used in conjunction with other systemic means of pain control. Data supporting wide-field radiation therapy, or "half-body" irradiation, do exist; however, this modality is not generally used in the United States. Regardless, there are several randomized trials providing Level 1 evidence concerning the optimal schedule of local radiation treatment (Table 95.1).

The primary endpoint in all these studies is pain relief. Keep in mind that differences exist in the mechanism of ascertaining pain relief, for example, physician assessment versus

patient assessment, and that often, patients are given concurrent analgesia, which complicates the conclusions. The major question that is addressed in these trials is whether a shorter radiation therapy schedule results in comparable pain relief compared to the conventional schedule. Five prospective randomized trials performed during the 1980s to 1990s, examined variations in duration of treatment. Various treatment programs were compared, ranging from 30 Gy in 2 to 3 weeks (daily dose of 2–3 Gy) as the standard approach, with shorter durations of treatment utilizing three to five fractions of 15 to 20 Gy total. Overall, each study concluded that significant differences in pain relief did not occur with shorter duration of treatment. Clearly, these studies varied in sample size (57 to 759), performance status, and whether concurrent systemic antineoplastic therapy was permitted; however, these studies supported the trend in reducing duration of radiation treatment for palliation of osseous metastasis.^{64–68} Only one study performed by the Radiation Therapy Oncology Group (RTOG) was large enough to support Level 1 evidence; however, the remaining studies can be classified as having Level 2 scientific evidence.^{68,69}

Five additional prospective randomized trials compared the outcome of "conventional" duration of radiation treatment for bone metastasis with a single treatment fraction of 8 Gy. Again, these studies provide Level 1 evidence supporting equivalency in symptom relief with a single treatment dose. Two studies randomized a total of 1,200 patients to either a single dose of 8 Gy or a total of 24 Gy given in 6 fractions, and found no difference in pain scores.^{70,71} These results were supported by three prospective randomized trials involving a total of 1,294 patients receiving treatment, either with a single fraction of 8 Gy or 20 to 30 Gy given over 5 to 10 frac-

TABLE 95.1. Radiation schedule and the treatment of osseous metastasis.

<i>Trial</i>	<i>Year</i>	<i>No. of patients</i>	<i>Randomized</i>	<i>Disease</i>	<i>Design</i>	<i>Median follow-up</i>	<i>Results</i>	<i>Conclusions</i>
Bone ⁷³ Pain Trial Working Party	1999	765	Prospective	All	8 Gy single fraction vs. 20 Gy/5 fractions or 30 Gy/10 fractions	12 months	No difference in pain relief or overall survival	Single-fraction treatment is comparable to multifraction treatment
Gaze ⁷⁵	1997	245	Prospective	All	10 Gy single vs. 22.5 Gy/ 5 fractions	2 years	Median duration of pain relief: 13.5 weeks (single) vs. 14 weeks (multi)	Single-fraction treatment is comparable to multifraction treatment
Nielsen ⁷²	1998	241	Prospective, Phase III	All	8 Gy single vs. 20 Gy/4 fractions	2 years	At 20 weeks follow-up: 72% pain relief (single) vs. 82% (multi); duration of relief is same	Single-fraction treatment is comparable to multifraction treatment
Steenland ⁷¹	1999	1171	Prospective	All	8 Gy single vs. 24 Gy/6 fractions	4 months	Time to pain relief is same, 3 weeks; no difference in pain scores (<i>P</i> = 0.24)	Single-fraction treatment is comparable to multifraction treatment
Price ⁷⁴	1986	288	Prospective	All	8 Gy single vs. 30 Gy/10 fractions	3 months	Incidence of complete relief at 4 weeks = 27% (same); same duration of relief	Single-fraction treatment is comparable to multifraction treatment

TABLE 95.2. Efficacy of radioisotopes in the treatment of osseous metastasis.

Trial	Year	No. of patients	Randomized	Disease	Design	Median follow-up	Results	Conclusions
Serafini ⁹²	1998	118	Double-blind	All	¹⁵³ Sm-EDTMP 0.5 vs. 1.0 mCi/kg or placebo	16 wks	31% pain relief by week 4	Benefit in higher-dose ¹⁵³ Sm
Lewington ⁹¹	1991	32	Double-blind, crossover	Prostate	⁸⁹ Sr 150 MBq vs. placebo	5 wks	Only patients receiving ⁸⁹ Sr were pain free	Benefit with ⁸⁹ Sr
Porter ⁹⁰	1993	126	Double-blind	Prostate	⁸⁹ Sr 10.8 mCi vs. placebo	6 mo	At 3 months follow-up: 40% pain free with ⁸⁹ Sr vs. 23% placebo	Reduced pain-score in 70% ⁸⁹ Sr vs. 55% placebo; benefit with ⁸⁹ Sr
Buchali ⁸⁹	1988	49	Double-blind	Prostate	75 MBq ⁸⁹ Sr vs. placebo	5 wks	No difference in pain; increased survival with ⁸⁹ Sr: 46% vs. 4% 2-year OS	Survival benefit with ⁸⁹ Sr

OS, overall survival.

tions. Pain relief was comparable between the two regimens.⁷²⁻⁷⁴ A single trial using 10Gy as its single treatment fraction supported the previous results when compared with a 22.5Gy treatment given over 5 fractions.⁷⁵ Two additional randomized trials investigated the optimal single fraction dose of radiation therapy; 4Gy versus 6Gy versus 8Gy. In general, 8Gy was considered the "lowest" dose that would result in adequate pain control of bone metastasis.^{76,77}

Three systematic reviews of the literature describing randomized trials comparing short versus long duration of radiation therapy for palliation have concluded that shorter therapy (single fraction of 6-10Gy) is comparable to longer treatment.⁷⁸⁻⁸⁰ Overall, there is sufficient Level 1 evidence to support single-fraction therapy for the palliation of bone metastasis.⁸¹ An additional benefit of single-dose therapy that was discussed within these randomized trials was the ability of retreating the disease site if symptoms reoccurred. This action was deemed acceptable in the majority of studies, yet clearly the need for retreatment suggests an inadequate disease response to the original radiation received. These difficulties in comparing pain relief due to radiation therapy among the various studies is being addressed by a task force (International Bone Metastasis Consensus Working Party) that will enable further prospective randomized trials utilizing radiation therapy to be performed in a more consistent fashion and support stronger evidence for treatment strategies.⁸²

SYSTEMIC RADIONUCLIDE THERAPY

Several radiopharmaceuticals are approved for palliative treatment of bone metastasis in the United States; however, the Level 1 and Level 2 data are scarcer than those available for conventional radiation therapy. The characteristics of all radionuclides used in this setting are the need for the nuclide to be preferentially deposited in the bone, and that the product emits particulate radiation that is locally absorbed.⁸³ Phosphorus-32 has been widely used for the control of myeloproliferative diseases because it is also preferentially incorporated into bone marrow; however, it can also be used to effectively control pain caused by osseous metastasis from solid tumors.⁸⁴

Physician practice is not as supportive of radionuclide therapy for palliation, and specifically, ³²P is used less than newer approved treatments because of concerns with myelosuppression.⁸⁵ This concern was supported in a randomized trial of 31 patients receiving either ³²P or ⁸⁹Sr, a radioactive calcium analogue that is a beta emitter which has less hematologic toxicity and is effective in the treatment primarily of blastic metastasis.^{86,87} More than 90% of the patients in each group achieved pain relief; however, bone marrow suppression was slightly more common in the ³²P-treated patients.⁸⁸ Three randomized control trials with ⁸⁹Sr and one trial with samarium-153 (both approved for use in the United States) provide Level 1 evidence supporting the use of radionuclides in reducing pain due to osseous metastasis.^{89,90,91,92} Two systematic reviews lend Level 1 support and confirm the optimal dose of ⁸⁹Sr (150-200 MBq) and ¹⁵³Sm (1.0mCi/kg) that result in pain relief after approximately 1 to 2 weeks, lasting for approximately 2 to 4 months in 60% to 80% of patients treated with a single administration of nuclide.^{78,93} Caution must be used in the application of these therapies because of the potential for bone marrow suppression; repeated administration of nuclide has not been thoroughly investigated. Patients with multiple osteoblastic metastasis or mixed lesions that have not been extensively pretreated with radiation therapy and chemotherapy offer the optimal patient population for response with minimal toxicity with radiopharmaceuticals.⁹⁴ These results are presented in Table 95.2.

Medical Treatment

BISPHOSPHONATE THERAPY

Bisphosphonates are analogues of pyrophosphate wherein a carbon atom replaces the central oxygen atom. This structure permits binding to hydroxyapatite within bone and results in an increased resistance to hydrolysis and consequent reduction in bone mineral dissolution because of their phosphorus-carbon-phosphorus bond. For this reason, bisphosphonates are extremely effective in the treatment of hypercalcemia that occurs in approximately 10% to 20% of

patients with cancer. In addition, bisphosphonates have been shown to inhibit osteoclast activity, lessen chemotaxis of osteoclasts to sites of bone resorption, and induce osteoclast apoptosis by inhibiting the enzyme farnesyl diphosphate synthetase and inhibiting cytokine synthesis by stromal cells, for example, IL-6 production.⁹⁵⁻⁹⁷ Consequently, the use of bisphosphonates is effective in reducing the morbidity of skeletal events associated with metastatic disease, such as fracture and pain, and may contribute to the delay in the progression of osseous metastasis by interfering with tumor cell adhesion to bone or directly inducing tumor apoptosis.^{98,99} Although the majority of data supporting the use of bisphosphonates primarily involve patients with metastatic breast and prostate cancer or multiple myeloma, several recent trials also support the use of this class of drugs for adjunctive treatment of osseous metastasis due to other solid tumors.

HYPERCALCEMIA

Level 1 evidence does exist that supports the use of bisphosphonates in the treatment of hypercalcemia of malignancy.¹⁰⁰ However, these studies are very heterogeneous and they could not be analyzed in a meta-analysis. Overall, the randomized trials demonstrate that the administration of bisphosphonates (pamidronate, clodronate, etidronate, ibandronate) resulted in greater than 70% incidence of normalization of calcium levels within 2 to 6 days, which is significantly superior to either saline infusion or mithramycin.¹⁰¹⁻¹⁰⁵ There is a single randomized trial involving 71 patients that demonstrated superiority of gallium nitrate compared with etidronate in controlling hypercalcemia.¹⁰⁶

A summary of the randomized trials presented in Table 95.3 demonstrates nonstatistically significant superiority by

TABLE 95.3. Comparisons of bisphosphonates in the treatment of cancer-related hypercalcemia.

<i>Trial</i>	<i>Year</i>	<i>No. of patients</i>	<i>Randomized</i>	<i>Disease</i>	<i>Design</i>	<i>Median follow-up</i>	<i>Results</i>	<i>Conclusions</i>
Gucalp ¹⁰⁷	1992	65	Randomized after 24 h IV hydration	All	60 mg IV pamidronate vs. 7.5 mg/kg IV etidronate × 3	7 days	Pamidronate normalized calcium in 70% vs. 41% ($P = 0.26$)	Pamidronate normalizes calcium more frequently than etidronate
Purohit ¹⁰⁸	1995	41	Randomized after 48 h IV hydration	All	90 mg IV pamidronate vs. 1,500 mg IV clodronate	28 days	Pamidronate normalized calcium in 100% vs. 80% (NS) Median duration of normalization 28 days pamidronate vs. 14 days ($P < 0.01$)	Pamidronate results in a longer duration of normal calcium levels than clodronate
Ralston ¹⁰⁹	1989	48	Randomized after 48 h IV hydration	All	30 mg IV pamidronate vs. 600 mg IV clodronate vs. 7.5 mg/kg IV etidronate × 3	9 days	At day 6, calcium levels were lower with pamidronate vs. clodronate ($P = 0.01$) vs. etidronate ($P = 0.001$) Longer median time to relapse with pamidronate, 29 days vs. 12 days vs. 10.5 days	Pamidronate results in a longer duration of normal calcium levels than clodronate or etidronate
Major ¹¹²	2001	287	Two identical parallel concurrent double-blind, double-dummy	All	90 mg IV pamidronate vs. 4 mg or 8 mg IV zoledronic acid	56 days	Zoledronic acid normalized calcium within 10 d in 88.4% (4 mg, $p = 0.002$), 86.7% (8 mg, $p = 0.015$) vs. 69.7% pamidronate. Median duration of normalization 30 d (4 mg, $p = 0.001$), 40 d (8 mg, $p = 0.007$) vs. 17 d pamidronate	Zoledronic acid results in a longer duration of normal calcium levels than pamidronate

pamidronate in the time to normalization of calcium levels and prolongation of the time to relapse of hypercalcemia compared with etidronate and clodronate.¹⁰⁷⁻¹¹¹ Two parallel multicenter double-blind, double-dummy randomized trials, involving a total of 275 patients, compared two dose levels of zoledronic acid (4 mg and 8 mg) to pamidronate (90 mg) in the treatment of malignancy-induced hypercalcemia. Interestingly, both dose levels of zoledronic acid were superior to pamidronate in both response rates, resulting in normalization of calcium levels and duration of normocalcemia.¹¹²

Several other studies investigated the optimal dose of each bisphosphonate, including pamidronate and zoledronic acid. A well-designed randomized trial demonstrated a dose-response relationship using pamidronate, with the optimal dose equaling 90 mg IV. There did not appear to be any advantage among the various dosing durations or schedules.¹¹³ The toxicity associated with bisphosphonate use in this setting is minimal. Self-limiting fever appears to be the most common effect, followed by hypocalcaemia and hypophosphatemia, which did not require metabolic correction.

SKELETAL MORBIDITY

Several bisphosphonates have demonstrated the ability to reduce the incidence of bone pain and fracture due to metastatic disease. Most of the current evidence supports the use of intravenous administration, because approximately 5% of bisphosphonates are absorbed with oral administration, and this absorption is quite variable depending upon concurrent intake with other medicines and food. Level 1 evidence supports the inclusion of bisphosphonates as adjunctive therapy in the treatment of osseous metastasis to reduce skeletal morbidity. This Level 1 evidence is presented in the form of a meta-analysis involving 18 randomized clinical trials that compare bisphosphonate use with placebo and result in a statistically significant reduction in the odds ratio (OR) for vertebral fractures of 0.692 [95% confidence interval (CI), 0.570-0.840], nonvertebral fractures of 0.653 (95% CI, 0.540-0.791), combined fractures of 0.653 (95% CI, 0.547-0.780), and need for radiation therapy of 0.674 (95% CI, 0.573-0.791).¹⁰⁰ Several bisphosphonates were included in this analysis, including zoledronic acid, pamidronate, and clodronate, administered either orally or intravenously.

Among those randomized placebo-controlled studies included in the meta-analysis, the majority of trials involved patients with metastatic breast cancer, evaluating the efficacy of either adjunctive pamidronate or clodronate versus placebo.¹¹⁴⁻¹¹⁹ Again, a dose response was demonstrated with regard to skeletal-related events, and the administration of bisphosphonates orally was problematic due to gastrointestinal (GI) toxicity.¹²⁰⁻¹²⁴ The efficacy of zoledronic acid compared with placebo was examined among patients with metastatic prostate cancer, lung cancer, and other malignancies.^{125,126} In two very large randomized trials comparing zoledronic acid with pamidronate, they appear to have equal efficacy in the reduction of skeletal events among a total of 2,128 patients with breast cancer or multiple myeloma.^{127,128} This Level 1 evidence establishes the role of bisphosphonates in the reduction of the incidence of skeletal-related events compared with placebo, regardless of the type of underlying cancer.

Although the majority of skeletal-related events discussed in the foregoing section referred to bone fractures, skeletal pain has been significantly reduced with the administration of bisphosphonates, and is often included in the description of "skeletal-related events" identified in clinical trials. Level 1 evidence exists supporting the addition of bisphosphonates as adjunct therapy to reduce the level of pain and to prolong the time to progression of pain associated with bone metastasis, regardless of the concurrent use of antineoplastic therapy.¹²⁹ Two randomized trials involving a total of 465 patients with metastatic breast cancer determined that pamidronate administration statistically significantly increased the time to progression of tumor pain and resulted in a significant reduction of bone pain.^{130,131} Identical results were demonstrated in a randomized trial of 55 patients with metastatic breast cancer treated with oral clodronate.¹³² The administration of zoledronic acid among 635 patients with metastatic prostate cancer resulted in lower pain and analgesic scores compared with placebo.¹³³

TUMOR PROGRESSION

One large, placebo-controlled trial has specifically investigated the benefit of adding bisphosphonates to systemic therapy for the treatment of metastatic osseous neoplasm and its impact upon disease progression (Level 2 evidence). This European Phase III trial involved 295 patients with metastatic breast cancer, and it showed that the addition of a bisphosphonate to traditional systemic therapy, whether it is chemotherapy or hormonal therapy, will result in a statistically significant delay in the progression of disease. These 295 patients were concurrently receiving chemotherapy and were randomized to either placebo or pamidronate, 45 mg intravenously, every 3 weeks. The group receiving the pamidronate had a 48% increase in the median time to bone progression: 249 days versus 168 days in the control arm ($P = 0.02$).^{134,135} Other randomized trials did not specifically address the issue of disease progression and its association with bisphosphonate use; however, they clearly demonstrate that the addition of bisphosphonate therapy did not affect overall survival.

Emerging Medical Therapy

Although there are good evidence-based data supporting several adjunctive therapies available for supportive treatment of osseous metastasis, many questions remain unanswered. We have yet to determine the optimal bisphosphonate, or whether it should be used in prevention strategies to reduce the risk of developing bone metastasis. It also is unclear as to what the optimal duration of bisphosphonate therapy is, or whether bisphosphonates in fact affect tumor growth and impact on survival. These are questions that future clinical trials need to address, and fortunately, the American Society of Clinical Oncology has presented some guidelines to aid the clinician in the application of bisphosphonate therapy in the treatment of breast cancer.¹³⁶ Increasing knowledge of the underlying pathogenesis of osseous metastasis has prompted several new therapies that target the biologic mechanisms responsible for the development of osteolytic bone metastasis and subsequent hypercalcemia. Biologic tumor necrosis factor-alpha antagonists, such as etanercept, are currently being investigated as therapies that

relieve painful metastasis that are otherwise refractory to treatment.¹³⁷ Col-3 is a modified form of tetracycline and its inhibitory effects on matrix metalloproteinases are currently being explored as a potential treatment for osseous metastasis. A similar mechanism of action has been noted with doxycycline, which also suppresses osteoclast differentiation and consequent survival.¹³⁸ Recent studies using calcitonin to reduce bone pain and the incidence of pathologic fractures have not been very encouraging, and the use of gene therapy, specifically targeting osteocalcin, continues to require ongoing investigation.^{139,140} Promising investigation is continuing using a humanized monoclonal antibody to parathyroid hormone-related protein that does not cross-react with parathyroid hormone.¹⁴¹ These are just some of the current clinical investigations in the pursuit of controlling the adverse consequences of metastatic disease involving bone.

Image-Guided Treatment

Approximately 50% of patients who develop metastatic disease have poorly controlled pain, and management of pain in patients with metastatic disease can be difficult.¹⁴² Traditional treatment modalities, such as radiation therapy, chemotherapy, surgery, and analgesic medication, may not satisfactorily address the needs of patients with skeletal metastases. Both radiation and chemotherapy have thresholds above which their toxic side effects become too severe to continue therapy. Additionally, side effects of conventional opioid analgesics can have a detrimental effect on the patient's quality of life.

Early research into image-guided, site-specific therapies has shown promise in the management of pain and immobility related to skeletal metastatic involvement. Initial studies involving injection of 95% ethanol into bone metastases under CT guidance led to decreased analgesic requirements in 60% of patients within 2 weeks.⁴⁵

More recent work has focused on the use of radiofrequency ablation of tumors as an additional option for pain management in metastatic disease. This research has borrowed from the collective experience using ablation to treat solid tumors of the abdomen and pelvis, especially the liver.^{143,144} This experience led to use of the technique to treat benign primary neoplasms of bone, such as osteoid osteoma and chondroblastoma, a practice that has since gained widespread acceptance.¹⁴⁵⁻¹⁴⁷

Applying radiofrequency (RF) ablation to painful skeletal metastatic lesions represents an exciting new option for patients for whom conventional therapies have been exhausted. Callstrom et al. demonstrated significant decreases in the pain scores and pain interference with daily activity in a series of patients treated with ablation. Eighty percent of patients using analgesic medication reported a decrease in use after the treatment.¹⁴⁸ In another study, 10 patients with unresectable spine metastases were treated with RF ablation. The patients reported an average of 74% decrease in pain scores, with 9 of 10 patients reporting an improvement in symptoms. Postprocedure MRI showed no further tumor growth at a mean follow-up time of 5.8 months.¹⁴⁹

Several studies have reported the use of cementoplasty under image guidance as a potential treatment for pathologic fractures. Conventionally used to prevent further collapse in the setting of osteoporotic compression fractures, this tech-

nique is being applied to existing and potential sites of pathologic fracture as well. Most reports concern treatment of sites of vertebral body involvement, with marked improvement in pain management, stability, and patient mobility.¹⁵⁰⁻¹⁵³ Significant pain relief and improved mobility were seen in 70% to 80% of patients treated with vertebroplasty in various studies.¹⁵⁰ In these patients, pain relief was apparent within 1 to 2 days of the procedure and persisted for several months to several years. Complications reported have been rare, with occasional symptoms related to extrusion of cement and subsequent compression of neural structures. When compared to the relatively higher cost and risk associated with spinal surgery, vertebroplasty may be an increasingly viable option in these settings.¹⁵⁰ Although most studies have dealt with treatment of spinal lesions, cementoplasty in combination with RF ablation has even been used to treat long bone metastases.¹⁵⁴

Although these findings represent the potential of new, more effective treatment of skeletal tumors, the number of patients studied remains low. Also, the small number of patients with various histopathologic diagnoses makes it impossible to determine whether certain types of malignancies are more susceptible than others to RF ablation.

Surgical Treatment

INDICATIONS FOR OPERATIVE TREATMENT

Patients with cancer metastatic to bone often present with pathologic fracture. Pathologic fracture of vertebral bodies and flat bones can often be treated nonsurgically. Pathologic fractures of long bones, however, are associated with significant morbidity and are often best managed with surgical intervention (Figure 95.5). If the patient's general medical status does not prohibit the risk of anesthesia, open reduction

FIGURE 95.5. AP radiograph of a peritrochanteric left femur pathologic fracture secondary to metastatic breast carcinoma in a 79-year-old woman stabilized with a cephalomedullary nail.

and rigid internal fixation or resection and reconstruction should be considered. There are also many cases in which prophylactic stabilization should be considered. Prophylactic stabilization of impending fracture can spare the patient significant morbidity. The difficulty lies in deciding which lesions represent impending fracture.²³ The decision of whether to perform prophylactic surgery should depend on several factors, including (1) the biologic activity of the lesion, as demonstrated by serial radiographs over time; (2) how the lesion responds to nonsurgical management, such as chemotherapeutics and radiation therapy; (3) the location of the lesion, for example, a periarticular lesion in the weight-bearing long bone demands stronger consideration than a lesion in a non-weight-bearing bone; and (4) the overall health and expectations of the individual patient.¹⁵⁵

Any cortical defect in a bone compromises its biomechanical properties, making it more prone to fracture. Cortical defects lead to an uneven distribution of stresses and are therefore, termed stress risers. Stress risers created by cortical screw holes were studied by Burstein et al. in a rabbit model. In their study, they demonstrated a 70% decrease in energy storage capacitance created by a single drill hole. The loss of bone strength is most significant in torsion.¹⁵⁶

Lesions creating cortical defects are generally divided into two categories, based on the relationship between the diameter of the involved bone and the maximum dimension of the lesion. Smaller lesions are simply referred to as stress risers, whereas larger lesions are termed open-section defects. Frankel and Burstein demonstrated through biomechanical testing of cadaveric bone that, by creating stress risers, the bone strength in torsion decreased by 60%, whereas open-section defects can decrease the load to failure of a bone by 90%.¹⁵⁷

These *in vitro* studies correlate with clinical findings and have led to some recommendations regarding prophylactic treatment. It has been recommended that for lesions greater than 2.5 cm in maximum dimension or lesions that are greater than 50% of the cross-sectional area of the bone, prophylactic treatment may be warranted.¹⁵⁸ Plain radiographs can be used to measure the maximum linear dimension and can also be used with orthogonal views to estimate the cross-sectional area involved. CT will give more accurate measures of cross-sectional involvement. Even with advanced imaging, however, interobserver variability exists. Using the criterion of a 2.5-cm or larger defect, Hipp et al. found up to a 42% probability of clinical errors on predicting fracture risk in metastatic lesions in 60 femurs (i.e., 19 of 60 femurs that were predicted not to fracture, did fracture), and up to 10% error in predicting fracture based on the criterion of 50% of cross-sectional area.^{23,159}

The clinical symptom of pain and specifically, the character of the pain, can be helpful in determining the need for prophylactic fixation. Pain that is worsened with activity and particularly, weightbearing, is suggestive of compromised mechanical integrity of the bone and potential for fracture. On the other hand, pain that is present at all times and not affected by activity is more likely associated with the biologic activity of the tumor and not necessarily a lack of mechanical integrity of the bone. Nonetheless, pain is a subjective factor, and as reported by Keene et al., there has been no study that has shown any value in the use of pain scores alone in estimating risk for pathologic fracture.¹⁶⁰

TABLE 95.4. Mirels objective scoring system.

Score	1	2	3
Site of lesion	Upper extremity	Lower extremity	Peritrochanteric
Pain	Mild	Moderate	Functional
Lesion	Blastic	Mixed	Lytic
Size	Less than 1/3	1/3 to 2/3	More than 2/3

Data from Mirels.¹⁶³

The biologic activity of the metastatic lesion, as best demonstrated by serial radiographs, can be very useful in predicting impending fracture. Serial radiographs should be used whenever possible to monitor the response of a lesion to conservative treatment. It is important to remember that bone is a living tissue, the form and function of which is a result of dynamic interplay among many factors. In the case of lytic metastatic lesions to bone, it is thought that the tumor cells tip the balance in favor of osteoclasts; not all metastatic lesions are purely lytic, however. They may be lytic or blastic or mixed lytic and blastic. Zickel and Mouradian reported that purely lytic lesions were the most likely to fracture, whereas purely blastic lesions were the least likely to fracture.^{161,162}

With the foregoing in mind, it is important to treat each patient on an individual basis. The patient must have sufficient life expectancy to consider undergoing surgical treatment. The outcome of the surgical intervention must be expected to expedite mobilization or facilitate the general care of the patient, barring any complication. Mirels created a scoring system to help predict the need for prophylactic fixation and retrospectively applied the system to 78 metastatic lesions to bone that were treated with radiation and without surgery.¹⁶³ Through his review, he was able to estimate pathologic fracture risk based on his objective scoring system. The scoring system rates four criteria from 1 to 3: anatomic site, pain level, lesion type, and fraction of cortex destroyed (Table 95.4). Mirels recommended prophylactic fixation of patients with a score of 8 or greater (Table 95.5). By his scoring system, a patient with functional pain (described as severe pain at rest, or pain with use of the extremity) in a weightbearing bone, automatically scores at least 8. This scoring system can be used as a guideline; however, it was created before bisphosphonates and some other nonsurgical treatment options were available.

TABLE 95.5. Risk of pathologic fracture by Mirels objective scoring system.

Perioperative Considerations

The typical cancer patient with disease metastatic to bone is elderly, malnourished if not cachectic, and has a limited physiologic reserve. The majority of these patients have significant medical comorbidities, including cardiovascular, respiratory, and metabolic disturbances. Careful preoperative medical evaluation and optimization are necessary to minimize the risk of operative and postoperative complications.¹⁶⁴ Preoperative assessment will identify patients that simply do not have the medical reserve to tolerate the anesthetic event or the surgical insult. Careful screening will identify these patients and direct them toward other treatment modalities. Special attention should be paid to patients who have been treated with chemotherapeutic agents with cardiotoxic side effects, or patients who have received radiation therapy that has exposed the heart or great vessels. Cancer patients are also prone to electrolyte disturbances and deep venous thrombosis.¹⁶⁵ These problems should be identified and managed appropriately preoperatively.

Metastatic tumors of certain origin, particularly kidney cancer, or in specific locations, are notorious for hypervascularity. These tumors should be considered for preoperative arteriogram followed by embolization before undergoing a planned resection. Sun and Lang reported a 40% decrease in operative blood loss achieved by preoperative embolization.¹⁶⁶ This successful use of preoperative embolization has been reported in metastatic lesions from renal cell, breast, thyroid, and bronchogenic carcinomas.¹⁶⁷⁻¹⁶⁹ Periacetabular lesions of any origin should be considered for preoperative embolization. Preoperative embolization should be performed within 24 to 36 hours of surgery. Embolization procedures are not without complication, however. Reported complications include transient lower extremity paresis, local muscle and soft tissue flap necrosis, cardiac arrest, and sciatic nerve impairment.¹⁷⁰ Tumor embolization has also been used as a palliative treatment for unresectable bone metastases and has demonstrated significant decreases in pain and improvement in patient mobility.¹⁷¹⁻¹⁷³

Operative Treatment

It is important to address the goals of surgery before outlining the different options in operative management. It is critical that both the surgeon and the patient understand the goals and expectations of operative treatment. The goals fall into the following general categories: palliation, fracture stabilization and healing, ease in patient care, maintenance of limb function, and restoration of the ability to ambulate. Underlying all these goals is the basic principle to do no harm. The patient must be expected to have the physiologic reserve to tolerate the planned procedure. This concern creates a difficult balance between sparing the patient with a poor prognosis from extensive surgery and rehabilitation that they may not tolerate, and undertreating patients who might have the quality of their remaining life improved by operative intervention. Schneiderbauer et al. recently published a retrospective study of 306 patients who underwent hip arthroplasty for treatment of pathologic or impending pathologic hip fracture. In their series, the median duration of survival after arthroplasty was 8.6 months, with a range from 0 days to 19 years. The survival rate reported was 78% at 3 months, 60% at 6

months, 40% at 1 year, 21% at 2 years, and 6% at 5 years postarthroplasty. Only 17 patients were alive after 5 years.¹⁷⁴

There are a number of surgical options available, which include fracture fixation with plates and screws or intramedullary rods. This fixation can be accompanied by resection of the lesion and allograft bone grafting or by augmentation of stabilization with methylmethacrylate cement. Resection of the lesion may require an intercalary prosthesis or bone graft for reconstruction. Periarticular lesions may be treated by resection arthroplasty, or resection and reconstruction with standard endoprostheses or mega-metallic endoprostheses.

In general, the operative treatment of metastatic bone disease can be categorized according to the site of the lesion. Lesions of flat bones that are symptomatic and refractory to conservative treatment can be treated with resection alone. Lesions involving the diaphysis of long bones are often optimally treated with intramedullary or plate fixation with or without cementation of the defect left by curettage of the lesion. Periarticular lesions often require reconstruction with endoprostheses. Depending on the extent of bone loss, complex reconstruction may be required; this may include a long-stemmed endoprosthesis in combination with a periarticular allograft in an attempt to preserve muscle attachments. Another alternative is to use an endoprosthesis designed to include segmental metallic replacement of the involved bone.

Many operative considerations are specific to the anatomic site of metastatic disease. Some site-specific considerations follow.

The axial skeleton is more commonly affected by metastatic disease than the appendicular skeleton. The axial skeleton consists of the spine and pelvis. The spine is particularly vulnerable to metastatic disease because of the anatomic relationship of the venous plexus of Batson,⁷ as previously described. Autopsy studies have reported that from 36% to 70% of patients who die with cancer have spinal metastasis.¹⁷⁵ Many spinal metastases are not detectable on plain radiographs. Spinal metastases most often occur in the anterior and middle columns.¹⁷⁶ Harrington devised a classification scheme for metastatic disease of the spine that is useful in formulating treatment plans.^{177,178} This classification scheme places patients into one of five classes. In class I, there is no significant neurologic involvement. In class II, there is bony involvement without any collapse. In class III, there is neurologic impairment and the absence of vertebral body involvement. In class IV, there is vertebral collapse or instability without significant neurologic involvement. In class V, there is vertebral collapse with major neurologic impairment. Typically, only patients with Harrington class IV or V spine disease are indicated for surgical intervention. In general terms, surgical treatment consists of neurologic decompression and stabilization of any mechanical instability. The decompression is typically achieved through an anterior approach. Stabilization of mechanical instability often requires structural grafting anteriorly combined with posterior instrumentation.¹⁷⁹⁻¹⁸¹ The majority of metastatic disease to the spine, however, can be managed nonoperatively.

The bony pelvis is the second most common site of metastatic disease to bone.⁶ Metastatic disease to the bony pelvis is often amenable to nonoperative treatment.¹⁸² However, many patients with periacetabular lesions will develop progressive functional pain or pathologic fracture

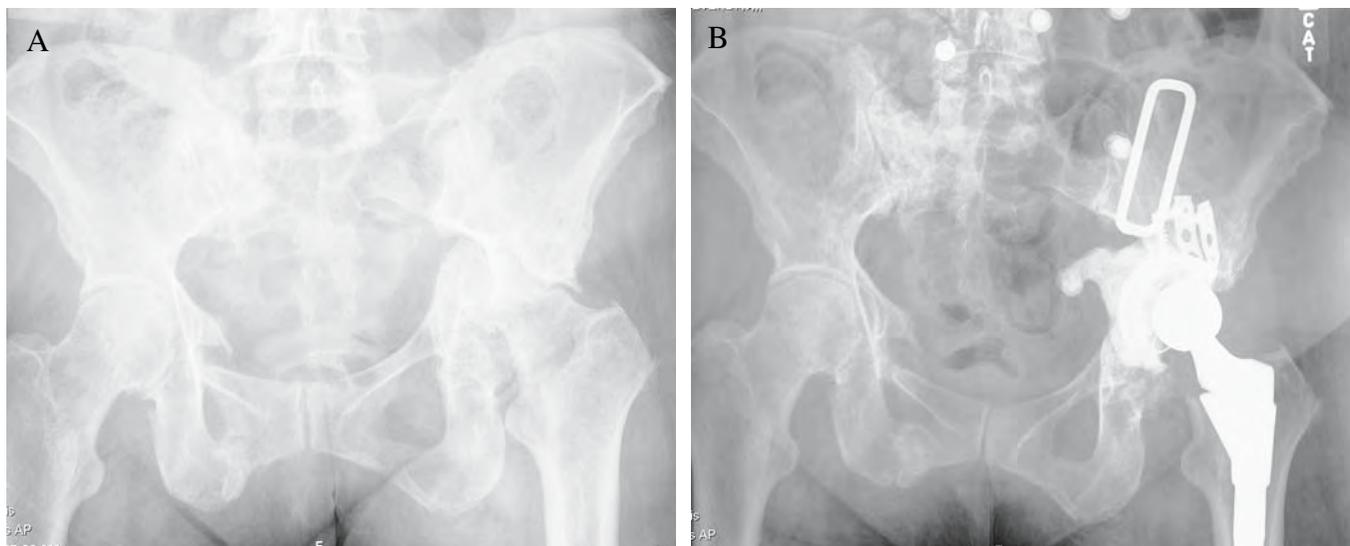

FIGURE 95.6. Preoperative (A) and postoperative (B) AP pelvis radiographs of a 46-year-old woman with metastatic breast carcinoma to her left acetabulum. Because of the destruction of the medial wall of the acetabulum, the hip was reconstructed with a cemented acetabular cup and protrusio plate reinforcement.

accompanied by the inability to ambulate; these patients' conditions can often be improved by operative reconstruction (Figure 95.6). Harrington devised a classification of acetabular insufficiency secondary to metastatic disease that helps direct the type of reconstruction the patient will need.¹⁸³ Class I acetabular insufficiency is one in which the lateral cortices, the superior and medial walls, are structurally intact; these lesions are amenable to conventional total hip arthroplasty. Class II insufficiencies include a deficient medial wall with a resulting hip protrusio. Class II deficiencies require a protrusio cup and cemented total hip arthroplasty. Class III insufficiencies include a deficient lateral and superior acetabulum. Harrington recommended a Steinmann pin-reinforced protrusio cup along with cemented total hip arthroplasty for these deficiencies. Class IV acetabular insufficiency is reserved for lesions for which complete resection is desirable, for example, renal cell carcinoma or thyroid carcinoma. These lesions require resection with reconstruction with saddle prostheses or custom implants, or resection without reconstruction could be considered (resection arthroplasty). Any reconstruction for an acetabular lesion should allow for immediate weightbearing.

The most common site of metastasis in the appendicular skeleton is the proximal femur.⁶ According to Ward et al., the femur is the most common site affected by metastatic disease of the bone that requires surgical treatment.¹⁸⁴ As alluded to previously, treatment options are based on the site of disease

within the femur. Diaphyseal lesions may be treated by curettage and cementing with plate and screw fixation or with an intramedullary device (Figure 95.7). Advantages to the use of plate and screws include direct exposure of the tumor site, which allows for open biopsy and confirmation of diagnosis. The major disadvantage of plate and screw fixation is that it only stabilizes the bone across the plate fixation. Intramedullary nailing has the advantage of providing a load-sharing device that can stabilize the entire length of the bone, including the lesion in question as well as any future lesions that might develop. A disadvantage to intramedullary nailing is the potential to spread the tumor locally along the extent of the bone during the reaming process. Ward recommends curettage of large lytic lesions before nail placement to minimize the risk of this complication.¹⁸⁴ Ward also recommends the use of a cephalomedullary nail as opposed to a standard intramedullary femoral nail to stabilize the femoral head and neck in the event of future spread to these areas.¹⁸⁴

Lesions at the proximal end of the femur, including the femoral head, neck, and intertrochanteric area, are often treated with arthroplasty. Depending on the extent of involvement, the reconstruction may involve a standard hemiarthroplasty or total hip arthroplasty, whereas extensive involvement of the proximal end of the femur may require proximal femoral resection and reconstruction with a customized megaprosthesis (Figure 95.8).¹⁸⁵⁻¹⁸⁷ Distal femoral

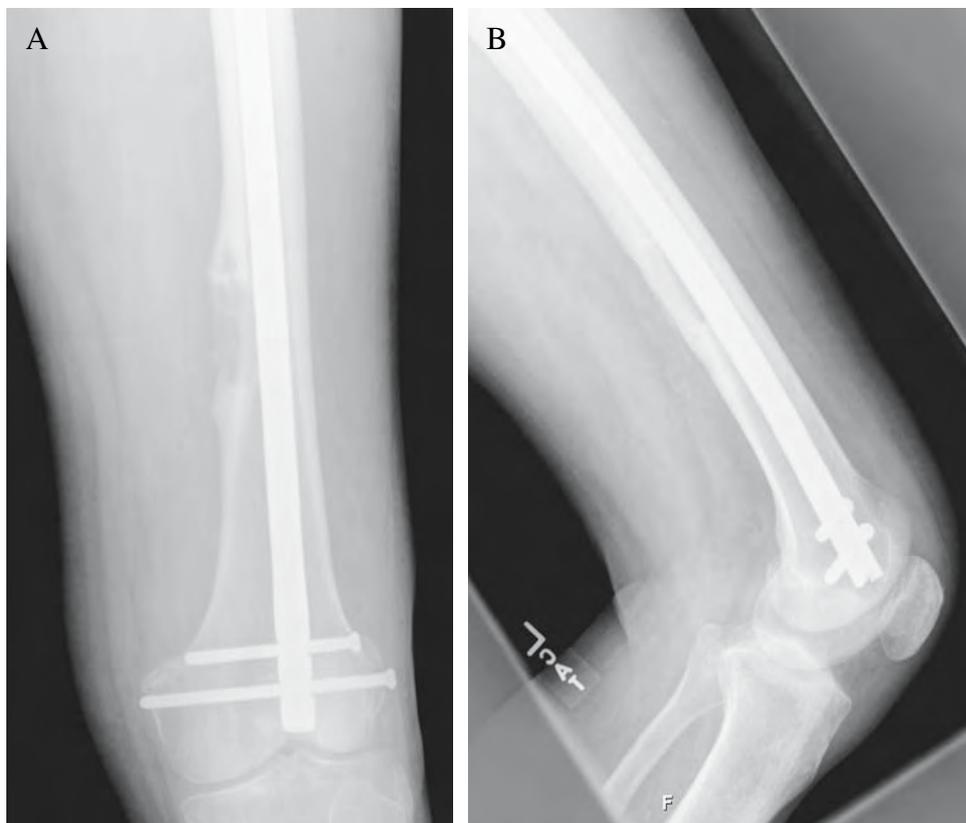

FIGURE 95.7. AP (A) and lateral (B) distal left femoral radiographs of a 65-year-old man with an intracortical metastasis from lung carcinoma. He underwent prophylactic fixation with a retrograde intramedullary femoral nail.

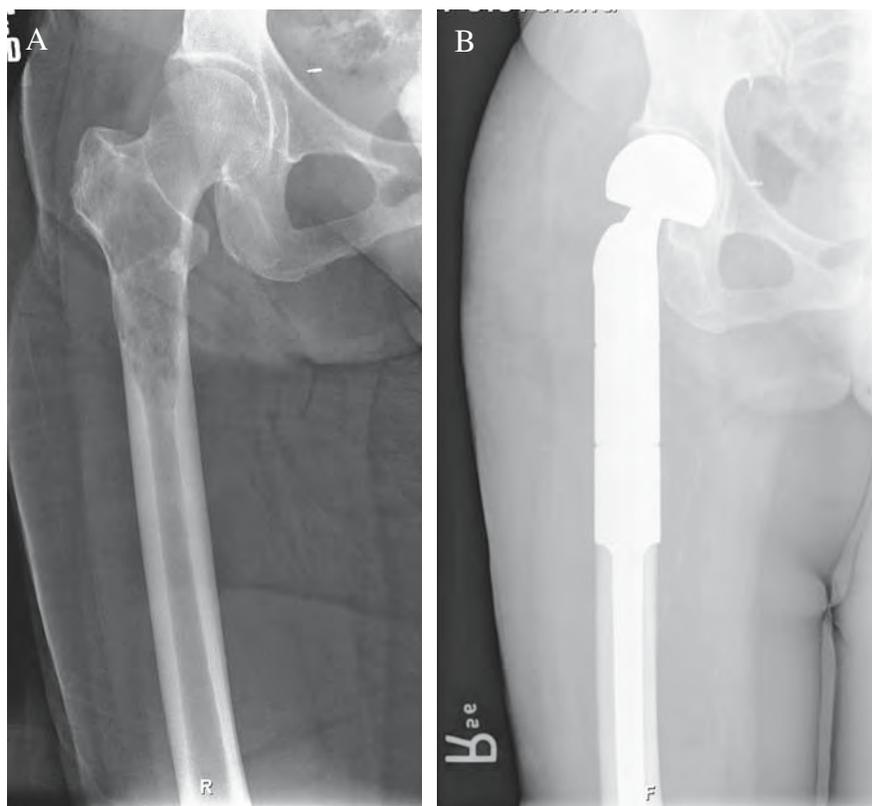

FIGURE 95.8. Preoperative (A) and postoperative (B) AP right hip radiographs of a 56-year-old woman with metastatic kidney carcinoma. Because this was her only known site of disease, she was treated with a proximal femoral resection and prosthetic reconstruction.

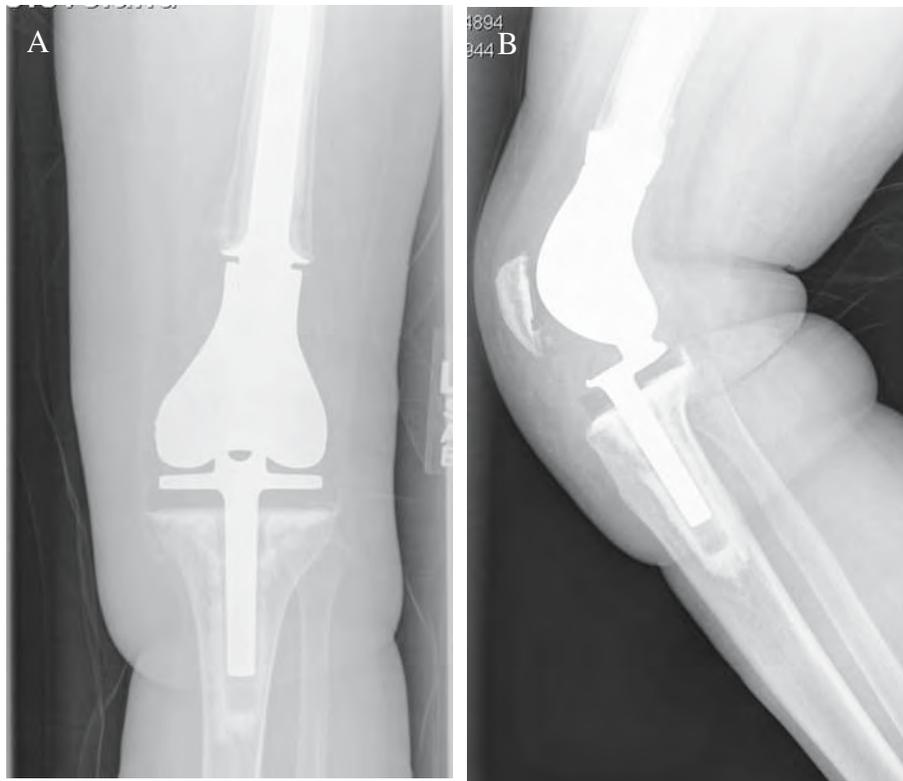

FIGURE 95.9. Postoperative AP (A) and lateral (B) radiographs of a 64-year-old woman with metastatic lung carcinoma to the distal femur. Because of extensive bone destruction, she was treated with distal femoral resection and prosthetic reconstruction.

metaphyseal lesions can occasionally be treated with a periarticular plate and screw construct along with curettage and cementing. If the lesion involves the articular surface, this can be treated with distal femoral resection and reconstruction, along with total joint replacement (Figure 95.9). Reconstructions of this type use a rotating-hinge total knee due to the loss of ligamentous attachments. Customized or modular megaprotheses can be utilized to reconstruct large intercalary segments of lost bone in the diaphysis, the proximal femur, the distal femur, or, in cases of massive involvement of the entire femur, the entire femur can be replaced with a megametallc prosthesis along with a proximal tibia replacement. Resection arthroplasty and amputation are very rarely required for treatment of metastatic disease to bone.

The treatment of metastatic disease to the humerus can be approached in a fashion similar to the treatment of the femur. Diaphyseal lesions may be treated with

intramedullary nailing or with plate and screw fixation (Figure 95.10). Intercalary prosthetic reconstruction is an option for cases requiring diaphyseal resection or revision of failed fixation with segmental bone loss (Figure 95.11). Lesions in the proximal humerus may be amenable to periarticular plate and screw fixation with local curettage and cementing or may require proximal humeral resection and reconstruction with a megametallc prosthesis (Figure 95.12).

Lesions that have not been radiated before surgery should receive postoperative external-beam radiation. In a retrospective study, Townsend et al. demonstrated a 15% failure rate requiring reoperation in patients treated with surgery alone. Only 3% of patients treated with surgery and postoperative radiation required reoperation.¹⁸⁸

Regardless of the location of the operative treatment, there is a constant goal of rapid return to weightbearing and functional rehabilitation.

FIGURE 95.10. AP (A) and lateral (B) right humerus radiographs of a 72-year-old woman with metastatic breast carcinoma showing a lytic lesion at risk for pathologic fracture. Postoperative AP (C) and lateral (D) radiographs demonstrate curettage and cementation of the lesion with prophylactic plate fixation.

Cancer in the Immunosuppressed Patient

Patrick Whelan and David T. Scadden

During the 1960s, as oncology research was rapidly expanding, MacFarlane Burnett's idea that cancer resulted from a failure of tumor surveillance by the aging immune system was broadly acknowledged. The development of cancer genetics focused the field on mutational causes of tumorigenesis. However, a new appreciation for the role that a well-functioning immune system plays in protecting against virally induced tumors was brought to light in the 1980s with the acquired immunodeficiency syndrome (AIDS) epidemic. The phenomenon of the human immunodeficiency virus (HIV)-associated cancer epidemic within defined populations, particularly due to the recent dramatic responses to treatment of the underlying immunodeficiency, has given insight into other etiologic factors for a variety of tumors.

A greater appreciation of the elevated lymphoma risk for children with congenital immunodeficiencies developed in association with the early literature in this area. The advent of solid organ and bone marrow transplantation in the 1960s and 1970s added pressure to more quickly reach an understanding of the relationship between immunosuppression and cancer. Careful epidemiologic studies to delineate increased cancer risks for patients with more complex immune dysfunction, such as thyroiditis, celiac sprue, and Sjögren's disease, have begun only in this past decade.

The inability to control viruses with a direct transforming capability, such as Epstein-Barr virus (EBV), is just a part of the explanation. Persistent immune stimulation by chronic viral or microbial infection, or as a result of the loss of normal lymphocyte homeostatic mechanisms, may play a crucial role, particularly with regard to hematologic malignancies. The newly recognized role of the hepatitis C virus and gastric *Helicobacter pylori* infection in the eruption of characteristic lymphomas, are the only prototypes to date. Treatment of these two infections can often lead to regression of the related lymphomas.^{1,2} This chapter examines some of the unique considerations that influence the diagnosis and treatment of cancer in the immunocompromised patient. Generally, these immunodeficiencies are divided into inherited and acquired forms. Among the acquired deficiencies are the special cases of malignancy in the posttransplant period, in adults with common variable immunodeficiency, and finally, in people suffering from infection with HIV/AIDS.

Congenital Immunodeficiency

Congenital immunodeficiency-associated lymphoproliferative disorders share several characteristics that differentiate them from spontaneous non-Hodgkin's lymphoma (NHL) and other lymphoproliferative disease³ (Table 96.1). First, lymphoma is disproportionately represented among all cancers in this population. Between 50% and 65% of cancers among children with immunodeficiency diseases are lymphomas, compared to about 12% of cancers in the general pediatric population. Children who are posttransplant fall in between, with lymphoma constituting about a third of malignancies in this group.

Second, one might expect impairment of specific immune defenses to predispose to certain kinds of infections. In general, impaired immune defenses against EBV appear to result in a high rate of B-cell transformation. With the exception of ataxia telangiectasia (AT), congenital immunodeficiency patients frequently develop EBV-infected lymphoproliferative lesions, either secondary to natural infection or potentially from graft-derived virus in those who undergo stem cell transplantation.

Third, these children develop lymphoma in a distinct anatomic distribution compared to other children with lymphoma. Most of these tumors occur outside of lymph nodes, particularly in the central nervous system and in the gastrointestinal tract. For example, a pediatric cancer registry in Britain, studying 51 children who developed lymphoproliferative disorders secondary to congenital or acquired immunodeficiency, found 32 nonlocalized tumors compared to 10 that were localized.⁴ AT-related NHL may be mostly extranodal, similar to other immunodeficiency-related NHL.⁵

Finally, the histology of these lymphomas is typically of the diffuse large cell type and is associated with rapid clinical progression in untreated patients. Lymphoproliferative disease is the second leading cause of death, after opportunistic infection, for children with congenital immunodeficiency. The risk of lymphoproliferative disease may approach 10,000-fold compared with the general pediatric population,⁶ and risk of death exceeds three times that of children who develop these lymphomas posttransplantation.⁴ The one silver lining may be that, as in posttransplant lymphoma pediatric patients, those with congenital immunodeficiency

TABLE 96.1. Lymphoma in congenital versus sporadic immunosuppression.

	<i>Congenital immunodeficiency</i>	<i>Sporadic childhood cancer</i>
Lymphoma as percent of all cancers	50%–65%	12% (ALL and brain tumors are more prevalent)
Role of EBV in lymphomagenesis	Prevalent ^a	Rare
Anatomic localization of lymphoma	Predominantly extranodal	More lymph node centered ^b
Predominant lymphoma type	Diffuse large cell	Burkitt's and lymphoblastic types are more common

EBV, Epstein–Barr virus.

^aExcept for ataxia telangiectasia.

^bAdult lymphoma generally more nodal than childhood disease.

have a risk of death that largely evaporates about 18 months after diagnosis, probably because of compensatory increases in the remaining elements of the immune system.

Ataxia Telangiectasia

Defects in the ataxia telangiectasia mutated (ATM) gene, when inherited from both parents, result in dysfunctional angiogenesis in the ocular and cutaneous circulation, immune impairment with sinus and pulmonary infection susceptibility, and an ataxic gait secondary to a spinocerebellar neurodegenerative process. Children with AT also represent the largest subpopulation of congenital immunodeficiency patients with lymphoma in a national cancer registry for these patients.⁷ AT patients are thought to have a risk for leukemia about 70-fold over the general pediatric population, and the risk for lymphoma may approach 300-fold.⁸ African-Americans with AT appear disproportionately affected by cancer in general and lymphoma in particular. One retrospective study of 263 ATM homozygotes found a 184-fold-increased incidence of cancer and a 750-fold increased risk for lymphoma among black patients, compared with 61-fold and 252-fold, respectively, for homozygotes of European descent compared to the general population.⁸

More than 10% of ATM homozygotes develop some form of malignancy, most in the lymphoid lineages.^{9,10} After age 20, the incidence of lymphoid malignancies drops to less than half and the incidence of solid tumors rises. The solid tumors most commonly described, include gastric adenocarcinomas, astrocytomas, medulloblastomas, and cancers of the oral cavity, pancreas, breast, ovary, and bladder. The relationship between *Helicobacter pylori* and development of gastric carcinoma in AT patients is unclear, but there appears to be an important link in patients with common variable immunodeficiency and gastric cancer.¹¹

The increased incidence of breast cancer in female relatives of AT patients led to studies suggesting that ATM missense mutations may be involved in up to 5% of all breast cancer in the general population.^{12,13} Some controversy persists on this point, because the truncation mutants that appear to predominate in AT patients may not predispose to breast cancer in heterozygotes¹⁴ in the same way that dominant negative missense mutations apparently do.¹⁵ ATM mutations are found in as many as 2% of the U.S. population.¹⁶ Furthermore, ATM carriers are thought to have an increased risk of cancer, with a relative risk of cancer death

before age 80 estimated at 2.6-fold compared to noncarriers¹⁰ and as high as 5-fold before age 45.¹⁷

The ATM gene is composed of 66 exons on chromosome 11q22-23 and has sequence homology to an enzyme involved in intermediary metabolism, phosphatidylinositol-3-kinase (Table 96.2). The PI-3-kinase family is perhaps best known for its role in transmembrane signal transduction in response to a number of extracellular growth factors, but plays an important related role in cell-cycle regulation. ATM mutations inherited from both parents lead to inefficient DNA repair and dysfunctional cellular immunity,¹⁸ resulting in a combination of genetic instability and potential impairment of putative immune surveillance. ATM is believed to function normally as part of the sensing mechanism for double-stranded breaks in DNA, which rapidly activate its kinase activity and lead to repair by homologous recombination or nonhomologous end-joining. Mutations may serve to disrupt the kinase activity and subsequent signaling to other proteins involved in DNA repair, resulting in dysfunctional cell-cycle checkpoint regulation and DNA repair.

The immune dysfunction is a combination of abnormal B-cell and T-cell receptor rearrangement and disrupted thymic organogenesis. γ/δ T-cell numbers are within the normal range, but α/β T-cells are significantly reduced.¹⁹ Because ATM knockout mice frequently develop thymomas with rearrangements in the TCR α/δ locus, it had been assumed that lymphomagenesis in these patients represented an ATM-dependent disruption of VDJ recombination.^{20,21} However, both the Rag-1 and Rag-2 genes, essential components of the VDJ recombination machinery, are dispensable for thymoma development in ATM knockout mice.²² This finding suggests that the inability to deal with double-stranded DNA breaks is likely to represent the more central defect predisposing to the development of lymphoma.

ATM-deficient mice are markedly sensitive to gamma irradiation.²³ As noted previously, studies of the recurrence of breast cancer in women treated with radiation, have failed to show a predisposition to second cancers among women with ATM mutations.¹⁴ Inhibition of homologous recombination in ATM-deficient mice partially rescues them from lymphoma development, suggesting that excessive homologous recombination is at least partially responsible for the propensity toward lymphomagenesis.²⁴

Among the ATM homozygotes who develop cancer, lymphoma and leukemia in the lymphocytic lineages predominate. Those with NHL have presented with diverse histologic

TABLE 96.2. Pathways involved in congenital immunodeficiency.

Disease	Molecular defect	Clinical manifestations	Cancer risk	Tumor type
Ataxia telangiectasia	<i>atm</i> gene, 11q22-23	Sinopulmonary infection Ocular telangiectasiae Spinocerebellar ataxia	10%	Early NHL Solid tumors later
X-linked lymphoproliferative	Sh2D1A, Xq25	Severe mononucleosis	>30%	Burkitt-type lymphoma

Common variable immunodeficiency	Acquired	Recurrent infection Intestinal lymphoid hyperplasia Splenomegaly Autoimmune cytopenias	Variable	NHL, gastric adenocarcinoma

NHL, non-Hodgkin's lymphoma.

phenotypes, in contrast to the overrepresented subtypes typical of other childhood immunodeficiencies.²⁵ The ATM gene product appears to act early in the response to DNA damage, initiating a pause in cell-cycle progression and then facilitating the repair of double-stranded DNA breaks. Apart from patients with congenital AT, inactivation of the ATM gene has been found in cases of mantle cell lymphoma and in both B-cell and T-cell leukemias.

At least five different functional domains have been identified in addition to the critical kinase domain in the ATM gene.²⁶ This multifunctionality, and the identification of more than 100 distinct ATM mutations scattered throughout the gene, may explain the considerable phenotypic heterogeneity among affected homozygotes. Curiously, most mutations appear to be frame-shift and nonsense mutations, predicted to cause truncation of the ATM protein, and relatively few are base-pair substitutions.²⁷

As suggested previously, the biology of ATM-associated lymphoma differs from that of other immunodeficiencies. Most are not EBV-infected and do not have characteristic *c-myc* translocations. More than 80% of these lymphomas are T-cell derived, in stark contrast to the B-cell predominance seen in other immunodeficiencies and among sporadic cases in the general population. Ataxia telangiectasia patients appear to have a preferential disruption of the VDJ recombination process in the T-cell lineage, although functional ATM is required for receptor gene rearrangement in both T cells and B cells.²⁸ Myeloid malignancies are not overrepresented in this population.

Does the development of malignancies in children with AT result from a relative decline in immune function over time? Patients with AT demonstrate a variety of immune defects. B and T lymphocytes are severely depleted, and func-

tional tests reveal poor proliferative responses to antigens and mitogens,^{29,30} leading to prominent deficiencies in serum IgA, IgG2, IgG4, and IgE. Although AT patients have a rising susceptibility to lower respiratory infections with age, non-respiratory infections are not increased. Upper respiratory infections may actually decline with age, as in the general population, and AT patients are not susceptible to chronic upper respiratory infections.³¹ The function of natural killer and lymphokine-activated killer cells appears to be maintained.³² Furthermore, AT patients do not demonstrate progression of their lymphopenia or hypogammaglobulinemia with age.³¹ If an age-related decline in immune function contributes to the cancer risk, it would have to be a somewhat specific element of antitumor immunity that has not been identified to date.

X-Linked Lymphoproliferative Syndrome

X-linked lymphoproliferative (XLP) syndrome, also referred to as Duncan disease after one of the first described patients, is an immunodeficiency associated with mutation in the SLAM-associated protein (SAP, also known as SH2D1A) gene on chromosome Xq25.³³ These boys have a marked susceptibility to EBV infection, and a resulting hepatonecrosis is a significant cause of death.³⁴ About half develop severe mononucleosis during the first decade of life, with pronounced pharyngitis, hepatosplenomegaly, diffuse lymphadenopathy, hepatitis, and occasionally, aplastic anemia. Lymph nodes showing an immunoblastic appearance, and circulating atypical lymphocytes, can be mistaken for signs of acute leukemia in these very ill mononucleosis patients. Among the important immune defects are severe hypogammaglobulinemia and a loss of cytotoxic T-lymphocyte-derived

interferon-gamma production and cytotoxic activity toward EBV-infected cells.³⁵ Interestingly, the SAP protein is not physiologically expressed in activated B cells, which are presumably the precursors for development of the B-cell-predominant lymphomas that afflict XLP patients.³⁶

SAP functions as an adaptor protein, binding via an Src-homology domain (SH2) to a common motif in the cytoplasmic domain of the CD2 and SLAM family of cell-surface signaling molecules (CD84, CD150, CD229, CD244, and NTB-A).³⁷ Because SAP is expressed only physiologically in activated T cells and NK cells, the inability of these cells to regulate B cells is suspected to be at the heart of lymphomagenesis in XLP. As many as a third of patients are thought to develop lymphoma eventually, including some who are not infected with EBV.^{34,38} The most common presenting symptoms are nausea, emesis, and abdominal pain, and most have prominent constitutional symptoms, including fever.

The small, noncleaved type (Burkitt) predominates with a risk estimated at 200-fold that of the general population, although multiple other lymphoma types have been described.³⁹ Anatomically, these lymphomas are extranodal, arising in the small bowel most of the time (commonly in the ileocecal area). Lymph node pathology shows effacement of the normal architecture by uniform-appearing lymphoblasts that are predominantly of follicular center cell origin, in contrast to the infectious mononucleosis process that typically preserves lymph node architecture amid polymorphous lymphoid elements.⁴⁰ In an early series of 17 patients,⁴¹ the median age at diagnosis was 4 years (range, 2 to 19 years) with a median survival of 12 months. The 40% of patients with the Burkitt's phenotype had the worst prognosis, despite treatment, representing 7 of 9 deaths among these 17 boys; most deaths were attributable to bacterial infection. The series included single cases of lymphoma in the lung, liver, and central nervous system (CNS),⁴¹ and renal involvement has also been described.⁴²

Hematopoietic stem cell transplantation (HSCT) is thought to be the best chance for remission in XLP patients with Burkitt-type tumors.⁴³ The largest study to date was also the earliest, reporting a series of seven XLP patients who received allogeneic HSCT.⁴⁴ All seven had HLA-identical donors, six from siblings (five bone marrow and one cord blood), and one bone marrow transplant from an unrelated donor. All the patients successfully engrafted, with six demonstrating low-grade graft-versus-host reactions without any attributable deaths. Two patients died of infectious complications posttransplant and one of multiorgan failure. The other four were healthy at the time of publication, more than 3 years after HSCT. Risk factors for poor HSCT outcome were age greater than 15 years, preconditioning with total-body irradiation, and significant infection problems pretransplant. More recently, success has been reported using unrelated umbilical cord stem cell transplantation.⁴⁵

X-Linked Agammaglobulinemia

Bruton's agammaglobulinemia is an immunodeficiency manifested only after maternal immunoglobulin begins to wane, typically presenting with recurrent otitis in the absence of obvious tonsils or cervical lymph nodes. Patients often develop sinus and pulmonary infections because they lack circulating B cells, fail to form B-cell follicles in the lymph node

and spleen, and thus fail to generate a good antibody response to bacterial infection.⁴⁶ Affected children may suffer onset of lymphoma in late infancy,⁴⁷ and an increased incidence of gastric and colorectal cancer has been reported in older children.^{48,49} A contributing factor to colorectal cancer susceptibility may be a decreased expression of distal colonic glutathione-S-transferase in these patients, resulting in decreased detoxification of bacterial products of metabolism.⁵⁰

Most affected individuals have a mutation in the *btk* gene on chromosome Xq22, which is critical for intracellular signaling by surface immunoglobulin and for early B-cell development. *Btk* is a member of the TEC family of tyrosine kinases. Immunoglobulin ligation results in mobilization of *btk* into a signaling complex at the cell membrane, where it is activated by src family kinases. *Btk* then acts in part by phosphorylating key residues within phospholipase C-gamma-2, an enzyme critical to the release of inositol trisphosphate and the early intracellular calcium flux.⁵¹ Activation of cellular calcium channels is essential to the phosphorylation of I κ B, resulting in disinhibition of the critical transcriptional factor NF- κ B that translocates to the nucleus and activates several families of immune-related genes in response to antigen.^{52,53} Other activation pathways are also affected, namely, interleukin (IL)-5, IL-10, and CD38 signaling.⁵⁴⁻⁵⁶ The CD40-CD40 ligand interaction that partly mediates T-cell help for B-cell differentiation may also be impaired by *btk* mutation.⁵⁷ Consequently, boys lacking functional *btk* are unable to form germinal centers, have markedly decreased levels of serum immunoglobulin, and are significantly impaired in mounting T-cell-dependent humoral immune responses. Their state of immune compromise results in susceptibility to infection with the common encapsulated bacterial pathogens of infancy (e.g., *Hemophilus influenzae* and *Streptococcus pneumoniae*), mycoplasma pneumonia, and common enteroviruses.

The pathogenesis of lymphoma development in these patients remains a mystery, in part, because healthy older X-linked agammaglobulinemia patients lack evidence for infection with the Epstein-Barr virus.⁵⁸ EBV may lack sufficient target cells for infection in these patients, who have minimally detectable B cells in their peripheral circulation and an absence of pharyngeal tonsils. Compromised antibody production in these patients may possibly impair homeostatic mechanisms that normally control EBV or other viral factors that contribute to lymphomagenesis. Another possibility is a role for *btk* as a tumor suppressor gene. Mutated *btk* has not to date been shown to act as an oncogene, but the *btk* protein has been shown to be capable of nuclear translocation and to function in both up- and downregulation of apoptosis.⁵⁹ Thus, *Btk* loss may result indirectly in an increased susceptibility to lymphoma by playing a role in either regulation of apoptosis or transcriptional activation.

Wiskott-Aldrich Syndrome

Children with a mutation in the Wiskott-Aldrich-associated protein (WASP) gene present in late infancy with eczema, low platelets, and functional deficiencies in their T cells, B cells, and neutrophils. About one in six also develop lymphoma, most commonly, large cell immunoblastic non-Hodgkin's lymphoma,⁶⁰ at a median age of 6.5 years.⁶¹ The WASP gene

is located on Xp11.22. WASP is a cytoskeletal protein that is phosphorylated in B cells by btk (Bruton's defect) in the immunoglobulin signaling pathway,⁶² and in T cells by fyn in response to TCR cross-linking.⁶³ When T cells interact with their cognate antigens on antigen-presenting cells, the TCR signal results in a WASP-dependent reorganization of the actin cytoskeleton and formation of an "immunologic synapse" between the two cells.⁶⁴ Deficiency of WASP appears to compromise the ability to fully polarize T-cell cytoskeletal elements at low doses of antigen, although production of IL-2 is substantially impaired even at saturating antigen levels.⁶⁵ The defect appears to be in directional secretion of cytokines, though not in chemokines that have been studied.⁶⁶

Historically, more than 10% of WAS patients eventually contracted some form of cancer, with median onset at age 6⁶⁷ and an incidence estimated to climb by 2% per year.⁶¹ Competing pressures on these rates include the increased cancer risk created as patients live longer, and the increasing number of children who are transplanted early in life for nonneoplastic complications. About 40% of patients develop some autoimmune manifestations (i.e., immune cytopenias, nephritis, inflammatory bowel disease, uveitis, and occasionally, arthritis), and these individuals appear to be at increased risk for subsequent development of cancer⁶⁸; this may be because those with autoimmune symptoms typically have more severe disease in general. CNS involvement appears to predominate among the diffuse, high-grade lymphomas that constitute at least half of all malignancies in WAS patients. The tumors are almost exclusively extranodal with a large cell immunoblastic phenotype, and are distinctly lacking in Burkitt or lymphoblastic histology.⁶⁹ One survey found these lymphomas to be universally infected with EBV.⁶⁷ Nonsense and frame-shift mutations in the WASP gene, which usually result in nonexpression of the protein, are associated with more severe disease and with at least a threefold-greater risk for lymphoma compared with patients who have missense mutations.⁷⁰ Some of the clinical heterogeneity in the disease may result from differing levels of WASP expression in different cell types, with lower expression correlating with greater dysfunction.⁷¹

Bone marrow transplantation is an effective treatment for the thrombocytopenia and immunosuppressive elements of WAS, which is probably the second most common immunodeficiency indication for transplantation.⁷² In a study of 170 transplants accumulated in the International Bone Marrow Transplant Registry and/or National Marrow Donor Program, WAS patients achieved a 5-year probability of survival that was 87% for HLA-identical sibling donors, 52% for other related donors, and 71% for unrelated donors.⁷³ Boys younger than age 5 who received an unrelated donor transplant had survival similar to those receiving HLA-identical sibling transplants, so good survival outcomes are possible with unrelated donors in younger children. Cord blood stem cells may be particularly useful in younger children who are cytomegalovirus (CMV) negative, and five reported cases have offered good outcomes to date.^{74–76} EBV-induced B-cell proliferative disorders, and other viral infections, are a significant cause of mortality in this transplanted population, developing most prominently in those children with slower development of full T- and B-cell functions and subsequent severe infectious complications.⁷⁷

Severe Combined Immunodeficiency

The severe combined immunodeficiency (SCID) term covers an array of different genetic defects that impair some combination of cellular and humoral immunity, resulting in severe infections after maternal transplacental antibody wanes.⁷⁸ Many of these children died before the era of immune reconstitution. Following bone marrow or stem cell transplantation, a susceptibility emerges to lymphoproliferative disease, often related to naturally acquired or transplant-transmitted EBV infection.⁷⁹ As in Wiskott–Aldrich syndrome, lymphoma represents 75% of all malignancies in SCID patients and almost universally demonstrates EBV infection.⁴⁷

Children with an unusually aggressive variant of SCID, termed Omenn syndrome, die early in life if not recognized and treated for their severe hypogammaglobulinemia. These patients present with rash, elevated IgE levels, swollen lymph nodes, and hepatosplenomegaly. Stem cell transplantation is required to avoid fatal complications.

Autoimmune Lymphoproliferative Syndrome (ALPS)

Also known as Canale–Smith syndrome, autoimmune lymphoproliferative syndrome (ALPS) usually results from inherited mutations in the CD95 (Fas) gene.⁸⁰ Less common mutations in the Fas ligand, caspase 8, and caspase 10 genes have been described with a similar phenotype. Fas is a member of the tumor necrosis factor receptor family and is critical to normal apoptosis during development and post-infection immune senescence. The Fas defect results in reduced apoptosis and increased proliferation of T cells. Consequently, lymph node pathology shows marked paracortical hyperplasia, expanded interfollicular areas, follicular hyperplasia, and a polyclonal plasmacytosis. The paracortical lymphoid cells have a high proliferative index and frequent mitoses.⁸¹

These patients develop massive splenomegaly and liver infiltration with a unique subpopulation of T cells akin to those in the lymph nodes and peripheral blood. These α/β -TCR-bearing T cells, lacking both the CD4 and CD8 markers, are normally found as minor populations in the thymus, skin, and spleen.⁸² Although *in vitro* studies have suggested that these cells are poorly responsive to mitogens or antigen,⁸³ their expansion in patients with lupus has fueled speculation that they may help drive some of the autoimmune phenomena observed in ALPS patients.⁸⁴ Also seen in the peripheral circulation, is a polyclonal expansion of CD5+ B cells, which produce most of the circulating IgM antibody. ALPS patients are frequently misdiagnosed as having systemic lupus, particularly given their propensity to hemolytic anemia, thrombocytopenia, neutropenia, and glomerulonephritis.⁸¹ The prognosis in this condition is not necessarily that of progressive disease.⁸⁵

Fas germ-line mutations, mostly in the cytoplasmic "death domain," impose a risk estimated at 14-fold for non-Hodgkin's lymphomas and as high as 51-fold for Hodgkin's disease. These numbers were based on a series of 10 patients with lymphoma among 130 with heterozygous germ-line Fas mutations.⁸⁶ Among those with Hodgkin's lymphoma, the atypical nodular lymphocyte predominant form was particularly prominent, having been reported in three separate

families with ALPS cases.⁸⁷ Aside from patients with ALPS, somatic mutations in Fas have been identified in sporadic cases of non-Hodgkin's lymphomas. These constituted about 11% in one series of 150 cases and may represent a higher percentage of MALT-type lymphomas. Similarly, somatic mutations in the caspase 10 gene have been found in a significant number of NHLs.⁸⁸ B cells often develop missense mutations in the Fas gene, as they do in the Bcl-6 gene, once they become germinal center centroblasts.⁸⁹ Consequently, the relationship of these mutations to lymphomagenesis is unclear.

Chediak-Higashi Syndrome

This autosomal recessively inherited immunodeficiency is characterized by oculocutaneous hypopigmentation, abnormal platelets, and susceptibility to bacterial infections. At a molecular level, many of these patients' cells display exaggerated lysosomes and melanosomes. The neutrophils in particular, show impaired degranulation, resulting from mutations in the lysosomal trafficking regulator (LYST) gene that appear to be present in all affected patients.⁹⁰ This cytoplasmic protein has been shown to interact with other proteins important in vesicular transport and signal transduction (among others, the casein kinase II protein, the SNARE complex protein HRS, and the 14-3-3 adaptor protein).⁹¹ Among the immune defects, is difficulty controlling EBV replication in infected individuals, with abnormal serologic responses to EBV resulting in a chronic active EBV infection that may predispose to lymphoproliferative disease.⁹² These patients experience what is frequently referred to as an accelerated phase, with a lymphocyte and macrophage infiltration of bone marrow, spleen, lymph nodes, liver, and central nervous system that resembles lymphoma and can lead to significant functional compromise.

Chemotherapy with combinations of etoposide, glucocorticoids, methotrexate, cyclophosphamide, and vincristine can restrain the accelerated phase, but relapses are common.⁹³ Allogeneic bone marrow transplant, particularly from HLA-identical related donors, has shown good success in reconstituting immune function and controlling recurrence of the accelerated phase.⁹⁴

Acquired Immunodeficiency

Three forms of acquired immunodeficiency have offered accelerating clarity as to the causes and predisposing factors to cancer. In the 1950s and 1960s, it was appreciated that loss of the ability to make immunoglobulin during adulthood was a relatively common immunodeficiency, and that it predisposed to cancer.^{95,96} The advent of the 1970s brought a wide expansion of organ transplantation, and a new appreciation for cancer risk in individuals whose immunity was iatrogenically suppressed. Of course, the HIV epidemic in the 1980s ultimately revealed how important immune function is to controlling the development of cancer. Studies on these three categories of illness have served to highlight the interplay of genetic, infectious, and immunologic phenomena in the genesis of cancer. A fourth category of acquired immune dysfunction, namely the rheumatic or autoimmune diseases, has reinforced an appreciation of the complexity that sur-

rounds susceptibility to cancer in general and lymphoma in particular.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) is the most common cause of non-HIV-related immunodeficiency, associated with low levels of immunoglobulin and poor humoral responses to vaccination. The pathophysiology may be secondary to a variety of other observed deficiencies, including low NK cell levels,⁹⁷ reduced T-cell expression of CD40L, relative CD4 T-cell lymphopenia, and poor T-cell responses to mitogen.⁹⁸⁻¹⁰⁰ A defect in B-cell generation of somatic hypermutation may also contribute.¹⁰¹ Disease onset is usually after age 20 but has been described in toddlers.¹⁰² Most patients have no identifiable genetic defect, but mutations have been found in the CD40 ligand, btk (Bruton's), and SAP (X-linked lymphoproliferative syndrome) genes.¹⁰³ Affected individuals have an increased susceptibility to otitis and sinusitis problems caused by encapsulated organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, akin to the susceptibility seen in early childhood and in splenectomized adults.¹⁰⁴ Beyond respiratory infections, some patients present with diarrhea and crampy abdominal pain. Some cases of irritable bowel syndrome have turned out to be CVID on immunologic testing. Patients experience an increased incidence of immune cytopenias, inflammatory arthritis, and granulomatous vasculitis.

A high incidence of atrophic gastritis, possibly related to *H. pylori* infection, appears to contribute to these patients' increased risk for gastric carcinoma.¹⁰⁵ CVID patients in general, are at increased risk for lymphomas of the CNS and gastrointestinal tract. The risk of lymphoma has been estimated at 8.5% in those diagnosed with CVID as adults.¹⁰⁶ One registry of 120 CVID patients with malignancies demonstrated a breakdown showing 46% of cancers were NHL, 16% gastric carcinoma, and 7.5% Hodgkin's disease.¹⁰⁷ Clinical presentation crosses a spectrum from atypical or reactive lymphoid hyperplasia to malignancy, with a predominance of benign disease.¹⁰⁸ The elevated lymphoma risk has diverged widely in different studies, from 12.0-fold among the 176 patients in the Scandinavian cohort¹⁰⁹ to 30-fold in a British study of 220 CVID subjects,⁴⁹ to 259-fold among 98 patients followed at Sloan-Kettering in New York.¹¹⁰ Women with CVID may have a particularly pronounced susceptibility to lymphoma.¹¹⁰

The pathology of these tumors is largely that of postgerminal center B cells, or centrocytes,¹¹¹ with a diffuse large cell phenotype and frequent mutations and rearrangements within the Bcl-6 locus.¹¹² Similar pathology is seen in HIV-related and posttransplant lymphoma, although in contrast, the CVID-related tumors are EBV negative.¹¹² Reexamination of these lymphomas has led to speculation that a significant percentage of CVID-related NHL may be lymphomas of the mucosa-associated lymphoid tissue (MALT),¹¹³ also referred to in the REAL classification as marginal zone B-cell lymphomas. From a mechanistic standpoint, it is appealing to think that chronic antigenic stimulation in the absence of effective humoral immunity could lead to a type of lymphoma that has been associated specifically with certain chronic infections (e.g., *H. pylori*-associated gastric lymphoma, HCV-associated MALT lymphoma). Perhaps more

aggressive treatment of underlying chronic infections could serve to prevent the development of these tumors or retard their growth once diagnosed.

The increased risk for gastric carcinoma has been confirmed in several studies, with a standardized incidence ratio of 10.3 in the largest study.¹⁰⁹ Two women in their thirties have been described with CVID and breast cancer,¹¹⁴ but no cases were seen in a retrospective study of 176 CVID patients.¹⁰⁹ Similarly, 2 cases of thymoma were described from one center's experience with 36 Dutch CVID patients, but other larger series did not identify such patients.¹⁰⁹

Acquired Immunodeficiency Syndrome

According to the Joint United Nations Program on HIV/AIDS, an estimated 40 million people are living with HIV infection, with close to 20 million deaths attributable to the virus since its discovery in 1984. Most cases are in Africa, but Asia may represent the part of the world with the most explosive HIV problem.^{115,116} Malignancy is probably the most difficult complication of HIV in the developed world from a treatment standpoint. The relative risk of death from opportunistic infection has declined for many infectious complications and for Kaposi's sarcoma, but has remained stubbornly persistent for AIDS-related lymphoma. The characteristic features of both these opportunistic neoplasms have changed in the context of antiretroviral therapy.

Kaposi's Sarcoma

Among the first clues to the emerging AIDS epidemic was the diagnosis of clusters of Kaposi's sarcoma (KS) among young

men in California. At the time, the three primary populations to present with this intermittently aggressive tumor of skin and visceral organs included elderly men of Mediterranean origin, an endemic form prevalent in Central Africa that affects both men and women, and posttransplant patients under immunosuppression. Ten years after the discovery of HIV, the Kaposi's sarcoma-associated herpesvirus (KSHV), also referred to as human herpesvirus 8 (HHV-8), was identified as an etiologic agent strongly connected with all forms of Kaposi's sarcoma, including the HIV-associated cases.¹¹⁷ In addition, primary effusion lymphoma (PEL) and multicentric Castleman's disease were two other HIV-associated illnesses to be quickly linked to KSHV infection.¹¹⁸ KSHV appears to represent a sexually transmitted cancer threat that is exposed by subsequent HIV infection or immunosuppressive therapy, although the exact route of KSHV transmission has not been definitively demonstrated.

SEROLOGY AND EPIDEMIOLOGY

KSHV is a sizeable double-stranded DNA virus (165 kb).¹¹⁹ Closely related viruses have been found in three monkey species, the horse, cow, rabbit, and mouse, and together comprise the rhabdoviridae genus of the gamma herpesviruses. The most closely related human pathogen is the Epstein-Barr virus (EBV), a lymphocryptogenous gamma herpesvirus that shares a similar genomic structure with three large regions of conserved, mostly lytic cycle genes (Figure 96.1). Chang and colleagues first described KSHV in 1994.¹¹⁸ This group was motivated to search for the virus by circumstantial epidemiologic evidence of a transmissible agent for KS.¹²⁰ Among HIV-infected people in the West, for example, KS is uncom-

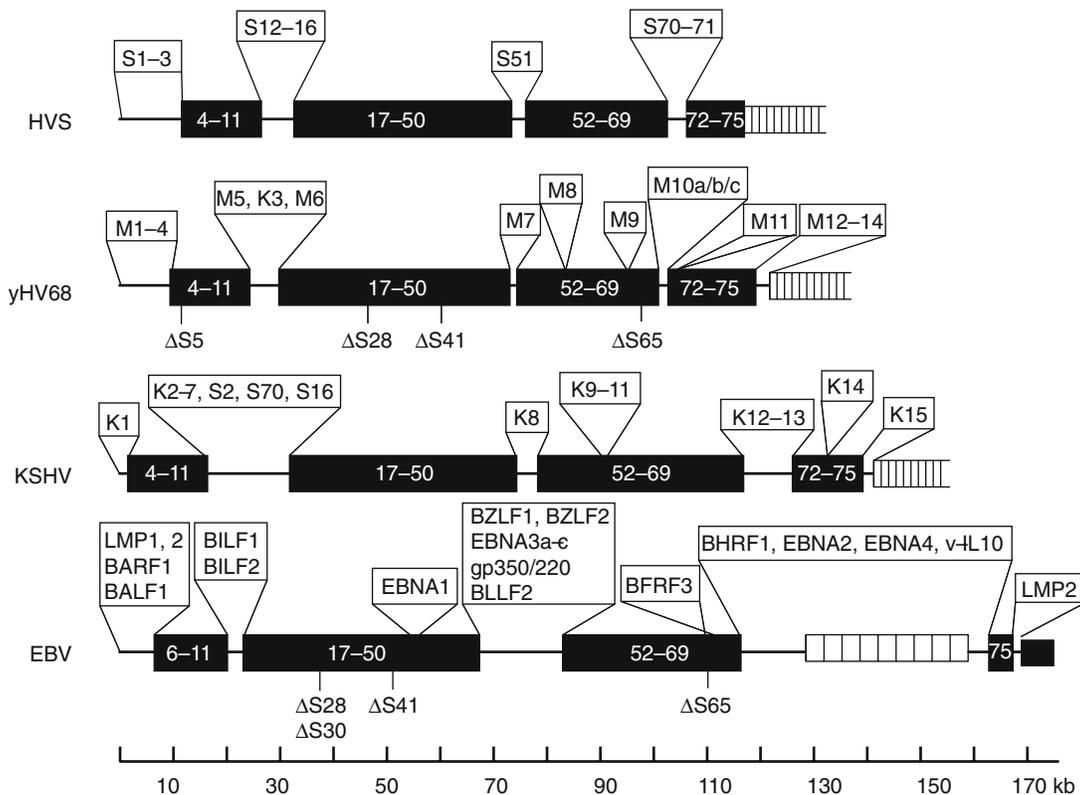

FIGURE 96.1. Comparative maps of KSHV, EBV, HSV, and GHV68 genomes. (By permission of Virgin et al. *J Virol* 1997;71:5894-5904.)

mon in women, and spares almost completely, patients with transfusion-acquired HIV infection.¹²¹ KS is principally found in HIV-infected persons whose HIV risk group is men having sexual relations with men. Accordingly, a second transmissible agent was long hypothesized, and growing evidence strongly indicates that this agent is KSHV^{120,122}: infection precedes tumor formation, the prevalence of KSHV infection tightly correlates with the epidemiology of the disease,¹²¹ and the virus infects the cell types implicated in tumor formation.¹²³

Found in about 80% of HIV-infected KS patients,¹²¹ are antibodies directed against a latency-associated nuclear antigen (LANA) that have been the basis for the first generation of serologic tests available to detect previous exposure or active infection with KSHV. The incidence of infection appears to be at least 1% to 2% in the healthy HIV-negative U.S. blood donor population, compared with 2% of people with hemophilia, 3% to 4% of HIV-positive women,¹²⁴ and 25% to 30% of HIV-positive gay men by that assay.¹²⁵ A new enzyme-linked immunosorbent assay (ELISA), based on a whole virus lysate from the KS-1 cell line, may be even more sensitive¹²⁶: 92% of 134 KS patients, independent of HIV status, were shown to have positive titers for anti-KSHV antibodies, compared with 11% of 91 healthy blood donors. Another study analyzing antibodies to lytic antigens in 1,400 serum samples, may suggest an even higher exposure rate in the U.S. general population: 25% of nonselected individuals were positive, as were 90% of HIV-infected homosexual men assessed by this method.¹²⁷ The sensitivity and specificity of these various assays, however, need additional definition and a standardized test developed to better evaluate this issue.

Detailed epidemiologic studies of the prevalence and mode of viral spread among various susceptible populations around the world have been made possible through the availability of specific oligonucleotide primers and of these serologic tests. Research in Italy, involving a cohort of healthy individuals and non-KS dermatology patients, showed 24% to have KSHV sequences in their peripheral blood.¹²⁸ In Sardinia, a region where classic KS is particularly prevalent, KS patients were shown to be seropositive for antibodies against a minor capsid antigen in 95% of individuals. Additionally, 39% of their family members were also positive, compared with 11% of age- and sex-matched controls.¹²⁹ Therefore, in Mediterranean countries, where cases of classic KS are focused, the prevalence of KSHV infection appears to be higher. Vertical transmission is suggested by the evidence that communicability of the virus may occur preferentially among family members, although recent evidence suggests that breast milk is not a vector.¹³⁰

Among the endemic KSHV-infected populations of sub-Saharan Africa, where children contract a less aggressive form of Kaposi's sarcoma both with and without coincident HIV infection, vertical or paravertical transmission is also evident. In some studies, KSHV appears to be independently associated with hepatitis B infection,¹³¹ and seropositivity to LANA and the open reading frame (ORF) 65 proteins reached adult levels of about 50% before puberty. Vertical and multiple modes of horizontal transmission may be prevalent in endemic populations of southern Europe and in Africa, although detailed mechanisms of transmission remain to be defined.

The role of sexual transmission is clear and has been best demonstrated in a cohort of men from whom serum samples were gathered over a 10-year period. The frequency of seroconversion was linearly related to male sexual intercourse contacts, with no seropositivity among 195 exclusively heterosexual men.¹²⁵ The seropositivity rate reached 65% among men with more than 250 sexual partners in the preceding 2 years. Where the virus resides within the male genitourinary tract, if indeed this is a route of transmission, is not clear. Studies have supported¹³² or contradicted¹³³ the presence of KSHV in semen, and one report found KSHV in glandular epithelial cells of the prostate.¹²³

CLINICAL MANIFESTATIONS

Kaposi's sarcoma represented the AIDS-defining illness in more than 10% of HIV-infected individuals, and ultimately occurred in approximately 20% of the HIV-infected population before the availability of potent anti-HIV therapy. Among those HIV-positive patients who are seropositive for KSHV, the risk of developing KS was noted to be 50% at 10 years in one large study.¹²⁵ Interestingly, that risk is expected to be much lower in the era of highly active antiretroviral therapy (HAART), as discussed next.

Erythematous or violaceous macules or nodules on any mucocutaneous surface in the body may occur in isolation or in clusters. Cutaneous KS lesions are found more often on the lower extremities, where they can become confluent and circumferential, and on the face with a particular predilection for the ears and nose. The heterogeneity of their appearance covers a spectrum from faint salmon-colored macules to plaques, prominent nodular densities in some patients, and occasionally ulceration with superinfection. In dark-complexioned individuals, KS lesions may be somewhat more subtle. The highly vascular nature of the macules lends a characteristic reddish-blue tint that blanches minimally, if at all, on palpation. The natural history may vary widely, ranging from spontaneous remission in some individuals to explosive, fatal progression in others.

Edema is also frequently seen and may be distant from any cutaneous KS lesions. One-third of KS patients present with edema localized to affected extremities,¹³⁴ frequently in the legs. A peau d'orange appearance may result from obstruction of dermal lymphatics locally, or lymph node enlargement may be seen with attendant distal edema. In addition to mechanical causes of edema induced by obstructing lymphatic flow, KS lesions are composed of abnormal vessels with poor integrity. Surrounding the vessels in lesions are extravasated red blood cells that account for the pigmentation of the lesions. A KSHV viral protein has been shown to induce local vascular endothelial growth factor (VEGF),¹³⁵ a known permeability factor. Therefore, normal vessels surrounding KS lesions may also be altered in their integrity, contributing to interstitial fluid in KS lesions or affected limbs.¹³⁵ Lower extremity involvement can lead to disabling loss of joint mobility. Considerable morbidity can occur when peculiar syndromes of periorbital edema or peripubic edema are seen.

In addition to skin and lymphatics, KS can involve any epithelial surface in the body, including the oral cavity, pulmonary tree, and gastrointestinal tract. In one report, patients with cutaneous KS had a 50% incidence of coexistent oral

involvement, 30% had pulmonary lesions, and 10% had KS in the gastrointestinal (GI) tract.¹³⁴ Many patients have GI lesions noted on endoscopic procedures, but clinical consequences are infrequent. Chronic or acute blood loss or protein-losing enteropathy is occasionally caused by GI involvement.

One particular type of KS that is life threatening and mandates aggressive therapy, is pulmonary parenchymal involvement. Chest X-rays are routinely performed on patients initially diagnosed with cutaneous KS to assess the possibility of lung lesions. Other screening studies for organ involvement are targeted to symptoms and are not recommended simply for observation.

The differential diagnosis for nonblanching lesions resembling KS includes¹³⁶ hematoma, purpura, sarcoid plaques, lichen planus, pyogenic granuloma,¹³⁷ mycosis fungoides, bacillary angiomatosis (usually due to *Bartonella* infection, with increased frequency in advanced HIV patients), secondary syphilis, pityriasis rosea (possibly associated with HHV-7 reactivation),¹³⁸ drug-related erythema multiforme, prurigo nodularis, nevi, vascular lesions of the phakomatoses (e.g., neurofibromatosis), epithelioid hemangioendothelioma, angiosarcoma, melanoma, and basal cell carcinoma. The potential for processes requiring entirely different therapeutic approaches strongly supports the need for histologic confirmation upon initial presentation, even though the CDC definition of KS does not require biopsy.

With the pervasiveness of KSHV infection in the general population, the virus is presumed to spread insidiously with disease manifestations occurring only in the context of some form of immunosuppression. However, a possible acute viral syndrome caused by KSHV in an HIV-positive patient has been described.¹³⁹ Kikuchi's disease, a cervical lymph node hyperplasia syndrome seen predominantly in women in the Far East, is another systemic syndrome that has been associated with KSHV. These patients typically present with fever, flu-like symptoms, neutropenia, an atypical lymphocytosis, and an elevated erythrocyte sedimentation rate (ESR). One retrospective analysis of 26 lymph node biopsies found polymerase chain reaction (PCR) evidence of KSHV sequences in 23%, with none in 40 controls.¹⁴⁰

PATHOLOGY AND PATHOGENESIS

The KS lesion can best be described as a complex array of endothelial cells, surrounded by spindle cells and extravasated blood elements. The spindle cell mass typically forms a cluster around slitlike endothelium-lined vascular spaces in the dermis, and becomes more densely packed in nodular lesions; both the spaces and the spindle cells characteristically lie parallel to the epidermis.¹⁴¹ The spindle cell mass is thought to produce paracrine cytokines, which recruit neoangiogenic elements and inflammatory cells.¹²⁰ Spindle cells are not themselves infected with HIV, but KSHV sequences can often be amplified from them.^{123,142} The origin of the spindle cells is controversial, alternately being viewed as having mesenchymal or endothelial cell features. One report demonstrated a phenotype more typical of the sinus-lining cells of spleen and lymph nodes than of other vascular or lymphatic endothelium.¹⁴³ These investigators and others have suggested that the cells of origin may be circulating in the blood. Expression of the mannose receptor and CD68 by these cells suggests

that the spindle cells may derive from a macrophage-like population in the sinuses of secondary lymphoid organs that enter the bloodstream, and spread hematologically to the epithelial surfaces where KS lesions are found. This origin may explain the peculiar histology of KS lesions, with vascular spaces reminiscent of splenic sinuses. A newer marker, the VEGF-C receptor that appears specific for lymphatic endothelium, has been reported to be expressed in KS biopsy tissue.¹⁴⁴ In contrast, endothelial nitric oxide synthase, expressed in vascular endothelium, is not detectable in KS cells.¹⁴⁵

An autocrine or paracrine secretion of cytokines, such as VEGF and basic fibroblast growth factor (bFGF), appear to maintain the spindle cells. The absence of a signal sequence in bFGF motivated one group to postulate that its export from KS cells may be mediated by one of the ATP-binding cassette transport proteins.¹⁴⁶ They showed that the multidrug resistance gene (MDR) is expressed in KS cells, and that the secretion of bFGF can be blocked by the MDR inhibitor probenecid. Furthermore, probenecid induced apoptosis in these cells in vitro. These data are compatible with an MDR or other probenecid-sensitive channel mediating an essential secretion of bFGF that then protects virally infected cells from apoptosis.

Even in the presence of exogenous growth factors, such as the IL-6-IL-6R complex, IL-1b, TNF- α , and oncostatin M, antibodies¹⁴⁷ to bFGF block the proliferation of KS cells and prevent them from entering the S phase of the cell cycle. However, exogenous growth factors do not completely explain the phenotype and growth potential of KS cells, which have been shown to overexpress the antiapoptotic bcl-2 gene independently of any factors contained in conditioned medium from these cells.¹⁴⁸

Regardless of the HIV-1 status of the patients,¹⁴⁹ the phenotype of the tumor-infiltrating lymphocytes in KS lesions is CD8+ T-cell predominant. Other significant populations include CD4+ T cells and CD4/CD8 double-negative T cells. Compared to biopsy-derived lymphocytes in other dermatologic conditions, stimulation of KS-derived leukocytes in culture results in high levels of IFN- γ but no IL-2. CD68/CD14+ cells of the monocyte lineage are a minority population, but also contribute to this strong IFN- γ production.¹⁵⁰ These monocytic cells produce a variety of other proinflammatory cytokines, including IL-1 and TNF- α , which in turn induce the KS spindle cells to produce bFGF and VEGF. These latter factors have been shown to induce angiogenic lesions resembling KS in nude mice, and cause increased vascular permeability and edema in guinea pigs.¹⁵¹

Regardless of whether the underlying context is HIV disease, organ transplantation, or endemic KS, KSHV appears necessary for the induction of KS and is found in KS lesions. The exact mechanisms, however, by which the virus participates in the oncogenic process are uncertain.

The methods of cell transformation seem to be unique among human viruses. None of the EBV genes expressed in its latent phase of infection has a homologue in KSHV, even though KSHV is closely related to the known transforming virus EBV.¹²² Four open reading frames in KSHV have been identified as having the ability to transform mammalian cells when expressed (K1, K9, K12, and CRF74), but whether they participate in vivo is not entirely clear.¹⁵²⁻¹⁵⁵

Several other genes have also been isolated for their possible role in host cell transformation. These genes can be

divided into three classes of KSHV homologues to known mammalian genes: (1) apoptosis: ORF 16 (related to human Bcl-2); (2) cell-cycle interference: ORF 72 (cyclin D) binds and activates human cdk-6, making it resistant to the normal inhibition of the CDK inhibitors p16(Ink4a), p27Kip1, and p21Cip1^{44,156}; and (3) immunomodulating cytokines: K2 (IL-6), K4 (MIP-II), and K6 (MIP-I). Subsequently, viral proteins could possibly act in a paracrine manner and affect neighboring cells. In addition, viral gene products in the infected cell may affect its growth, apoptotic potential, or vulnerability to immune defense targeting.

The pervasiveness of KS in populations that are HIV infected, post-solid organ transplant, of elderly Mediterranean extraction, or in economically disadvantaged tropical Africa, suggests that expression of a KS disease phenotype requires a degree of immunosuppression. The introduction of HAART for HIV treatment offers remarkable support to a central role for immunosuppression: complete remissions of cutaneous¹⁵⁷ and pulmonary KS are well recognized in the context of increases in CD4 count and declines in HIV viral load induced by HAART.¹⁵⁸

TREATMENT

Over the past several years, the treatment of KS has changed dramatically. Antiretroviral therapy has had a major impact on the natural history of HIV disease, reducing its incidence and inducing regression in some patients with established disease. Specific therapies for KS have also improved dramatically, and most patients can anticipate a satisfactory outcome with limited treatment toxicity. One issue of which patients and providers need to be mindful is that even with regression of lesions, a disfiguring pigmentation can remain.

The prominent extravasation of red blood cells in active KS lesions leads to hemosiderin deposition that can leave gray-brown macules when KS can no longer be histologically identified. Therefore, even successful treatment for KS masses may leave a residual stain that fades only after prolonged intervals. Laser therapy has been used to hasten the process for some with particularly disfiguring macules.

Quantitative methods have been developed for monitoring KSHV viral loads in patients under treatment. KSHV DNA level has been shown in transplant patients to increase with time after transplantation, and to correlate with progression of KS, stage of disease, and loss of the graft. In one multivariate analysis, the clinical activity of the tumor independently correlated with levels of KSHV DNA in the blood ($P = 0.01$).¹⁵⁹ KSHV viral loads may have more limited utility in HIV-infected individuals under treatment but do correlate with HIV viral load, CD4 cell counts, and the serologic response to KSHV lytic antigens.¹⁶⁰

ANTI-HIV THERAPY

Extraordinary declines in HIV-related mortality in the Western world have occurred since the advent of HIV-1 protease inhibitors and combination therapy for HIV. The rate of death fell by 70% among those with AIDS following the introduction of HAART in one U.S. study.¹⁶¹ Declines in opportunistic diseases associated with advanced immunosuppression have correspondingly been observed. Clinical entities, such as CMV retinitis, disseminated atypical mycobacterial disease, and *Pneumocystis* pneumonia are increasingly unusual events among patients on HAART. KS is the opportunistic neoplasm with the most dramatic decrease in incidence.¹⁶² Table 96.3 presents a summary of the

TABLE 96.3. Effect of highly active antiretroviral therapy (HAART) on incidence of cancer in AIDS patients.

largest studies to date. The first large survey study of KS among HIV patients found that incidence dropped by half when comparing the period before 1994 to the first half of 1997.¹⁶³ Although fewer cases were seen for both treated and untreated patients among the nearly 20,000 patients studied, HAART-treated patients experienced a more dramatic decline.

There is a well-recognized clinical phenomenon of established KS responding to HAART, in addition to the decrease in new cases of KS. This anti-KS effect has been demonstrated in four small series reported to date. A Swiss study of 9 individuals with cutaneous KS who were treated for a median 7 months with a protease inhibitor showed partial response in 6, stabilization in 2, and progression in 1 noncompliant patient.¹⁶⁴ In another trial examining 8 HIV-infected men with cutaneous disease, 4 experienced a complete remission following a mean of 12 months of HAART.¹⁶⁵ Another study of 10 KS patients showed a decrease to undetectable in the anti-KSHV peripheral blood titer following HAART in 7 of the 8 patients who showed partial or complete regression of KS.¹⁶⁶

Although most likely due to the recovery of immune function rather than a direct inhibitory effect on KSHV replication, KSHV sequences have been noted to disappear from peripheral blood following commencement of HAART.¹⁶⁷ There is no known impact of HIV therapy on KSHV directly. The effects of anti-HIV treatment are likely similar to the KS remission seen in posttransplant patients following withdrawal of their immunosuppression. KS is an immunologically responsive tumor, and the partial restoration of immune function with HAART is sufficient for tumor regression in many, but not all, patients.

ANTIHERPESVIRAL THERAPY

KSHV replication can be inhibited *in vitro* by the antiherpes drugs foscarnet, ganciclovir, and cidofovir.¹⁶⁸ Quantitation of KSHV copy number in peripheral blood of individuals on ganciclovir or foscarnet for other reasons has shown a decrease in KSHV viral load.¹⁶⁹ Although some studies have indicated a response,¹⁷⁰⁻¹⁷³ most results have been disappointing.¹⁷²⁻¹⁷⁴ Currently available antiherpesvirus drugs are too toxic to be considered a reasonable part of the therapeutic armamentarium.

Local Antitumor Chemotherapy

KS therapy is either local or systemic. Small, singular lesions on the trunk or an extremity may be more appropriate for local therapy. Local therapy is either liquid nitrogen, intralesional injection of vinblastine, topical 9-*cis*-retinoic acid, or radiation therapy.

Intralesional vinblastine is particularly useful for palatal or buccal mucosa lesions with a response rate estimated at 90%.¹³⁴ Vinblastine can be administered at 0.1 to 0.4 mg/mL, injecting approximately 0.1 to 0.2 mL into a 1-cm² lesion. As with liquid nitrogen, local discomfort is common and skin breakdown may occur. Regrowth of lesions is common.

Radiotherapy has taken on a new role in the treatment of KS in the HIV population, being used principally in the treatment of anal and cervical cancer with the advent of the

HAART era.¹⁷⁵ However, orthovoltage irradiation and electron beam radiotherapy have been shown to be effective for treatment of larger dermal KS plaques.¹³⁴ In France, 643 HIV-infected patients with KS showed a complete response rate of 92% from 20 Gy over 2 weeks, followed 2 weeks later by 10 Gy over 1 week.¹⁷⁶ Other studies have shown a response rate of 77% with a single dose of 8 Gy.¹⁷⁷ Radiation therapy generally can be useful for large or clustered lesions but can cause severe mucositis. HIV-infected individuals appear to have a heightened sensitivity to radiation injury of mucosa.

Topical use of 9-*cis*-retinoic acid cream was approved after a placebo-controlled, randomized trial of 82 patients.¹⁷⁸ Responses were sixfold higher in retinoic acid-treated patients, but the local side effects were often substantial. Patients often have discomfort and erythema at the site of application.¹⁷⁸ Open label trials of the same compound given systemically showed partial or complete responses in 37%.^{179,180} Tolerability was limited by complications that included dry skin, rash, alopecia, exfoliation, and headache (70%).¹⁷⁹

Systemic Antitumor Chemotherapy

Among the first agents available for treatment of KS were type I interferons, and their use has been comprehensively reviewed.¹⁸¹ Interferon- α_2 has been shown to induce remission of KS in a dose-dependent fashion when given in combination with AZT, with 31% of 54 patients responding to 8 million units given daily subcutaneously.^{74,182} Interferon therapy is most effective in those with relative preservation of immune function, generally reserved for those with 100 CD4 cells/mm³ or more. The use of interferon is limited by its slow commencement of action (median time to response of 10 weeks in some studies) and the numerous and troubling side effects. Initially, and most prominent, are flu-like symptoms, followed by depression and fatigue after prolonged use.

For patients with advanced symptomatic KS, particularly those patients with edema, extensive mucocutaneous disease, and pulmonary or GI involvement, chemotherapy is recommended. Symptomatic pulmonary disease can be rapidly fatal and is particularly important to treat aggressively. Combination cytotoxic therapy with vincristine, bleomycin, and doxorubicin has served as a standard for comparison for newer treatment regimens, having demonstrated a 40% KS regression rate. The treatment involves a variety of difficult side effects, including nausea, alopecia, fatigue, peripheral neuropathy, acral cyanosis, and Raynaud's phenomenon.¹⁸³ Two Phase III studies, with about 250 HIV-related KS patients each, found a 25% response rate to this triple therapy or to bleomycin + vincristine; this compared to 46% and 58% for liposomal doxorubicin in the two studies, respectively.^{184,185} In contrast, a large, randomized study comparing the BVD triple combination to liposomal daunorubicin found them to be of comparable efficacy.¹⁸⁶ Whether liposomal doxorubicin is truly superior to liposomal daunorubicin is unclear. These agents have different kinetic profiles, and the longer half-life of liposomal doxorubicin may account for its differential activity and association with the hand-foot syndrome. Many practitioners use these agents interchangeably for first-line therapy of patients with advanced, symptomatic KS, although

current U.S. Food and Drug Administration (FDA) approval for liposomal doxorubicin is for use only in refractory or relapsed KS.

One newer class of agents being examined is the taxane tubulin stabilizers. Paclitaxel, for instance, was shown in a Phase I trial involving 28 patients to induce a major response in 71%,¹⁸⁷ including those previously and unsuccessfully treated with anthracyclines. This treatment appears to have both profound activity and highly durable responses. Tumor breakthrough is relatively rare and patients can tolerate low-dose paclitaxel (100mg/m² every 2 weeks) extremely well. Some patients have received this therapy for over 2 years at our center, with cessation of therapy resulting in prompt regrowth of tumors.

KS lesions are highly vascular, which has led to the investigation of antiangiogenic therapies. Thalidomide was studied in a Phase II trial of 20 patients, with 8 of them achieving partial responses and 2 with stable disease; other than drowsiness and depression, the drug was well tolerated over a median 6-month treatment period.¹⁸⁸ Fumagillin (TNP-470) was well tolerated in a study of 38 patients but had poor activity.¹⁸⁹ In an effort to bridge the gap between antiretroviral regimens and systemic chemotherapy, halofuginon and other agents are all currently under in-depth investigation.

Summary

The identification of the human pathogen KSHV has been a major boon to understanding the basis of KS. This newest of human tumor-associated viruses appears to act via unique means of cell transformation, the understanding of which is likely to contribute novel paradigms for viral oncogenesis. In addition, virus-related antibodies may ultimately provide a means of screening for KS risk among immunosuppressed patients, and the virus itself may represent a target for future therapies. At present, the treatment of choice for AIDS-related KS is potent anti-HIV therapy. Those patients with advanced KS who require prompt improvement in symptoms, or who fail anti-HIV therapy, have a number of active chemotherapy options. Those who are not appropriate for cytotoxic agents still await a satisfactory systemic treatment, but local therapies can provide temporary improvement and the antiangiogenesis compounds offer promise that this gulf may soon be bridged.

AIDS-Associated Lymphoma

EPIDEMIOLOGY

The risk of developing lymphoma for HIV patients is estimated to be 60- to 110-fold higher than that of the general population. Genetic background, use of HAART, and subtype of lymphoma greatly influence the development and course of AIDS-related lymphoma (ARL). ARL is about twice as common among people of European ancestry compared with African-Americans and among men as compared with women.¹⁹⁰ It is the most common malignant complication of AIDS in children, representing 42 of 64 cancer cases in a British registry.⁴ These are generally high-grade tumors, though a minority are low-grade lymphomas of the mucosa-associated lymphoid tissue termed maltomas. The estimated

incidence of ARL in patients with symptomatic HIV infection is 1.6% per year.¹⁹¹

Specific genotypes appear to alter the risk of ARL. Specifically, polymorphisms in the 3'-region of the gene encoding the chemokine SDF-1 were associated with a higher risk of AIDS-related lymphoma.¹⁹² Those heterozygous for the polymorphism had a twofold increase in risk whereas homozygous individuals had a fourfold-increased risk of lymphoma. The polymorphism was detected in 37% of whites, but only 11% of African-Americans, possibly accounting for the noted infrequency of this complication in black Americans with HIV. Other chemokine alterations also may affect lymphoma incidence, including a reduced incidence of ARL among those with a deletion within the CCR5 chemokine receptor gene (CCR5-delta32) that has been shown to be protective against HIV-1 infection. A threefold reduction in risk of ARL was noted in individuals with the CCR5 deletion. CCR5-delta32 is thought to affect the sensitivity of cells to the chemokine ligand of CCR5, RANTES, possibly causing altered B-cell function, either directly or through T-cell-mediated events.¹⁹³ The polymorphism in SDF-1 may change expression of RANTES, which is a known B-cell growth factor. Therefore, regulatory genes of the immune system may enhance or decrease an individual's likelihood of developing a lymphoproliferative disease.

Primary CNS lymphoma has been most dramatically altered in incidence since the advent of HAART therapy. It is a complication of far-advanced HIV disease that is now rarely seen, and generally only among those who have either failed antiretroviral therapy or for whom it is not available.

Among the ARL, primary CNS lymphoma in AIDS closely resembles posttransplant lymphoproliferative disease (PTLPD). Both tumors manifest a type II pattern of EBV latent gene expression (EBNA1-6 and LMP1-2).^{194,195} EBNA-2 and -3 gene products are those generally well targeted by cytotoxic T lymphocytes (CTL), and the reduced incidence of primary CNS lymphoma with HAART may reflect an improved anti-EBV immune response. Of note, even among HIV-infected individuals with relatively normal numbers of EBV-specific CTL, there are abnormalities in cell function that have been linked to the development of EBV-associated lymphoproliferation.¹⁹⁶

Systemic lymphomas have been less markedly reduced in the era of HAART than has ARL, the primary CNS lymphoma subset of AIDS-related lymphomas, in which the risk of systemic lymphomas is less dramatically reduced by HAART.^{197,198} Systemic ARLs have a more complex pathophysiology, discussed next, that likely accounts for this less dramatic decrease in incidence since the advent of HAART. The estimated decline in systemic lymphoma incidence is approximately two- to sevenfold since the introduction of potent antiretroviral therapy (see Table 96.3).¹⁹⁹⁻²⁰² An observational cohort analysis of 8,500 HIV-positive individuals across Europe (EuroSIDA),²⁰¹ demonstrated a significant decrease in the incidence of all subtypes of lymphoma after 1999, when the use of combination antiretroviral therapy was widespread compared with the period before HAART.²⁰⁰ Similarly, an international multicohort study found a reduced incidence of ARL of approximately twofold following the introduction of HAART. Subtypes of lymphomas were also investigated in this study, and the greatest difference in incidence was observed in immunoblastic and primary CNS lym-

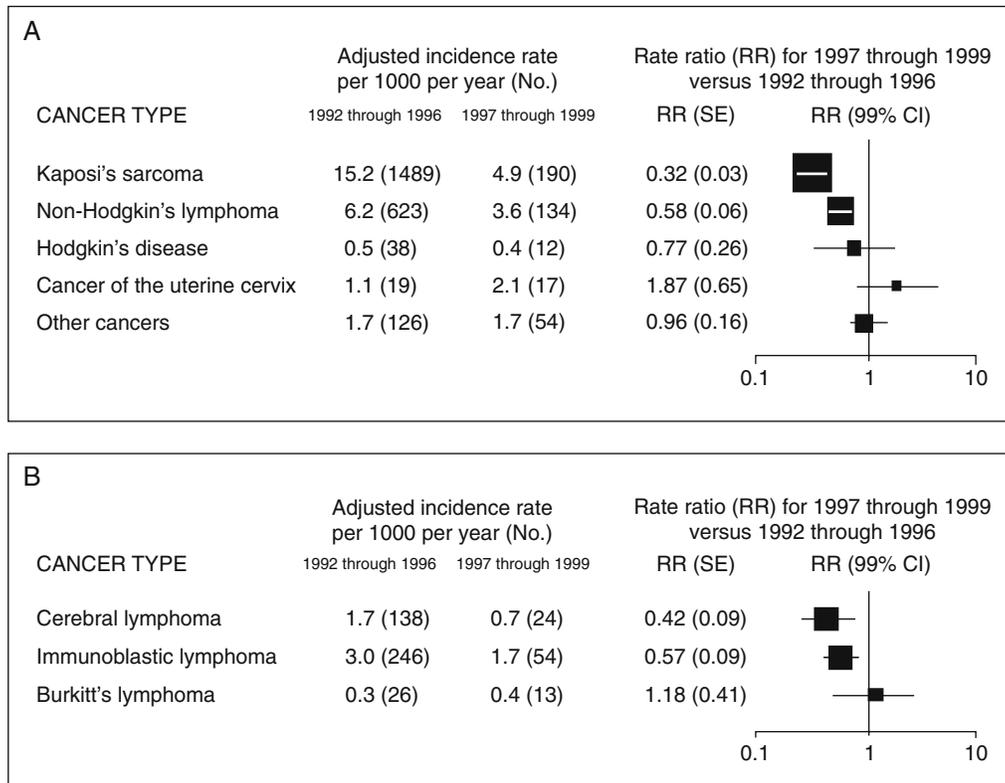

FIGURE 96.2. Meta-analysis of highly active antiretroviral therapy (HAART) effect on (A) cancer incidence and (B) certain non-Hodgkin's lymphoma subtypes in HIV-infected adults, comparing pre-HAART to the treatment era. Rate ratios are adjusted for factors including

study type, age, gender and transmission group. (From the International Collaboration on HIV and Cancer,²⁰⁰ by permission of *Journal of the National Cancer Institute*.)

phoma. Both those lymphomas are closely associated with EBV, although EBV DNA in the tumor specimens was not specifically assessed in this study. In contrast, as noted in Figure 96.2, a large meta-analysis found there was no change in incidence of either Burkitt's lymphoma or Hodgkin's disease.²⁰⁰ Therefore, the effect of antiretroviral therapy and the resultant improvement in immune function were not globally effective. Thus, although poor control of EBV plays a critical role in the genesis of ARL, susceptibility represents a complex interplay of immunity and other factors, such as lymphocyte growth control.

Non-Hodgkin's Lymphoma

Pathophysiology

The simplest scenario by which altered immunity could affect lymphoma occurrence is that in which an infectious agent directly alters the molecular basis of cell growth regulation. One rare example of this is HIV itself. HIV is tropic for CD4+ T cells and within that subset HIV has been implicated in rarely inducing T-cell non-Hodgkin's lymphomas.^{203,204} Some of these tumors have been molecularly analyzed and noted to have an insertion site for HIV-1 in the host genome that juxtaposes HIV with the *c-fes/fps* protooncogene.²⁰⁵ Dysregulated expression of *c-fes/fps* by the presence of HIV may result in altered cell proliferation or survival.

In contrast to HIV, gammaherpesviruses are commonly implicated in ARL. Within the gammaherpesvirus family, two have been implicated in AIDS-related lymphomas and in immunodeficiency-related lymphomas generally: EBV and the Kaposi's sarcoma-associated herpesvirus (KSHV). Two distinct subsets of AIDS-related lymphomas are directly linked to one or both of these viruses. Primary CNS lymphomas are infected with EBV, whereas primary effusion lymphomas uniformly have the KSHV genome present in tumor tissue. The EBV latent membrane protein 1 (LMP-1) is the gene most directly associated with transforming capability and is widely expressed in primary CNS lymphomas.^{206,207} LMP-1 activates the tumor necrosis receptor-associated factor (TRAF) family signaling pathway,²⁰⁸ resulting in enhanced expression of the transcription factor NF- κ B and in transformation of B lymphocytes.

The mechanism of KSHV-mediated transformation remains controversial, although a number of viral gene products, such as IL-6, have been implicated. In addition, KSHV encodes an interferon regulatory factor homologue (vIRF1 or K9) that is capable of repressing interferon-induced host genes and inhibiting pathways of apoptosis normally enhanced by interferon, thereby further impairing a critical host antiviral defense mechanism.^{152,209}

KSHV may be capable of altering immune recognition of virus-infected cells through inhibition of the MHC class I-dependent pathway of antigen presentation by preventing attachment to NK cells. Although EBV and KSHV may directly alter target cell growth in the genesis of CNS NHL

and PEL, respectively, other mechanisms are clearly at work in the majority of AIDS-related lymphomas. Aside from these two minor subsets, other lymphomas in AIDS patients are often negative for EBV, which, for example, infects only about 30% of AIDS-related Burkitt lymphomas.²¹⁰ Of those tumors that are EBV infected, the type III latent gene pattern seen in infectious mononucleosis and low-grade B lymphoproliferative disorders is not consistently observed.²¹¹⁻²¹³ These lymphomas often express a type II profile of EBV genes more consistent with that seen in Hodgkin's disease. Among those ARL without EBV DNA, there are often genetic abnormalities. Large cell histology ARL demonstrate EBV infection in approximately 80% of tumors but show other genetic abnormalities that include nonoverlapping subsets with rearrangements of the *Bcl-6* (21%) and *c-myc* (21%) transcription factor genes. *p53* tumor suppressor gene rearrangements are generally not present.²¹⁴ The pattern is somewhat different in AIDS-related lymphoma of Burkitt histology, with *c-myc* rearrangements being almost universal (as in non-HIV-associated forms of Burkitt lymphoma), *p53* mutations seen in 61%, and *Bcl-6* rearrangements very uncommon. There is no clear link between EBV and any specific genetic mutation.²¹⁵⁻²¹⁸

Large cell lymphomas, whether in endemic or HIV-associated settings, are thought to be germinal center in origin. The *Bcl-6* gene expressed in these tumors is characteristic of germinal center cells.²¹⁹ Burkitt cells are also a mature B-cell lymphoma thought to represent a transformed germinal center blast cell. They have *c-myc* translocations into either the heavy- or light-chain immunoglobulin gene loci. The translocation of the HIV-associated Burkitt tumor is distinct from endemic Burkitt's. In the HIV patients, *c-myc* has translocated into the immunoglobulin heavy-chain gene switch region rather than the joining region of the immunoglobulin locus that is characteristic of the endemic tumors.²²⁰ This finding suggests that the rearrangement in the HIV-associated tumors occurred at a later time in B-cell maturation when heavy-chain class switching was occurring rather than during early B-cell differentiation when VDJ recombination takes place.

Although direct effects of herpesviruses may be relevant for transformation, and the interaction with other somatic mutations in host cells may enhance tumorigenicity, these events alone would be unlikely to account for the high incidence of lymphoma in AIDS patients. HIV-induced impairment of the immune system is likely to provide the critical context in which lymphoma can emerge. HIV-induced impairment of the immune system first enables transforming herpesviruses to propagate but may facilitate secondary transforming events by other means. B-cell proliferation is common in HIV infection independent of secondary herpesvirus, as is clinically manifest as the frequent lymphadenopathy and hypergammaglobulinemia seen in HIV-infected individuals. HIV may directly contribute to the process through antigenic drive, and the HIV envelope glycoprotein has also been reported to directly enhance B-cell activation.^{221,222} Further, the HIV gp120 engages with the CXCR-4 chemokine receptor and may directly alter B-cell proliferation, as this receptor is known to provide a growth-promoting signal to B-cell subsets akin to the SDF-1 discussed earlier.²²³⁻²²⁷ B-cell proliferation may be further augmented by viral perturbation of the T-cell compartment, with expansion

of the Th2 subpopulation that releases B-cell stimulatory factors, such as IL-10 and IL-4.^{228,229} HAART may reduce the incidence of ARL partly through reverting these direct and indirect mechanisms driving B-cell proliferation.

Clinical Biology

Virtually all ARL are high grade and of mature B-cell origin. The histology is usually either large cell anaplastic or small cell (Burkitt), and these are thought to be either germinal center or postgerminal center B cell in origin. Subsets of tumors have been more finely divided into other stages of B-cell differentiation as well. For example, by staining with antibodies against *Bcl-6* (associated with germinal center cells), *MUM1/IRF4* (associated with late or postgerminal center cells), and *CD138/syndican-1* (associated with postgerminal center cells), Carbone et al. noted that the majority of large cell or Burkitt lymphomas were germinal center. In contrast, immunoblastic histology was described as late germinal center and primary CNS, primary effusion, plasmablastic, Hodgkin's, and some large immunoblastic lymphomas were characterized as postgerminal center.²³⁰

The localization of systemic AIDS-related lymphomas frequently extends beyond involved lymph nodes and affects extranodal tissues. Extranodal sites that are particularly common are the gastrointestinal tract, bone marrow and central nervous system, although virtually any tissue may be involved.^{201,231-248} The tumor histology significantly influences its localization. In particular, large cell tumors preferentially involve the gastrointestinal tract, whereas Burkitt tumors often involve the bone marrow and meninges. The presenting symptoms of ARL can be very variable and do not appear to be appreciably affected by HAART.^{250,251}

The different histologic subtypes of systemic ARL may occur in different settings and have unique features. AIDS-related Burkitt's lymphoma usually arises in patients with a less severe degree of immunosuppression than other histologic subtypes.²⁵² In those cases of Burkitt's that are EBV infected, only two EBV-encoded RNAs and only a single protein-encoding gene (*EBNA-1*) are expressed; this is the type I program of latent gene expression.²⁵³ Immune reconstitution of EBV-infected cells typically does not include *EBNA-1* because infected cells cannot process this protein and therefore, cannot present the antigens on class I MHC.²⁵⁴ The basis for the approximately 1000-fold increase in risk for Burkitt's lymphoma among HIV-infected individuals compared with other immunosuppressed populations remains an unresolved mystery.

CNS involvement with ARLs was noted early in the HIV epidemic with up to 20% incidence reported.²³⁶ That has resulted in an emphasis on aggressively evaluating the CNS in patients with systemic AIDS-related lymphoma, including imaging and cerebrospinal fluid sampling studies. Some centers prophylactically treat all patients with intrathecal therapy, but data suggest EBV in the primary tumor is of strong predictive value for an increased risk of CNS relapse ($P = 0.003$).²⁵⁵ Extranodal involvement has also been noted as a strong predictive factor for CNS involvement ($P = 0.006$).^{255,256}

The prognosis for patients with AIDS-related lymphoma has been markedly affected by HAART. Prognostic factors

defined before the advent of HAART need to be revised, but one large multivariate analysis indicated that CD4 count less than 100 cells/mm³, age greater than 35 years, intravenous drug use, and stage III/IV disease, were negative prognostic factors. When only one or none of these factors was present, the overall survival was 46 weeks; when two factors were present, 44 weeks; and when three or four factors were present, 18 weeks.

The International Prognostic Index (IPI)²⁵⁸ has been validated in the context of AIDS,²⁵⁹ and other studies have indicated that factors used in the IPI, such as elevated lactate dehydrogenase (LDH)²⁵⁸ or age more than 40 years do provide independent prognostic information in ARL. Curiously, given its impact outside the setting of HIV, Burkitt histology has not been consistently found to be of prognostic significance. Similarly, treatment protocols have not specifically evaluated this subset, and it remains unclear whether they do better with a more aggressive regimen in the setting of HIV.

Primary effusion lymphoma is a very unusual subset of systemic ARL. It is a liquid-phase tumor that rarely involves the blood, lymph nodes, or solid organs. Body cavity effusions²⁶¹⁻²⁶³ laden with large anaplastic or immunoblastic-appearing cells are characteristic. The cells can be identified as hematologic by staining for surface CD45 (common leukocyte antigen), but antibodies specific for B cells (CD20 or CD19) or T cells (CD3) generally do not stain the tumor cells. Molecular analysis of tumor cells is required to demonstrate VDJ rearrangement of the immunoglobulin locus, thereby defining the cells as being of B-cell origin. These cells also uniformly are infected with KSHV and are frequently coinfecting with EBV. These tumors are not restricted to HIV-related immunodeficiency and may be found in other immunodeficient states. They provide a unique and intriguing paradigm for virus-induced human malignancy.

Another rare form of systemic AIDS-related lymphoma is that of plasmablastic lymphoma of the oral cavity.²⁶⁴ This is an aggressive B-cell lymphoma that is distinct from other HIV-related large cell lymphomas in their presentation, histology, and immunohistochemistry (CD20 is not expressed). EBV is often, but not uniformly, present in these tumors.

Treatment

The ability to effectively treat ARL has long been complicated by the coincident presence of other complications of immunosuppression, which led to an approach of compromised dose chemotherapy early in the HIV epidemic. Although such therapies were found to result in comparable response rates to full-dose chemotherapy,²⁶⁵ they are generally now reserved for those patients who have failed HAART or for whom it is not available. The introduction of HAART has resulted in far superior tolerance of chemotherapy, and full-dose regimens are now the standard of care. The specific regimen remains controversial. Full-dose CHOP or infusional regimens, such as modified-dose EPOCH have both been shown to be effective.^{266,267} The response rate of the infusional EPOCH regimen was particularly impressive, with 74% of patients achieving a complete remission. Overall and disease-free survival were 92% and 60%, respectively, at a median of

53 months of follow-up. However, this was a single-center trial and validation in a larger, multicenter setting is currently being tested through the U.S. AIDS Malignancy Consortium (AMC).

The issue of whether rituximab adds benefit when added to standard chemotherapy is also still unclear in the setting of ARL. Preliminary data from a randomized trial comparing CHOP versus CHOP plus rituximab by the AMC, suggest that there may be an increased risk of infectious death in those patients receiving the rituximab without any clear improvement in tumor outcomes (Kaplan, in press). If rituximab is used, these data would indicate that it is prudent to include antibiotic prophylaxis; an intervention currently being tested in an EPOCH plus rituximab trial.

Whether specific subsets of tumors require distinct therapies has not been well defined. The numbers of patients have generally been too small to run histology-specific trials, and subgroup analysis of larger trials has not provided clear indication of histology-specific outcomes. Given the uniquely aggressive nature of Burkitt histology outside the setting of HIV, however, many centers employ a treatment regimen designed for Burkitt histology rather than using a more conventional CHOP-like regimen. One study of hyper-CVAD in AIDS-related Burkitt lymphoma demonstrated a 92% complete remission rate with tolerable toxicity and some long-term disease-free survivors.²⁶⁸ Primary effusion lymphomas generally do poorly regardless of regimen, but again the data are mostly anecdotal, and no systematic evaluation has been performed.

For patients who have relapsed beyond initial therapy, the potential for high-dose chemotherapy with stem cell rescue was thought prohibitively toxic until recently. There have now been several trials that have indicated the tolerability of this approach and the potential for durable tumor control for those with ARL.²⁶⁹⁻²⁷² Somewhat unexpectedly, hematopoietic engraftment or infectious complication have not been problematic. Long-term outcomes remain poorly defined, but this therapy appears to be a useful intervention in the setting of lymphoma relapse and HIV disease.

Managing antiretroviral therapy during cancer chemotherapy is an issue that has been addressed by clinical trials. In one study by the AMC, a set regimen of HAART (indinivir, d4T, and 3TC) was prescribed for those receiving CHOP or modified CHOP, and it was maintained throughout the chemotherapy program.²⁶⁶ No unusual or unusually severe toxic reactions were noted, and there was no change in the pharmacokinetics of either daunorubicin or indinivir. There was, however, a prolonging of the area under the curve for cyclophosphamide levels, although this did not have apparent clinical consequences. This approach was generally well accepted by patients, but only a small number of the now wide range of antiretroviral agents available have been studied. It remains possible that untoward drug-drug interactions will emerge if cancer and antiretroviral therapies are given concurrently. Taking the opposite tack to entirely avoid this issue, Little and colleagues suspended all antiretrovirals during dose-adjusted EPOCH therapy and noted that CD4 and viral loads returned to baseline when HAART was reinitiated after the completion of cancer treatments.²⁶⁷ Stopping anti-HIV medications can be particularly difficult for patients to accept, however. The decision of whether to continue or interrupt HAART is a complicated one with limited available

data; many centers proceed only after extensive open discussion with the patient weighing the relative likelihood of adverse effects from pharmacologic principles of the drugs in question. If anti-HIV medications are to be continued, compromised dosing or schedule should be avoided to reduce the likelihood of resistant viral strains emerging.

Hodgkin's Disease

The incidence of Hodgkin's disease has been estimated to be increased 2.5- to 8.5-fold above that of the uninfected population,²⁷³⁻²⁷⁸ with certain geographic groups reporting an increase of up to 18.3-fold.²⁷⁵ The risk of Hodgkin's disease appears to be uniformly increased across the risk groups for HIV infection, and independent of age or gender.²⁷⁸ The clinical features of the disease in HIV-positive persons are substantially different from uninfected counterparts with a higher incidence of advanced-stage disease, B symptoms, and extranodal disease.²⁷⁹⁻²⁸² Stage III or IV disease was reported in 91% of HIV-infected patients compared with 46% in individuals without HIV.²⁸³ Bone marrow may be involved in up to 50% of patients,²⁸⁴⁻²⁸⁶ in addition to less common extranodal sites, such as the tongue, rectum, skin, and lung. Staging procedures should follow guidelines in the HIV-uninfected population, but with particular care to assess for coincident infectious causes of B symptoms.

Pathologic features of Hodgkin's disease are also different in the HIV-infected individual, with mixed cellularity histology more commonly noted.^{279-281,287} EBV is also much more frequently detected in the tumor specimens. EBV has been estimated to be present in 80% to 100% of Hodgkin's tumors from individuals with HIV,²⁸⁷⁻²⁹⁰ typically expressing LMP-1 but not EBNA2.²⁹⁰ The transcription factor Bcl-6, expressed as noted earlier in germinal center B cells, is present in Reed-Sternberg cells from both HIV-1-infected and uninfected individuals. However, syndecan 1 (a proteoglycan associated with the postgerminal center) is restricted to the HIV-1-positive population,^{291,292} suggesting that the postgerminal center B cell may be the cell of origin in HIV-1-related Hodgkin's disease. In contrast, the germinal center cell is considered to be the source of Reed-Sternberg cells in HIV-negative patients with Hodgkin's disease.

Treatment guidelines for patients with Hodgkin's disease in the setting of HIV should be the same as those without HIV. The one caveat is that HIV patients with CD4 depression should receive prophylaxis for PCP during therapy.

Posttransplant Lymphoproliferative Disease

Epidemiology

Posttransplant lymphoproliferative disease (PTLPD) is a severe complication of organ transplantation resulting from iatrogenic immunosuppression. PTLPD is the most common malignancy in the posttransplantation population; the other major complicating neoplasms are Kaposi's sarcoma, basal cell carcinoma, and cutaneous squamous cell carcinomas, which are generally less frequent or severe. PTLPD is seen both early and late after transplantation, with distinct pathophysiologic factors distinguishing these two settings. In the

immediate posttransplant setting, PTLPD is uniformly EBV related. The median time to onset of PTLPD has been variably reported, but was 10 months after surgery in a series of 4,000 consecutive liver transplants in one retrospective series.²⁹³ PTLPD is rarely seen after 5 years posttransplantation, and its frequency and perhaps time to occurrence are related to the magnitude of immunosuppression.²⁹⁴ For this reason, lung and multiorgan transplants are generally associated with a higher incidence and more rapid onset of disease than kidney transplants. European centers using regimens that are less immunosuppressive, generally see less PTLPD than centers in the United States. In one multicenter study of more than 50,000 patients, the incidence of PTLPD during the first posttransplant year was 1.2%, with subsequent years estimated at 0.3% per year in cardiac transplant recipients, but these rates vary considerably depending upon the center.²⁹⁵

A number of features factor into the risk of developing PTLPD. Perhaps most important is whether the organ recipient is EBV seropositive before transplant and whether the recipient is a child or an adult. The incidence of PTLPD is significantly greater (~3-fold) in children, probably because of the lower incidence of preceding EBV infection, and is approximately 24-fold higher in EBV-seronegative versus EBV-seropositive recipients.^{293,296,297} In those not previously exposed to EBV, primary EBV infection via the graft or from transfusions during surgery can result in florid lymphoproliferative disease that is generally polymorphic and polyclonal and responds to reduction in immunosuppression.²⁹⁸ Although often mentioned in conjunction with PTLPD in previously EBV-infected adults or children, the pathophysiology of disease in patients with perioperatively acquired EBV is distinct, as discussed next.

The extent of immunosuppression is one of several reported risk factors, and studies have indicated that the therapeutic use of antibodies directed against T cells (for graft rejection) provide a particular enhancement of risk.²⁹⁹ Alcoholic cirrhosis, and notably, the presence of hepatitis C, as a cause of liver failure in liver transplants, also appear to increase the risk of PTLPD, for reasons that are not clear.³⁰⁰

When assessing patients in the posttransplant setting, it has been reported that elevated titers of EBV viral load in the blood (more than 25,000 copies/ μ g DNA) are associated with the development of PTLPD and have been correlated with a suppression of EBV-reactive T cells.^{297,301} Inversion of these parameters has been associated with improvement in PTLPD, usually seen in conjunction with a decrease in therapeutic immunosuppression.

The late-occurring lymphoproliferative disorders seen in the posttransplant patient are not EBV associated, may be either B or T cell in origin, and are generally similar to lymphoma in the immunocompetent population.

Pathophysiology

Posttransplantation lymphoproliferative disorders often have a polymorphic histologic appearance that may complicate diagnosis and likely reflect some of the underlying pathophysiologic differences within this group. Knowles has advocated dividing PTLPD into plasmacytic hyperplasias, polymorphic lymphoproliferative disorders, and malignant lymphomas/multiple myeloma.³⁰² The plasmacytic hyper-

plasias are polyclonal and generally regress spontaneously following withdrawal of immunosuppression. The malignant lymphomas are monoclonal, possess a variety of genetic alterations, and generally progress despite aggressive therapy. The polymorphic lymphoproliferative disorders are also monoclonal but display variable clinical behavior, their progression and response to chemotherapy apparently correlating with Bcl-6 gene mutation.^{302–304} These correlations between clonality and mutation, with responsiveness to alteration of immunosuppression, support the following model. In the posttransplant setting, EBV reactivation induces a reactive lymphoid hyperplasia. The lifting of pharmacologic suppression results in restoration of the ability to control the consequences of EBV lytic replication through rejuvenated CTL responsiveness. The recalcitrance of some more blastoid PTLPD tumor types to the lifting of immunosuppression supports the notion that these tumors represent a fundamentally different disease process. EBV may serve as an initiation factor in this subset, but progression may be secondary to genomic mutation and resultant dysregulation of the cell cycle; thus, restoration of an anti-EBV CTL response may no longer be sufficient to control a rapidly progressive tumor.

Overall, PTLPD may be regarded as a relatively straightforward failure of immune control of EBV. Pharmacologically induced immunosuppression is clearly the central factor in the susceptibility, and may serve as a model for the genesis of similar lymphomas in the broader context of autoimmune disease and congenital immunodeficiency. Other genetic traits (e.g., a polymorphism in the hMSH2 DNA mismatch repair gene)³⁰⁵ and environmental factors (e.g., alcohol use)³⁰⁶ likely also contribute to lymphomagenesis in these patients, but any discussion of causation must begin with a focus on the host interaction with chronic EBV infection.

Despite its ubiquity as a chronic infecting agent in more than 90% of adults worldwide, EBV was first identified in 1964 by a British team³⁰⁷ that found viral particles in tumor biopsies from patients with the endemic non-Hodgkin's lymphoma subtype first identified in African children by Burkitt in 1958.³⁰⁸ B lymphocytes appear to be the most important targets of primary infection through exposure to oral secretions. Patients with the infectious mononucleosis symptom complex demonstrate activated B-cell blasts in the paracortical region of the tonsils.³⁰⁹ EBV-infected T cells and oropharyngeal epithelial cells are only rarely identified during acute mononucleosis.³¹⁰ Viral particles release their double-stranded linear DNA in the B-cell cytoplasm, subsequently circularizing and surreptitiously assuming control of cellular replication. This viral episome is transcriptionally active in as few as 3 of the 90+ viral genes.³¹¹ As many as 10 latency genes are active in *in vitro* transformed B cells, which are sufficient to cause a relative immortalization of the host cell. This parsimony of viral gene expression is believed to contribute significantly to the ability of the virus to hide from immune recognition in the normal host.

Independent of the immunosuppression factor, the specific steps leading to transformation of infected B lymphocytes are still poorly understood. Three different latency gene expression patterns have been described in most EBV-related lymphomas as previously noted, constituted by different combinations of the 10 genes expressed in B-cell lines transformed *in vitro*. All three patterns are represented among PTLPD patients, with the full complement expressed in poly-

morphic lymphoproliferative disease and a more restricted expression profile in monoclonal lymphomas.³¹⁰

Successful suppression of viral replication is maintained in large part by the generation of cytotoxic T cells directed against several splice products of the Epstein-Barr nuclear antigen (EBNA) genes. The ability of renal transplant patients who develop PTLPD to respond to therapy (acyclovir treatment and a decrease in immunosuppression) has been shown to correlate with the recovery of the CD8+ CTL population.³¹² This finding suggests that the mechanism behind regression of PTLPD in the setting of the withdrawal of immunosuppression is the release of pharmacologic impairment of CTL function. Because of the ubiquity of EBV infection in PTLPD, it is tempting to speculate that the invigoration of CTL function restores a previously suppressed ability to control EBV in these patients. Indeed, administration of autologous EBV-specific CTL has also been shown to induce regression of PTLPD in both renal transplant patients³¹³ and following allogeneic bone marrow transplantation.³¹⁴ One of these studies³¹³ found that in three patients with EBV reactivation in association with lymphoproliferation, serum EBV DNA concentrations dropped as much as three logs, back to the control range, within a month after CTL infusion.

Although PTLPD is generally due to EBV if seen in the first 2 years posttransplant, there can be rare cases of EBV-negative tumors, including KSHV-related primary effusion lymphomas. Primary effusion lymphoma associated with KSHV in the tumor has been reported in the heart allograft of a patient who had a prior history of Kaposi's sarcoma.³¹⁵

Clinical Biology

PTLPD after solid organ transplantation often presents as lymphadenopathy or a mass. As with AIDS-related lymphomas, extranodal involvement is common. Sites of particular proclivity are the CNS and the gastrointestinal tract. A site not uncommonly involved is that of the allograft itself, where presumably the antigenic stimulation is greatest in magnitude and perturbations in immune regulation may be most dramatic. The transplanted organ has been estimated to be involved in about 20% of cases involving heart, lung, or liver transplants. Depending on the nature of the lymphomatous infiltration, distinguishing between PTLPD and graft rejection may be difficult and may require biopsy and supportive clinical information, such as EBV viral load.

The clinical approach to patients with PTLPD is generally multistep and involves reduction in immunosuppression, as tolerated. Antiherpesvirus agents are often given, though their use outside the context of primary EBV infection is highly controversial. These antiviral medications generally target the viral thymidine kinase, a gene expressed only during the lytic replication phase of the viral life cycle. Consequently, use of these drugs is appropriate in PTLPD resulting from primary EBV infection in recipients who were EBV seronegative at the time of transplant. In contrast, these antivirals are unlikely to affect the predominantly latent viral gene expression seen in PTLPD of the polymorphic or monoclonal type. In patients who do not respond to reduction in immunosuppressive drugs or are critically ill at presentation, treatment with the anti-CD20 monoclonal antibody rituximab may be highly successful.^{316–318} The use of rituximab has been reported only in limited studies to date,

but the results are highly encouraging. The apparent toxicities are relatively few, although hypogammaglobulinemia is an expected and potentially important clinical outcome. Interestingly, rituximab induces a reduction in EBV viral load, but this reduction does not exactly correlate with antitumor effect. Quite probably different populations of B cells are producing EBV versus those that are malignant.³¹⁹ For those patients who are refractory to anti-CD20, other antibody therapies may be useful, but no published results are available. Cytotoxic chemotherapy is another alternative, although the sensitivity of patients to the toxic side effects of these agents is increased.³²⁰

Drug-Associated Risk for Lymphoma in Autoimmune Disease Patients

The relationship between treatment for rheumatoid arthritis and the development of lymphoproliferative disorders is controversial, with numerous suggestive case reports³²¹ but no validation in large series.³²² Early studies had shown an increased risk in patients receiving cyclophosphamide³²³ or chlorambucil,³²⁴ but neither of these drugs has been widely used in rheumatoid arthritis since the advent of methotrexate therapy in the 1980s and the very effective biologic agents in the late 1990s. As indicated in Figure 96.3, these agents are associated with some risk for development of lymphoma.

The possibility of treatment-associated lymphoma has been a cause of great recent concern, particularly that associated with the most frequently used drug in rheumatoid arthritis, methotrexate.³²⁵ The dilemma at the heart of this analysis has been whether methotrexate use is a surrogate marker for those patients with the most severe disease and thus possibly the highest risk of disease-associated lymphoma.

However, many of these NHL cases have demonstrated a tumor regression following cessation of methotrexate therapy. If not a causative relationship, this observation suggests that there is something unique about the immunosuppression induced by the drug that leads to lymphoma in this disease context. One analysis of 9 new cases and review of 28 published cases³²⁶ found that 10 of 16 patients who were diagnosed with lymphoma at the time of methotrexate discontinuation, subsequently experienced a complete or partial spontaneous remission with no other therapy. Of these responders, 8 of the 9 who were studied showed evidence of EBV infection in the tumor. Only 1 of 6 without evidence of EBV responded to methotrexate withdrawal. A more recent prospective study was performed seeking to identify all rheumatoid arthritis patients in France over a 3-year period who developed lymphoma while on methotrexate.^{327,328} The estimated annual incidence of NHL was 33.3 per 100,000 population for male rheumatoid arthritis patients treated with methotrexate and 16.7 per 100,000 for women. The standardized mortality ratio was 1.07, based on the observed NHL incidence in the general French population when adjusted for age and gender, suggesting no increased risk of NHL for these rheumatoid arthritis patients. In contrast, the standardized mortality ratio for Hodgkin's disease was 7.4, with 27.8 cases per 100,000 treated male patients and 2.8 per 100,000 women. The number of cases identified in this study was much higher than those expected, based on U.S. population incidence of Hodgkin's disease, and this association has not been previously reported.

One is tempted to speculate that the success of methotrexate in treating the systemic inflammation in rheumatoid arthritis patients could decrease the established risk of NHL generally, while causing a small increase in the

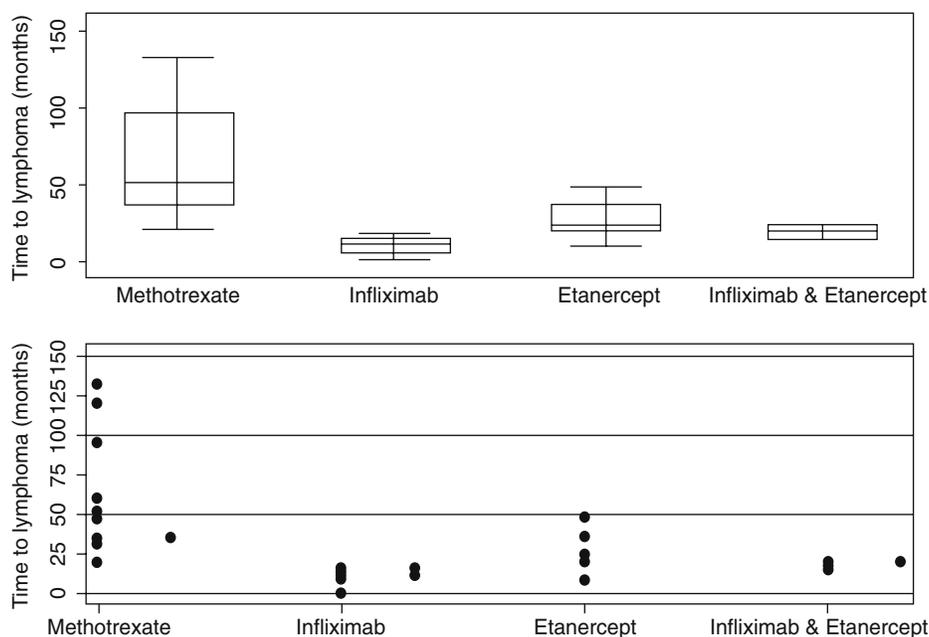

FIGURE 96.3. Lymphoma development in rheumatoid arthritis (RA) patients treated with immune-modulating therapy. Figure depicts the number of months from the start of therapy to the development of lymphoma, with bars showing the 5th and 95th percentiles. Lymphoma incidence in this study of 18,572 RA patients in the National Data Bank for Rheumatic Diseases, at the University of Kansas School of Medicine, showed overall standard incidence ratio

(SIR) for lymphoma of 1.9 [95% CI, 1.3–2.7]. SIR for lymphoma was 2.9 [95% CI, 1.7–4.9] in patients receiving biologics, 2.6 [95% CI, 1.4–5.0] in those receiving infliximab, with or without etanercept, and 3.8 [95% CI, 1.9–7.5] in patients treated with etanercept, with or without infliximab. Results do not show an increased SIR in patients receiving MTX compared with those who were never exposed to MTX. (From Wolfe,³³⁰ by permission of *Arthritis Rheumatism*.)

risk for both Hodgkin's disease and NHL associated with dysregulation of anti-EBV immunity. The overall result might be neutral with regard to the lymphoma incidence in methotrexate-treated patients, at least as concerns NHL. An important new study has suggested that all-cause mortality is strongly decreased in rheumatoid arthritis patients who are treated with methotrexate, particularly cardiac-related death.³²⁹ All in all, cytotoxic treatments for rheumatoid arthritis are unlikely to play a significant role in the genesis of the increased susceptibility to non-Hodgkin' lymphoma, and the balance of benefit for disease activity and overall mortality strongly favor the use of drugs, such as methotrexate.

Since the 1990s, rheumatologists have achieved dramatic success in treating many types of inflammatory arthritis with a new class of biologic agents that block the effects of TNF- α . Roughly 80% of patients experience significant responses in the first week of therapy with these agents, compared with the 6 to 8 weeks that typically elapse before the first benefits of methotrexate therapy. However, MedWatch postmarketing surveillance for adverse events among patients with either rheumatoid arthritis or Crohn's disease, identified 26 cases of lymphoproliferative disorders following treatment with etanercept (18 cases) or infliximab (8 cases). A third drug, adalimumab, was more recently FDA approved (December 2002), and has been reported preliminarily to be similarly associated with increased risk³³⁰; 81% of these cases were non-Hodgkin's lymphomas, primarily diffuse large cell phenotype. Lymphoma-related symptoms typically developed in only a median of 8 weeks after initiation of etanercept or 6 weeks after starting infliximab therapy. In 2 cases, 1 apiece for each drug, lymphoma regression occurred (similar to the experience with methotrexate) following discontinuation of anti-TNF therapy without specific cytotoxic lymphoma therapy. Besides the 16 etanercept-treated patients with NHL, 1 case each of thymoma and Hodgkin's disease was reported. Also of note, 13 of 18 patients were simultaneously or previously treated with methotrexate. Among the infliximab patients, most of whom were being treated for Crohn's disease, 5 developed NHL, and the other 3 had Hodgkin's. In the year following publication of this report, the authors noted an additional 68 case reports, with 54 classified as probable medication-associated lymphomas (29 infliximab, 25 etanercept), and 14 as possible medication-associated lymphomas (10 infliximab, 4 etanercept).³³¹

More recently, another group studied 18,572 patients with rheumatoid arthritis (RA) enrolled in a national databank for rheumatic disease. About a third of the lymphoma cases were logged prospectively. The overall standard incidence ratio (SIR) for lymphoma was 1.9 [95% confidence interval (CI), 1.3–2.7]. The SIR for biologic agent use was 2.9 (95% CI, 1.7–4.9), for etanercept was 3.8 (95% CI, 1.9–7.5), and for infliximab was 2.6 (95% CI, 1.4–4.5). They found a SIR for methotrexate of 1.7 (95% CI, 0.9–3.2). Duration of RA did not influence lymphoma risk. Factors predisposing to lymphoma in this patient group were increasing age [odds ratio (OR), 1.7 for each 10 years], male gender (OR, 2.6), and to a minor degree, the level of education (a variable that correlated with likelihood of receiving TNF blockers).

There is a biologically plausible explanation for an association between TNF inhibition and tumor development. TNF knockout mice that are transgenic for a B-cell differentiation factor (BAFF), have a significantly increased incidence

of lymphoma compared with the transgenic mice alone.³³² This finding may reflect the several decades of work in tumor immunology that had suggested that TNF is part of the body's armamentarium in fighting tumor development. Treatment with these agents is clearly a surrogate marker for the sicker patients, but also appears to represent an independent risk factor for lymphoma.³³⁰

Looking prospectively at the use of another class of biologic agents, the IL-1 receptor antagonists, preliminary data with relatively short follow-up for 233 patients, found no cases of lymphoma. Similarly, there were no cases among patients treated with leflunamide, a newer cytotoxic agent used in place of methotrexate but sullied by problems with comparatively greater hepatotoxicity.³³⁰

Cancer in the Older Population

Karim S. Malek and Rebecca A. Silliman

Epidemiology

Cancer Burden in the Older Population

Advancing age comes bundled with increased cancer incidence and mortality.^{1,2} Indeed, the median age at diagnosis of all cancers combined is 69 years for men and 67 for women.³ Age-adjusted cancer incidence is 10 times higher in the 65+ population compared to their younger counterparts (2,151.2 versus 208.8/100,000 persons).² Similarly, age-adjusted cancer mortality is 15-fold higher in the 65+ population (1,068.2 versus 67.3/100,000 persons).² Figure 97.1 illustrates the proportions of the commonest cancers incidence and mortality in the 65+ population.⁴ As a result, although the total U.S. population is expected to grow by 9% between 1990 and 2010, the incidence of cancer is expected to increase by a disproportionate 32% in the same time frame.^{5,6} These trends are mirrored in countries across the globe.^{7,8}

These figures have pressed many private and public institutions to sponsor the development of geriatric oncology as a separate subspecialty. Recent literature has seen a surge in the number of seminal publications specifically devoted to the management of older patients with cancer.⁹⁻¹² Geriatric oncology is a rapidly growing field and, although not exhaustive, this chapter outlines the challenges that are unique to this new discipline and briefly explores future research directions.

How Old Is Old?

Physiologically, however, there are no data to favor one particular age cutoff over the other. Although chronologic aging and organ function decline with advancing age are undeniable realities, individual organ functions decline at different rates in different persons.

Practical Approach to Geriatric Oncology

Geriatric oncologists are faced with a two-sided challenge: on the one hand, they have to carefully select evidence-based data that are applicable to older cancer patients from an ever-expanding oncology literature addressed to a wider audience. This is a difficult task given the limited representation of older individuals in cancer clinical trials.¹³ Indeed, even after removing age as an exclusion criterion from collaborative group trials, only 13% of all participants in Southwest Oncology Group (SWOG) and 8% of all participants in European

Organization for Research and Treatment of Cancer (EORTC) clinical trials are older than 70 years^{14,15} compared to 47% of the total U.S. population with cancer in the same age group.¹⁴ A retrospective review of National Cancer Institute (NCI)-sponsored clinical trials active between 1997 and 2000 yielded similar conclusions.¹⁶ On the other hand, treating cancer in older patients requires that four unique points be addressed: (1) estimating the patient's life expectancy; (2) evaluating the patient's comorbidities and functional status; (3) increased susceptibility to treatment toxicity in older patients; and (4) putting treatment benefits in perspective: absolute versus relative gains.

Estimating the Patient's Life Expectancy

Although the *average* life expectancy of the general population has doubled in the last century, it is important to note that those who live close to or beyond the *average* expectancy are not condemned to imminent death but, on the contrary, have the highest odds of surviving even longer.¹⁷ The average life expectancy at ages 65, 75, and 85 years is respectively, 17.5, 11.2, and 6 years.¹⁸ This concept is key in avoiding the temptation of undertreating older patients based solely on their advanced age.^{12,19}

Evaluating the Patient's Comorbidities and Functional Status

Eighty percent of individuals who are 65 years of age and older have at least one comorbidity.²⁰ The interaction of comorbidity and cancer is a very complex one and is the subject of the following detailed discussion. Comorbidities are independent predictors of survival in cancer patients.^{21,22} Accounting for them is an essential step in the management of older patients with cancer.

There are many tools to assess comorbidity with variable content and different goals,²³⁻²⁶ but there is no consensus on which one to use in routine geriatric oncology. Additionally, these tools often require lengthy administration, rendering them less practical for regular use in a busy oncology practice. For example, the Multidimensional Assessment of Cancer in the Elderly (MACE), although specifically developed to evaluate comorbidity in older cancer patients, requires 27 ± 7 minutes for scoring.²⁷ We and others have implemented shorter screening questionnaires as a practical substitute to exhaustive geriatric assessment scales (Table 97.1).^{28,29} This screening questionnaire can often be self-

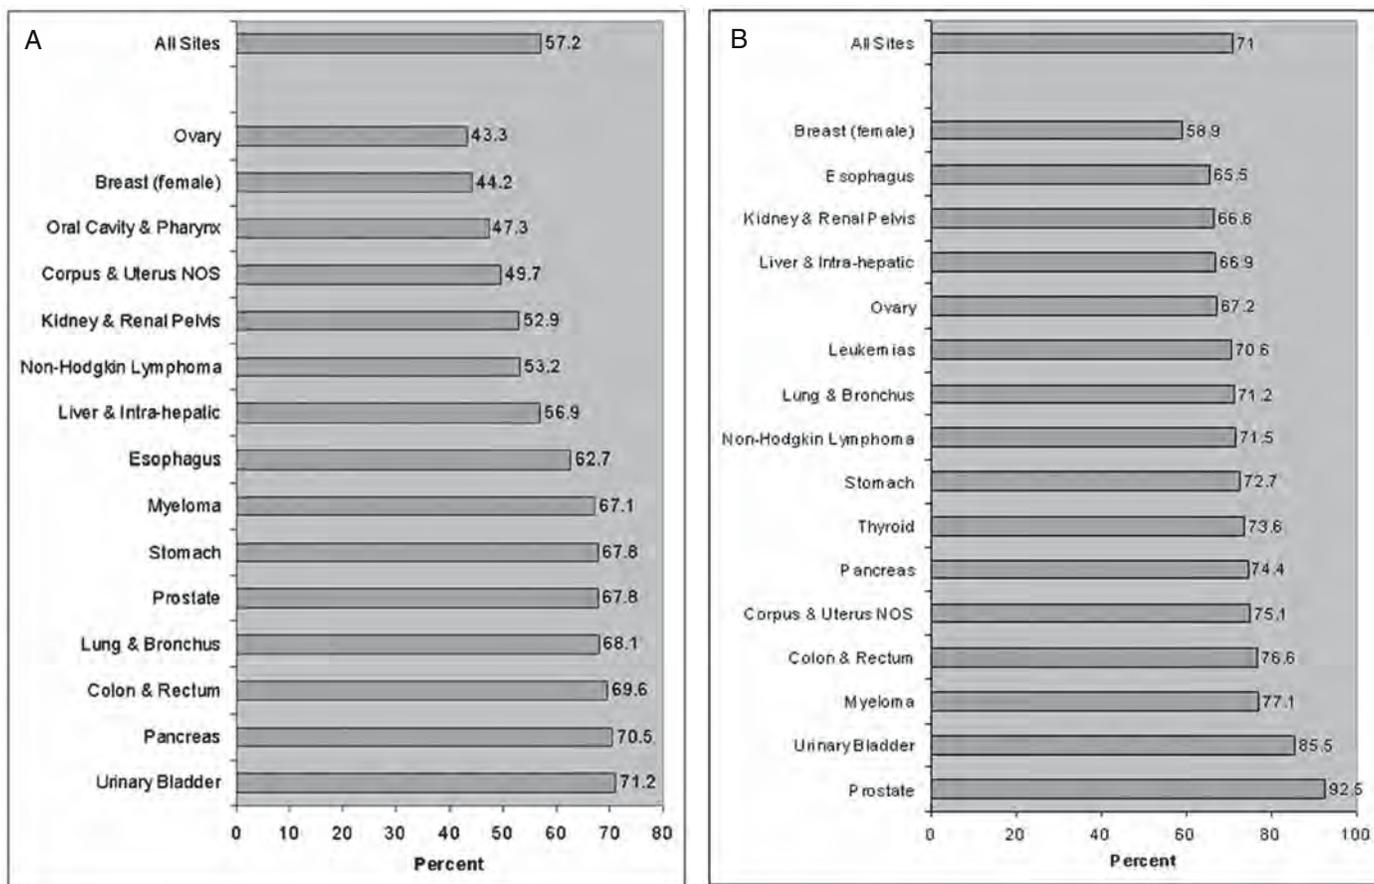

FIGURE 97.1. (A) Age-adjusted cancer incidence in the 65+ population. (B) Age-adjusted cancer mortality in the 65+ population. [Data from Ries et al. (eds) SEER Cancer Statistics Review, 1975–2000. Bethesda, MD: National Cancer Institute, 2003. http://seer.cancer.gov/csr/1975_2000.]

TABLE 97.1. Geriatric screening questionnaire.

<i>To be filled by the patient (Yes/No)</i>	
1.	Have you lost 10 pounds or more in the last 6 months without trying to do so?
2.	How are you able to walk? Independent _____ Assist _____ Cane _____ Walker _____ Dependent _____
3.	(A) In the past year, have you ever lost your urine and gotten wet? (B) If you have answered "Yes" to the above question, have you lost urine on at least 6 separate days?
4.	Are you able to: • Do strenuous activities, like fast walking or biking? • Do heavy work around the house like washing windows, walls or floors? • Go shopping for groceries or clothes? • Get to places out of walking distances? • Bathe (either a sponge bath or tub bath) or shave? • Dress, like putting on a shirt, buttoning or zipping, or putting on shoes?
5.	Do you feel that your needs at home are not being met?
<i>To be filled by healthcare professional</i>	
6.	Do you feel unsafe or threatened by someone around you?
7.	Do you often feel sad or depressed?
8.	I am going to give you the names of three objects. Please repeat them after me: "Apple, penny, table". Recall at 1 minute: _____ (of 3)

administered by the patient with minimal help from family members. The sensitivity, specificity, positive, and negative predictive values of the questionnaire items are well established.³⁰ Results of the screening test are reported as part of the initial geriatric oncology evaluation, and the test can be subsequently repeated at the physician's discretion. Patients who perform poorly in the initial screening test are candidates for referral to a geriatrician who would then perform a comprehensive geriatric assessment.

Increased Susceptibility to Treatment Toxicity in Older Patients

This susceptibility is the subject of ongoing research and is one of the main barriers to extrapolating clinical trial data obtained from younger trial participants to older cancer patients. Older patients are more susceptible to the side effects of chemotherapeutic agents.³¹ Additionally, cancer treatment modalities may affect older patients in a unique fashion. For example, a chemotherapeutic agent that causes peripheral neuropathy may worsen imbalance in an older individual and increase his or her risks of falling and the subsequent morbidity that ensues. Increased treatment toxicity may also negatively affect an often-compromised quality of life. The common problem of polypharmacy in older age increases the likelihood of drug-drug and/or drug-food interactions.³²⁻³⁴ The impact of treatment modalities on older cancer patients is detailed below.

Putting Treatment Benefits in Perspective: Absolute Versus Relative Gains

Barring untoward side effects, a treatment that offers a 25% relative reduction of mortality at 10 years may be an attractive modality for a 65-year-old patient, whose average life expectancy is otherwise 17.5 years. The same relative risk reduction may not, however, represent a significant survival gain in an 85-year-old with the same disease stage and whose life expectancy is limited to 6 years. Treatment gains and side effects should be carefully weighed against the individual's life expectancy *and* quality of life. How comorbidities affect life expectancy is also an integral part of the equation.^{21,22}

Comorbidity and Cancer

Importance of Integrating Comorbidity and Cancer

Comorbidity is defined as the presence of more than one concomitant chronic health condition in an individual. Conditions, such as diabetes, hypertension, and/or other age-related conditions, such as limited self-reliance, dementia, malnutrition, or incontinence, represent a problem of significant magnitude while managing older patients. Eighty percent of individuals who are 65 and older have at least one comorbidity; 30% have three or four and 15% have seven or more such conditions.^{20,21} Comorbidity and cancer interact intimately. On one hand, comorbidities affect cancer in multiple ways: They influence survival, independent of patients' age and/or tumor stage.^{22,35} They compete with cancer as a cause of death and increase the risks of disability among cancer patients.^{21,36} Their presence is often associated with the receipt of less

definitive cancer therapy,³⁷ which in turn leads to poorer treatment outcomes.¹² On the other hand, cancer and its treatment modalities, even the adjunct ones, may affect preexisting morbidities. For example, steroids are potent antiemetics but they can wreak havoc on diabetic control. Similarly, erythropoietin is an effective treatment for cancer-related anemia, but it can worsen hypertension. This is especially true given that older patients are generally more susceptible to developing treatment-related side effects.³¹ The concomitant management of comorbidities and cancer presents its own challenges, because primary and specialty care may not always be well coordinated. Patients themselves may not think that the continued management of other conditions is as important after a cancer diagnosis is established.

An important aspect of integrating comorbidities and cancer is the understanding of their impact on clinical trials in older cancer patients. Patients with severe organ dysfunction are often excluded from clinical trials, limiting the applicability of the trial results to such groups of patients. Comorbidities may also introduce a confounding bias in the results of cancer clinical trials.³⁸ The presence of multiple comorbidities may increase morbidity and mortality in any given trial, outweighing its projected benefits. Care should therefore be exercised in the extrapolation of trial outcomes to older cancer patients. The interaction of cancer and comorbidity can be better accounted for through patient stratification by severity and/or number of existing morbidities and/or balanced randomization.³⁸

Sources of Comorbidity Data

Multiple sources could be exploited to collect comorbidity data and they should ideally be used in a complementary fashion: (1) medical records, (2) medical interviews, and (3) administrative datasets. The computerization of billing information has resulted in large databases, often coded using ICD-9-CM nomenclatures.

Note should be made that some comorbidities are often overlooked and therefore underrecorded in routine clinical practice. Depression and anxiety are classic examples of under-recognized morbidities.^{39,40} Others include fatigue, malnutrition, pain, and/or anemia.

Comorbidity Indices

There are multiple tools to evaluate and score morbidities, each with different goals and outcomes.^{22,25,27,41-45} Their description is outlined in Table 97.2. As stated earlier, there is no consensus on which tool is best adapted to routine clinical practice.^{24,26}

Quantification of the Impact of Comorbidities on Cancer

This area has largely benefited from the work of Yancik et al.²¹ Using an established model of high-, moderate-, and low-impact comorbidities,^{46,47} the relationship between select comorbidities and increased mortality risk was examined in a cohort of colon cancer patients who were 55 years and older (Table 97.3).²¹ Patients with five or more comorbidities were also found to have lower survival rates than those with four or fewer (Table 97.4). Other studies had also reached similar

TABLE 97.2. Commonly used comorbidity indices.

	Description	Advantages	Disadvantages
Charlson Index ²⁵	Provides an overall score based on a composite of values assigned to 19 comorbidity conditions; estimates risk of death from comorbid conditions	Shorter administration time than ICED Validated in breast cancer patients Derived from medical records	No measure of severity of comorbidity No functional evaluation Dichotomous
Satariano and Ragland ^{22,23}	Modified Charlson index providing survival estimates in breast cancer	Validated in breast cancer patients	No measure of severity of comorbidity No functional evaluation
Index of Co-Existing Diseases (ICED) ⁴⁴	Integrates measures of 10 functional areas, each divided into three levels of severity; chart-based review	Provides functional evaluation Provides an estimate of severity of disease	Average overall reliability (kappa, 0.5–0.6) and Index of Disease Severity subindex (kappa, 0.4–0.5)
Kaplan and Feinstein ⁴³	Assigns scores from 1 to 3 to comorbidity in various organ systems	Provides and estimate of severity of disease Validated in several cancers, including breast, prostate, and head and neck	No functional evaluation
Multidimensional Assessment of Cancer in the Elderly (MACE) ²⁷	Integrates measures of comorbidity, functional status, depression, balance, physical function and disability	Validated in cancer patients Provides a structured evaluation of functional status	Lengthy administration (27 ± 7 min)
Multiple Informants Analysis ⁴²	Combined scoring of the Charlson, ICED, PS and American Society of Anesthesiologists Index	Superior in estimating the overall effect of comorbidity than separate models that included only one index	Lengthy administration (average, 30 minutes ^a)

conclusions in breast cancer patients, where those with an increasing number of comorbidities had a progressively lower relative risk of dying of their breast cancer compared to all other causes combined.²²

Cancer Screening in Older Individuals

Cancer screening in older individuals comes with its own sets of problems and characteristics.⁴⁸ (1) The characteristics of a given screening test may change with age. For example, the sensitivity and specificity of mammography gradually increases with advancing age.⁴⁹ Similarly, the specificity of prostate-specific antigen (PSA) screening for prostate cancer decreases with age because of the increased prevalence of benign prostatic hyperplasia. (2) Tumors may have a different biology in older patients (e.g., slower growth rate),⁵⁰ leading

to an increased detection of slowly growing tumors, known as *length-time bias*. (3) Older individuals have a shorter life expectancy compared to younger counterparts, by virtue of their advanced age or associated comorbidities. The detection of an asymptomatic tumor may not translate into a longer survival in the older individual, therefore questioning the rationale of screening at extremes of age. In general terms, the effect of screening is evident 3 to 5 years later, and the value of screening may be therefore limited in individuals with shorter life expectancy.^{51,52} (4) This *overdetection* of clinically nonsignificant tumors may lead to treatments that adversely

affect the quality of life of the older individual and may represent an unjustified healthcare cost to the community.⁵¹

Breast Cancer Screening in Older Individuals

Breast cancer remains the leading cancer by incidence in women in the United States. Annual incidence is expected to top 217,000 new cases in 2004, and 48,000 women are expected to die of their disease in the same time period, making breast cancer-specific mortality second only to lung cancer. Breast cancer screening is an attractive intervention in an attempt to reduce breast cancer mortality, but data are restricted to mammography.

MAMMOGRAPHY

Mammography is considered the standard approach to breast cancer screening and is thought to reduce breast cancer mortality by 20% to 40% in women who are 50 to 70 years of age at the time of their first screening.⁵³⁻⁵⁶ Fewer studies have, however, looked at the impact in women in the 70 or older age group. One retrospective, one case-control and two randomized clinical trials did include patients who were 70 years or older (Table 97.5). The case-control Dutch study suggested that screening mammography was associated with reduced breast cancer mortality in women who were 65 to 74 years of age [relative risk (RR), 0.34; 95% confidence interval (CI), 0.12-0.97], but not in women who were older than 75.⁵⁷ Similarly, the large retrospective SEER study showed that screening mammography reduces the relative risk of breast cancer mortality by about one-half.⁵⁸ In women who were at least 69 years of age, mammography screening in the 2 years preceding a diagnosis of breast cancer was also found to eliminate the age-related disparities in size and stage of the breast tumor at diagnosis.⁵⁹ The results of the two randomized trials were less conclusive, with a meta-analysis showing that the relative risk of breast cancer mortality is 0.94 (95% CI, 0.6-1.6) in women aged 70 to 75 years.⁵⁶ In addition to the reduction in breast cancer mortality, a retrospective cohort of more than 690,000 women aged 66 to 79 years, showed that screening mammography was associated with a decreased risk of detecting metastatic breast cancer (RR, 0.57; 95% CI, 0.45-0.72) and increased chances of detecting localized breast cancer (RR, 3.3; 95% CI, 3.1-3.5).

The U.S. Preventive Services Task Force analyzed the cost-effectiveness of continued screening after age 65. It was estimated that extending the biennial screening to age 75 or 80 years costs between \$34,000 and \$80,000 per life-year gained, compared to stopping the screening at age 65. This was thought to be a reasonable cost and that targeting healthy older women may be more cost-effective than extending

screening to those with multiple competing causes of death.^{60,61}

Overall, evidence-based data support screening mammograms at least until the age of 75. The absence of data in older women should not be interpreted that no such benefit exists, at least on an individual basis. It is the authors' opinion that mammograms should continue to be offered based on individual life expectancy and associated morbidities.

Screening for Colorectal Cancers

FECAL OCCULT BLOOD TESTING

Three randomized controlled trials have previously demonstrated that annual or biennial fecal occult blood testing (FOBT) reduces colorectal cancer mortality in patients who are 50 to 80 years of age.⁶²⁻⁶⁵ One prospective study followed 46,551 individuals for an average of 18 years and demonstrated that annual and biennial FOBT significantly also reduce the *incidence* of colorectal cancer (0.80 and 0.83 for annual and biennial screening, respectively).⁶⁶ *One-time* screening with FOBT and sigmoidoscopy still failed to detect 24% of colorectal cancer in 2,885 individuals who were 50 to 75 years of age.⁶⁷ There are no data on the value of screening in individuals who are older than 80 years. Similar to breast cancer patients reaching an extreme age, individualized decision should be made regarding screening based on life expectancy and existing comorbidities.

ENDOSCOPY SCREENING

The value of endoscopy screening has been elegantly outlined elsewhere.^{68,69} Two case-controlled trials showed that serial flexible sigmoidoscopies or colonoscopies are associated with reduced colorectal cancer mortality.^{70,71} The value of colonoscopy over sigmoidoscopy in detecting advanced colorectal cancer has been demonstrated in the study of 3,121 patients with a mean age of 62.9 years, of whom 19% were older than 69. Patients with small (less than 10 mm) or large (10 mm or larger) distal adenomas were more likely to have a proximal colon cancer than those who did not have any distal lesion [odds ratio (OR), 2.6; 95% CI, 1.7-4.1 and OR, 3.4; 95% CI, 1.8-6.5, respectively].⁷² Colonoscopy every 10 years is also more cost-effective than sigmoidoscopy every 5 years.⁷³

Prostate Cancer Screening

DIGITAL RECTAL EXAMINATION (DRE)

Annual DRE has long been part of prostate cancer screening. It remains, however, operator dependent, and two prospective

TABLE 97.5. Mammography screening for breast cancer in the older population.

TABLE 97.6. Age-related changes and increased surgical risks.

<i>Organ system</i>	<i>Physiologic and pathologic age-related changes</i>	<i>Surgical risks</i>
Cardiovascular	Increased atherosclerosis Increased risk of arrhythmias Decreased ventricular distensibility Increased dependence on pre-load	Increased sensitivity to fluid shifts Increased risk of cardiac ischemia Increased risk of congestive heart failure
Kidney	Decreased renal mass Decreased renal blood flow Decreased glomerular filtration rate (GFR)	Risks of acid-base balance disturbances Risk of electrolytes imbalance Increased sensitivity to renally cleared drugs Increased risk of renal ischemia
Liver	Decreased hepatic mass Decreased hepatic blood flow	Increased sensitivity to hepatically cleared drugs
Pulmonary	Decreased pulmonary volumes Decreased compliance Decreased ciliary function	Risk of postoperative atelectasis Risk of postoperative pneumonia
Central nervous system	Decreased cerebral mass Decreased cerebral blood flow Dementia	Difficulty obtaining informed consent Risk of postoperative delirium Slow postoperative recovery and prolonged hospitalization

studies have demonstrated its inferiority to annual PSA measurements.^{74,75} No study has yet demonstrated that DRE reduces prostate cancer mortality.

PROSTATE-SPECIFIC ANTIGEN (PSA)

Two randomized controlled trials have demonstrated the value of PSA in reducing prostate cancer mortality.^{76,77} PSA is usually performed annually; however, less frequent screening may be as effective in select cases (every 5 years in men with PSA less than 1 ng/ml and every 2 years in men with PSA in the 1- to 2-ng/ml range). Ultrasound-guided prostate biopsy is recommended once PSA is higher than 4.0ng/ml; however, this cutoff was demonstrated to miss an impressive 65% of prostate cancers in older individuals.⁷⁸ The use of the percentage of free PSA level was proposed as a means to increase the test specificity in men with benign prostatic hyperplasia.⁷⁹

Specific Cancer Management Issues in the Older Population: Treatment Modalities

Older cancer patients benefit from the same treatment modalities widely used in the management of cancer, including surgery, radiation therapy, and chemotherapy. The following section highlights how these modalities are applied to older cancer patients. It is important to note, however, that treatment choices in older patients go beyond the mere age-associated physiologic and/or pathologic changes. Older patients often have a different outlook on life, caring more about their quality of life rather than longevity; how they opt for one therapeutic modality over the other has not been fully studied. Additionally, social and/or financial considerations may ultimately affect their choice. For example, lumpectomy followed by radiation therapy for breast cancer has yielded similar survival results as a more extensive mastectomy; however, older patients may still opt for mastectomy because it obviates the need for postoperative radiation therapy, which would require additional logistic arrangements over several weeks.

Cancer Surgery in the Older Patient

Surgery is an integral part of a multimodality approach to the treatment of most cancers; its use is very frequently a prerequisite for treatment plans with a curative intent. Geriatric surgery has been the subject of excellent reviews elsewhere.⁸⁰⁻⁸² The following section highlights some of its most salient aspects.

INCREASED OPERATIVE RISKS IN OLDER AGE

Age-related physiologic changes and accumulating comorbidities continue, however, to expose older patients to specific risks.⁸³⁻⁸⁶ These changes involve all major organ systems, as summarized in Table 97.6. The mortality risks of a select number of surgical interventions in older patients are outlined in Table 97.7.

PREOPERATIVE RISK ASSESSMENT

Careful preoperative evaluation of older patients is a crucial step in estimating operative risk and planning interventions to reduce it to a minimum.⁸⁷ Controversy persists on how extensive preoperative risk assessments should be.⁸⁸⁻⁹¹ Of interest, several preoperative risk assessment scales consider age per se as a factor that increases the risks of an adverse

TABLE 97.7. Mortality from select surgical procedures in older patients.

<i>Surgical procedure</i>	<i>Average mortality risk (%)</i>
Breast cancer surgery ¹⁵⁸	0.5-1.5
Elective colorectal cancer surgery ¹⁵⁹⁻¹⁶¹	6-15
Emergent colorectal cancer surgery ^{160,161}	15-53.5
Gastric resection ¹⁶²⁻¹⁶⁴	5-15
Liver resection (primary or secondary tumors) ¹⁶⁵	4
Pancreatic resection ¹⁷⁵	6

Source: Data from Busch et al.¹⁵⁸ Hesterberg et al.,¹⁵⁹ Arnaud et al.,¹⁶⁰ Mulcahy et al.,¹⁶¹ and Bonenkamp et al.¹⁶² Viste et al.,¹⁶³ Tsujitani et al.,¹⁶⁴ Fong et al.¹⁶⁵

cardiac event in noncardiac surgical interventions. For example, age greater than 70 years contributes 5 points to the Goldman index of cardiac risk in noncardiac surgical procedures.^{92,93} Similarly, being 80 years of age or older automatically puts a patient in class II (of a possible V) in the American Society of Anesthesia (ASA) scale.⁹⁴ However, these scales remain heavily weighted by the presence or absence of comorbid conditions, rather than by age alone. For example, clinical evidence of congestive heart failure and a history of recent myocardial infarction contribute 11 and 10 points, respectively, to the Goldman index,⁹² overshadowing the more limited contribution of age to the final score.

REDUCTION OF OPERATIVE RISKS

Multiple interventions have been advocated to reduce operative risks in older patients: these include (1) correction of reversible metabolic parameters,⁹⁵ (2) use of beta-blockers to reduce perioperative mortality from cardiac events,⁸⁷ (3) adequate blood pressure control,⁸⁷ (4) close monitoring of volume status using invasive pulmonary artery catheters,⁹⁶ although their benefit is contested,⁹⁷ and (5) most importantly, avoiding the delay in surgery that exposes the patient to higher risks of needing an emergent intervention⁸¹ or a more extensive surgery secondary to tumor progression.

In conclusion, surgical risks related to aging are mostly related to coexisting morbidities, rather than to age by itself. Therefore, older patients should not be denied a chance at curative treatment based on their age alone.

Radiation Therapy in Older Cancer Patients

Similar to surgery, radiation therapy plays a central role in the treatment of older cancer patients, both as part of a multimodality approach and/or with a palliative intent.⁹⁸ There are no convincing data that tissue tolerance to radiation therapy is different in older than in younger patients. Most laboratory data were obtained in rapidly growing tissue cultures and apply only to acute radiation toxicity.⁹⁹ Tolerance of radiation therapy in older patients is modulated by existing comorbidities. Specifics of radiation treatment in older patients with breast, lung, gastrointestinal, and genitourinary cancers are beyond the scope of this chapter and have been extensively reviewed elsewhere.^{100,101} Radiation therapy improves the quality of life in older patients and it has proven a special efficacy in controlling tumor-induced pain.¹⁰²⁻¹⁰⁴ Social issues, such as transportation continue to pose a significant logistic and financial burden on those who have lost their physical and/or financial independence.

Chemotherapy in Older Cancer Patients

Chemotherapy is a mainstay treatment of many types of cancer. Two retrospective trials showed that chemotherapy toxicity does not differ between older and younger patients.^{105,106} Results of these trials, however, should be carefully interpreted, because stringent exclusion criteria may preclude their generalization to the average older patient. The pharmacology of individual antineoplastic agents in older patients is extensively reviewed elsewhere.¹⁰⁷

Every aspect of drug pharmacokinetics is potentially affected in older patients, in part, explaining why they have an increased rate of chemotherapy toxicity.

ABSORPTION

Mucosal atrophy, decreased gastrointestinal motility, and splanchnic blood flow are all documented changes in older patients and can account for decreased absorption of drugs in the older population.¹⁰⁸ This limitation is especially important, given that an increasing number of new chemotherapeutic agents, such as capecitabine and imatinib, are orally administered.

DISTRIBUTION

Several factors affect drug distribution in older patients: (1) decreased body water by about 20% in older patients leads to decreased volume of distribution of polar drugs, such as methotrexate and mitomycin-C; (2) plasma albumin is decreased by an average of 15% to 20% in older patients, leading an increase in the unbound fraction of protein-bound drugs, such as etoposide, anthracyclines, and taxanes¹⁰⁹; (3) increased body fat leads to increased half-life and lower clearance of fat-soluble agents; (4) changes in the shape of the area under the curve (AUC), with water soluble drugs showing higher plasma concentrations and shorter half-lives, while fat-soluble drugs show lower plasma concentrations and prolonged half-lives, changes affecting both drug efficacy and toxicity profile; and (5) anemia can significantly increase the toxicity of red blood cell-bound drugs, such as taxanes and anthracyclines.

HEPATIC CLEARANCE

Decreased liver size and reduced hepatic blood flow both contribute to reduced clearance of hepatically cleared chemotherapeutic agents.¹¹⁰ Several of the cytochrome P-450 enzyme activities decline with age, leaving the patient at risk of increased toxicity from delayed clearance.^{111,112} Moreover, older patients are commonly subject to polypharmacy. CYP3A4 is inhibited by a large number of commonly prescribed drugs, leaving patients at risk for increased toxicity from CYP3A4-dependent chemotherapy agents, such as cyclophosphamide, ifosfamide, taxanes, tamoxifen, and vinca alkaloids.

RENAL CLEARANCE

Glomerular filtration rate (GFR) steadily decreases at the rate of 1 mL/year in individuals who are 40 years or older.¹¹³ This decrease is not proportionally translated into an increased serum creatinine value because of the parallel reduction in muscle mass. Serum creatinine and estimates of creatinine clearance such as the Cockcroft-Gault formula may therefore overestimate the renal GFR.¹¹⁴ This in turn may result in increased serum levels and toxicity of any of the renally excreted agents. Doses of drugs, such as carboplatinum and bleomycin, should be reduced by 25% to 30% in moderate renal insufficiency (creatinine clearance of 10–30 mL/min), whereas the use of other agents, such as cisplatinum, methotrexate, and nitrosoureas should be completely avoided.

Prevention of Chemotherapy-Induced Toxicity in Older Patients

NEUTROPENIA

Older patients are at a higher risk of hematopoietic toxicity because of limited hematopoietic reserves and decreased response to hematopoietic growth factors.¹¹⁵ Older patients are more liable to develop clinically significant neutropenia, although this finding was contested by other studies.^{106,116} Several trials have demonstrated the value of adding a granulocyte colony-stimulating factor (G-CSF) to moderately myelosuppressive chemotherapy regimens.¹¹⁷⁻¹¹⁹ These trials serve as a sufficient basis for the regular use of G-CSF in older patients receiving such chemotherapy. Although G-CSF use is associated with reduced neutropenia and risk of sepsis, complete remissions and overall survival remain generally unchanged.¹²⁰

ANEMIA

Anemia of chronic disease is a common complication of cancer and its various treatment modalities. Several studies have shown that anemia is an independent predictor of survival in older individuals.¹²¹⁻¹²³ Anemia significantly affects quality of life, with increased fatigue,¹²⁴ difficulty in concentration, impaired memory,¹²⁵ and increased susceptibility to complications from red blood cell-bound chemotherapy agents.¹²⁶ Synthetic erythropoietin use has been associated with relief of anemia of chronic disease and improved quality of life.¹²⁷ Newer agents, such as glycosylated erythropoietin, have a very long half-life that allows their administration on a bimonthly basis. Interestingly, concomitant G-CSF administration may augment erythropoietin efficacy in treating anemia in diseases, such as myelodysplastic syndromes.¹²⁸

MUCOSITIS AND DIARRHEA

Two reports have yielded contrasting results regarding the incidence of mucositis in older cancer patients, one arguing for an increased incidence, while the other stating that there was no age-associated differences in the incidence of gastrointestinal toxicities.^{129,130}

Interventions to reduce oral mucositis include oral cryotherapy and careful oral hygiene. The use of G-CSF is associated with reduced mucosal ulcerations, presumably through its effect in increasing salivary neutrophils.

Although this section discussed the physical brunt of various treatment modalities, older cancer patients are further confronted with complex psychosocial and social functioning challenges, which are detailed in the following section.

Psychosocial Issues in Older Cancer Patients

Psychologic Issues in Older Cancer Patients

Forty-seven percent of cancer patients suffer from a form of psychiatric disorder. The majority of these (32%) present with adjustment disorder, while the remainder is divided between major depressive disorder (6%), mood disorder secondary to

medical conditions (4%), personality disorders (3%), and anxiety (2%).¹³¹

Older cancer patients suffer less from depression and psychosocial distress compared to their younger counterparts.¹³² These findings remain true even after adjusting for physical impairment and symptoms severity.¹³³ It is unclear, however, whether these are related to better adaptation and fewer psychologic needs in older adults or whether they result from underreporting of depressive symptoms in this age group.^{134,135}

Social Isolation

Psychiatric disorders, physical impairment, and social isolation are often intricately related¹³⁶⁻¹³⁸; all three can feed into each other, leading the patient into a downward-spiraling path. For example, 48% and 49% of older cancer patients have difficulty with at least one activity of daily living (ADL) and one instrumental activity of daily living (IADL), respectively.¹³⁹ Additionally, more than 33 million of the 65+ population live below the poverty line.¹⁴⁰ These factors increase patients' need for social support. Unfortunately, the same factors predispose to social isolation. This dual relationship makes older cancer patients particularly vulnerable. The recognition of such an interaction is key in managing older cancer patients because social isolation is associated with an increased mortality in this population (age-adjusted relative risk of death = 2.3 in men and 2.8 in women).¹⁴¹ This was found to be independent of self-reported physical health, socioeconomic status, and associated morbidities.

Evaluation of Psychosocial Needs in Older Cancer Patients

This is an integral part of the initial Geriatric Oncology evaluation. A number of self-administered tools can be routinely implemented, even in a busy practice. Several dimensions are typically assessed:

1. *Emotional needs:* Several tools can be used to evaluate depression in older patients. The self-administered Beck Depression Inventory is a simple screening tool that can be routinely used as part of the initial Geriatric Oncology evaluation.¹⁴² More extensive testing includes the Hamilton Depression Rating Scale (HAM-D), Geriatric Depression Scale (GDS), and Inventory for Depressive Symptomatology (IDS).¹⁴³⁻¹⁴⁵

2. *Cognitive impairment:* The incidence and prevalence of cognitive impairment increases with advancing age and significantly complicates several aspects of cancer management, not the least of which are building the direct doctor-patient relationship and issues pertaining to informed consent. The Modified Mini-Mental State Examination (MMMSE) is a simple test that translates patient-specific performance into age-matched percentile.^{146,147}

3. *Comorbid conditions:* These have been discussed in detail earlier. Their functional impact can be assessed using the Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADL) tools.¹⁴⁸

4. *Other issues,* such as stressful life events, the presence of a structured social support, and economic resources, should be tactfully probed.

Management of Psychosocial Distress in Older Cancer Patients

Complexly ill older cancer patients—those with multiple comorbidities, cognitive and functional impairments, and psychosocial needs—can benefit from involvement of geriatricians and their interdisciplinary teams. Patients with major depression, a history of major psychiatric disorders earlier in life, and/or those with depression and dementia can also benefit from the involvement of a geropsychiatric team. However, even less complexly ill patients are likely to need comprehensive psychosocial support as they progress from diagnosis, to treatment, and on to posttreatment management. As no one resource can single-handedly provide this, it represents one of the strongest arguments for developing a “case management” approach that incorporates geriatric oncologists, specialized geriatric oncology nurses, and social workers.

1. *Symptoms management*: Particular attention should be devoted to this issue, whether the symptoms are cancer or treatment related. Pain control, management of nausea, vomiting, mucositis, anemia, malnutrition, and other potential side effects are all key components that have been extensively addressed elsewhere.¹⁴⁹ This care results not only in improved quality of life but also in improved physical function.

2. *Patient–doctor communication*: Caring for older cancer patients is inherently more time-consuming than for younger ones. Older patients cannot—and should not—be rushed. Physicians’ interpersonal skills are associated with better psychologic adjustment in cancer patients.^{150,151} Ideally, geriatric oncology clinics should be places where pace is dictated by patients rather than by scheduling constraints. Medicare and other insurers are pressed to recognize the management of cancer in the older population as a highly complex encounter.

3. *Counseling*: Patient-tailored services and coordination of existing support structures by a social worker or other professional case manager can be particularly helpful. For example, such interventions have been shown to reduce depression in older cancer patients and improve psychologic adaptation to cancer.^{152,153}

4. *Psychologic support*: Psychotherapy, provided by a social worker, psychologist, psychiatrist, and/or other mental health professionals, should be routinely offered to older cancer patients. This is especially true in view of the older patients’ tendency to stoicism and underreporting their symptoms. Nonetheless, many older adults are reluctant to use such services, recalling the stigmatization associated with such services earlier in their lives. In such instances, the care team will need to provide such care as best as possible, including psychotropic medication management. Several volunteer and professional organizations that provide cancer support groups in many areas of the United States may be particularly helpful in these instances.¹⁵⁴

Future Considerations and Research Venues

Geriatric oncology is a field in full expansion. Integrated research agendas are needed to challenge the limitations of the single-specialty approach to the complex problem of

aging.¹⁵⁵ A comprehensive research map of aging and cancer has been elegantly outlined in the National Cancer Institute/National Institute on Aging common workshop, and includes the study of the biology of aging and cancer, patterns of care, risk assessment and cancer prevention, palliative care, psychologic issues, and pain relief.¹⁵⁶ The study of the intricate relationship between comorbidity and cancer deserves special attention.¹⁵⁷ This research will benefit the growing number of older cancer patients in America and the world.

Chemotherapy in Patients with Organ Dysfunction

John L. Marshall, Jimmy Hwang,
Shakun Malik, and Asim Amin

Clinical studies of chemotherapy, or other antineoplastic therapies, are usually conducted in physiologically otherwise normal patients with cancer. As a result, limited information is typically available about the optimal dosage and schedule of chemotherapy for patients with organ dysfunction and the impact of chemotherapy in such patients. This is a potentially important problem, because most chemotherapies, as with other pharmacologic agents, are metabolized by the liver or kidney. Over the past decade, a concerted effort has been made to focus on chemotherapy in this patient population. The new generation of biologic therapies may not possess this difficulty, as the monoclonal antibodies that, to date, comprise the most successful of these agents are metabolized by the reticuloendothelial system and may not require these modifications. However, these concerns regarding the appropriate administration of antineoplastic agents will persist with the new small molecule inhibitors, including tyrosine kinase inhibitors, which also may require individual evaluation in patients with organ dysfunction.

This chapter focuses on the administration of chemotherapy in patients with organ dysfunction. Given the limitations in the available data regarding the correct dosing in these settings, we briefly review the methods of evaluating organ function, the drugs metabolized or excreted predominantly by those pathways, disease-specific studies, and finally the Phase I studies that may help guide recommendations for treatment in these patients.

Chemotherapy-Specific Trials in End-Organ Dysfunction

Paclitaxel

The taxoids comprise a class of antineoplastic agents originally derived from several plants in the yew family, but some of which are now synthetically derived. Paclitaxel is metabolized hepatically by the cytochrome P-450 system. Therefore, the Cancer and Leukemia Group B (CALGB) performed a Phase I study in 87 patients with varying levels of hepatic dysfunction (trial 9264).¹ Patients with a primary hepatic

tumor, or metastatic solid tumors and evidence of hepatic insufficiency, were enrolled in this study in one of three cohorts, each of which participated in a separate dose-escalation program. Cohort I included patients with aspartate serum transaminase (AST) of at least twice the upper limit of normal (ULN), and a total bilirubin of 1.5 mg/dL or less. Cohorts II and III had AST, but the former included patients with a total bilirubin of 1.6 to 3.0 mg/dL, and cohort III patients had a total bilirubin of greater than 3.0 mg/dL. At the time this study was designed, paclitaxel infusion was typically accomplished (60 patients) over 24 hours, with cycles repeated every 3 weeks. As the study proceeded, the typical administration of paclitaxel became intravenously over 3 hours, and several cohorts of patients on this study, primarily cohorts II and III, were treated accordingly.

In the CALGB studies, dose-limiting toxicities were defined as grade 4 nonhematologic toxicities, grade 3 neurotoxicity, grade 3 stomatitis, esophagitis, or dysphagia of more than 3 days duration, and grade 4 neutropenia or thrombocytopenia lasting more than 3 days. The determination of the maximum tolerated dose (MTD) was based upon toxicities encountered in the first cycle of therapy only.

Somewhat surprisingly, in all cohorts of patients, the doses administered had to be serially deescalated. In cohort I (elevated ALT [alanine aminotransferase]), evaluation started at 200 mg/m², but the eventual dose recommended was 50 mg/m². All except 1 of the 36 patients treated on this level received paclitaxel over 24 hours, and no recommendations could be made for patients who received the shorter infusion of paclitaxel. Similarly, cohort II patients were evaluated at decreasing doses of paclitaxel from 150 mg/m² to the recommended 75 mg/m². Two-thirds of the 24 patients on this level received paclitaxel over 24 hours. In cohort III (total bilirubin greater than 3.0 mg/dL), most patients (12 of 21) were given paclitaxel with the shorter infusion, but the results were similar to the other cohorts, with the doses administered being decreased from 75 mg/m² to 50 mg/m². The authors recommended a dose of 50 to 75 mg/m² of paclitaxel over 24 hours for patients with a bilirubin of more than 1.5 mg/dL. With a limited number of patients overall receiving a 3-hour infusion of paclitaxel, the recommendations carry less strength, but the authors considered a dose of 75 mg/m² of

paclitaxel reasonable for patients with hyperbilirubinemia. Because granulocyte colony-stimulating factor (G-CSF) was not employed in this study, the authors acknowledge that the doses recommended could be somewhat conservative. However, the hepatic metabolism of paclitaxel clearly requires a modification of the doses of paclitaxel employed when treating patients with biochemical evidence of hepatic dysfunction.

Across the cohorts, the dose-limiting toxicity (DLT) was similar, primarily myelosuppression in 27 patients and thrombocytopenia in 3, with grade 4 fatigue occurring in 2 patients. Four patients died during the first cycle of therapy, 2 of sepsis. Although grade 3 fatigue was not considered to be a DLT, it occurred in 15 patients who received the 24-hour infusion of paclitaxel.

Pharmacokinetic studies were obtained from 56 of the participating patients. The results were similar to historical controls who were treated with similar doses of paclitaxel, with no apparent difference in the free paclitaxel detected in the plasma. In the latter part of the study, with the increasing use of 3-hour infusions, and the recognition of the potential importance of the duration of time of paclitaxel concentrations exceeding $0.05\ \mu\text{mol/L}$, the latter parameter was evaluated in a limited subset of patients. The results suggested that in patients with hepatic dysfunction the duration of paclitaxel concentrations exceeding $0.05\ \mu\text{mol/L}$ was higher than that expected for patients with normal hepatic function. With only 9 patients having both detailed pharmacokinetic information and neutrophil data, no correlation of these parameters was performed. In 4 patients who had external biliary drains, the excretion of paclitaxel and its metabolites detected in the biliary fluid ranged from 2.3% to 50.1% of the administered dose, primarily as 6- α -hydroxypaclitaxel.

Despite the relatively low doses of paclitaxel, the therapy was not bereft of anti-tumor activity, with three partial responses noted, two in breast cancer (cohort I at $150\ \text{mg/m}^2$ over 24 hours, and cohort II at a dose of $125\ \text{mg/m}^2$ over 3 hours), and one in a woman with germ cell tumor ($100\ \text{mg/m}^2$ over 24 hours in cohort II). However, all these doses exceed the recommended doses.

Because paclitaxel is not excreted renally, it has been assumed that paclitaxel can be administered in patients with renal insufficiency without significant difficulty. However, Conley et al. reported a series of four patients with renal dysfunction, as defined by a creatinine clearance of less than $60\ \text{mL/min}$ (0–58), who were treated with paclitaxel at a dose of $135\ \text{mg/m}^2$ over 3 hours.² The mean duration of a paclitaxel concentration exceeding $0.05\ \mu\text{mol/L}$ was 37.7 hours, which is slightly higher than historical reports. In addition, a single case report of a patient with recurrent ovarian cancer and chronic renal insufficiency who worsened with the use of both cisplatin and later, carboplatin, in conjunction with cyclophosphamide, confirmed this finding. At the time of treatment with paclitaxel, $157\ \text{mg/m}^2$ (a 10% dose reduction from the authors' usual dose of $175\ \text{mg/m}^2$) over 3 hours (cycles repeated every 3 weeks), the patient's creatinine clearance was $20\ \text{mL/min}$.³ During the third cycle of therapy, the patient was administered G-³H-paclitaxel. In this single patient, the disposition half-life was 29 hours, about 50% longer than in patients with normal renal function. In addition, the authors reported a "surprisingly high" plasma AUC (area under the curve) of about 26. The clearance of paclitaxel

was primarily fecal, with only 1.58% of paclitaxel excreted unchanged in the urine at 24 hours. The pharmacokinetic parameters of Cremphor were similar to historical controls. Despite these changes in pharmacokinetic parameters of paclitaxel in this patient with renal insufficiency, no significant toxicity aside from severe fatigue occurred, and she was able to attain a partial response to therapy. Thus, the authors recommended that paclitaxel could be safely administered in patients with renal insufficiency, with a 10% dose reduction.

Gemcitabine

The CALGB has also performed a Phase I and pharmacokinetic study in 43 patients with hepatic or renal dysfunction evaluating gemcitabine (CALGB 9565).⁴ Broadly, the schema was similar to the paclitaxel study, but with cohorts defined differently. The first two escalation cohorts were in patients with hepatic dysfunction. Cohort I included patients with AST that was more than $2\times$ ULN, but with normal bilirubin and creatinine, whereas in cohort II patients had a total bilirubin between 1.6 and 7.0, and AST. In cohort III, patients could potentially have a serum creatinine between 1.6 and 5.0, but required normal liver function tests. In fact, all the patients in cohort III had a relatively mild to moderate renal dysfunction, with serum creatinine between 1.6 and 3.2.

Gemcitabine was administered intravenously over 30 minutes on days 1, 8, and 15, with cycles repeated every 28 days. The starting dose in each cohort was $800\ \text{mg/m}^2$. In cohort I, the initial 3 patients tolerated therapy well, with no DLT, and at $950\ \text{mg/m}^2$, 1 of the 4 patients enrolled had DLT, and elevation in AST. However, because of results in the concurrently enrolled cohort II, the dose escalation was halted. In cohort II, however, DLT was reported in 3 of 8 patients treated with $800\ \text{mg/m}^2$ of gemcitabine, and in 8 of 10 patients who received $950\ \text{mg/m}^2$ of gemcitabine. Seven of these DLT were elevations in the bilirubin, and another was a rise in the serum transaminases. Two DLT were grade 3 diarrhea, and 1 patient experienced angina. In the patients with renal insufficiency who were enrolled in cohort III, 3 of 9 patients who were treated at the initial dose level of gemcitabine experienced DLT, including 2 with a severe rash and 1 with hepatic transaminase elevation. Doses were then decreased to $650\ \text{mg/m}^2$, at which level only 1 of 6 patients had a DLT.

Pharmacokinetic studies were performed in 36 of the patients. The concentrations of gemcitabine and its inactive metabolite 2',2'-difluorodeoxyuridine (dFdU) were not significantly different among the cohorts and doses evaluated.

Again, an important conclusion from these investigators is that there is much heterogeneity among patients with organ dysfunction, and that all patients must be considered individually. The results of this study demonstrate that, in patients with hepatic insufficiency as manifested by a total bilirubin between 1.5 and 7.0 or an AST greater than $2\times$ ULN, gemcitabine can be safely administered at a dose of $800\ \text{mg/m}^2$ when it is infused over 30 minutes, weekly for 3 consecutive weeks, with cycles repeated every 4 weeks. In patients with renal insufficiency, as determined by a serum creatinine between 1.6 and 3.2, although the data, as derived from this study, suggest that gemcitabine can be delivered safely on the same schedule at a dose of $650\ \text{mg/m}^2$, and despite the fact that there was no clear difference in pharmacokinetics in patients with renal insufficiency, the authors concluded that

no dose of gemcitabine could be safely recommended because of the variability in toxicities.

Fludarabine

There is little information available regarding the administration of other nucleoside analogues. Martell et al. performed a retrospective analysis regarding the toxicity of fludarabine in chronic lymphocytic leukemia. They reported that the renal insufficiency, as determined by an estimated creatinine clearance less than 80 mL/min, was associated with an increased incidence of toxicity, particularly anemia. However, given the nature of the study, no recommendation was made regarding dose modification of fludarabine in patients with renal insufficiency.⁵

Camptothecins

IRINOTECAN

Irinotecan has now been well characterized to be metabolized by the liver and may serve as one of the early models of pharmacogenomics in oncology. Initially, Wasserman et al. reported life-threatening neutropenia and diarrhea in two patients with Gilbert's syndrome who were treated with irinotecan.⁶ This finding was provocative because patients with Gilbert's syndrome present with asymptomatic unconjugated hyperbilirubinemia as a result of deficiency in UGT1A1. This result was further highlighted by Gupta et al.⁷ In patients treated on a dose-escalation study of irinotecan, the glucuronidation of irinotecan's active metabolite, SN-38, was inversely correlated with higher biliary concentration. Thus, patients with impaired glucuronidation suffered from greater diarrhea. It has subsequently been reported that patients with Gilbert's syndrome may also suffer from a higher incidence of diarrhea than other patients.⁸ The enzyme UGT1A1 was subsequently targeted as the putative gene that most affected the metabolism of irinotecan, and in particular, the presence of the 7/7 genotype has been demonstrated to result in an impaired glucuronidation, and therefore, the greater toxicity of irinotecan.

In an attempt to formalize recommendations regarding the administration of irinotecan in patients with hepatic dysfunction, Raymond et al. categorized 33 patients into four groups: I, total bilirubin within the range of normal; II, total bilirubin 1.1–1.5 \times ULN; III, total bilirubin 1.51–3.0 \times ULN; IV, total bilirubin 3.01 \times ULN, or greater. Patients were then treated with irinotecan every 3 weeks.⁹ In the first two cohorts, the standard dose (350 mg/m²) of irinotecan was well tolerated. In patients with moderate hepatic dysfunction in cohort III, the initial dose of 175 mg/m² every 3 weeks was well tolerated. However at the next planned dose, 240 mg/m², three of the six patients treated experienced DLT, including grade 4 diarrhea in two patients, and one with grade 4 neutropenia. Thus, an intermediate dose of 200 mg/m² was explored, with DLT in only one (grade 4 neutropenia) in five patients. In addition, in cohort IV, three patients were treated with 100 mg/m², with no dose-limiting toxicity, but all these patients had a rapid decline in performance status, and no dose escalation was performed.

Pharmacokinetic studies were also performed in this study, and demonstrated that in all the groups with bilirubin elevation, the clearances of irinotecan diminished and the AUC of its active metabolite, SN-38, increased. Indeed, the

irinotecan clearance was inversely correlated with the level of bilirubin, but plateaued at 40 μ mol/L of bilirubin. The clearance of irinotecan was also correlated with the alkaline phosphatase and γ Glutamyl Transferase (GGTP), but not AST, ALT, albumin, or prothrombin time. Very little of the irinotecan (15%) and SN-38 (less than 0.3%) was excreted renally, and this finding was similar in all the cohorts.

Based upon these results, the authors recommended that no modification in the dose of irinotecan, when administered every 3 weeks, was necessary for patients with a total bilirubin less than 1.5 \times ULN. For patients with a total bilirubin 1.5–3.0 \times ULN, the recommended dose of irinotecan is 200 mg/m². However, too limited data were available to make a recommendation for therapy in patients with a total bilirubin of more than 3 \times ULN.

The CALGB has also performed a dose-escalation study in patients with hepatic or renal dysfunction.¹⁰ Liver dysfunction, as defined by AST, of more than 2 \times ULN (cohort I) or direct bilirubin 1.6–7.0 mg/dL (cohort II) was evaluated. Cohort III was composed of patients with renal insufficiency as defined by a serum creatinine of 1.6 to 5.0 mg/dL. A fourth cohort (IV) included patients who had received prior pelvic radiation. As with prior CALGB studies, doses were escalated individually in separate cohorts.

Given the heterogeneous population of patients, the authors did not make any recommendations regarding the dosage of irinotecan in these diverse populations of patients with organ dysfunction, either measured by laboratory studies or potential, as indicated by prior pelvic radiation. Taken together, the data demonstrate that patients with renal insufficiency, as defined by an elevated bilirubin, should receive, at best, attenuated doses of irinotecan.

TOPOTECAN

Investigators from the Johns Hopkins University have performed dose-escalation studies of topotecan in patients with hepatic or renal insufficiency. In the former study, 14 patients with hepatic dysfunction, as defined by a total bilirubin greater than 1.2 mg/dL, and 7 patients with normal hepatic function, were treated with topotecan intravenously for 5 days, with cycles repeated every 21 days.¹¹ In both groups, the standard dose of topotecan, 1.5 mg/m² daily, was well tolerated, with similar pharmacokinetic results, and no changes in the dose of topotecan administered was deemed necessary to compensate for hepatic dysfunction. Moreover, no concomitant increase in renal elimination was noted.

In the companion to this study, O'Reilly et al. treated 28 patients with renal insufficiency and 14 with normal renal function (creatinine clearance 60 mL/min or greater, as defined by 24-hour urine collection) with the daily \times five schedule of topotecan.¹² The patients with renal insufficiency were divided into three separate cohorts (by creatinine clearances of 40–59, 20–39, and less than 20 mL/min, respectively), which were dose escalated individually. In this study, different MTDs were ultimately determined for patients who were heavily and minimally pretreated. Patients with mild renal impairment (creatinine clearance, 40–59 mL/min) were primarily heavily pretreated but were able to receive the standard dose of topotecan. However, patients with moderate renal insufficiency (creatinine clearance, 20–39 mL/min) were able to receive significantly lower doses of topotecan. In patients who were heavily pretreated were recommended to

receive 0.5 mg/m^2 , but those who were minimally pretreated were able to tolerate 0.75 mg/m^2 . These investigators were unable to recommend any dose of topotecan for patients with severe renal dysfunction, as both patients enrolled on this study experienced dose-limiting thrombocytopenia at the initial dose of 0.5 mg/m^2 .

The toxicities that were reported in this study were similar to those reported in patients with normal renal function, mainly myelosuppression. With renal impairment, the clearance of topotecan was clearly diminished, with a direct association with creatinine clearance. Interestingly, the pharmacokinetic studies also demonstrated a second peak of topotecan, suggesting the possibility of enterohepatic circulation, although the authors' companion study in hepatic dysfunction did not report a major impact of hepatic metabolism upon topotecan disposition.

Platinums: Oxaliplatin

The platinums comprise a pharmacologically interesting family of agents. It is well known that one of the primary toxicities of cisplatin is nephrotoxicity, which can be ameliorated by hyperhydration and forced diuresis. As noted earlier in this chapter, the second-generation platinum carboplatin can be safely dosed in a fashion to accommodate renal insufficiency. The third-generation platinum oxaliplatin, a DACH platinum, has been approved for use in colorectal cancer and has been demonstrated to have antitumor activity in other malignancies, including breast and prostate cancer. In Phase I and II studies, the appropriate dose of oxaliplatin has been determined to be 85 mg/m^2 every 14 days, or 130 mg/m^2 every 3 weeks. The impact of hepatic and renal dysfunction on the toxicity and pharmacokinetics of oxaliplatin have been evaluated in several Phase I studies.

In a dose-escalation study, 37 patients with various advanced solid malignancies were enrolled.¹³ Twelve patients had normal renal function, defined as a creatinine clearance of 60 or more mL/min, and all were treated at 130 mg/m^2 every 3 weeks. Patients with renal insufficiency were assigned cohorts (B, 40–59 mL/min; C, 20–39 mL/min; D, less than 20 mL/min) based upon the level of their renal function, and then dose escalation was performed within each cohort. Ten patients with "mild" insufficiency in cohort B could be escalated from 105 to 130 mg/m^2 without any occurrence of severe toxicities. In cohort C, 14 patients were treated at doses that were successfully increased from 80 to 105 to 130 mg/m^2 . At the usual dose of 130 mg/m^2 , 3 patients experienced severe, non-dose-limiting thrombocytopenia. No other severe toxicities were reported. With repeated dosing in this cohort, 2 patients did experience a worsening of serum creatinine, but both cases were attributed to progressive disease and obstructive uropathy. Only 1 patient with severe renal impairment (cohort D) was treated. He experienced a nonneutropenic urosepsis with the first dose (60 mg/m^2) of therapy, and was withdrawn from the study. Although the systemic platinum exposure increased with worsening renal insufficiency, there was no significant difference in the toxicity profile of oxaliplatin in the different cohorts of patients treated on this protocol. Thus, the authors recommended that oxaliplatin could be administered at the full dose of 130 mg/m^2 every 3 weeks in patients with a creatinine clearance of 20 mL/min or greater.

The same group of investigators performed a similar study in patients with liver dysfunction.¹⁴ Forty-three patients were treated in the report, 11 of whom had normal hepatic function. Liver dysfunction was defined as mildly impaired [cohort B: normal bilirubin; serum glutamic-oxaloacetic transaminase (SGOT), less than $2.5\times\text{ULN}$; alkaline phosphatase, less than $5\times\text{ULN}$], moderately impaired (cohort C: total bilirubin less than 3; SGOT, less than $2.5\times\text{ULN}$; alkaline phosphatase, less than $5\times\text{ULN}$), and severely impaired (cohort D: total bilirubin of 3, but any level of SGOT or alkaline phosphatase). One patient who had a prior orthotopic liver transplant (cohort E) was also treated. Doses were escalated from 60 mg/m^2 to the full dose of 130 mg/m^2 , if possible. The dose of oxaliplatin was successfully escalated to the full dose in cohorts A, B, and C. In these groups, only one DLT occurred, with grade 3 neurotoxicity in one of seven patients in cohort C treated with 80 mg/m^2 . Seven patients with severe liver dysfunction were enrolled in this study, with no DLT at 60 or 80 mg/m^2 . In addition, no DLT was noted in the single patient who had a prior liver transplant and was treated with 60 mg/m^2 of oxaliplatin. Pharmacokinetic studies were performed on 15 of the patients who were enrolled in this study. They demonstrated a decrease in the clearance of ultrafilterable platinum with increasing hepatic dysfunction, as indicated by total bilirubin and alkaline phosphatase, with the patients in cohort C having a clearance of 35% less than the patients with normal hepatic function. This finding was not accompanied by any difference in toxicity, however. Thus, the authors of this study recommended that the full dose of oxaliplatin can be administered to patients with moderate hepatic dysfunction, as defined by a total bilirubin of 3.0, SGOT $2.5\times\text{ULN}$, and alkaline phosphatase of $5.0\times\text{ULN}$ or less.

Antifolates

The fluoropyrimidines have long been available as an important component of therapy for gastrointestinal malignancies and breast cancers. Because of the broad spectrum of activity of these agents and the schedule-dependent nature of antitumor activity, fluoropyrimidines are an area of extensive investigation and development, in particular, the oral fluoropyrimidines. Although 5-fluorouracil (5-FU) has been available for more than 40 years, limited information is available regarding the dosing of 5-FU in patients with organ dysfunction.

5-FLUOROURACIL

In patients with renal or hepatic dysfunction, Fleming et al. have performed a dose-escalation study of infusional (weekly 24-hour infusion) 5-FU from 1,000 to 18,000 to $2,600\text{ mg/m}^2$, admixed with 500 mg/m^2 leucovorin.¹⁵ Patients were divided into three groups: Cohort I was composed of 16 patients with renal insufficiency as defined by a serum creatinine of 1.5 to 3.0 mg/dL. Cohorts II and III included patients with a total bilirubin of greater than 1.5 to less than 5.0 mg/dL, and 5.0 mg/dL or greater, respectively. In all the cohorts, the typical doses of 5-FU ($2,600\text{ mg/m}^2$ over 24 hours) and leucovorin (500 mg/m^2 over 24 hours) were safely attainable. The dose-limiting toxicities that were encountered were the expected ones of fatigue, diarrhea, anemia, and thrombocy-

topenia. The pharmacokinetic results for 5-FU were similar to those reported by others evaluating a 24-hour infusion of the drug, with no clear evidence of any relationship between 5-FU clearance and either bilirubin or creatinine. However, the authors pointed out that given the pharmacokinetic differences between bolus and infusional 5-FU, it cannot be assumed that bolus 5-FU can be administered safely to patients with hepatic or renal insufficiency. This recommendation has been buttressed by some of the findings from studies with the oral fluoropyrimidines, which may act more like multiple "mini-boluses" of 5-FU, rather than a continuous infusion of 5-FU.

Supporting this concern were the results of a retrospective analysis of a pair of studies in patients with metastatic colorectal cancer who were randomly assigned to receive either capecitabine or 5-FU/leucovorin by IV bolus according to the Mayo clinic schedule.¹⁶ A total of 1,207 patients were enrolled in the study and 605 were randomly assigned to receive 5-FU/leucovorin. Patients and their toxicities were analyzed according to calculated creatinine clearance (by the Cockcroft-Gault formula). Of the patients who received 5-FU/leucovorin, the incidence of any grade 3 or 4 toxicity was higher among the patients with moderate renal insufficiency (creatinine clearance, 30–50 mL/min) than in patients with mild renal insufficiency (51–80 mL/min) or normal renal function, at 51%, 35%, and 31% of patients, respectively. The primary difference was in the occurrence of severe stomatitis 26%, compared to 16% and 11%. The difference in the toxicities were reflected in the fact that 30% of patients with moderate renal insufficiency withdrew from therapy because of toxicity, compared to 14% of patients with mild renal dysfunction, and 10% of patients with normal renal function.

CAPECITABINE

The only oral fluoropyrimidine that has been approved by the U.S. Food and Drug Administration (FDA) for use in the United States is capecitabine. It is also the member of this class that has been most extensively evaluated in the setting of organ dysfunction.

Poole et al. performed a study in 27 patients, all of whom were given the standard dose of capecitabine, 1,250 mg/m² twice daily for 14 days, with cycles repeated every 3 weeks.¹⁷ Six (group A) had normal renal function, as defined by a creatinine clearance of greater than 80 mL/min. The other patients were divided into mild impairment (group B, 8 patients; creatinine clearance, 51–80 mL/min), moderate impairment (group C, 6 patients; creatinine clearance, 30–50 mL/min), and severe impairment (group D, 4 patients; creatinine clearance, less than 30 mL/min).

In this study, there was no significant impact of creatinine clearance upon the systemic exposure to capecitabine in any of the groups. In contrast, patients with moderate and severe renal insufficiency (creatinine clearance, 50 mL/min or less) had lower day 14 AUC of the metabolite 5'-DFCR and higher levels of 5'-DFUR and FBAL. The AUC of 5-FU was elevated only in patients in group D. The half-life and C_{max} of these agents were generally similar among the groups. However, all four of the patients with severe renal insufficiency experienced toxicity, including one patient who died (sepsis) and another who discontinued therapy as a result of

toxicity. Patients with mild and moderate renal insufficiency had toxicity profiles similar to those of patients with normal renal function.

As a result of these findings, the investigators recommended that capecitabine could safely be administered to patients with mild renal insufficiency (creatinine clearance of 50 mL/min or greater) at the full dose but should not be prescribed to patients with severe renal dysfunction. Although patients with moderate renal insufficiency (creatinine clearance, 30–50 mL/min) did not experience any greater toxicity than patients within other cohorts, based on the pharmacokinetic studies, the authors recommended the administration of capecitabine with an initial dose reduction of 25%, which should result in a system exposure similar to that in patients without renal dysfunction.

Bolstering these data were the results of a retrospective analysis of a pair of studies in patients with metastatic colorectal cancer who were randomly assigned to receive either capecitabine or 5-FU/leucovorin by IV bolus.¹⁵ A total of 1,207 patients were enrolled in the study and 603 were randomly assigned to receive capecitabine. Patients and their toxicities were analyzed according to calculated creatinine clearance (by the Cockcroft-Gault formula). About 10% of patients who received capecitabine had moderate renal insufficiency (creatinine clearance, 30–50 mL/min), and 5 patients had severe insufficiency. The patients who had moderate renal insufficiency experienced more severe toxicities (54%), especially hand-foot syndrome (25.4%), than those with mild renal impairment (41% and 18.3%) or normal renal function (36% and 12.3%). This difference resulted in a more frequent incidence of dose reduction of capecitabine in patients with moderate renal insufficiency (44% of patients, compared to 32% and 33%), and a greater likelihood of withdrawing from therapy because of toxicity, especially diarrhea. However, the objective response rates were similar among these subgroups of patients.

The pharmacokinetics of capecitabine have also been explored in 16 patients with hepatic dysfunction that resulted from liver metastases and compared to results in patients with normal hepatic function.¹⁸ Hepatic dysfunction was graded by serum total bilirubin, transaminases, and alkaline phosphatase in a unique scale, and the patients in this study were determined to have had "mild-to-moderate hepatic dysfunction." Patients were treated with a single dose of capecitabine at a dose of 1,255 mg/m². The patients with hepatic dysfunction attained higher plasma concentrations of capecitabine, 5'-DFUR, and 5-FU but lower levels of 5'-DFCR. Similarly, the C_{max} and AUC of capecitabine, 5'-DFUR, and 5-FU were lower, but higher with 5'-DFCR in patients with hepatic dysfunction. Despite the differences that were detected, none were found to be statistically significant, and overall results were similar to the results for patients with normal hepatic function. There did not appear to be any compensatory changes in the urinary excretion of capecitabine or its metabolites. No significant differences in the toxicity profiles in the two groups were noted, although this was a single-dose study of capecitabine. As a result of these findings, Twelves et al. recommended that, in patients with mild and moderate hepatic insufficiency, capecitabine can be cautiously administered at full doses. However, no comment can be made regarding patients with severe hepatic dysfunction.

S-1

S-1 is another oral fluoropyrimidine that is composed of a combination of tegafur, a prodrug of 5-fluorouracil, with a drug that inhibits dihydropyrimidine dehydrogenase (5-chloro-2,4-dihydroxypyridine, CDHP) and another that reduces gastrointestinal toxicity (potassium oxonate) in a 1:0.4:1 ratio. Based on the findings from an animal model of induced renal failure that suggested that the clearance of both 5-FU and CDHP were correlated with the degree of renal failure, Ikeda et al. treated four patients with unresectable gastric cancer and renal insufficiency with S-1.¹⁹ Three of the patients had a relatively mild renal insufficiency, with a creatinine clearance greater than 50 mL/min, and were treated with 20 mg/m²/day of S-1, half the usual dose. The fourth patient, with a creatinine clearance of 36 mL/min, received one-third the usual dose of S-1. In the patients with minimal renal insufficiency (creatinine clearance, 75 mL/min or greater) demonstrated no differences in single- and multiple-dose pharmacokinetics of any of the drugs in S-1. However, in the two patients with mild and moderate renal insufficiency, there was a notably longer half-life of both 5-FU and CDHP with multiple-dose administrations when compared to a single dose. Despite these findings, no serious toxicities were reported in any patient when receiving S-1 with these dose modifications. Based on these findings, the authors suggest that S-1 may be administered to patients with renal insufficiency, but only with close monitoring, and no specific dosing recommendations could be made.

5-FU/ENILURACIL

An important limitation to the administration of oral 5-FU as a single agent appears to be its metabolism by dihydropyrimidine dehydrogenase (DPD). Eniluracil is an inhibitor of DPD, which may then allow the administration of oral 5-FU by increasing the latter's bioavailability. The combination has been evaluated in patients with metastatic colorectal cancer. O'Donnell et al. have also performed a study of this combination in 17 patients with refractory solid tumors.²⁰ Nine patients had renal insufficiency (creatinine clearance, less than 50 mL/min), and the others were considered to have "normal" renal function (group A). Treatment was divided into a test period and treatment period. Based on the pharmacokinetic results from the test period, patients with renal insufficiency were then subsequently treated with the eniluracil/5-FU. The patients in group A received eniluracil 50 mg on days 1 to 7 and 5-FU 20 mg/m² on days 1 to 5. The clearance of 5-FU and eniluracil decreased with worsening renal function. However, there did not appear to be an increase in toxicity in the patients with renal impairment, suggesting that the test dose strategy was successful, but would be necessary for eniluracil/5-FU.

PEMETREXED (MTA, LY231514)

Pemetrexed disodium is a new multitargeted antifolate that inhibits thymidylate synthase, dihydrofolate reductase, and glycinamide ribonucleotide formyl transferase. It has demonstrated notable antitumor activity in combination with cisplatin in mesothelioma and promising antitumor activity in other solid tumors. Takimoto et al. performed a dose-escalation study in 29 patients with renal insufficiency.²¹

Renal function was determined by technetium 99m-DPTA glomerular filtration rates. Cohort 1B included patients with creatinine clearance of 60 to 79 mL/min; cohort 2, 40–59 mL/min; cohort 3, 20–39 mL/min; and cohort 4, 19 mL/min, or less. Eighteen patients with normal renal function were also treated (cohort 1A). In cohort 1B, myelosuppressive DLT were found with pemetrexed in 3 of 5 patients who were treated with a higher than standard dose of pemetrexed (600 mg/m²). At the standard dose of 500 mg/m², pemetrexed was well tolerated. Patients with creatinine clearance of 40 to 59 mL/min were also able to receive the standard dose of pemetrexed. No patients were enrolled in cohort 3, but 1 patient with severe renal insufficiency died with febrile neutropenia, and no further accrual was performed in either arm. In this study, the clearance of pemetrexed was strongly correlated with glomerular filtration rate (GFR). Based on these results, the investigators recommended that, with vitamin B₁₂ and folic acid supplementation, the standard dose of pemetrexed, 500 mg/m² every 21 days, could be administered to patients with mild renal dysfunction, as defined by a creatinine clearance of greater than 40 mL/min.

RALITREXED

Thymidylate synthase (TS) has proven to be a fruitful target in the therapy of many different tumors, including colorectal cancers. Raltitrexed is a synthetic TS inhibitor that can be administered intravenously once every 3 weeks. An important limitation of raltitrexed is that it cannot be administered to patients with significant effusions. Because of these considerations, raltitrexed has undergone limited evaluation in patients with renal insufficiency.²² Judson et al. treated 8 patients with renal insufficiency (creatinine clearance, 25–65 mL/min) and 8 with "normal" renal function with raltitrexed at 3 mg/m² every 21 days. The $t_{1/2\gamma}$ and AUC of raltitrexed were significantly greater in the patients with renal insufficiency. The clearance of raltitrexed was clearly related to creatinine clearance. Given these findings, and that the doses of raltitrexed were similar in the two groups, it is not surprising that the patients with renal insufficiency had substantially more toxicity, with 6 patients requiring hospitalization (compared to 2 of the patients with normal renal function). Based on these results, Judson et al. recommended that if raltitrexed is being administered to patients with a creatinine clearance of 25 to 65 mL/min, the dose be decreased by 50%, and the interval between treatments be increased to 4 weeks, rather than the usual 3 weeks. Moreover, they recommended that raltitrexed not be administered to patients with severe renal insufficiency, as indicated by a creatinine clearance less than 25 mL/min.

Anthracyclines

Anthracyclines were among the first agents to have demonstrated a clear propensity to have greater toxicity in patients who had organ dysfunction, in particular, hepatic insufficiency. As a result, some of the first evidence-based recommendations were with doxorubicin.

ADRIAMYCIN

Benjamin et al. performed a pharmacologic study of adriamycin 60 mg/m² every 3 weeks in 96 patients with a variety

of malignancies.²³ Eight of the patients had hepatic insufficiency, and these patients experienced significantly more toxicity than the patients with normal hepatic function. For example, all 8 had severe pancytopenia, 3 had severe mucositis, and 3 died (37.5%). In five patients with hepatic insufficiency, the plasma levels of adriamycin and its metabolites were four to five times as great as those for patients with normal hepatic function, with significantly delayed excretion. By comparison, the 79 patients with normal hepatic function experienced less toxicity with no cases of severe mucositis and 3 drug-related deaths (3.8%). As the result of these experiences, 9 further patients with abnormal liver function studies, as defined by bilirubin, were treated with a lower dose of adriamycin. Patients with a bilirubin of 1.2 to 3.0 mg/dL received a 50% reduction in the dose of adriamycin (30 mg/m²), and those with a bilirubin of greater than 3.0 mg/dL received adriamycin with a 75% dose reduction (15 mg/m²). After receiving adriamycin with these dose modifications, the toxicity profile of adriamycin in these patients was similar to that in patients with normal hepatic function. An additional patient with severe renal insufficiency (serum creatinine, 9.0 mg/dL) received a full dose of adriamycin, with only mild toxicity reported. This result likely reflected the fact that the urinary excretion of adriamycin was "limited." Based on these results, these dose modifications for patients with hyperbilirubinemia have been employed for adriamycin.

However, in some contrast to these results, Brenner et al. treated 64 patients with acute nonlymphocytic leukemia with adriamycin and cytosine arabinoside.²⁴ Hepatic function was determined by bromsulphalein (BSP) retention, a functional test. The standard dose of adriamycin in this study was 30 mg/m² for 3 consecutive days. This dose was administered to 28 patients with normal hepatic function (group I) and 26 patients with mild hepatic dysfunction by BSP retention (greater than 5% over 45 minutes). In the other 10 patients, who had an elevated BSP retention, adriamycin was delivered at a 50% to 67% dose reduction (10–15 mg/m²/day). In groups I and II, which were treated with similar doses of adriamycin, there was no significant difference in acute toxicity, as defined by mucositis, patient outcomes, or in pharmacokinetic profiles. The patients in group III, receiving a lower dose of adriamycin because of hepatic insufficiency, had perhaps less toxicity, but were found to have a significantly lower drug exposure, and possibly shorter survivals, than the patients treated at the higher doses. The authors believe that, based on these results, perhaps the recommendations from Benjamin et al. require further validation before widespread application.

EPIRUBICIN

Epirubicin is a derivative of adriamycin that may have somewhat less cardiotoxicity at equipotent doses. As a derivative of adriamycin, several studies have evaluated the administration of epirubicin in patients with hepatic insufficiency, believing that a dose reduction may be necessary for such patients. These expectations have indeed been borne out by the study results.

Camaggi et al. performed a study with epirubicin in 22 patients with previously treated advanced solid tumors.²⁵ Half the patients, who had normal hepatic and renal function, received 90 mg/m² epirubicin intravenously, and were used as

controls. Five patients had an elevated serum creatinine, which suggested renal insufficiency, and 6 patients had abnormal liver function studies as a result of hepatic metastases. All except 1 (with normal bilirubin, but other elevated transaminases and alkaline phosphatase) of these patients received 35.7 mg/m² epirubicin. The patients with hepatic insufficiency demonstrated a decrease in the plasma clearance and increase in the area under the curve, but similar half-life of epirubicin. The patient with a liver function study abnormality who received the full dose of epirubicin had higher epirubicin and epidoxorubicinol levels than those patients who had normal liver function. Based on these findings, in conjunction with previously reported results with the parent compound doxorubicin, the authors suggested that a 50% dose reduction of epirubicin be considered for patients with liver metastases, even in the absence of overt hepatic dysfunction. However, they also recommended that further studies be conducted to refine the recommendations, given the small number of patients evaluated in this study. With regard to the patients with renal insufficiency, who received a lower dose of epirubicin, the pharmacokinetic parameters of epirubicin were similar to those in patients without renal insufficiency; this confirms the finding that renal excretion is a minor pathway of elimination for epirubicin. Thus, the authors concluded that epirubicin may be administered without dose modification in patients with renal dysfunction.

Furthering the studies of epirubicin and hepatic function, Twelves et al. evaluated the drug in 52 women with advanced breast cancer.²⁶ These patients were divided into three populations. The first group comprised women with normal hepatic function, and they were treated with varying doses of epirubicin (12.5–120 mg/m²) every 3 weeks. Twenty-two patients in group 2 had elevated AST, but normal bilirubin, and 8 patients in group 3 had elevations in both AST and bilirubin. Most of the women in these groups received epirubicin 25 mg/m² weekly. The authors found that the patients in groups 2 and 3 had decreased epirubicin clearance and a prolonged terminal half-life of epirubicin compared to the patients in group 1 (normal hepatic biochemistry studies). The strongest correlation was between AST elevation and clearance.

Based on these findings, this group then attempted to derive a more specific dose modification plan in women with breast cancer.²⁷ Again, group 1 included 15 patients with normal liver biochemistry studies (AST less than 2× ULN and bilirubin less than 2.0 μmol/L) served as the controls, receiving various doses of epirubicin (25–120 mg/m²) to define a "high" and "low" AUC (2,400 mg/mL/h and 1,600 mg/mL/h, respectively) that would correspond to epirubicin doses of 90 and 60 mg/m², respectively. The formula that was derived was $\text{dose} = \text{AUC} \times [87.5 - (34.2 \times \log_{10} \text{AST})]$. Group 2 consisted of 16 patients with abnormal liver function who were treated with epirubicin 25 mg/m² to confirm the results in this population. In this population, the clearance of epirubicin was again correlated with the log₁₀ of AST.

A third group then included 41 women with abnormal liver function who were prospectively treated with epirubicin that was dosed according to the AST, targeted to attain either the "high" AUC in 25 patients or "low" AUC in the other 16. Finally, the fourth group of patients was composed of 25 patients with hepatic metastases and abnormal hepatic transaminases who were treated with epirubicin 25 mg/m²

weekly. In the last two groups of patients, epirubicin therapy was well tolerated. However, the median survival in these patients with hepatic dysfunction and breast cancer was only 14 weeks. Ten of the 38 evaluable patients had a partial response to therapy, and all had some improvement in their liver biochemistries, including two who had an initial worsening of these studies.

As a result of these findings, the authors concluded that the epirubicin could be dosed safely according to a target AUC, with the actual dose dependent on the pretreatment AST. Doing so appears to decrease the pharmacokinetic variability of the administered epirubicin in comparison to the patients treated with a fixed dose regardless of hepatic function. However, the potential benefits of these recommendations await confirmation by a randomized study.

Etoposide

Similar to the anthracyclines, etoposide is an inhibitor of topoisomerase II. Its administration has also been explored in several studies in patients with hepatic and renal insufficiency. In the mid-1980s, the initial reports were made by D'Incalci and Arbus, respectively. In the first report, D'Incalci et al. treated 15 patients with hepatic insufficiency, as defined by a total bilirubin greater than 1.2, GGTP greater than 28, or alkaline phosphatase greater than 170, and compared pharmacokinetic results to a control population of 18 patients.²⁸ Both groups of patients received varying doses and schedules of etoposide, sometimes in combination with other drugs. Overall, the pharmacokinetic results in the two populations were similar, but with somewhat more interpatient variability in the patients with hepatic dysfunction.

Arbus et al. observed eight patients with hepatic insufficiency (total bilirubin, greater than 1.0, including six values greater than 3.0) with etoposide.²⁹ As in the prior study, these patients often also received other chemotherapy drugs, and on varying schedules. Very little (less than 3%) of the etoposide was excreted in the bile, but much of the clearance of etoposide was unaccountable. Etoposide clearance in patients with hepatic insufficiency appeared to be similar to historic control patients with normal renal function.

More recently, Hande et al. treated 11 patients with obstructive jaundice and total bilirubin greater than 2.0 mg/dL, comparing the results to 23 control patients with normal hepatic function (including bilirubin less than 1.4 mg/dL).³⁰ Again, patients received varying doses of etoposide (100–800 mg/m²), many in combination with other drugs. There was no significant difference in the pharmacokinetic profiles and urinary excretion in the two populations. Thus, the authors recommended that dose modifications are not necessary for patients with obstructive jaundice or hepatic dysfunction, if they have normal renal function.

However, Stewart et al. reported some interesting findings that, although consistent with the others, also raise interesting questions.³¹ They treated 21 patients with etoposide 100 mg/m² intravenously over 1 hour on days 1, 3, and 5, with cisplatin 70 mg/m² IV on day 1. Fourteen patients had liver metastases, but only 6 patients had a total bilirubin greater than 1, including 4 with a total bilirubin greater than 2, 4 with ascites, and 6 had a creatinine clearance less than 70 mL/min. The authors specifically reported on the results in the patients with hepatic dysfunction. They found that the

clearance of total etoposide was similar in patients with hepatic dysfunction, hepatic metastases, ascites, and normal hepatic function. The clearance of unbound etoposide was significantly lower, resulting in a higher AUC in the patients with hyperbilirubinemia than in the other patients. Toxicity was not reported, so it is unclear if this increase in the exposure to unbound etoposide has any clinical impact. Overall, these data suggest that perhaps the dose of etoposide should be decreased in patients with an elevated bilirubin. This finding requires confirmation, and was not explored in the other studies.

Taken together, the burden of the data suggests that in patients with hepatic dysfunction, etoposide can probably be administered safely without dose modification. However, the study reported by Stewart et al. certainly indicates that caution must continue to be used when administering etoposide in patients with hepatic insufficiency.

Less information is available regarding the administration of etoposide in patients with renal insufficiency. D'Incalci also treated eight patients with normal hepatic function, but impaired renal function, as defined by a serum creatinine greater than 1.5 or creatinine clearance less than 60 mL/min.²⁷ Five of these patients had renal dysfunction from cisplatin. In this small group of patients, 2% to 23% of the dose was recovered in the urine, which was less than in the control group of 18 patients (40%) with normal organ function. In addition, the plasma clearance and half-life of etoposide were significantly less in the patients with renal dysfunction than the control patients. Arbus also treated nine patients with renal insufficiency (creatinine clearance less than 70 mL/min, but only three less than 50 mL/min).²⁸ Although the pharmacokinetic findings in the patients with renal insufficiency were similar to those in the patients with hepatic dysfunction, creatinine clearance was found to be the strongest predictor of etoposide clearance. Thus, the results from these limited studies suggest that etoposide clearance is correlated with creatinine clearance, and both sets of authors suggested that the dose of etoposide be decreased in patients with renal insufficiency.

Targeted Therapy

IMATINIB MESYLATE (GLEEVEC, STI 571)

Imatinib was the first oral "targeted therapy" to be approved for use in the United States. It is metabolized in the liver, which suggests that its toxicity profile may be altered in patients who have hepatic insufficiency. However, two reports, each composed of two patients, suggested that despite the hepatic metabolism of the drug, imatinib can be given safely to patients with gastrointestinal stromal tumors and hepatic dysfunction, as determined by bilirubin and hepatic transaminases, with no clear worsening of drug toxicity.^{32,33}

The administration of imatinib in patients with organ dysfunction has been explored more formally through the National Cancer Institute Cancer Therapy Evaluation Program (NCI CTEP) in a pair of studies that have been reported in preliminary form. Ramanathan et al. reported on the administration of imatinib in patients with hepatic dysfunction, primarily the result of liver metastases, or 15 patients with normal liver function.³⁴ The severity of hepatic dysfunction was defined by total bilirubin and SGOT, in ref-

erence to laboratory normals. Thus, the mild hepatic dysfunction cohort included patients with total bilirubin less than $1.5 \times \text{ULN}$, or SGOT above normal. Moderate dysfunction encompassed patients with a total bilirubin $1.5\text{--}3.0 \times \text{ULN}$, but any SGOT, whereas severe hepatic dysfunction included patients with a total bilirubin $3\text{--}10 \times \text{ULN}$, and any SGOT. At the time of the abstract presentation, 13, 9, and 12 patients had been enrolled in the study, with only 1 DLT (vomiting/diarrhea in 1 patient in the mild hepatic dysfunction cohort at 400mg daily). Generally, therapy was well tolerated, and the toxicity profile was similar to that reported in gastrointestinal stromal tumors, including nausea/vomiting, edema/weight gain, fatigue, and elevation in liver function studies. Preliminary evaluation of the pharmacokinetic studies that have been performed demonstrated a large inter-patient variability, but also with a 50% increase in steady-state levels of imatinib in the patients with hepatic dysfunction compared to the normal patients. However, as the dose escalation was continuing, no specific recommendations have yet been made.

For the same consortium, Remick et al. reported on a similar study in patients with renal dysfunction.³⁵ Again, four cohorts of patients underwent parallel dose escalations. These cohorts were patients with normal renal function and patients with mild (creatinine clearance between 40 and 59 mL/min), moderate (20–39 mL/min), or severe (less than 20 mL/min) renal dysfunction. At the time of the report, therapy had been well tolerated, with patients again having typical toxicities for imatinib. The clearance of imatinib declined with creatinine clearance, and appeared to be inversely correlated with plasma alpha-1-acid glycoprotein. However, in patients with mild and moderate renal insufficiency, the toxicity profile did not appear to be significantly different than for patients with normal renal function. Only one DLT was reported (nausea/vomiting) in a patient with moderate renal dysfunction who received imatinib at 200mg daily. Dose escalation was continuing in this study as well, and again, no specific dose recommendations were made for patients with renal insufficiency.

GEFITINIB (IRESSA, ZD 1839)

Another in the new generation of targeted therapy is gefitinib, which inhibits the tyrosine kinase of epidermal growth factor receptors and has demonstrated antitumor activity, with suggested symptomatic benefit in patients with non-small cell lung cancer. Twelves et al. evaluated the role of hepatic insufficiency in patients who were treated with gefitinib at the standard dose of 250mg daily.³⁶ Hepatic insufficiency was defined by serum aspartate aminotransferase and total bilirubin. Forty-one patients were treated in this study, including 18 with normal hepatic function, 16 with moderate hepatic insufficiency, and 7 with severe hepatic dysfunction. No significant differences in systemic exposure, as defined by AUC and C_{max} , or toxicities were noted among the groups.

Vincristine

Although the vinca alkaloids have been used as antineoplastic therapy for several decades, limited information is available regarding the administration of these microtubule inhibitors in patients with organ dysfunction. Van den Berg

et al. reported on a series of 39 patients who received vincristine at various doses, usually in combinations with other drugs.³⁷ Fifteen patients had elevated alkaline phosphatase, 3 of whom had elevated bilirubin, and 7 also had elevated GGTP. In these patients, the half-life and AUC of vincristine were elevated. With the limitations of this study, no recommendations regarding dosing of vincristine in patients with elevated alkaline phosphatase and likely, impaired hepatic function.

Renal Dysfunction

Our knowledge of the elimination of drugs remains incomplete, which makes dose modifications for end-organ dysfunction difficult (Tables 98.1, 98.2). The narrow therapeutic index of antineoplastic drugs makes a solid understanding of drug metabolism critical when administering chemotherapy in patients with renal dysfunction. In this section, we review the available evidenced-based recommendations for chemotherapy administration in renal dysfunction to serve as a reference for treatment decision making.

Disease-Specific Trials in Renal Dysfunction

Few disease-specific studies exist in the literature addressing the role of chemotherapy in patients with renal dysfunction. The majority of the trials have been performed in genitourinary cancer, as renal insufficiency is commonly observed in this patient population. Transitional cell carcinoma of the urinary bladder is a moderately chemosensitive tumor with published response rates of 60% to 70% and complete responses in 20% to 30% using cisplatin-based chemotherapy.^{38–40} Almost half the patients presenting with advanced bladder malignancies have compromised clinical status due to advanced age, comorbidities, and renal dysfunction, making the delivery of full-dose cisplatin-based chemother-

apy difficult if not dangerous. This issue has thus led to several initiatives exploring systemic chemotherapy in the presence of renal dysfunction and perhaps representing genitourinary (GU) malignancies, giving us the most extensive body of literature in a disease-specific setting.

Paclitaxel, primarily metabolized by the liver, has been evaluated in several studies of patients with renal insufficiency.⁴¹ Dreicer et al. treated six chemotherapy-naïve bladder cancer patients with renal insufficiency defined by median serum creatinine of 2.25 mg/dL (range, 1.6–3.2), with paclitaxel 175–250 mg/m² over 24 hours every 21 days.⁴² Four of the patients had a documented partial response while another had stabilization of disease. Three of the patients had experienced neutropenia with an associated fever, and 2 had severe neurotoxicity. This toxicity profile is similar to that reported with paclitaxel when used as a single agent in patients with normal renal function.

Dimopoulos et al. treated a similar group of 11 patients with docetaxel 100 mg/m² every 21 days, with G-CSF support.⁴³ Five of the patients had an objective response and 3 had stable disease. Three of the responding patients nor-

malized their renal function after relief of ureteral obstruction. The median survival in these patients was 11 months. The regimen was considered to be safe. Five patients experienced severe neutropenia, including two episodes of neutropenic fever; no other severe toxicities were reported.

Having exhibited activity with acceptable toxicity in patients with mild renal insufficiency, taxanes were then studied in combination with carboplatin, adjusting for renal function. Bekele et al. reported a case of a patient with metastatic transitional cell carcinoma and chronic renal insufficiency (baseline serum creatinine, of 6.6 mg/dL) secondary to poststreptococcal glomerulonephritis.⁴⁴ The patient was treated with carboplatin (AUC = 5) and paclitaxel 135 mg/m² every 3 weeks. This chemotherapy combination induced a partial regression of disease and was well tolerated. The patient experienced grade 2 anemia, grade 1 neuropathy, did not require hemodialysis, and died 17 months later with progressive disease.

Vaughn et al. reported a Phase I/II study of carboplatin and paclitaxel in 33 patients with a median creatinine clearance of 52 mL/min (range, 24–100). Sixteen patients were accrued

in Phase I and administered carboplatin AUC 6 and paclitaxel 150 to 225 mg/m² IV over 3 hours.⁴⁵ Subsequently, 17 patients were treated with carboplatin AUC 6 and paclitaxel 225 mg/m² IV over 3 hours. Although responses were observed at all dose levels, an objective response rate of 50% was documented in this Phase II setting.

Drawing from this experience, the Eastern Cooperative Oncology Group carried out a Phase II study (E2896) of carboplatin and paclitaxel in 42 patients with advanced urothelial cancer and renal dysfunction.⁴⁶ A serum creatinine between 1.6 and 4.0 mg/dL was required for study entry. Nine of the 37 evaluable patients had an objective response (24.3%); 3 complete responses were observed. The median survival was 7.1 months and the median progression-free survival 3.0 months. The toxicity profile of the combination in this study was typical for the regimen, with severe neutropenia observed in 60% and anemia in 18% of the 40 evaluable patients. Severe neurotoxicity was reported in 35% and nausea/vomiting in 10% of the patients. Of note, 4 patients died on therapy; 1 with neutropenic sepsis, 1 with gastrointestinal bleeding in the setting of grade 4 thrombocytopenia, 1 with pulmonary embolism, and 1 of an unknown cause. The authors concluded that the combination of carboplatin and paclitaxel could be administered safely to patients with renal insufficiency and should be subjected to further evaluation as an optimal therapeutic option.

The Southwest Oncology Group (SWOG) replicated this study, treating 29 patients with a median creatinine clearance of 61 mL/min with carboplatin at AUC 5 and paclitaxel 200 mg/m² every 21 days.⁴⁷ Six partial responses with an overall response rate of 20.7% were observed. Toxicity was primarily hematologic, with 38% experiencing grade 4 neutropenia. Neurologic toxicity was observed in 16 patients; grade 1 in 4, grade 2 in 5; grade 3 in 6; and grade 4 in 1 patient. Although the regimen was deemed to be well tolerated, the response proportion in this study was considerably lower than prior studies.

Single-agent gemcitabine has been shown to have activity and excellent tolerance in patients with transitional cell carcinoma.^{48,49} Gemcitabine in combination with cisplatin has been shown to have equivalent activity compared to methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) in advanced urothelial cancer.⁵⁰ Llado et al. treated 16 patients with renal insufficiency, substituting carboplatin AUC 4.5 in combination with gemcitabine 1,000 mg/m² with an overall response rate of 43.7%. One patient had a complete response while 6 had partial responses.⁵¹ Toxicity was primarily hematologic. The combined regimen with carboplatin (AUC = 5, on day 1) and gemcitabine (1,000 mg/m² over 30 minutes on days 1 and 8), repeated every 21 days, has been studied by several investigators. Shannon et al. administered this combination to 17 patients with poor prognostic factors; 13 of these patients had a creatinine clearance less than 60 mL/min.⁵² Overall, 10 patients had an objective response (58.8%). The median survival was 10.5 months and the median time to progression 4.6 months. As expected, the primary toxicity was myelosuppression; 12 patients (70%) experienced severe neutropenia without neutropenic fever, 8 (47%) had thrombocytopenia, and 3 (18%) had anemia. Severe nonhematologic toxicity was relatively uncommon, with 2 patients experiencing nausea/vomiting and 1 mucositis. It was concluded that this combination was active, with accept-

able toxicity. Carles et al. treated 17 patients with median creatinine clearance of 45 mL/min (range, 20–55 mL/min) using the same regimen.^{53,54} An objective response of 56% was observed; the median survival was 10 months. Overall, this schedule of carboplatin/gemcitabine was tolerated well; severe neutropenia occurred in 4 patients (23.5%) and thrombocytopenia and anemia in 18% each. The authors concluded that this combination is active in patients with renal insufficiency and had similar antitumor efficacy as observed in patients with normal renal function.

The largest series of patients treated with this schedule of carboplatin and gemcitabine was reported by Nogue-Aliguer et al.⁵⁵ Twenty-two of the 41 patients in this series had renal insufficiency as defined by a creatinine clearance between 30 and 60 mL/min. The remainder of the patients were considered to be poor candidates for cisplatin-based chemotherapy because of age or performance status. The results mirrored those from the reports from Shannon and Carles, with a response rate of 56.1%, median survival of 10.1 months, and median progression-free survival of 7.2 months. Unfortunately, the results for the patients with renal insufficiency were not reported separately from the poor performance status patients. The toxicity profile was again similar to the previous reports. Severe myelosuppression was the primary toxicity, with neutropenia in 63% of patients (including 3 episodes of neutropenic fever), anemia in 54%, and thrombocytopenia in 32%. Twenty percent of patients had severe asthenia and 7% severe nausea/vomiting. One patient had an increase in serum creatinine.

Seeking to avoid the use of any platinum in patients who may be poor candidates for such therapy, Ricci et al. investigated a combination of epirubicin and gemcitabine.⁵⁶ Epirubicin was administered on day 1 at a dose of 70 mg/m² and gemcitabine 1,000 mg/m² on days 1 and 8, with cycles every 21 days. Thirty of the 38 patients enrolled had a creatinine clearance of less than 60 mL/min. Fifteen of the patients (39.5%) had an objective response. The median survival was 8.0 months, with a 1-year survival of 38% and median progression-free survival of 4.8 months. The combination was well tolerated, with severe neutropenia in 22% of all cycles, and 2 episodes of neutropenic fever. Severe anemia occurred in 11% of cycles, and thrombocytopenia in 7% of cycles; no severe nonhematologic toxicities were noted. The authors concluded that this regimen could have potential utility for patients with advanced urothelial carcinoma who are considered to be suboptimal candidates for platinum-based therapy, including those with renal insufficiency.

Taken together, these series of studies suggest that taxanes, platinum, gemcitabine, and epirubicin may be administered safely in patients with mild renal insufficiency without compromising antitumor activity or increased toxicity, alone or in combination.

Chemotherapy and Hemodialysis

With the improvement in hemodialysis techniques and supportive care, the prognosis of patients with chronic renal failure has improved. The improvement in survival in turn, has led to the increased number of hemodialysis patients with development of various types of cancers.⁵⁷ Many chemotherapeutic agents are dependent on renal excretion, and the role

of chemotherapy in adult patients who require hemodialysis has rarely been reported.

The impact of chemotherapy in adult patients who require hemodialysis has rarely been reported, and specific recommendations cannot be made for most agents. The literature reveals only case reports and small series. The largest of these series was performed in lung cancer. Watanabe et al. treated five patients with increasing doses of cisplatin on day 1, and etoposide on days 1, 3, and 5.⁵⁸ Hemodialysis was performed within an hour after completion of chemotherapy. Two patients were treated with an inpatient dose escalation to determine the toxicity of the regimen in these patients. Full doses of cisplatin (80 mg/m^2) and etoposide (100 mg/m^2) could be administered in the other three patients. Four of the patients had partial responses, two of two in small cell and two of three in non-small cell lung cancer. The toxicity profile was similar to other series of patients with normal renal function. All the patients had severe grade 3/4 anemia and neutropenia. Two each had severe thrombocytopenia and nausea/vomiting. The pharmacokinetic results in this study were similar to those from patients with normal renal function, although the free platinum was somewhat higher in the patients on hemodialysis. These findings suggest that full doses of cisplatin and etoposide could be administered safely to patients requiring hemodialysis.

Two case reports have also been published suggesting the safety of paclitaxel in patients requiring hemodialysis. One woman with ovarian cancer was treated with escalating doses of paclitaxel, from 175 to 300 mg/m^2 over 3 hours, on nondialysis days. Pharmacokinetic studies were performed, and demonstrated nonlinear pharmacokinetics with the high doses, similar to other studies. Paclitaxel could not be dialyzed. Similar results were reported in an iatrogenically anephric child requiring hemodialysis who received paclitaxel at 250 and 350 mg/m^2 over 24 hours. The peak concentration and systemic exposure of paclitaxel was similar to historically reported values in children. Again, paclitaxel could not be detected in the dialysate. Taken together, these results suggest that paclitaxel can be safely administered in full doses to patients requiring hemodialysis.

There also have been two cases of the use of gemcitabine in patients requiring hemodialysis. An 81-year-old man with metastatic pancreatic adenocarcinoma received gemcitabine 650 mg/m^2 on days 1, 8, and 15 every 28 days. Hemodialysis was performed 5.5 hours after completion of the infusion. No significant toxicities were reported. The C_{max} , AUC, and clearance of gemcitabine were similar to prior reports of gemcitabine in patients without renal dysfunction. However, the metabolite dFdU did not decrease until dialysis started. However, upon the initiation of dialysis, the dFdU levels decreased by 46%. Kiani et al.⁵⁹ reported a 64-year-old man with locally advanced pancreatic cancer who received gemcitabine $1,000\text{ mg/m}^2$ on days 1 and 10 every 28 days. Hemodialysis was performed 24 hours after completion of the chemotherapy. Again, the pharmacokinetics of gemcitabine were similar to those for patients with normal renal function. The half-life of dFdU was prolonged, but without apparent clinical consequence. These reports also suggest that gemcitabine may also be administered at the full doses to patients who are undergoing hemodialysis.

Cisplatin and Paclitaxel

Most of the cases reports using carboplatin and paclitaxel combinations in dialysis patients have been patients with gynecologic malignancies. A high proportion of the carboplatin administered remains free in plasma. Because the major route of elimination of carboplatin is through glomerular filtration and tubular secretion, it has high dialysis efficacy. By contrast, the majority of cisplatin is rapidly protein bound, and renal excretion accounts for a minority of the elimination of free platinum.⁶⁰ Thus, due to its predictable kinetics, similar efficacy, and limited toxicity, carboplatin is usually preferable to cisplatin in patients with gynecologic malignancies on hemodialysis.

The carboplatin AUC observed in a hemodialysis patients is not only dependent on the dose and GFR but also on the interval between the drug administration and hemodialysis. Kurata et al. compared the AUC of carboplatin followed by hemodialysis 1 and 2 hours after administration.⁶¹ Although the predicted AUC was 9.6 mg/min/mL after administration of carboplatin at the dose of 240 mg/m^2 , the observed AUC was 3.1 mg/min/mL for 1 hour and 5.1 mg/min/mL for 2 hours after the dose. Niikura et al. reported three cases of long-term dialysis patients with gynecologic malignancies. They chose the dose of 200 mg/m^2 for the initial administration of carboplatin with expectation of an AUC of 4 mg/min/mL during hemodialysis 2 hours after administration based on pharmacokinetic data.⁶² Severe or prolonged thrombocytopenia during chemotherapy in two of three patients was observed, and thus the authors suggest that a dose of 200 mg/m^2 may be too high in these patients. Clinically complete remission was observed in a patient receiving a carboplatin dose of 100 mg/m^2 in this series. Similarly, a case report by Chatelut et al. noted a complete response in an advanced ovarian cancer patient on hemodialysis with carboplatin at the dose of 100 to 150 mg/m^2 .⁶³ The authors thus recommend 100 to 150 mg/m^2 of carboplatin as an appropriate dose for patients undergoing hemodialysis in spite of a low AUC achieved pharmacokinetically. Patients on long-term hemodialysis may have an abnormal bone marrow function and therefore, the dose of carboplatin may need to be reduced in spite of reported pharmacokinetic data.

Watanabe et al. reported a case of stage III ovarian cancer treated with carboplatin/paclitaxel combination chemotherapy after debulking surgery.⁶⁴ Paclitaxel was administered at 150 mg/m^2 and carboplatin at AUC 5, according to the Calvert formula. Chemotherapy was given on nondialysis days and an acceptable degree of thrombocytopenia and neutropenia was noted. The patient had a complete response after five cycles and remained disease free for 8 months after completion of the therapy. The authors suggest administering chemotherapy at least 16 hours before the scheduled hemodialysis.

Furuya et al. reported a case of a dialysis patient with metastatic urothelial carcinoma treated with a combination of carboplatin dosed at AUC of 5 mg/min/mL , calculated according to the Calvert formula, and a full dose of paclitaxel, 175 mg/m^2 .⁶⁵ The patient was able to tolerate four courses of chemotherapy with minimal toxicity (grade 3 neutropenia and grade 1 thrombocytopenia) while achieving a 20% tumor regression.

Paclitaxel is extensively metabolized by the liver and secreted in bile, with less than 10% extracted by the

kidneys.^{66,67} Paclitaxel is not eliminated by hemodialysis; no dose adjustment has been required based on renal failure alone.⁶⁸ Tomita et al. collected dialysate samples 30 min after the start of hemodialysis for measurement of paclitaxel concentration, but none was identified.⁶⁹

Cisplatin and Etoposide

Several small case series have been reported with use of attenuated doses of cisplatin in hemodialysis patients. Tomita et al. reported a case of a recurrent ovarian cancer patient undergoing hemodialysis treated with cisplatin and paclitaxel.⁶⁹ At a dose of cisplatin 30 mg/m² and paclitaxel 150 mg/m², a 42% tumor size reduction was noted after two cycles; however, grade IV neutropenia and grade 3 thrombocytopenia were noted. Similar case studies have been reported with use of cisplatin in hemodialysis patients in testicular cancer, bladder cancer, gastric cancer, and lung cancer.⁷⁰⁻⁷³

Kamizuru et al. reported a pharmacokinetic study in a hemodialysis patient with stage IIIA seminoma treated with cisplatin at 7 mg/m² on days 1, 3, and 5, 14 mg/m² cisplatin on days 2 and 4, with etoposide 70 mg/m² on days 1 to 5.⁷⁰ They noticed a high degree of myelosuppression and thus had to attenuate their chemotherapy doses of cisplatin to 14 mg/m² on days 1, 3, and 5 and etoposide to 35 mg/m² on days 1 to 5 for the next three cycles. The AUC of free cisplatin found on pharmacokinetic study was 6.82 µg/h/min in the first course, and 4.07 µg/h/min in the second course. The AUC of etoposide was 241.9 µg/h/mL in the first course and 216.9 µg/h/mL in the second course. A complete response was achieved, and the patient did not have any recurrence for 5 years. The authors concluded that the cisplatin and etoposide could be given to the patients receiving hemodialysis, and suggested the use of lower doses to prevent side effects.

Obana et al. reported three cases of small cell lung cancer patients with underlying renal failure treated with carboplatin and etoposide.⁷³ Hemodialysis was used in two of three cases. Two of the three patients had a partial response and there was improvement in quality of life in the third. The need for selection of suitable chemotherapy regimens, their optimal dose, and the timing of hemodialysis was raised by the authors. A recent case series by Watanabe et al., was published in the *British Journal of Cancer*.⁵⁸ They reported a dose-escalation study of cisplatin and etoposide for hemodialysis patients with lung cancer. A starting dose of cisplatin at 40 mg/m² on day 1, and etoposide at 50 mg/m² on days 1, 3, and 5, was escalated course by course and patient by patient by monitoring toxicity and pharmacokinetic data. In their series of five patients they were able to give the full dose of cisplatin at 80 mg/m² on day 1 and 100 mg/m² etoposide on days 1, 3, and 5. Pharmacokinetic data were comparable to those from the patients with normal renal function except for uncleared free platinum in renal insufficiency patients. All patients in their series developed anemia, neutropenia, and prolonged thrombocytopenia. The authors concluded that, in this small number of patients, further studies in larger patient populations are warranted, even though dose escalation showed that full-dose chemotherapy administration in hemodialysis patients was possible.

Hepatic Dysfunction

Evaluating Hepatic Function

One of the primary difficulties in the evaluation of the appropriate role and dose of chemotherapy in patients with hepatic dysfunction is determining an appropriate definition of hepatic insufficiency. The liver is an organ with multiple functions, and as one of the largest organs in the body, one with great reserve. Different medical disciplines have evaluated hepatic function differently, based on biochemical function (synthetic or metabolic), or more grossly, as with the Childs' classification. Similarly, there is no agreement on what constitutes hepatic dysfunction in regard to pharmacology. Even within a relatively uniform and consistent group of investigators, such as the Cancer and Leukemia Group B Pharmacology and Experimental Therapy group, the definition of hepatic dysfunction used in protocols has evolved.

Some studies have based the definition of hepatic insufficiency upon function studies. Most protocols have defined laboratory values, some based upon synthetic function, and others related to metabolism, or the transaminases.

Disease-Specific Trials in End-Organ Dysfunction, Primarily Hepatocellular Carcinoma

As with renal dysfunction, few disease-specific studies have been conducted for patients with hepatic dysfunction (Table 98.3). The studies that have been reported are primarily with anthracyclines, which require dose modification in the setting of hepatic insufficiency, in patients with hepato-

cellular cancer (HCC). This disease often occurs in the setting of cirrhosis, and the dysfunction is often not a specific reflection of the malignancy.

Chan et al.⁷⁴ treated 7 patients with hepatocellular carcinoma, three of whom had biopsy-proven cirrhosis, but normal LFTs with various doses of doxorubicin (10–45 mg/m²) and methyl CCNU. The pharmacokinetic results in these patients were compared to the results in 10 patients with

other malignancies who received the same combination. The results were similar in the two populations, suggesting that cirrhosis does not inherently change the clearance of doxorubicin.

Similarly, Johnson et al.⁷⁵ evaluated 30 consecutive patients with hepatocellular cancer who were treated with doxorubicin, 60 mg/m². Sixteen of the patients had hyperbilirubinemia, defined by a total bilirubin greater than 1.7.

TABLE 98.4. Recommendations for dose modifications in hepatic or renal dysfunction, based on clinical data, compared with “Standard Recommendations.”

<i>Agent</i>	<i>Standard recommendations for dose modifications</i>	<i>Recommendations for modification based on clinical studies</i>
Capecitabine	R: CrCl 30–50: 25% reduced	R: CrCl 30–50: 25% reduced
Carboplatin	R: Area under the curve (AUC)	R: AUC

R, renal dysfunction; H, hepatic dysfunction; ULN, upper limit of laboratory normals; CrCl, creatinine clearance, as measured by mL/min; PCr, serum creatinine, as measured by mg/dL; Tbili, total bilirubin, as measured by mg/dL; AST, aspartate serum transaminase.

These patients had a greater AUC but similar terminal half-life as those with normal hepatic function. The antitumor efficacy was similar (2/11 evaluable patients) in each group. The patients with hyperbilirubinemia were significantly more likely to have leukopenia on day 7, however.

Subsequent explorations have involved liposomal formulations of anthracyclines. Hong et al.⁷⁶ reported a single case of a patient with inoperable hepatocellular cancer, and severe hepatic dysfunction, as indicated by an abnormally increased indocyanine green clearance (ICG) study: 30 mg/m² of pegylated liposomal doxorubicin was given every 3 to 4 weeks. The patient tolerated therapy well, with grade 2 stomatitis and grade 2 and 3 leukopenia, and he was able to receive therapy for eight cycles, with an initial partial response. The pharmacokinetic studies were compared to results from eight patients with normal hepatic function and found that the volume of distribution and clearance of doxorubicin were higher, and AUC lower, in this patient. Based on this result, the authors then performed a Phase II study with this drug and dose in this population. Forty patients with hepatocellular cancer were enrolled; they were required to have a total bilirubin of 3.0 mg/dL or less. The overall response rate was 10%, with a median survival of 3.0 months. The toxicity was acceptable, with severe neutropenia in 9% of cycles and stomatitis in 7% of cycles. The results from the pharmacokinetic studies were variable, with no clear correlation to toxicity. Hepatic function as determined by ICG studies also did not correlate with pharmacokinetic or toxicity results. Compared to the results from a Phase I study, the results from this study again suggested a lower initial concentration of doxorubicin, larger volume of distribution, and more rapid clearance of doxorubicin in these patients with hepatocellular carcinoma.

Daniele et al.⁷⁷ planned a dose-escalation study of liposomal daunorubicin in patients with hepatocellular carcinoma and cirrhosis. However, because of the toxicity encountered in this study, dose deescalation, from 80 to 60 to 40 mg/m² every 21 days, occurred. Indeed, even at the lowest level, three of the four patients encountered dose-limiting toxicity. No objective responses were noted. The primary toxicity in this study, however, was elevations in bilirubin and other hepatic biochemical studies. This study was ultimately also discontinued in part because of the finding of significant uptake of the liposomes in the "normal" liver parenchyma. Specific recommendations based on the previous discussion are presented in Table 98.4.

Management of the Pregnant Cancer Patient

Deepjot Singh and Paula Silverman

One in every 1,000 pregnant women will be diagnosed with cancer.¹ Despite this fact, the level of evidence-based medicine² available in the field of cancer during pregnancy is low. Randomized controlled trials in this area do not exist. Instead, retrospective collections of patients treated with varying treatment regimens and strategies, collected case reports, studies based on events, such as the Japanese atomic bomb experience, and, for rare malignancies, isolated case reports generally constitute the medical literature on pregnancy and cancer. Nonetheless, this chapter may guide oncologists facing patients in this relatively uncommon, but serious position. We discuss the use of the major diagnostic and treatment modalities in oncology during pregnancy: surgery, diagnostic imaging and therapeutic radiation, and antineoplastic agents. Therapeutic strategies for malignancies seen most frequently during pregnancy are addressed: these include breast cancer, cancer of the uterine cervix, Hodgkin's disease, and non-Hodgkin's lymphoma. Medical management of symptoms of malignancy and its treatment that are unique to the pregnant patient are discussed.

Cancer is the second leading cause of death in women between the ages of 20 and 39, following closely behind accidents.³ The most frequent cancer deaths in this age group are cancers of the breast, lung, colon, and rectum, leukemia, and nervous system cancers. Because of differences between incidence and mortality, the malignancies seen most often in conjunction with pregnancy are lymphoma, leukemia, melanoma, and cancers of the breast, cervix, ovary, thyroid, and colon.¹ Evidence does not support an increased incidence of cancer during pregnancy. The coincidence of pregnancy and cancer does not influence the biology of cancer, nor does it worsen the prognosis of cancer, except when it delays diagnosis or alters therapy. No firm data exist supporting a greater likelihood of a previously treated cancer relapsing during pregnancy. Cancer itself rarely affects the fetus, with only rare reports of placental metastases or fetal malignancy.⁴ The impact on mother and fetus may, however, be profound. Diagnostic and therapeutic interventions that are selected may affect the fetus and may even include terminating the pregnancy. Delays in diagnosis or alterations in treatment based on the coincidence of cancer and pregnancy may affect maternal outcome.

The optimal management of a cancer associated with pregnancy requires cooperation and collaboration with a multidisciplinary team that may include obstetricians, gynecologists, medical and radiation oncologists, surgeons, neonatologists, psychologists, nurses, and social workers.

It demands intensive interaction between the patient and her care team, and increases the burden of education of the patient and her family members. *Ideally*, a desired pregnancy will continue without fetal injury or interruption, with delivery of a normal infant at term. *Ideally*, the mother will receive optimal cancer treatment without delay. Balancing these ideals and making reasonable compromises constitute the crux of medical decision making when cancer is diagnosed during pregnancy.

The management of malignancy in the pregnant woman depends on factors including the type of cancer, its stage, maternal and fetal prognosis, and the week of gestation.⁵ The need for therapy may be deemed "relative" or "absolute" depending on the urgency of treatment with regard to maternal well-being. Figure 99.1 illustrates one author's overview of potential therapeutic choices.⁵ With some malignancies (e.g., low-grade lymphoma), treatment may be delayed until week 24 of gestation or longer, when early cesarean section or cancer therapy can be more safely performed. In other cases (e.g., acute leukemia), delay will endanger the mother's life. Diagnosis early in pregnancy of a life-threatening malignancy requires consideration of therapeutic abortion and careful assessment of treatment-related risks to the fetus. Diagnosis in late trimesters may allow treatment during pregnancy with less fetal risk.

Use of Specific Treatment Modalities in Pregnant Patients

Surgery During Pregnancy

Surgical interventions and procedures may be indicated for cancer diagnosis, staging, or treatment. For the most part, uncomplicated surgery or anesthetic procedures do not increase the risk of an adverse pregnancy outcome.

Although primarily nononcologic, the largest report and analysis of surgical and anesthetic risk to pregnancy is from the Swedish Birth Registry.⁶ The authors found increases in perinatal morbidity associated with nonobstetric surgery during pregnancy. The significant adverse outcomes were low birth weight and increased early infant mortality. The authors concluded that the morbidity was most likely attributable to the disease prompting surgery, rather than the adverse effects of surgery or anesthesia. An updated report by the same group⁷ linked three Swedish healthcare registries and reviewed outcomes after surgery during pregnancy. They

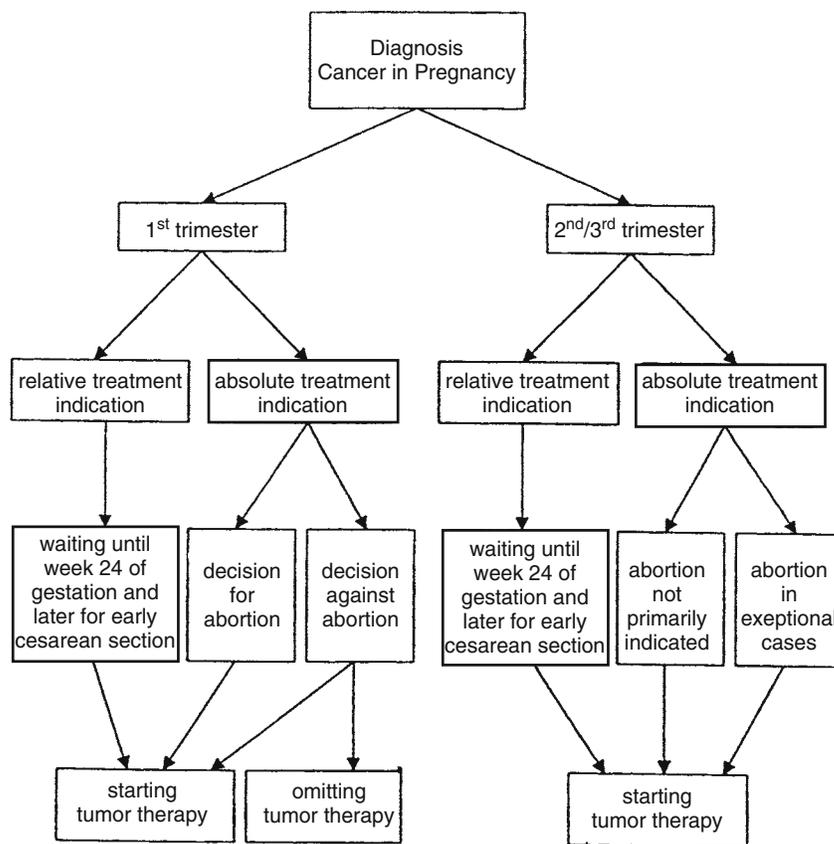

FIGURE 99.1. Potential treatment options during different stages of pregnancy. For Oduncu et al.,⁵ the distinction between the terms *absolute* and *relative* treatment indication refers to the therapeutic necessity with regards to the mother's well-being. (From Oduncu et al.,⁵ by permission of *Journal of Cancer Research and Clinical Oncology*.)

found that offspring of mothers who had undergone surgery in the first trimester had increased neural tube defects (6 versus expected number, 2.5). The significance of this finding is greater because five of the six mothers with affected offspring had surgery during the fourth or fifth week of gestation, the period of neural tube formation. However, the association between neural tube defects and maternal surgery during the period of neural tube formation was thought by the authors to be unclear and hypothetical.

Based on these findings, Sylvester et al.⁸ used the Atlanta Birth Defects Registry to do a population-based case control study that evaluated whether general anesthesia exposure during the first trimester of pregnancy is associated with increased central nervous system defects (Table 99.1). They

found a strong association between exposure and the combination of hydrocephalus and eye defects. The limitation of this study is the self-reporting of anesthesia exposure, which is subject to recall bias.

Laparotomy during pregnancy has become safer in recent years. In 1987, Kort et al.⁹ reported a fetal death rate of 3.8% after major intraabdominal or extraabdominal surgery, with no postoperative fetal deaths after 60 laparotomies. This result was comparable to a fetal death rate of 2% in pregnancy controls not undergoing surgery, and superior to studies from the 1960s and 1970s, where the fetal wastage after surgery was four to six times higher.¹⁰ However, in Kort's study, premature deliveries were 21.8% after major surgery, twice the rate seen in controls.⁹ Another series, reported by Duncan and

TABLE 99.1. Association between multiple central nervous system defects and first-trimester exposure to general anesthesia: Atlanta Birth Defects Case-Control Study, 1968–1990.

	N	Exposed number (%)	Odds ratio	95% confidence interval (CI)
Mothers of control infants	2,846	32 (1.1)	1.0	Reference
Mothers of infants with central nervous system defects	204	7 (3.4)	2.9	1.2, 6.8
Neural tube defects	70	0 (0.0)	0.0	0.0, 4.0
Microcephaly	41	0 (0.0)	0.0	0.0, 7.0
Hydrocephalus				
All	70	7 (10.0)	9.6	3.8, 24.6
Eye defects	8	3 (37.5)	39.6	7.5, 209.2

colleagues in 1986,¹¹ compared 2,565 pregnant women who underwent surgery with pregnant controls who did not. No increase in congenital anomalies was observed. The greatest risk of spontaneous preterm birth or pregnancy occurred with intraabdominal surgery, especially in the presence of infection.

Laparoscopy is a safe surgical option during pregnancy. It has been used for the exploration and treatment of adnexal masses, cholecystectomy, and appendectomy. Reedy et al.¹² used the Swedish Birth Registry to study the impact of laparoscopy on pregnancy. They compared the outcomes of more than 2 million pregnancies, of whom 2,181 had laparoscopy and 1,522 had laparotomy. Nearly all the laparoscopic procedures were in the first trimester, whereas the laparotomies were evenly distributed throughout, with fewer in weeks 32 to 40. The authors found an increased risk of low birth weight infants, preterm delivery, and fetal growth retardation in the operative group compared to pregnancies without surgery. However, there was no increased risk when laparoscopy was compared with laparotomy.

Fine-needle aspiration, core needle, or excisional biopsy under local anesthesia pose essentially no risk to the fetus.^{5,13} Modified radical mastectomies have been performed during pregnancy without fetal compromise or preterm labor.¹⁴ Mastectomy with axillary dissection is considered the treatment of choice for operable breast cancer in the pregnant woman.^{14,15} Breast reconstruction should be delayed until after delivery.

Antineoplastic Agents During Pregnancy

Drug metabolism is altered by several mechanisms during pregnancy.^{4,16} Delayed gastric emptying during late pregnancy may alter the rate of oral drug absorption. Plasma volume increases by approximately 50%, allowing a greater space for drug dilution. Plasma unbound drug concentration is altered as albumin concentration decreases and plasma protein levels increase. Both the hepatic drug metabolism and glomerular filtration rate increase during pregnancy. It is unknown whether the amniotic fluid acts as a functional third space. These changes may alter the narrow therapeutic window of cancer chemotherapy and potentially have an impact on its efficacy.

Before the thalidomide disaster of the early 1960s, the placenta was believed to be an effective barrier, protecting the fetus from drugs given to the mother.¹⁷ Placental transfer is now understood to depend on maternal metabolism, protein binding and storage, molecular size, electrical charge, and lipid solubility.¹⁸ Many antineoplastic agents share properties that permit placental transfer. Because of immaturity of the fetal metabolic and excretory processes, drugs that do cross the placenta may cause severe toxicity in the fetus.

A brief review of fetal development¹⁸ underscores the potential effects of chemotherapy on the fetus. The first phase of gestation is preimplantation, occurring in the first 2 weeks following conception. Administration of chemotherapy during this time period may cause spontaneous abortion. All major organs and organ systems are formed during the period of organogenesis in the second to eighth week of gestation (first trimester). Most congenital malformations caused by drugs occur because of injury during this critical period. Although the development of many organ systems is com-

pleted during this period, the nervous system, eye, respiratory, and hematopoietic systems continue to develop throughout gestation. These systems may continue to be susceptible to damage from antineoplastic agents. The final phase of fetal development is characterized by growth and maturation of tissues, beginning with the third month of pregnancy. Growth retardation and low birth weight are the major effects of insults from drugs or disease during this period.

A birth defect is defined as a major deviation from normal morphology or function that is congenital in origin. Birth defects are common, and 3% of children born in the United States have a birth defect.¹⁸ A teratogen is any agent that acts during embryonic or fetal development to produce a permanent alteration of form or function. Only 10% of malformations identified at birth are caused by teratogens.

The U.S. Food and Drug Administration (FDA) developed a rating system to provide guidance to drug use during pregnancy. In this system, drugs are divided into five categories depending on the fetal risk demonstrated in animal or human studies. A summary of these categories is provided in Table 99.2. Most antineoplastic drugs are classified as category D, drugs that have fetal risk, but benefit is thought to outweigh these risks. Updates to the FDA ratings are somewhat slow, and information that is more current may be obtained through online services, such as reprotox (<http://reprotox.org>).

Much of the medical literature on chemotherapy during pregnancy consists of retrospective series of patients with varying diseases treated with different multidrug regimens at times throughout pregnancy. Only limited information exists on outcomes of children exposed to chemotherapy in utero. For example, one of the larger series is that of Aviles et al.¹⁹ The authors reported a series from Mexico, examining the growth and development of 43 children of mothers treated with chemotherapy during pregnancy. The mothers had hematologic malignancies and were treated with a variety of antineoplastic agents. Drug exposure for the leukemia patients included combinations of vincristine, prednisone, doxorubicin, 6-mercaptopurine, methotrexate, cyclophosphamide, busulfan, and cytosine arabinoside. Lymphoma patients were given cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP), or CHOP with bleomycin, some with the addition of etoposide and methotrexate. Hodgkin's disease patients were given mechlorethamine

TABLE 99.2. U.S. Food and Drug Administration (FDA) classification of therapeutic agents based on fetal risk.

Category A	Drugs have shown no fetal risks in controlled studies in humans
Category B	Drugs do not show fetal risks in animal studies but human studies do not exist; or adverse effects have been demonstrated in animals but not in well-controlled human studies
Category C	No adequate animal or human studies, or there are adverse fetal effects in animal studies but no available human data
Category D	Fetal risk present, but benefits are thought to outweigh these risks
Category X	Drugs for which the proven fetal risks clearly outweigh any benefits

(nitrogen mustard), vincristine, prednisone, and procarbazine (MOPP), or doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) or a combination of both. Nineteen of the 43 mothers received treatment during the first trimester. Children were examined from ages 3 to 19 for physical, neurologic, psychologic, hematologic, and immune functions and cytogenetics. All children were found to be normal, leading the authors to conclude that chemotherapy during pregnancy, including the first trimester, is safe. In another report, Reynoso and colleagues reported the effects of intrapartum combination chemotherapy for acute leukemia in seven children.²⁰ The drugs used included vincristine, cytarabine, prednisone, cyclophosphamide, 6-thioguanine, and daunorubicin. With a follow-up interval ranging from 1 to 17 years, growth and development were reported as normal. No evidence of malignancy was found in any of the seven children.

Other authors do not concur with Aviles or Reynoso, and chemotherapy is generally avoided during the first trimester of pregnancy to reduce the risk of fetal loss and teratogenesis. In a retrospective review of 217 pregnant women treated with a variety of systemic therapies, there were 2 spontaneous abortions, 1 stillbirth, and 3 infants born with congenital anomalies. The majority of complications occurred when the chemotherapy was administered during the first trimester.²¹ During the second or third trimester, there does not appear to be an increased risk of teratogenesis. However, there is a risk of central nervous system or other major organ toxicity and intrauterine growth retardation, and the potential for premature labor.²² The timing of chemotherapy given late in pregnancy should be coordinated to avoid delivery during the nadir in the mother's blood count. This practice reduces the fetal risk of myelosuppression with resultant infectious complications or hemorrhage from thrombocytopenia.

SPECIFIC ANTINEOPLASTIC AGENTS IN PREGNANCY

CYCLOPHOSPHAMIDE AND OTHER ALKYLATING AGENTS

The alkylating agents, such as busulfan, chlorambucil, cyclophosphamide, and nitrogen mustard, show a rate of fetal malformation of approximately 13% with first-trimester exposure, compared with 4% with exposure in the later trimesters.¹⁶ Cyclophosphamide may inflict a chemical insult on developing fetal tissues, resulting in cell death and heritable DNA alterations in surviving cells.¹⁸ Anomalies of the extremities, including absent toes and fingers, palatal grooves and other facial abnormalities, microcephaly, and hernias have been attributed to cyclophosphamide exposure in early pregnancy.²³ Later in pregnancy, the drug is without significant reported fetal abnormalities and can therefore be given during the second and third trimester.^{15,18} Growth retardation has been reported with cyclophosphamide late in pregnancy.²⁴ The use of busulfan in pregnancy has been linked to a variety of fetal abnormalities.¹⁵ The use of chlorambucil during pregnancy has been associated with both normal and abnormal outcomes.¹⁵

METHOTREXATE AND OTHER ANTIMETABOLITES

Methotrexate is a folic acid antagonist; exposure to this drug during pregnancy is associated with fetal loss and a distinct pattern of fetal abnormalities. The principal features of the

abnormalities include growth restriction, failure of calvarial ossification, craniosynostosis, hypoplastic supraorbital ridges, micrognathia, and external ear and severe limb abnormalities.¹⁸ Methotrexate crosses the placenta¹⁵ and has been found in cord serum and fetal red cells. Inhibition of dihydrofolate reductase in fetal tissues is thought to be responsible for methotrexate-induced embryopathy.²⁵ Feldcamp and Carey stress that in cases of inadvertent methotrexate exposure during unanticipated pregnancy, it is important to define the period of drug exposure and the dose to avoid an unnecessary recommendation for abortion of a potentially healthy fetus.²⁶ The critical period of exposure to this drug appears to be weeks 6 through 8 from conception, with a teratogenic dose probably above 10 mg per week.²⁶

Other antimetabolites, such as 5-fluorouracil and cytosine arabinoside are less frequently associated with malformations.¹⁶ Although hydroxyurea is teratogenic in animals, no fetal abnormalities have been observed in 13 human pregnancies that resulted in live infants when the drug was used to treat maternal disease.¹⁵

DOXORUBICIN AND OTHER ANTITUMOR ANTIBIOTICS

Bleomycin, doxorubicin, dactinomycin, and daunorubicin infrequently cause fetal abnormalities. Doxorubicin has been used in breast cancer patients during second and third trimesters with infrequent adverse outcome.^{14,27} A number of reports support the use of anthracycline-based chemotherapy in pregnancy, but patients should be informed that long-term follow-up data on large numbers of children exposed to chemotherapy in utero are not available.²⁸ No reports have linked bleomycin use with congenital defects in humans.¹⁵ In six pregnancies, dactinomycin was administered in the second and third trimesters with delivery of normal infants.¹⁵

OTHER CHEMOTHERAPEUTIC AGENTS

Cisplatin use has been reported infrequently in pregnancy, but no fetal abnormalities have been identified.¹⁵ Vinca alkaloids (vincristine, vinorelbine, and vinblastine) have been associated with fetal abnormalities, spontaneous abortions, and low birth weight.¹⁵ Asparaginase use during pregnancy is limited, but it has been reported in combination with other agents.¹⁵ In six cases of exposure during the second trimester, no fetal abnormalities were noted.¹⁵ Two infants did suffer drug-induced bone marrow suppression.

The safety of the taxanes in pregnancy is unknown. The use of paclitaxel and docetaxel during pregnancy is limited to isolated case reports and case series.²⁹⁻³¹ In rats, the use of paclitaxel in early pregnancy has been associated with craniofacial malformations, diaphragmatic hernias, and kidney and cardiovascular defects.²⁹ The taxanes have been used mainly as part of combination chemotherapy regimens in the treatment of breast cancer and gynecologic cancers. Gaducci et al.³² used sequential epirubicin with paclitaxel from the 14th to 32nd weeks of gestation with no reported side effects in the patients or the fetus and normal development and growth at 36 months of follow-up. De Santis et al.³⁰ reported the use of docetaxel in the treatment of metastatic breast cancer in a pregnant patient during the second trimester. No adverse effects were noted in either the patient or the infant. Sood et al.²⁹ used cisplatin and paclitaxel in the case of a pregnant woman with advanced ovarian epithelial cancer with resultant maternal neutropenia. Similarly, Méndez et al.³¹

reported the use of combined paclitaxel and carboplatin in a woman with Stage IIIc ovarian cancer without any adverse effects on the infant.

IMMUNOMODULATING AGENTS

INTERFERON ALPHA

Interferon alpha is a family of similar subtypes of immunomodulating human proteins and glycoproteins. Interferon alpha does not appear to transfer across the placenta to the fetus. There are reports describing the use of interferon alpha in all phases of pregnancy without adverse fetal outcome.¹⁵ This agent is not thought to pose a significant risk when used during pregnancy. Interferon alpha is a class C agent.

THALIDOMIDE

The evidence implicating thalidomide as a teratogen is overwhelming. In pregnant women, exposure to even a single dose, from the 20th to the 35th day after conception, produced a unique syndrome characterized principally by deformities of the arms, legs and face, often with other more widespread abnormalities.¹⁷

Thalidomide was unavailable until recently, when applications for it were found in the immunomodulation of patients with neoplastic and immunologic diseases.^{33,34} Thalidomide has shown activity in the treatment of multiple myeloma and other lymphoproliferative and myeloproliferative disorders, malignant melanoma, glioblastoma multiforme, and renal cell carcinoma. Thalidomide is contraindicated throughout pregnancy. Its use is additionally prohibited by the manufacturer in women of childbearing age who are not using two reliable methods of contraception for 1 month before starting therapy, during therapy, and 1 month after stopping therapy.³⁵ Special precautions are taken in labeling and distribution to be sure no women of childbearing potential are exposed to thalidomide.³⁶

MONOCLONAL ANTIBODIES

Limited information exists regarding the use of monoclonal antibodies, such as trastuzumab or rituximab in malignancy associated with pregnancy. However, immunoglobulins appear safe and several are indicated for conditions occurring in pregnancy.¹⁵ Intramuscular immunoglobulin is recommended for postexposure prophylaxis for hepatitis A and measles.³⁷ Intravenous immunoglobulin is indicated in pregnancy for common variable immunodeficiency and in autoimmune diseases, such as immune thrombocytopenia and alloimmune diseases, such as severe Rh immunization.³⁸ Immunoglobulin crosses the human placenta if the gestational age is greater than 32 weeks.

Trastuzumab is a recombinant DNA-derived humanized monoclonal antibody that selectively binds to the extracellular domain of the human epidermal growth factor receptor 2 protein, HER2. Trastuzumab has proven efficacy in HER2-overexpressing metastatic breast cancer both as a single agent and in combination with chemotherapeutic agents.³⁹ Trastuzumab is classified as a category B drug, having shown no adverse effects when tested in monkeys during pregnancy.⁴⁰ However, the HER2 protein expression is high in many embryonic tissues in early gestation.⁴¹ Placental transfer of trastuzumab has been observed in monkeys.⁴⁰ There are no adequate or well-controlled studies in pregnant women.

Rituximab is a genetically engineered chimeric murine/human antibody directed against the CD20 antigen found on the surface of normal and malignant B lymphocytes.⁴² Rituximab is indicated for the treatment of patients with CD20-positive, B-cell non-Hodgkin's lymphoma, and is used as a single agent and in conjunction with chemotherapy. Rituximab has efficacy in both indolent and aggressive lymphomas. Recent studies have demonstrated efficacy in a variety of other B-cell-mediated disorders.⁴³ Rituximab is classified as a category C drug because animal studies in pregnancy have not been performed.⁴² It is not known whether rituximab can cause fetal harm when administered to a pregnant woman or whether it can affect reproductive capacity. A concern is that because human immunoglobulin is known to pass the placental barrier, rituximab could potentially cause fetal B-cell depletion.

HORMONAL AGENTS

Tamoxifen is a selective estrogen receptor-modulating agent that acts primarily as an antiestrogen but has some estrogenic properties. There are limited data pertaining to human fetal exposure. In a reported case in which tamoxifen was inadvertently used in all three trimesters, the fetus was born with a syndrome of ambiguous genitalia.^{15,21} Because of its long half-life, women should be informed that a pregnancy occurring within 8 weeks of stopping the drug could expose the fetus to tamoxifen.

Other hormonal agents primarily used to treat breast cancer include gonadotropin-releasing hormone agonists, aromatase inhibitors (e.g., letrozole, anastrozole, and exemestane), and progestins, primarily megestrol acetate. The gonadotropin-releasing hormone agonist leuprolide may theoretically cause spontaneous abortions because it suppresses endometrial proliferation. Its manufacturer maintains a registry of inadvertent human exposures during pregnancy and, with more than 100 cases reported, has found no congenital defects attributable to the drug.¹⁵ However, the numbers of cases are too few to draw conclusions regarding safety or risk. Aromatase inhibitors are recommended only for postmenopausal women, as they act by preventing the peripheral conversion of circulating androgens to estrogen. No information is available regarding their use in pregnancy. All progestins have had an FDA-mandated deletion of pregnancy-related indications because of a possible association with congenital abnormalities.¹⁵ Cases of ambiguous genitalia have been reported to the FDA, and a paired analysis of first-trimester fetal exposure has shown an increase in cardiovascular defects and hypospadias.¹⁵

Prednisone and other corticosteroids are widely used in treatment regimens for leukemia, lymphoma, and Hodgkin's disease. They appear to pose only small risks to the fetus, but may increase the incidence of orofacial clefts.¹⁵ The risk is greatest in the first trimester.

Ionizing Radiation and Diagnostic Imaging During Pregnancy

Ionizing radiation techniques are used during pregnancy both for diagnosis and staging of cancer and as a treatment modality. Ionizing radiation refers to waves or particles of sufficient energy to break chemical bonds, such as those in DNA, or

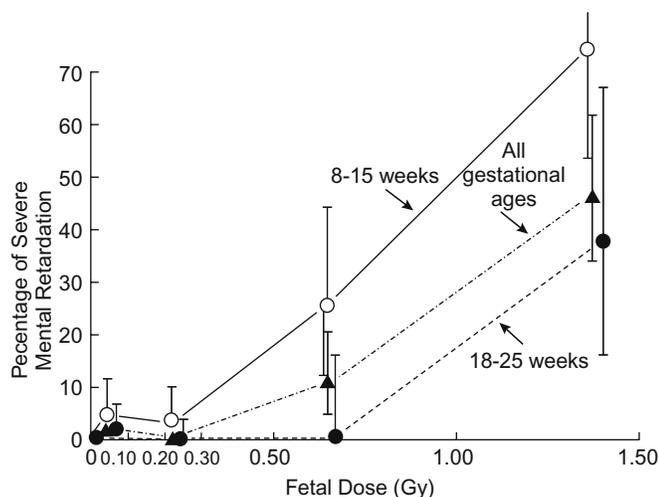

FIGURE 99.2. Effects of ionizing radiation on severe mental retardation in fetuses exposed at various gestational ages to the atomic bomb in Hiroshima and Nagasaki (1 Gy = 100 rad). The bar lines represent 90%. (From Sacher and King,³⁸ by permission of *Obstetrical & Gynecological Survey*.)

create free radicals that can cause tissue damage. The potential harmful effects on a fetus from ionizing radiation exposure are (1) cell death, affecting embryogenesis, (2) growth restriction, (3) congenital malformation, (4) carcinogenesis, (5) microcephaly and neonatal mental retardation, and (6) sterility.⁴⁴ Much of the pertinent research has been performed in animals. Human data have been obtained largely from studies of atomic bomb survivors from Hiroshima and Nagasaki.

Significant radiation exposure during preimplantation, the period in human development corresponding to the first 9 or 10 days after conception, results in prenatal death.⁴⁵ Preimplantation is the most sensitive time with respect to fetal death from radiation. Mouse and rat studies constitute the bulk of evidence for prenatal or neonatal death caused by ionizing radiation.^{46,47} The consequences of radiation of the fetus during the period of major organogenesis may include teratogenic effects on various organs, as shown in many experimental animal studies.⁴⁵ In humans, effects on the central nervous system are the best documented. Japanese atomic bomb survivors irradiated in utero show an increased risk of microcephaly and severe mental retardation with high prenatal exposure. The risk is greatest at 8 to 15 weeks of gestation, with even very low doses causing a slight increase in the risk of mental retardation. As shown in Figure 99.2, this risk is probably a nonthreshold linear function of dose, with the risk of severe mental retardation being as low as 4% for 10cGy and as high as 60% 150cGy.^{44,48} After 16 weeks, the risk is less, and there is no proven risk between 0 to 8 weeks or after 25 weeks. Fortunately, 10cGy is many times higher than exposure seen from diagnostic radiation.

It is controversial whether there is an association between in utero diagnostic radiation exposure and an increased risk of childhood cancers. Some investigators have found an increased risk of leukemia and other cancers; others have not.¹⁸ A major positive study used concordance data on twins exposed to diagnostic X-rays in utero; this led to a finding by the National Research Council Committee on Biological Effects of Ionizing Radiation to conclude that there is an asso-

ciation, with the estimated risk per unit absorbed dose to be about 200 to 250 excess cancer deaths per 10,000 person-Gy in the first 10 years of life.⁴⁹ Animal studies suggest that there are late-occurring cancers following prenatal exposure, but long-term studies of atomic bomb survivors are not available.⁴⁴ Retardation of growth has also been shown over a broad range of gestational ages in animal models and in humans.⁴⁹

Diagnostic Imaging

How then, do the doses of radiation delivered during a single exam or series of diagnostic X-rays compare with those doses that increase the risk of the effects discussed previously? Which of our diagnostic procedures involves exposure to ionizing radiation? Imaging modalities, including ultrasound, magnetic resonance imaging (MRI), and X-rays, are all used as adjuncts to the diagnosis and staging of cancer in pregnancy. Most diagnostic imaging procedures, even those involving X-rays, are associated with little or no known fetal risks. Fetal anomalies, growth restriction, or abortions are not increased with radiation exposure of less than 5cGy, which is above the range of exposure for diagnostic procedures.⁵⁰ The estimated fetal exposure from common radiologic procedures that involve ionizing radiation is summarized in Table 99.3. The uterus should be shielded for nonpelvic procedures during pregnancy.

Nuclear studies are performed by *tagging* a chemical agent with a radioisotope for tests, such as pulmonary ventilation-perfusion, thyroid, and bone scans. Bone scans that use technetium (^{99m}Tc) result in a fetal exposure of less than 0.5cGy.⁵¹ One of the more common nuclear medicine studies performed during pregnancy is the ventilation-perfusion scan for suspected pulmonary embolism. Both intravenous ^{99m}Tc and inhaled xenon gas are used. Nonetheless, in total, the fetal exposure is approximately 0.05cGy.⁵¹ Radioactive iodine readily crosses the placenta and can adversely affect the fetal thyroid, especially after 10 to 12 weeks of gestation. If a diagnostic scan of the thyroid is essential, ¹²³I or ^{99m}Tc should be used instead of ¹³¹I.⁵¹

Ultrasound uses sound waves and is not a form of ionizing radiation. Ultrasound appears to present minimal or no

TABLE 99.3. Estimated fetal exposure from common radiologic procedures.

Procedure	Fetal exposure (cGy)
Chest X-ray (two views)	0.00002–0.00007
Abdominal film (single view)	0.1
Intravenous pyelogram	≥1 ^a
Hip film (single view)	0.2
Mammography	0.007–0.02
Barium enema or small bowel series	2–4
CT scan of head or chest	<1
CT scan of abdomen and lumbar spine	3.5
CT pelvimetry	0.25

CT, computed tomography.

^aExposure depends on number of films.

risks to the fetus,⁵⁰ and there are no contraindications to ultrasound procedures during pregnancy.⁵¹ MRI employs magnets that alter the energy state of hydrogen protons to create diagnostic images. No documented adverse effects to the fetus have been reported. MRI has been proven useful for evaluation of maternal pelvic masses.⁵¹ Noncontrasted MRI can be used for detection of liver metastases in several malignancies. However, it is thought that there are insufficient data on fetal safety during the first trimester of pregnancy.⁵²

There are no known adverse effects to the fetus from use of either ionic or nonionic intravenous contrast media used in computerized tomography.⁵³ Iodinated contrast agents have not been studied in pregnant women. Gadolinium-based contrast medium used for MRI is not recommended for use during pregnancy. Gadolinium crosses the placenta, is filtered through the fetal kidneys, and then reingested through the amniotic fluid.⁵³

Therapeutic Radiation

Experience is greatest with therapeutic radiation used to treat cervical cancer, breast cancer, and Hodgkin's disease. Alternatives to radiation therapy during pregnancy should always be sought, recalling that fetal radiation doses above 10cGy increase the risk of malformations and nervous system damage during organogenesis. Options include delaying treatment until after fetal maturity to allow safer delivery, abortion, or alternative treatment that may include surgery or chemotherapy. If no alternatives exist that do not compromise maternal prognosis, radiation therapy may be used during pregnancy. The risk falls if treatment is delayed until fetal maturity passes the period of organogenesis (through week 8 of development). Risk to the developing nervous system appears to extend through the early and midfetal stages of development.

Radiation therapy for cancer generally uses a man-made source of ionizing radiation, including the linear accelerator, radioisotope, cyclotron, or nuclear reactor. Whatever the source of ionizing radiation, the pathway to both cellular damage and treatment effectiveness is through ionization of matter. The effects of cellular damage vary from none, when damage is repaired, to mutagenesis, carcinogenesis, or cell death. The benefits of radiation therapy are always balanced against the risk of ionization of normal tissues. These concerns also exist when the developing fetus is considered. The period of fetal development during which the conceptus is radiated, the dosage of ionizing radiation received, and the type of radiation given modify the risk.

Medical physicists must perform a fetal dose estimate before initiation of radiation therapy. Dose is estimated to the fundus, pubic symphysis, and umbilicus.⁵⁴ Dose measurements are repeated following modification of the treatment plan or application of appropriate shielding. Modifications of standard treatment plans to reduce fetal dose include using the smallest field possible, and minimizing the lead blocking and eliminating wedges used for field shaping as these increase radiation scatter. Collimating the field as close to the patient as possible, selecting photon energy between 4 and 10MV, directing field angles away from the pelvis, and minimizing the use of and field size of portal films all decrease the fetal dose.⁴⁷ Additional techniques include

shielding by placing heavy lead barriers above and below the abdomen and pelvis. Several designs have been published; each allows fetal dose reduction as well as patient and therapist safety.

Management and Outcome of Specific Malignancies During Pregnancy

Breast Cancer

Breast cancer is the second most common cancer in pregnant, lactating, or postpartum women, with an incidence of 1 in 3,000 pregnancies. The median age at diagnosis is between 32 and 38 years.⁵⁵ The incidence of pregnancy-associated breast cancer is projected to increase as more women choose to delay childbearing into their forties, a reflection of the increased incidence of breast cancer with advancing age.⁵⁶ One study suggested a genetic predisposition to pregnancy-associated breast cancer, as the authors found that 80% of these patients had allelic deletion and loss of heterozygosity at the hereditary BRCA2 locus compared with 20% of patients with sporadic breast cancer.⁵⁷

During pregnancy, marked lobuloalveolar growth in the breast results in engorgement and hypertrophy. The resultant dense, multinodular consistency of breast tissue makes clinical palpation of masses or thickening difficult, resulting in diagnostic delays.⁵⁸ Although 70% to 80% of breast biopsies performed in pregnant women reveal a benign diagnosis, all palpable masses persisting for 2 to 4 weeks warrant evaluation by biopsy.⁵⁸ Diagnostic mammography with abdominal shielding can be performed with minimal risk to the fetus, although the test's sensitivity is reduced by the higher density, water content, and loss of contrasting fat in breasts of pregnant or lactating women. Breast sonography is a safe, rapid, and accurate method of differentiating cystic from solid masses during pregnancy.⁵⁹ Gupta⁶⁰ demonstrated that fine-needle aspiration is highly accurate in the diagnosis of breast lesions in pregnant women. Core-biopsies have rarely resulted in milk-fistula formation.⁶¹ Although breast biopsies can be safely performed during pregnancy, the increased breast vascularity at this time may increase risk of hemorrhage.⁶²

Retrospective series have shown that breast cancers detected during pregnancy are larger and have a greater likelihood of nodal involvement than those diagnosed in nonpregnant women. Fifty-six percent of pregnant women have positive axillary lymph nodes compared with 38% to 54% positive nodes in their nonpregnant counterparts.²⁷ Between 25% and 33% of pregnancy-associated breast cancer is estrogen- and progesterone-receptor positive.⁶³⁻⁶⁵ Overexpression of the human epidermal growth factor receptor, HER2/neu, was seen in 58% of breast cancers in pregnancy compared to 16% in a nonpregnant control group. Higher rates of the markers associated with rapidly proliferating breast cancers, Ki-67 and p53, have been seen in breast cancers associated with pregnancy.⁶³

Reported case series have shown that survival in pregnant women is not improved by abortion, and therefore, this is not routinely recommended.⁶⁵ Approximately 60% of pregnancy-associated breast cancer is diagnosed in stage I or II (early stage) and should be approached with curative intent. Modified radical mastectomy with axillary lymph node dissection

can be performed with minimal risk to the developing fetus during any trimester of pregnancy.⁶³

Radiation therapy to the breast is a standard part of breast-conserving therapy. Chest wall radiation is indicated post-mastectomy for patients with large tumors, positive margins, or extensive lymph node involvement. Breast-conserving treatment during pregnancy has been considered contraindicated because mastectomy is equally curative and does not pose a risk to the fetus through radiation therapy.^{47,66} However, exceptions to this contraindication exist when radiation therapy can be delayed until after the fetus is delivered. Although delaying radiation raises concern for compromising local control, it is important to remember that a delay of up to 6 months during adjuvant chemotherapy has been found to be associated with maintained disease control.⁶⁷ In fact, there was a similar disease-free and overall survival when breast-conserving therapy and mastectomy were compared in early-stage breast cancer diagnosed during pregnancy.⁶⁸

When breast radiation is needed during pregnancy, information to estimate dose received by a fetus from tangential breast irradiation is provided by Mazonakis et al.⁶⁹ Using anthropomorphic phantoms, they found that a treatment course delivering 50Gy to the breast gave an estimated conceptus dose in the first trimester of 2.1 to 7.6 cGy. During the second and third trimesters, the estimated dose increases to 2.2 to 24.6 cGy and 2.2 to 58.6 cGy, respectively. These estimates do not include shielding of the uterus, which would further reduce conceptus dose. The authors suggest that delivered doses would, in many cases, be below the threshold doses that cause adverse effects in the middle fetal period.

Most women with pregnancy-associated breast cancer are candidates for systemic adjuvant chemotherapy, during or after the completion of the pregnancy. If chemotherapy is indicated, it may be delivered preoperatively (neoadjuvant) to more optimally treat the mother for locally advanced disease or to delay exposure to the fetus to the risk of surgery, anesthesia, and/or radiation. Methotrexate is contraindicated in all stages of pregnancy because of its abortifacient effects, teratogenic potential, and delayed elimination from sequestered spaces.²² Chemotherapy is inadvisable during the first trimester of pregnancy until fetal organogenesis is complete, as there is a substantial risk of fetal loss and teratogenesis. In a retrospective review of 217 pregnant women (14 with breast cancer), treated with a variety of systemic therapies, there were two spontaneous abortions, one stillborn, and three infants born with congenital anomalies. The majority of complications occurred when the chemotherapy was administered during the first trimester.²¹ During the second or third trimester, there does not appear to be an increased risk of teratogenesis. However, there is a risk of central nervous system or other major organ toxicity and intrauterine growth retardation, and the potential for premature labor is present.²²

The combination of doxorubicin, cyclophosphamide, and 5-fluorouracil has been evaluated in one prospective trial of 24 women with pregnancy-associated breast cancer at M.D. Anderson Medical Center.¹⁴ Patients were treated in their second and third trimesters with 5-fluorouracil (100mg/m²), doxorubicin (50mg/m² continuous infusion over 72 hours), and cyclophosphamide (500mg/m²) given every 3 weeks for a median of four cycles. No maternal or fetal deaths were observed. Three patients had preterm labor and 1 patient had severe preeclampsia requiring early delivery. The only com-

plication attributable to chemotherapy occurred after preterm delivery of an infant 2 days after the last chemotherapy dose. The infant had transient leukopenia without infectious complications.

The doxorubicin and cyclophosphamide (AC) combination regimen for 12 weeks is comparable in efficacy to 6 months of CMF (cyclophosphamide, methotrexate, and fluorouracil). The shorter duration and absence of methotrexate in the regimen makes AC safer in the treatment of the pregnant breast cancer patient. Standard doses of AC should be adequate, because this combination is not influenced by distribution into a third space (i.e., ascites, pleural or amniotic fluid).

Women with breast cancer in pregnancy have the same survival as nonpregnant women with breast cancer.⁶³ In a comparison of 56 pregnant patients and 166 nonpregnant controls, there was no statistically significant difference in survival.⁷⁰ The pregnant patients had a 5-year survival rate of 82% when lymph nodes were negative and 47% when positive. However, patients with pregnancy-associated breast cancer had more advanced disease at diagnosis.⁷⁰ Other series have shown similar results. Patients with breast cancer diagnosed during pregnancy may do more poorly because they present with more advanced disease.

Cervical Cancer

Invasive carcinoma of the cervix is the most frequent cancer associated with pregnancy in the United States. It occurs in approximately 1 in 2,200 pregnancies,¹ with an average age at diagnosis of 32 years. This rate may be falling because of improved screening leading to treatment of noninvasive lesions. Maternal prognosis in cervical cancer is not altered by pregnancy, but the fetus may suffer morbidity or mortality from treatment.⁷¹ Early diagnosis of cervical cancer in pregnant women is three times more likely than in their nonpregnant counterparts because of the frequent and detailed gynecologic examinations that are a part of routine prenatal care.⁷² The majority of women with early cervical cancer are asymptomatic, although a few may report vaginal bleeding, discharge, or pain.⁷³

Approximately 5% of all Papanicolaou (Pap) smears are abnormal,⁷⁴ usually representing cervical dysplasia. The cytopathologist should be notified that the Pap smear is from a pregnant patient because physiologic changes of pregnancy may alter the pathologist's interpretation.⁷³ Pregnant women with an abnormal Pap test should undergo colposcopy with punch biopsies to exclude invasive carcinoma.^{73,74} Conization is performed to rule out invasion when the colposcopic biopsy shows microinvasive disease or if the procedure is unsatisfactory.^{75,76} Conization is safest early in pregnancy. In a minority of patients (3% to 6%), this procedure may be associated with significant bleeding, infection, pregnancy loss, and preterm birth. Patients diagnosed with low- or high-grade dysplasia, carcinoma in situ, or microinvasive squamous carcinoma (up to 3mm in depth) can be followed to term and allowed to deliver vaginally.⁷⁷ Reevaluation and treatment are done at 6 weeks postpartum.

When invasive cervical cancer is diagnosed in the pregnant patient, staging procedures are modified to minimize radiation exposure to the developing fetus. Magnetic resonance imaging is a safe and noninvasive modality to

assess tumor extent, volume, and to monitor response to therapy.⁷⁸

The prognosis of early-stage cervical cancer appears similar in pregnant women and nonpregnant controls.⁷¹ Traditionally, if the diagnosis is made before 20 weeks of gestation, immediate radical hysterectomy with pelvic and paraortic lymphadenectomy is advised to avoid delay in treatment. For women with stage Ia or Ib cancer diagnosed after 20 weeks of gestation, several small series have shown that a delay in therapy of up to 17 weeks to achieve fetal lung maturity is reasonable.⁷⁹ In a retrospective series of 27 pregnant women with stage Ia or Ib cervical cancer, 8 patients waited for fetal lung maturity before delivery (mean diagnosis to treatment interval, 144 days). Fetal outcome was good in this group, and all women were disease free 2 years following treatment.⁸⁰ No randomized trials have evaluated the benefits of vaginal delivery versus cesarean section in pregnant women with cervical cancer. Jones et al.⁸¹ reported a poorer 5-year cumulative survival with vaginal delivery in comparison with cesarean section (55% versus 75%). In addition, rare recurrences of the cancer at the episiotomy site have been reported following vaginal delivery.⁷⁷ For these reasons, cesarean section is the preferred mode of delivery in pregnant women with cervical cancer.⁸²

For stage IIb or higher-stage cervical cancer, treatment is limited to radiation therapy. When the fetus is viable, delivery should be performed before the initiation of therapy. If the fetus is not considered viable, external-beam radiation therapy can be started before delivery. Patients will abort 20 to 24 days after the start of the radiation therapy, after a mean dose of 34 to 40 Gy.⁷⁹

Hodgkin's Disease and Non-Hodgkin's Lymphoma

The mean age of patients with Hodgkin's disease (HD) is 27 years, whereas that of those with non-Hodgkin's lymphoma (NHL) is 42 years. The incidence of pregnancy-associated lymphoma, both HD and NHL, is similar and ranges from 1 in 1,000 to 1 in 6,000. Most of the patients are diagnosed at stages II to IV, and on average at 22 weeks of gestation.^{83,84} In a series of 48 women with HD, the median age was 26 years, which is similar to other series.⁸³⁻⁸⁵ When matched with nonpregnant controls, there was no significant difference in the clinical presentation of HD.⁸⁵ Most pregnant patients present without B symptoms.⁸³⁻⁸⁵

Several studies have suggested that neither HD nor pregnancy has an independent impact on either condition.^{84,86-88} Barry et al.⁸⁶ evaluated 347 women with HD and found that the survival curves were similar in pregnant and nonpregnant women. There was no difference in survival between patients who underwent a therapeutic abortion and those who did not.⁸⁶ Lishner et al. obtained similar results⁸⁵ when cause-specific survival was compared in 33 pregnant women and 67 case-matched controls. No significant effect of age or stage at diagnosis on maternal or pregnancy outcome was seen. Infants did not have a higher risk of premature birth or intrauterine growth retardation. At 25 years of follow-up, 70% of patients were alive. Anselmo et al.⁸⁸ also reported that women with HD safely carry their pregnancy to term, giving birth to healthy children.

Most pregnancy-associated NHLs have an aggressive histologic subtype and present with advanced-stage disease.⁸⁹⁻⁹¹

In a retrospective review of 96 women with pregnancy-associated NHL, 60% of the patients presented with stage III/IV disease.⁹² An unusually high incidence of breast, uterine, cervical, and ovarian involvement is seen and has been attributed to changes in hormones and/or increased blood flow to these organs during pregnancy.⁹⁰ Some series report a stable course of the NHL in women while pregnant, followed by rapid progression postpartum.^{89,91} Others report a similar response to treatment, failure of treatment, and rate of progression in pregnant and nonpregnant patients. NHL has been reported by some to affect the pregnancy adversely by causing maternal death.⁹⁰ Others conclude that NHL does not have an effect on premature birth, spontaneous abortion, or malformations.⁹¹

Chemotherapy should be avoided when possible during the first trimester. The standard treatment for newly diagnosed HD is ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) and for diffuse large B-cell lymphoma is CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone).^{93,94} Treatment of HD and NHL during pregnancy carries risks, but as discussed next, retrospective series substantiate the safety and efficacy of its use.

In reviews of chemotherapy during pregnancy, the incidence of fetal malformations after exposure during the first trimester was about 15%.^{22,95} This risk was greatest with alkylating agents and antimetabolites (such as methotrexate) and lowest with vinblastine (1 of 14 first-trimester treated patients). The risk of fetal malformations decreased to 1.3% when chemotherapy was administered during the second or third trimester, which is similar to the 3.1% risk seen in the general population.

In one series of 14 women with HD treated with MOPP and ABVD (5 in the first trimester), all had full-term pregnancy without any congenital anomalies, and 11 remained in complete remission at 3 to 17+ years follow-up.⁹⁶ Another 18 women with NHL in the same series received CHOP (9 in the first trimester). No congenital malformations were noted on successful delivery at 35 to 40 weeks.

In a review of 24 pregnant women receiving chemotherapy for HD, Ebert et al.²¹ reported multiple fetal anomalies in some but not all of the infants exposed to MOPP (mechlorethamine, vincristine, procarbazine, and prednisone), ABVD, or cyclophosphamide with radiation in utero. In another series, 43 children exposed to chemotherapy during pregnancy were compared to a group of 25 case-control children. Fourteen of the pregnant women with HD received MOPP and/or ABVD (5 during the first trimester). At the time of evaluation, all 43 children, ranging in age from 3 to 19 years, were developmentally normal.¹⁹ Sutcliffe⁹⁷ treated three women with stage II nodular sclerosing HD with ABVD chemotherapy during the second and third trimester with normal fetal outcome in all, at 1+, 5+, and 7+ years follow-up.

In a series of 16 pregnant women with HD treated at the M.D. Anderson Cancer Center,⁹⁸ 2 patients received involved-field radiation to the neck (3,500 cGy), 3 patients received extended-field radiation to the neck or mediastinum (4,000 cGy), and the remaining 11 patients received full mantle irradiation (4,000 cGy). Four to five half-value layers of lead maximized uterine shielding. It was estimated that the fetal dose was 140 to 550 cGy with 6 MV photons and 10-13.6 cGy for cobalt 60. All offspring were reported as being physically and mentally normal with a 10-year-survival of 83%.

A number of authors have suggested treatment guidelines for pregnancy-associated lymphoma.^{44,91,92,99} Patients with HD presenting in the first trimester with B symptoms, bulky disease, advanced stage, or rapid progression require therapy. Therapeutic abortion should be recommended to enable treatment. If the patient desires to continue the pregnancy and is willing to accept the risks of therapy to the fetus and to herself, single-agent vinblastine can be used until disease progression or the second trimester. ABV in the first trimester, followed by ABVD in the second and third trimester, is given if combination chemotherapy is needed. If possible, patients presenting in their second or third trimester should be observed and treatment delayed until postpartum. If treatment is necessary, ABVD is given. Patients with clinical stage IA lymphocyte predominant disease or progression on chemotherapy may be offered mantle radiotherapy with extensive abdominal blocking.
